In a child with persistent asymptomatic proteinuria, the initial evaluation should include an assessment for orthostatic proteinuria. It begins with the collection of a first morning urine sample, with subsequent testing of any urinary abnormalities by a complete urinalysis and determination of a spot urine protein-to-creatinine ratio (see Fig. 566.1). The correct collection of the first morning urine sample is critical. The child must fully empty the bladder before going to bed and then collect the first voided urine sample immediately upon arising in the morning. The absence of proteinuria (dipstick negative or trace for protein; and a normal ratio of urinary protein [uPr; mg/dL] to urinary creatinine [uCr; mg/dL] = [uPr/uCr] <0.2) on the first morning urine sample for 3 consecutive days confirms the diagnosis of orthostatic proteinuria. No further evaluation is necessary, and the patient and family should be reassured of the benign nature of this condition. However, if there are other abnormalities of the urinalysis (e.g., hematuria), or if the urine uPr:uCr ratio is >0.2, the patient should be referred to a pediatric nephrologist for a complete evaluation.

The cause of orthostatic proteinuria is unknown, although altered renal hemodynamics and partial left renal vein obstruction in the upright, lordotic position have been proposed as possible causes. An increased body mass index is recognized as a strong correlate of orthostatic proteinuria. Long-term follow-up studies in young adults suggest that orthostatic proteinuria is a benign process, but similar data are not available for children. Therefore long-term follow-up of children is prudent. Patients should be monitored for the development of nonorthostatic proteinuria, particularly in the presence of hematuria, hypertension, or edema. Such findings may herald underlying kidney disease.

566.3 Fixed Proteinuria

Francisco X. Flores

Children found to have fixed proteinuria on a first morning urine sample on three separate occasions should be further investigated. Fixed proteinuria is defined as a first morning urine sample that is ≥1+ on dipstick testing with a urine specific gravity >1.015 or with a urine protein-to-creatinine ratio of ≥0.2. Fixed proteinuria indicates a potential kidney disease caused by either glomerular or tubular disorders.

GLOMERULAR PROTEINURIA

The glomerular capillary wall consists of three layers: the fenestrated capillary endothelium, the glomerular basement membrane, and the podocytes (with foot processes and intercalated slit diaphragms) (Fig. 566.2). Glomerular proteinuria results from alterations in the permeability of any of the layers of the glomerular capillary wall to normally filtered proteins and occurs in a variety of renal diseases (Table 566.1). Glomerular proteinuria can range widely from <1 g to >30 g of protein in a 24-hour period. The podocyte is the predominant cell of injury in most glomerular diseases characterized by heavy proteinuria.

Glomerular proteinuria should be suspected in any patient with a first morning urine protein-to-creatinine ratio >1.0, or significant proteinuria of any degree, accompanied by hypertension, hematuria with active urine sediment, edema, or renal dysfunction. Disorders characterized primarily by proteinuria include idiopathic (minimal change disease) nephrotic syndrome, secondary causes of nephrotic syndrome, focal segmental glomerulosclerosis, mesangial proliferative glomerulonephritis, membranous nephropathy, membranoproliferative glomerulonephritis, diabetic nephropathy, and obesity-related glomerulopathy. Other renal disorders that can include proteinuria as a prominent feature include acute postinfectious glomerulonephritis, immunoglobulin A nephropathy, systemic lupus erythematosus nephritis, IgA vasculitis (formerly Henoch-Schönlein purpura) nephritis, and Alport syndrome.

The initial evaluation of a child with fixed proteinuria should include the measurement of serum creatinine and an electrolyte panel, first morning urine protein-to-creatinine ratio, serum albumin level, complement levels, and antinuclear antibodies (ANA). The child should be referred to a pediatric nephrologist for further evaluation and management. Renal biopsy is often necessary to establish a diagnosis and guide therapy.

In asymptomatic patients with low-grade proteinuria (urine protein-to-creatinine ratio between 0.2 and 1.0) in whom all other findings are normal, renal biopsy might not be indicated, because the underlying process may be transient or resolving or because specific pathologic

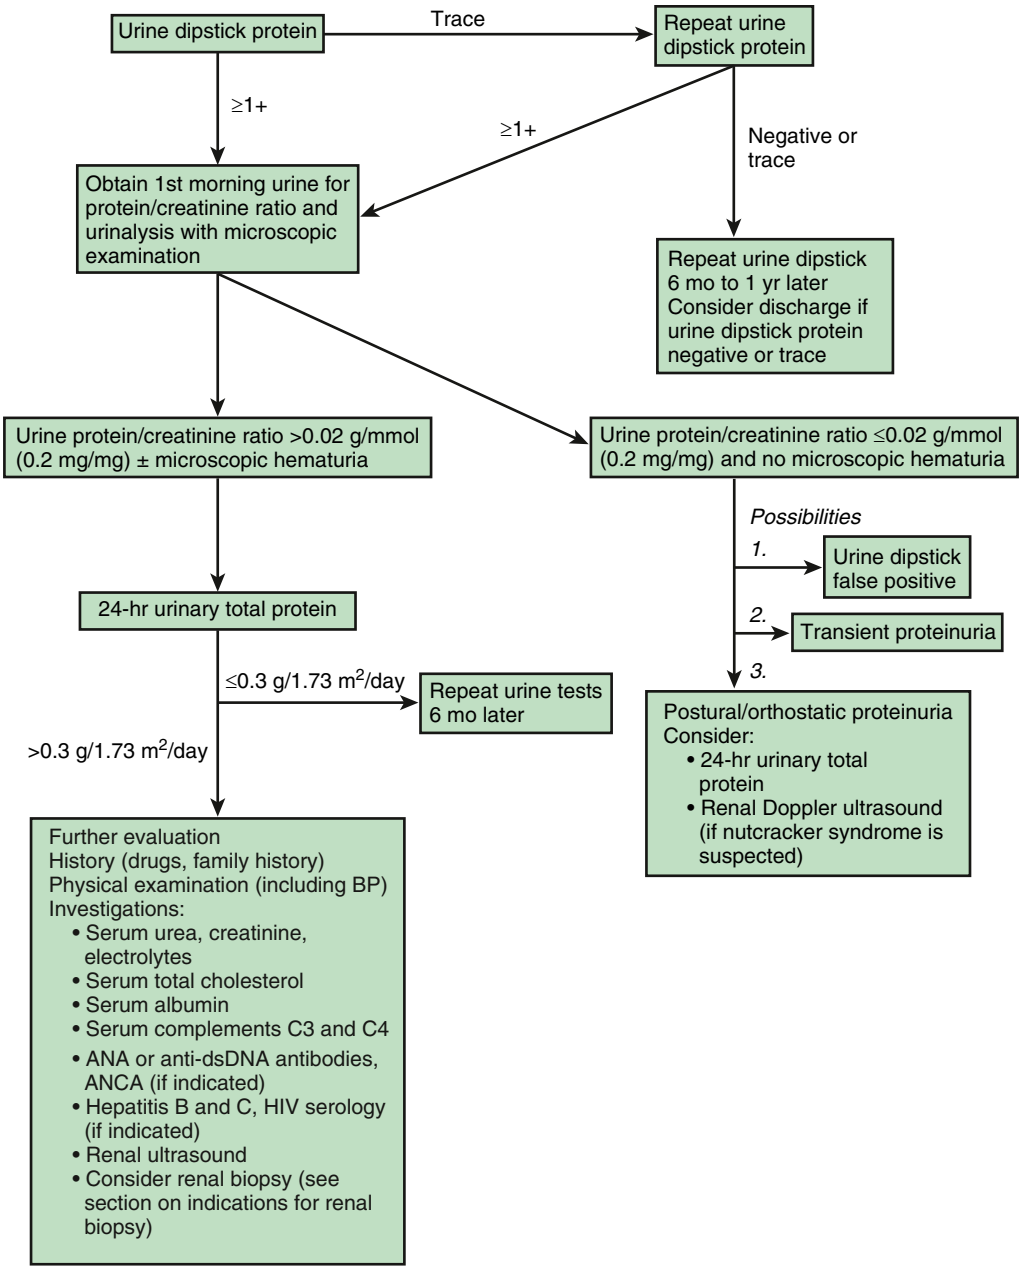

Fig 566.1 Algorithm for investigating proteinuria. ANA, Antinuclear antibody; ANCA, antinuclear cytoplasmic antibody; anti-dsDNA, anti–double-stranded DNA; BP, blood pressure. *(From Yap HK, Lau PYW. Hematuria and proteinuria. In: Geary DF, Scharfer F, eds. Comprehensive Pediatric Nephrology. Philadelphia: Elsevier; 2008: p. 190.)*

features of a chronic kidney disease might not yet be apparent. Such patients should have periodic reevaluation (ideally every 4-6 months unless the patient is or becomes symptomatic). The evaluation should consist of a physical examination with accurate blood pressure measurement, urinalysis, measurement of serum creatinine, and a repeat first morning urine protein-to-creatinine ratio. Indications for renal biopsy include increasing proteinuria (urine protein-to-creatinine ratio >1.0) or the development of hematuria with active urine sediment, hypertension, or reduced renal function.

TUBULAR PROTEINURIA

A variety of renal disorders that primarily involve the tubulointerstitial compartment of the kidney can cause low-grade fixed proteinuria (urine protein-to-creatinine ratio 0.2:1.0). In the healthy state, large amounts of proteins of lower molecular weight than albumin are filtered by the glomerulus and reabsorbed in the proximal tubule. Injury to the proximal tubules can result in diminished reabsorptive capacity and the loss of these low molecular weight proteins in the urine.

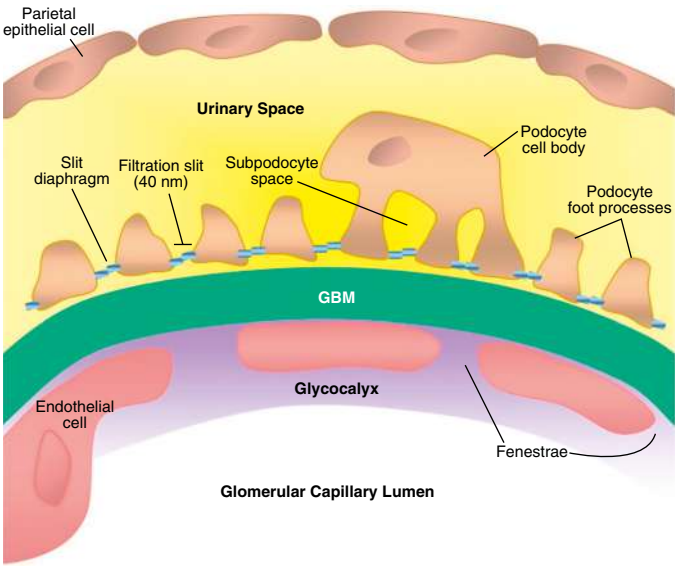

Fig. 566.2 Glomerular capillary wall. The three layers of the capillary wall (glomerular endothelial cell, glomerular basement membrane [GBM], and podocyte) act as the glomerular filtration barrier (GFB), preventing proteins and large molecules from passing from the capillary lumen into the urinary space. The podocyte cell body lies within the urinary space, and the cell is attached to the GBM through foot processes. Adjacent foot processes are separated by the filtration slit, bridged by the slit diaphragm. Disruption of the GFB leads the passage of protein across the capillary wall, leading to proteinuria. *(From Jefferson JA, Nelson PJ, Najafian B, et al. Podocyte disorders: core curriculum 2011. Am J Kidney Dis. 2011;58:666–677. Fig. 1.)*

Tubular proteinuria (see Table 566.1) may be seen in acquired and inherited disorders and may be associated with other defects of proximal tubular function, such as Fanconi syndrome (glycosuria, phosphaturia, bicarbonate wasting, and aminoaciduria). Tubular proteinuria is a consistent finding among patients with the X-linked tubular syndrome, Dent disease, caused by pathogenic variants of the renal chloride channel.

Asymptomatic patients having persistent proteinuria generally have glomerular rather than tubular proteinuria. In occult cases, glomerular and tubular proteinuria can be distinguished by protein electrophoresis of the urine. In tubular proteinuria, little or no albumin is detected, whereas in glomerular proteinuria, the major protein is albumin.

Nephrotic Syndrome

Elif Erkan

Nephrotic syndrome is the clinical manifestation of glomerular diseases associated with heavy (nephrotic range) proteinuria. Nephrotic-range proteinuria is defined as proteinuria >3.5 g/24 hr or a urine protein:creatinine ratio >2. The triad of clinical findings associated with nephrotic syndrome arising from the large urinary losses of protein are hypoalbuminemia (≤2.5 g/dL), edema, and hyperlipidemia (cholesterol >200 mg/dL).

Nephrotic syndrome affects 1-3 per 100,000 children <16 years of age. Without treatment, nephrotic syndrome in children is associated with a high risk of death, most commonly from infections. Fortunately, 80% of children with nephrotic syndrome respond to corticosteroid therapy. Although glucocorticoid therapy is standard therapy for nephrotic syndrome, neither the target cell nor the mechanism of action of steroids has been determined. Early referral to a pediatric nephrologist is recommended for initial management

of nephrotic syndrome. However, continued care of these children is always a collaborative effort between the nephrologist and the primary care physician.

ETIOLOGY

Most children with nephrotic syndrome have a form of **primary** or idiopathic nephrotic syndrome (Table 567.1). Glomerular lesions associated with idiopathic nephrotic syndrome include minimal change disease (most common), focal segmental glomerulosclerosis (FSGS), membranoproliferative glomerulonephritis, C3 glomerulopathy, and membranous nephropathy (Table 567.2). These etiologies have different age distributions (Fig. 567.1). Nephrotic syndrome may also be **secondary** to systemic diseases such as systemic lupus erythematosus, IgA vasculitis (formerly Henoch-Schönlein purpura), malignancy (lymphoma and leukemia), and infections (hepatitis, HIV, and malaria) (see Table 567.1). A number of **hereditary** proteinuria syndromes are caused by pathogenic variants in genes that encode critical protein components of the glomerular filtration apparatus (Table 567.3).

PATHOGENESIS

Role of the Podocyte

The underlying abnormality in nephrotic syndrome is an increased permeability of the glomerular capillary wall, which leads to massive proteinuria and hypoalbuminemia. The podocyte plays a crucial role in the development of proteinuria and the progression of glomerulosclerosis (Fig. 567.2). The podocyte is a highly differentiated epithelial cell located on the outside of the glomerular capillary loop. Foot processes are extensions of the podocyte that terminate on the glomerular basement membrane. The foot processes of a podocyte interdigitate with those from adjacent podocytes and are connected by a slit called the slit diaphragm. The podocyte functions as structural support of the capillary loop, is a major component of the glomerular filtration barrier to proteins, and is involved in synthesis and repair of the glomerular basement membrane. The slit diaphragm is one of the major impediments to protein permeability across the glomerular capillary wall. Slit diaphragms are not simple passive filters; they consist of numerous proteins that contribute to complex signaling pathways and play an important role in podocyte function. Important component proteins of the slit diaphragm include nephrin, podocin, CD2AP, and α-actinin 4. Podocyte injury or pathogenic variants of genes producing podocyte proteins may cause nephrotic-range proteinuria (see Table 567.3). Genetic screening of 1,655 patients with steroid-resistant nephrotic syndrome and congenital nephrotic syndrome in the European PodoNet Registry Cohort has shown that pathogenic variants in *NPHS1, WT1,* and *NPHS2* were the most common. The proportion of patients with pathogenic variants of podocyte genes decreased by age; it was 66% in patients with congenital nephrotic syndrome and 15–16% in school-age patients and adolescents.

In idiopathic, hereditary, and secondary forms of nephrotic syndrome, there are immune and nonimmune insults to the podocyte that lead to foot process effacement of the podocyte, a decrease in number of functional podocytes, and altered slit diaphragm integrity. The end result is increased protein leakiness across the glomerular capillary wall into the urinary space.

Role of the Immune System

Minimal change nephrotic syndrome (MCNS) may occur after viral infections and allergen challenges. MCNS has also been found to occur in children with Hodgkin lymphoma and T-cell lymphoma. That immunosuppression occurs with drugs such as corticosteroids and cyclosporine and provides indirect additional evidence that the immune system contributes to the overall pathogenesis of the nephrotic syndrome.

Considering the recurrence rate of 30% after kidney transplantation, a permeability factor was implicated in pathophysiology of FSGS. Rat glomeruli exposed to patient sera with FSGS has demonstrated increased permeability to albumin. A subset of adult and pediatric patients was found to have circulating nephrin autoantibodies, suggesting the role of circulating antibodies in the pathogenesis of MCNS.

CLINICAL CONSEQUENCES OF NEPHROTIC SYNDROME

Edema

Edema is the most common presenting symptom of children with nephrotic syndrome. Despite its almost universal presence, there is uncertainty as to the exact mechanism of edema formation. There are two opposing theories, the *underfill hypothesis* and the *overfill hypothesis,* that have been proposed as mechanisms causing nephrotic edema.

The *underfill hypothesis* is based on nephrotic-range proteinuria that leads to a fall in the plasma protein level with a corresponding decrease in intravascular oncotic pressure. This leads to leakage of plasma water into the interstitium, generating edema. As a result of reduced intravascular volume, there is increased secretion of vasopressin and atrial natriuretic factor, which, along with aldosterone, results in increased sodium and water retention by the tubules. Sodium and water retention therefore occur as a consequence of intravascular volume depletion.

This hypothesis does not fit the clinical picture of some patients with edema caused by nephrotic syndrome who have clinical signs of intravascular volume overload, not volume depletion. Treating these patients with albumin alone may not be sufficient to induce a diuresis without the concomitant use of diuretics. Also, reducing the renin-aldosterone axis with mineralocorticoid receptor antagonists does not result in a marked increase in sodium excretion. With the onset of remission of MCNS, many children will have increased urine output before their urinary protein excretion is measurably reduced.

The *overfill hypothesis* postulates that nephrotic syndrome is associated with primary sodium retention, with subsequent volume expansion and leakage of excess fluid into the interstitium. There is accumulating evidence that the epithelial sodium channel in the distal tubule may play a key role in sodium reabsorption in nephrotic syndrome. The clinical weaknesses of this hypothesis are evidenced by the numerous nephrotic patients who present with an obvious clinical picture of intravascular volume depletion: low blood pressure, tachycardia, and elevated hemoconcentration. Furthermore, amiloride, an epithelial sodium channel blocker, used alone is not sufficient to induce adequate diuresis.

The goal of therapy should be a gradual reduction of edema with judicious use of diuretics, sodium restriction, and cautious use of IV albumin infusions, if indicated.

Hyperlipidemia

There are several alterations in the lipid profile in children with nephrotic syndrome, including an increase in cholesterol, triglycerides, low-density lipoproteins, and very low-density lipoproteins. The high-density lipoprotein level remains unchanged or is low. In adults, this results in an increase in the adverse cardiovascular risk ratio, although the implications for children are not as serious, especially those with steroid-responsive nephrotic syndrome. Hyperlipidemia is thought to be the result of increased synthesis as well as decreased catabolism of lipids. Although commonplace in adults, the use of lipid-lowering agents in children is uncommon.

Increased Susceptibility to Infections

Children with nephrotic syndrome are especially susceptible to infections such as cellulitis, spontaneous bacterial peritonitis, and

Management of childhood onset nephrotic syndrome. Pediatrics. 2009;124:747–757.)*

bacteremia. This occurs as a result of many factors, particularly hypoglobulinemia, as a result of the urinary losses of immunoglobulin (Ig) G. In addition, defects in the complement cascade from urinary loss of complement factors (predominantly C3 and C5), as well as alternative pathway factors B and D, lead to impaired opsonization of microorganisms. Children with nephrotic syndrome are at significantly increased risk for infection with encapsulated bacteria and, in particular, pneumococcal disease. **Spontaneous bacterial peritonitis** presents with fever, abdominal pain, and peritoneal signs. Although pneumococcus is the most frequent cause of peritonitis, gram-negative bacteria also are associated with a significant number of cases. Children with nephrotic syndrome and fever or other signs of infection must be evaluated aggressively, with appropriate cultures drawn, and should be treated promptly and empirically with antibiotics. Peritoneal leukocyte counts >250 cells/μL are highly suggestive of spontaneous bacterial peritonitis.

Hypercoagulability

Nephrotic syndrome is a hypercoagulable state resulting from multiple factors: vascular stasis from hemoconcentration and intravascular volume depletion, increased platelet number and aggregability, and changes in coagulation factor levels. There is an increase in hepatic production of fibrinogen along with urinary losses of antithrombotic factors such as antithrombin III and protein S. Deep venous thrombosis may occur in any venous bed, including the cerebral venous sinus, renal vein, and pulmonary veins. The clinical risk is low in children (2–5%) compared with adults but has the potential for serious consequences.

567.1 Idiopathic Nephrotic Syndrome

Elif Erkan

Approximately 90% of children with nephrotic syndrome have idiopathic nephrotic syndrome. Idiopathic nephrotic syndrome is associated with primary glomerular disease without an identifiable causative disease or drug. Idiopathic nephrotic syndrome includes multiple histologic types: minimal change disease, mesangial proliferation, focal segmental glomerulosclerosis, membranous nephropathy, and membranoproliferative glomerulonephritis.

PATHOLOGY

In **minimal change nephrotic syndrome (MCNS)** (approximately 85% of total cases of nephrotic syndrome in children), the glomeruli appear normal or show a minimal increase in mesangial cells and matrix. Findings on immunofluorescence microscopy are typically negative, and electron microscopy simply reveals effacement of the

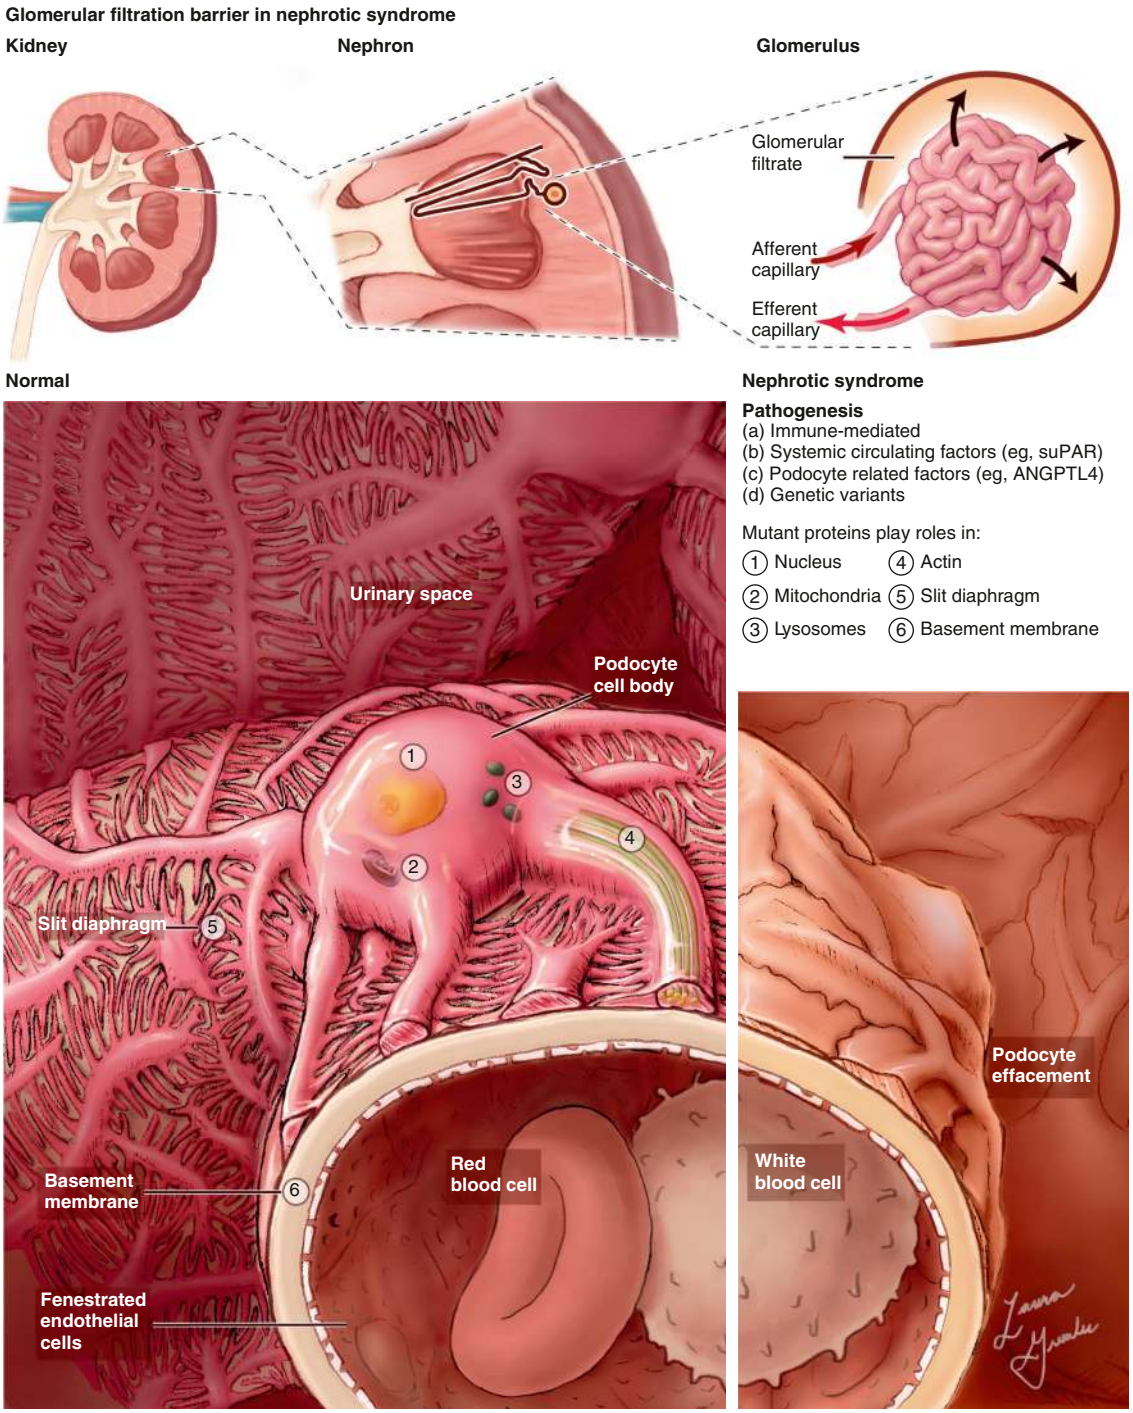

Fig. 567.2 The glomerular filtration barrier and pathogenesis of idiopathic nephrotic syndrome. Within the kidney is the glomerulus, a capillary tuft that filters the blood. The podocyte, glomerular basement membrane, and fenestrated glomerular endothelium form the glomerular filtration barrier, allowing the ultrafiltrate to enter the urinary space. The podocyte has extensive cellular extensions that interdigitate, and these foot processes are connected by the slit diaphragm. In nephrotic syndrome, there is extensive effacement of the podocytes and loss of this barrier to protein, allowing excessive serum albumin to leak into the urine. The pathogenesis of idiopathic nephrotic syndrome is hypothesized to be either immune mediated, due to a systemic podocyte-derived circulating factor, or, in rarer or familial forms, a genetic variant. Numerous pathogenic variants are associated with steroid-resistant nephrotic syndrome that affect various parts of the podocyte itself or the other constituents of the glomerular basement membrane. These include pathogenic variants affecting the podocyte nucleus, mitochondria or lysosomes, the slit diaphragm or actin cytoskeleton, and the glomerular basement membrane. Nephrin, podocin, and CD2AP, for example, are essential components of a zipper-like structure spanning the interdigitating foot processes of the podocyte and the slit diaphragm and link directly with the podocyte actin cytoskeleton. The actin cytoskeleton is further supported by microfilaments that maintain structural stability and facilitate the dynamic nature of the podocyte structure and function. The importance of these microfilaments is evident because pathogenic variants in both α-actinin 4 and INF2, which are involved in actin regulation and polymerization, lead to FSGS. *(From Noone DG, Iijima K, Parekh R. Idiopathic nephrotic syndrome in children. Lancet. 2018;392:61–72. Fig. 2.)*

epithelial cell foot processes. More than 95% of children with minimal change disease respond to corticosteroid therapy.

Mesangial proliferation is characterized by a diffuse increase in mesangial cells and matrix on light microscopy. Immunofluorescence microscopy might reveal trace to 1+ mesangial IgM and/or IgA staining. Electron microscopy reveals increased numbers of mesangial cells and matrix as well as effacement of the epithelial cell foot processes. Approximately 50% of patients with this histologic lesion respond to corticosteroid therapy.

In **focal segmental glomerulosclerosis (FSGS),** glomeruli show lesions that are both focal (present only in a proportion of glomeruli) and segmental (localized to ≥1 intraglomerular tufts). The lesions consist of mesangial cell proliferation and segmental scarring on light microscopy (Fig. 567.3; see Table 567.2). Immunofluorescence microscopy is positive for IgM and C3 staining in the areas of segmental sclerosis. Electron microscopy demonstrates segmental scarring of the glomerular tuft with obliteration of the glomerular capillary lumen. The tip variant of FSGS is more common in Caucasians and is associated with better renal survival; by contrast, the collapsing variant of FSGS has a faster progression rate to end-stage kidney disease and is more common in Black patients.

Lesions consistent with FSGS may be seen secondary to HIV infection, vesicoureteral reflux, and IV use of heroin and other drugs of abuse. Only 20% of patients with FSGS respond to prednisone. The disease is often progressive, ultimately involving all glomeruli with end-stage kidney disease in most patients.

MINIMAL CHANGE NEPHROTIC SYNDROME

Clinical Manifestations

Idiopathic nephrotic syndrome is more common in males than in females (2:1) and most commonly appears between the ages of 2 and 6 years (see Fig. 567.1). However, it has been reported as early as 6 months of age and throughout adulthood. MCNS is present in 85–90% of patients <6 years of age. In contrast, only 20–30% of adolescents who present for the first time with nephrotic syndrome have MCNS. The more common cause of idiopathic nephrotic syndrome in this older age group is FSGS. The incidence of FSGS is increasing; it may be more common in Black, Hispanic, and Asian patients. FSGS is the most common cause of end-stage kidney disease in adolescents.

The initial episode of idiopathic nephrotic syndrome, as well as subsequent relapses, usually follows minor infections and, uncommonly, reactions to insect bites, bee stings, or poison ivy.

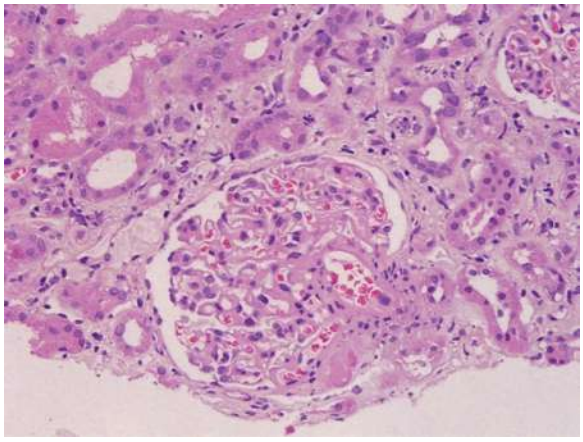

Fig. 567.3 Steroid-resistant nephrotic syndrome (SRNS). Kidney biopsy image of patient with SRNS shows focal segmental glomerulosclerosis. Segmental sclerosis is noted in a perihilar location with hyalinosis. Evidence of tubular atrophy and interstitial fibrosis is also present. H&E magnification 20×. *(From Tullus K, Webb H, Bagga A. Management of steroid-resistant nephrotic syndrome in children and adolescents. Lancet Child Adolesc Health. 2018;2:880–888. Fig. 1B, p. 881.)*

Children usually present with mild edema, which is initially noted around the eyes and in the lower extremities. Nephrotic syndrome can initially be misdiagnosed as an allergic disorder because of the periorbital swelling that decreases throughout the day. With time, the edema becomes generalized, with the development of ascites, pleural effusions, and genital edema. Anorexia, irritability, abdominal pain, and diarrhea are common. Important features of MCNS are the absence of hypertension and gross hematuria (the so-called nephritic features).

The differential diagnosis of the child with marked edema includes protein-losing enteropathy, hepatic failure, heart failure, acute or chronic glomerulonephritis, and protein malnutrition. A diagnosis other than MCNS should be considered in children <1 year of age, with a positive family history of nephrotic syndrome, and/or the presence of extrarenal findings (e.g., arthritis, rash, anemia), hypertension or pulmonary edema, acute or chronic renal insufficiency, and gross hematuria.

Diagnosis

Recommendations for the Initial Evaluation of Children with Nephrotic Syndrome

Confirming the Diagnosis of Nephrotic Syndrome. The initial workup for a child with nephrotic syndrome is shown in Table 567.4. Labs should be obtained including urinalysis with the first morning urine protein:creatinine ratio, CBC, serum electrolytes, BUN, creatinine, glomerular filtration rate, albumin, complement C3 and C4 levels, antinuclear and anti-streptococcal antibodies, and antineutrophil cytoplasmic antibodies.

The urinalysis reveals 3+ or 4+ proteinuria, and microscopic hematuria is present in 20% of children. A spot urine protein:creatinine ratio should be >2.0. The serum creatinine value is usually normal, but it may be abnormally elevated if there is diminished renal perfusion from contraction of the intravascular volume. The serum albumin level is <2.5 g/dL, and serum cholesterol and triglyceride levels are elevated. Serum complement levels are normal. Kidney ultrasound may be considered to exclude renal malformations and venous thrombosis but is not mandatory. A renal biopsy is not routinely performed if the patient fits the standard clinical picture of MCNS.

Treatment

Children with their first episode of nephrotic syndrome and mild to moderate edema may be managed as outpatients. Such outpatient management is not practiced in all major centers, because the time required for successful education of the family regarding all aspects of the condition can require a short period of hospitalization. The child's parents must be able to recognize the signs and symptoms of the complications of the disease and may be taught how to use a dipstick and interpret the results to monitor for the degree of proteinuria. Tuberculosis must be ruled out before starting immunosuppressive therapy with corticosteroids by placing a purified protein derivative skin test or obtaining an interferon-gamma release assay and confirming a negative result.

Children with onset of uncomplicated nephrotic syndrome between 1 and 12 years of age are likely to have steroid-responsive MCNS, and steroid therapy may be initiated without a diagnostic renal biopsy. Children with features that make MCNS less likely (gross hematuria, sustained hypertension, acute kidney injury, low C3 levels, arthritis and/or rash to suggest glomerulonephritis, or age <1 year or >12 years) should be considered for renal biopsy before treatment.

Use of Corticosteroids to Treat Minimal Change Nephrotic Syndrome

Corticosteroids are the mainstay of therapy for MCNS. The treatment guidelines for corticosteroid use presented in the following sections are adapted from and based on the 2021 Kidney Disease: Improving

Table 567.4 Investigations in a Child with Nephrotic Syndrome (NS)

BASELINE INVESTIGATIONS
1. Urinalysis and urine microscopy
2. Urine albumin or protein:creatinine ratio
3. 24-hr timed collection of urine for protein quantification
4. Serum electrolytes, albumin, total protein, renal function, and cholesterol
ADDITIONAL TESTING IF THERE IS A SUSPICION OF A GLOMERULONEPHRITIS
1. Serum complement C3 and C4 concentrations
2. Serum immunoglobulins
3. Antistreptolysin titers
4. Anti-DNase B antibodies
5. Antinuclear antigen antibodies
6. Anti–double-stranded DNA antibodies
7. Anti-neutrophil cytoplasmic antibodies
INFECTIOUS WORKUP DEPENDING ON CLINICAL CONTEXT
1. Hepatitis B and C, HIV, syphilis, or tuberculosis can also be considered depending on the clinical context
CONSIDERATION OF GENETIC TESTING
1. A positive family history of NS
2. Congenital NS
3. Failure to respond to steroid therapy
4. Persistent kidney dysfunction
5. Features suggestive of a known syndrome (appendix)
RENAL BIOPSY CONSIDERED IN THE FOLLOWING SITUATIONS
1. Age <1 or >12 years
2. Persistent or sustained elevation in creatinine
3. Significant hematuria or gross hematuria
4. Hypocomplementemia
5. Findings indicative of another autoimmune disease
6. Infection with hepatitis B or C, HIV, or tuberculosis
7. Hypertension
8. Glucocorticoid resistance

From Noone DG, Iijima K, Parekh R. Idiopathic nephrotic syndrome in children. *Lancet.* 2018;392:61–72. Panel 3.

Global Outcomes (KDIGO) clinical practice guidelines on glomerulonephritis (Fig. 567.4).

Treatment of the Initial Episode of Nephrotic Syndrome

In children with presumed MCNS, prednisone or prednisolone should be administered as a single daily dose of 60 mg/m^2/day or 2 mg/kg/day to a maximum of 60 mg daily for 4-6 weeks followed by alternate-day prednisone (starting at 40 mg/m^2 every other day or 1.5 mg/kg every other day) for a period ranging from 4-6 weeks. The issue of the duration of steroid treatment has been controversial, but current evidence suggests that prolonged (>12 weeks) glucocorticoid treatment increases the risk of adverse effects without further improving clinical outcomes. Approximately 80–90% of children respond to steroid therapy.

Response is defined as the attainment of remission within the initial 4 weeks of corticosteroid therapy. **Remission** consists of a urine protein:creatinine ratio of <0.2 or <1+ protein on urine dipstick testing for 3 consecutive days. Most children who respond to prednisone therapy do so within the first 5 weeks of treatment.

Managing the Clinical Sequelae of Nephrotic Syndrome

Edema. Children with severe symptomatic edema, including large pleural effusions, ascites, or severe genital edema, should be hospitalized. In addition to sodium restriction (<1,500 mg daily), water/fluid restriction may be necessary if the child is hyponatremic. A swollen scrotum may be elevated with pillows to enhance fluid removal by gravity. Diuresis may be augmented by the administration of loop diuretics (furosemide), orally or intravenously, *although extreme caution should be exercised.* Aggressive diuresis can lead to intravascular volume depletion and an increased risk for acute renal failure and intravascular thrombosis.

When a patient has severe generalized edema with evidence of intravascular volume depletion (e.g., hemoconcentration, hypotension, tachycardia), IV administration of 25% albumin (0.5-1.0 g albumin/kg) as a slow infusion followed by furosemide (1-2 mg/kg/dose IV) is sometimes necessary. Such therapy should be used only in collaboration with a pediatric nephrologist and mandates close monitoring of volume status, blood pressure, serum electrolyte balance, and renal function. Symptomatic volume overload, with hypertension, heart failure, and pulmonary edema, is a potential complication of parenteral albumin therapy, particularly when it is administered as a rapid infusion.

Dyslipidemia. Dyslipidemia should be managed with a low-fat diet. Dietary fat intake should be limited to <30% of calories with a saturated fat intake of <10% calories. Dietary cholesterol intake should be <300 mg/day. There are insufficient data to recommend the use of 3-hydroxy-3-methylgluataryl coenzyme A (HMG-CoA) reductase inhibitors routinely in children with dyslipidemia.

Infections. Families of children with nephrotic syndrome should be counseled regarding the signs and symptoms of infections such as cellulitis, peritonitis, and bacteremia. If there is a suspicion of infection, a blood culture should be drawn before starting empiric antibiotic therapy. In the case of spontaneous bacterial peritonitis, peritoneal fluid should be collected if there is sufficient fluid to perform a paracentesis and sent for cell count, Gram stain, and culture. The antibiotic provided must be of broad enough coverage to include pneumococcus and gram-negative bacteria. A third-generation cephalosporin is a common choice of IV antibiotic.

Thromboembolism. Children who present with the clinical signs of thromboembolism should be evaluated with appropriate imaging studies to confirm the presence of a clot. Studies to delineate a specific underlying hypercoagulable state are recommended. In children with thrombotic events, anticoagulation therapy including heparin, low molecular weight heparin, and warfarin are therapeutic options that appear to be effective.

Obesity and Growth. Glucocorticoids may increase the body mass index in children who are overweight when steroid therapy is initiated, and these children are more likely to remain overweight. Anticipatory dietary counseling is recommended. Growth may be affected in children who require long-term corticosteroid therapy. Steroid-sparing strategies may improve linear growth in children who require prolonged courses of steroids.

Relapse of Nephrotic Syndrome. Relapse of nephrotic syndrome is defined as a urine protein:creatinine ratio of >2 or ≥3+ protein on urine dipstick testing for 3 consecutive days. Relapses are common, especially in younger children, and are often triggered by upper respiratory or gastrointestinal infections. Relapses are usually treated similar to the initial episode, except that daily prednisone courses are shortened. Daily high-dose prednisone is given until the child has achieved remission, and the regimen is then switched to alternate-day therapy. The duration of alternate-day therapy varies depending on the frequency of relapses of the individual child. Children are classified as infrequent relapsers or frequent relapsers, and as being steroid dependent, based on the number of relapses in a 12-month period or their inability to remain in remission following discontinuation of steroid therapy.

Steroid Resistance. Steroid resistance is defined as the failure to achieve remission after 4 weeks of corticosteroid therapy. Children with steroid-resistant nephrotic syndrome require further evaluation, including a diagnostic kidney biopsy and genetic testing. Steroid-resistant nephrotic syndrome is usually caused by FSGS (80%), MCNS, or membranoproliferative glomerulonephritis.

Implications of Steroid-Resistant Nephrotic Syndrome. Steroid-resistant nephrotic syndrome, and specifically FSGS, is associated with a 50% risk for end-stage kidney disease within 5 years of diagnosis if patients do not achieve a partial or complete remission. Persistent nephrotic syndrome is associated with a poor

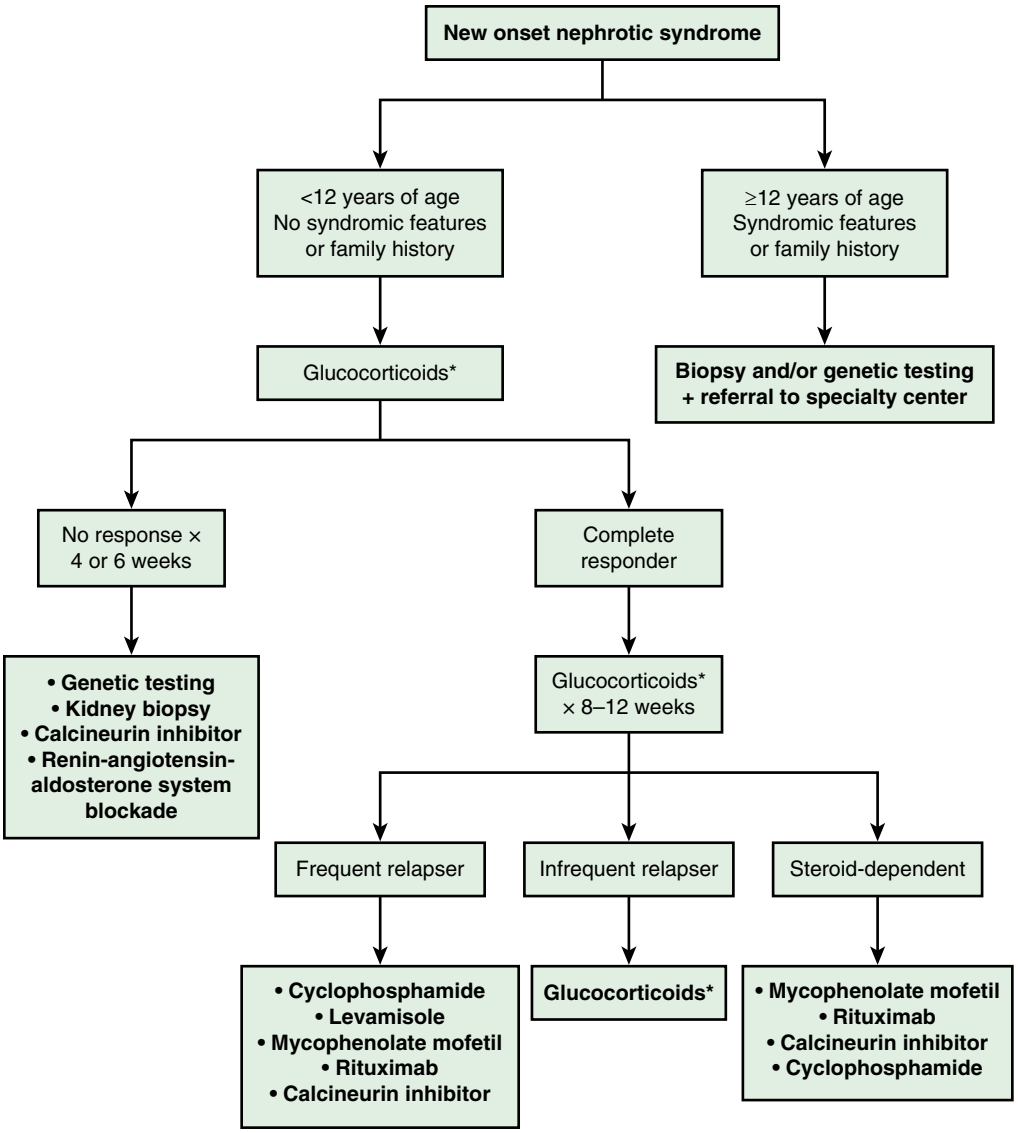

Fig. 567.4 Treatment algorithm for new-onset nephrotic syndrome (NS). Therapeutic approach to NS in children from onset. *Glucocorticoids include PO prednisone or prednisolone. NS, Nephrotic syndrome. *(From Kidney Disease: Improving Global Outcomes (KDIGO) Glomerular Diseases Work Group. KDIGO 2021 Clinical Practice Guideline for the Management of Glomerular Diseases. Kidney Int. 2021;100[4S]:S1–S276. Fig. 40.)*

patient-reported quality of life, hypertension, serious infections, and thromboembolic events. Children reaching end-stage kidney disease have a greatly reduced life expectancy compared with their peers.

Alternative Therapies to Corticosteroids in the Treatment of Nephrotic Syndrome. Steroid-dependent patients, frequent relapsers, and steroid-resistant patients are candidates for alternative therapies, particularly if they have severe corticosteroid toxicity (cushingoid appearance, hypertension, cataracts, and/or growth failure). **Cyclophosphamide** prolongs the duration of remission and reduces the number of relapses in children with **frequently relapsing** and **steroid-dependent** nephrotic syndrome. The potential side effects of the drug (neutropenia, disseminated varicella, hemorrhagic cystitis, alopecia, sterility, increased risk of future malignancy) should be carefully reviewed with the family before initiating treatment. Cyclophosphamide (2 mg/kg) is given as a single oral dose for a total duration of 8-12 weeks. Alternate-day prednisone therapy is often continued during cyclophosphamide administration. During cyclophosphamide therapy, the white blood cell count must be monitored weekly, and the drug should be withheld if the count falls below 5,000/mm^3. The cumulative threshold dose above which oligospermia or azoospermia occurs in males is >250 mg/kg.

Calcineurin inhibitors (cyclosporine or tacrolimus) are recommended as initial therapy for children with **steroid-resistant** nephrotic syndrome. Children must be monitored for side effects, including hypertension, nephrotoxicity, hirsutism, and gingival hyperplasia. **Mycophenolate** can maintain remission in children with steroid-dependent or frequently relapsing nephrotic syndrome. **Levamisole**, an anthelmintic agent with immunomodulating effects that has been shown to reduce the risk of relapse when compared with prednisone, is not available in the United States.

Rituximab, the chimeric monoclonal antibody against CD20-targeting B cells, was found to be effective in children by maintaining remission and decreasing the number of relapses in steroid-dependent and/or steroid-resistant nephrotic syndrome. Randomized trials with rituximab have shown promising results of an up to 80% drug-free remission rate at 1 year in patients with steroid-dependent nephrotic syndrome. However, rituximab is less effective in patients treated with calcineurin inhibitors and steroids and with multidrug-resistant nephrotic syndrome.

Most children who respond to cyclosporine, tacrolimus, or mycophenolate therapy tend to relapse when the medication is discontinued. Angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers may be helpful as adjunct therapy to reduce proteinuria in steroid-resistant patients.

Immunizations in Children with Nephrotic Syndrome. To reduce the risk of serious infections in children with nephrotic syndrome, give the full pneumococcal vaccination (with the 13-valent conjugant vaccine and 23-valent polysaccharide vaccine) and influenza vaccination annually to the child and their household contacts; defer vaccination with live vaccines until the prednisone dose is below either 1 mg/kg daily or 2 mg/kg on alternate days. Live virus vaccines are contraindicated in children receiving corticosteroid-sparing agents such as cyclophosphamide or cyclosporine. Following close contact with varicella infection, give immunocompromised children taking immunosuppressive agents varicella-zoster immune globulin if available; immunize healthy household contacts with live vaccines to minimize the risk of transfer of infection to the immunosuppressed child, but avoid direct exposure of the child to gastrointestinal or respiratory secretions of vaccinated contacts for 3-6 weeks after vaccination.

Table 567.5 provides monitoring recommendations for children with nephrotic syndrome.

Prognosis

Most children with steroid-responsive nephrotic syndrome have repeated relapses, which generally decrease in frequency as the child grows older. Although there is no proven way to predict an individual child's course, children who respond rapidly to steroids and those who have no relapses during the first 6 months after diagnosis are likely to follow an infrequently relapsing course. It is important to indicate to the family that the child with steroid-responsive nephrotic syndrome is unlikely to develop chronic kidney disease, that the disease is rarely hereditary, and that the child (in the absence of prolonged cyclophosphamide therapy) will remain fertile. To minimize the psychologic effects of the condition and its therapy, children with idiopathic nephrotic syndrome should not be considered chronically ill and should participate in all age-appropriate childhood activities and maintain an unrestricted diet when in remission.

Children with steroid-resistant nephrotic syndrome, most often caused by FSGS, generally have a much poorer prognosis. These children develop progressive renal insufficiency, ultimately leading to end-stage kidney disease requiring dialysis or kidney transplantation. Recurrent nephrotic syndrome develops in 30–50% of transplant recipients with FSGS.

567.2 Secondary Nephrotic Syndrome

Elif Erkan

Nephrotic syndrome can occur as a secondary feature of many forms of glomerular disease. Membranous nephropathy, membranoproliferative glomerulonephritis, postinfectious glomerulonephritis, lupus nephritis, and IgA vasculitis nephritis (formerly Henoch-Schönlein purpura nephritis) can all have a nephrotic component (see Tables 567.1 and 567.3). Secondary nephrotic syndrome should be suspected in patients >12 years and those with sustained hypertension, hematuria, renal dysfunction, extrarenal symptoms (e.g., rash, arthralgias, fever), or depressed serum complement levels. In certain areas of the world, malaria and schistosomiasis are the leading causes of nephrotic syndrome. Other infectious agents associated with nephrotic syndrome include hepatitis B virus, hepatitis C virus, filaria, leprosy, and HIV.

Nephrotic syndrome has been associated with malignancy, particularly in the adult population. In patients with solid tumors, such as carcinomas of the lung and gastrointestinal tract, the renal pathology often resembles membranous glomerulopathy. Immune complexes composed of tumor antigens and tumor-specific antibodies presumably mediate the renal involvement. In patients with lymphomas, particularly Hodgkin lymphoma, the renal pathology most often resembles MCNS. The proposed mechanism of

the nephrotic syndrome is that the lymphoma produces a lymphokine that increases permeability of the glomerular capillary wall. Nephrotic syndrome can develop before or after the malignancy is detected, resolve as the tumor regresses, and return if the tumor recurs.

Nephrotic syndrome has also developed during therapy with numerous drugs and chemicals. The histologic picture can resemble membranous glomerulopathy (penicillamine, captopril, gold, nonsteroidal antiinflammatory drugs, mercury compounds), MCNS (probenecid, ethosuximide, methimazole, lithium), or proliferative glomerulonephritis (procainamide, chlorpropamide, phenytoin, trimethadione, paramethadione).

567.3 Congenital Nephrotic Syndrome

Elif Erkan

Nephrotic syndrome (massive proteinuria, hypoalbuminemia, edema, and hypercholesterolemia) has a poorer prognosis when it occurs in the first year of life, when compared with nephrotic syndrome manifesting in childhood. **Congenital nephrotic syndrome** is defined as nephrotic syndrome manifesting at birth or within the *first 3 months of life.* Congenital nephrotic syndrome may be classified as primary or as secondary to a number of etiologies such as in utero infections (cytomegalovirus, toxoplasmosis, syphilis, hepatitides B and C, HIV), infantile systemic lupus erythematosus, or mercury exposure.

Primary congenital nephrotic syndrome is due to a variety of syndromes inherited as autosomal recessive disorders (see Table 567.3). A number of structural and functional abnormalities of the glomerular filtration barrier causing congenital nephrotic syndrome have been elucidated. In a large European cohort of children with congenital nephrotic syndrome, 85% carried pathogenic variants in four genes *(NPHS1, NPHS2, WT1,* and *LAMB2),* the first three of which encode components of the glomerular filtration barrier. The Finnish type of congenital nephrotic syndrome is caused by pathogenic variants in the *NPHS1* or *NPHS2* gene, which encodes nephrin and podocin, critical components of the slit diaphragm. Affected infants most commonly present at birth with edema caused by massive proteinuria, and they are typically delivered with an enlarged placenta (>25% of the infant's weight). Severe hypoalbuminemia, hyperlipidemia, and hypogammaglobulinemia result from loss of filtering selectivity at the glomerular filtration barrier. Prenatal diagnosis can be made by the presence of elevated maternal and amniotic α-fetoprotein levels.

Denys-Drash syndrome is caused by pathogenic variants in the *WT1* gene, which results in abnormal podocyte function. Patients present with early-onset nephrotic syndrome, progressive renal insufficiency, ambiguous genitalia, and Wilms tumor.

Pathogenic variants in the *LAMB2* gene, seen in **Pierson syndrome,** lead to abnormalities of β_2-laminin, a critical component of the glomerular and ocular basement membranes. In addition to congenital nephrotic syndrome, affected infants display bilateral microcoria (fixed narrowing of the pupil).

Galloway-Mowat syndrome is characterized by microcephaly with hiatal hernia and congenital nephrotic syndrome. Patients have distinctive kidney biopsy findings with loss of or poor basement membrane formation or permeation of their basement membranes with fibrils.

Regardless of the etiology of congenital nephrotic syndrome, the diagnosis is made clinically in newborns or infants who demonstrate severe generalized edema, poor growth and nutrition with hypoalbuminemia, increased susceptibility to infections, hypothyroidism (from urinary loss of thyroxin-binding globulin), and an increased risk of thrombotic events (urinary loss of antithrombin). Most infants have progressive renal insufficiency.

Focal segmental sclerosis
Membranous nephropathy

From Kliegman RM, Greenbaum LA, Lye PS, eds. *Practical Strategies in Pediatric Diagnosis and Therapy,* 2nd ed. Philadelphia: Elsevier; 2004: p. 418.

Albumin and diuretic infusions, providing high amounts of protein (3-4 g/kg), lipids, and a high caloric intake to maintain nutrition, along with vitamin and thyroid hormone replacement, have been the mainstream therapy for congenital nephrotic syndrome. Treatment of the congenital syndrome also consists of unilateral nephrectomy and use of angiotensin-converting enzyme inhibitors and/or indomethacin to decrease the proteinuria and glomerular filtration rate. Some centers prefer more aggressive therapy, including bilateral nephrectomy at 1-2 years of age, weight >7 kg, and initiation of peritoneal dialysis with subsequent kidney transplantation.

Secondary congenital nephrotic syndrome can resolve with treatment of the underlying cause, such as syphilis (Table 567.6). The management of primary congenital nephrotic syndrome includes intensive supportive care with IV albumin and diuretics, regular administration of IV γ-globulin, and aggressive nutritional support (often parenteral), while attempting to pharmacologically decrease urinary protein loss with angiotensin-converting enzyme inhibitors, angiotensin II receptor inhibitors, and prostaglandin synthesis inhibitors, or even unilateral nephrectomy. If conservative management fails and patients suffer from persistent anasarca or repeated severe infections, bilateral nephrectomies are performed, and chronic dialysis is initiated. Renal transplantation is the definitive treatment of congenital nephrotic syndrome, though recurrence of the nephrotic syndrome has been reported to occur after transplantation.

Section 4

Tubular Disorders

Chapter 568

Tubular Function

Eliza Blanchette and Bradley P. Dixon

Water and electrolytes are freely filtered at the level of the glomerulus. Thus the electrolyte content of ultrafiltrate at the beginning of the proximal tubule is similar to that of plasma. Carefully regulated processes of tubular reabsorption and/or tubular secretion determine the final water content and electrolyte composition of urine. Bulk movement of solute tends to occur in the proximal portions of the nephron, and fine adjustments tend to occur distally (see Chapter 73).

SODIUM

Sodium is essential in maintaining extracellular fluid balance and, thus, volume status. The kidney is capable of effecting large changes in sodium excretion in a variety of normal and pathologic states.

There are four main sites of sodium transport. Approximately 60% of sodium is absorbed in the proximal tubule by coupled transport with glucose, amino acids, and phosphate; 25% in the ascending loop of Henle (mediated by NKCC2, the loop diuretic-sensitive sodium-potassium-2 chloride transporter); and 15% in the distal tubule (mediated by NCCT, the thiazide-sensitive sodium chloride co-transporter) and collecting tubule (mediated by ENaC, the epithelial sodium channel).

The urinary excretion of sodium normally approximates the sodium intake of 2-6 mEq/kg/24 hr for a child consuming a typical American diet, minus 1-2 mEq/kg/24 hr required for normal metabolic processes. However, in states of volume depletion (dehydration, blood loss) or decreased effective circulating blood volume (septic shock, hypoalbuminemic states, heart failure), there may be a dramatic decrease in urinary sodium excretion to as low as 1 mEq/L. Changes in systemic volume status are detected by (1) baroreceptors in the atria, afferent arteriole, and carotid sinus and (2) by the macula densa, which detects changes in chloride delivery.

The major hormonal mechanisms mediating sodium balance include the renin-angiotensin-aldosterone axis, atrial natriuretic factor, and norepinephrine. Angiotensin II and aldosterone increase sodium reabsorption in the proximal tubule and distal tubule, respectively. Norepinephrine, released in response to volume depletion, does not directly act on tubular transport mechanisms but affects sodium balance by decreasing renal blood flow, thus decreasing the filtered load of sodium as well as stimulating renin release. With more severe volume depletion, antidiuretic hormone is also released (see Chapter 570). Sodium excretion is promoted by atrial natriuretic factor and suppression of renin.

POTASSIUM

Extracellular potassium homeostasis is regulated because small changes in plasma potassium concentrations have dramatic effects on cardiac, neural, and neuromuscular function (see Chapter 73.4). Essentially, all filtered potassium is fully reabsorbed in the proximal tubule and ascending loop of Henle. Therefore urinary excretion of potassium is completely dependent on tubular secretion by potassium channels (renal outer medullary potassium [ROMK] and big potassium [BK] channels) present in the principal cells of the collecting tubule. Factors that promote potassium secretion include aldosterone, increased sodium delivery to the distal nephron, and increased urine flow rate.

CALCIUM

A significant portion of filtered calcium (70%) is reabsorbed in the proximal tubule. Additional calcium is reabsorbed in the ascending loop of Henle (20%) and the distal tubule and collecting duct (5–10%). Calcium is reabsorbed by passive movement between cells (paracellular absorption) in a process driven by sodium chloride reabsorption and potassium recycling into the lumen. In addition, calcium uptake is actively regulated by calcium receptors, specific transporters, and calcium channels. Factors that promote calcium reabsorption include parathyroid hormone (released in response to hypocalcemia), calcitonin, vitamin D, thiazide diuretics, and volume depletion (see Chapter 610). Factors that promote calcium excretion include volume expansion, increased sodium intake, and diuretics such as mannitol and furosemide.

PHOSPHATE

The majority of filtered phosphate is reabsorbed in the proximal tubule by active transport coupled with sodium through the NaPi2a, NaPi2c, and PiT-2 channels. Reabsorption is increased by dietary phosphorus restriction, volume contraction, and growth hormone. Fibroblast growth factor 23 (FGF-23), parathyroid hormone, and volume expansion increase phosphate excretion.

MAGNESIUM

Approximately 25% of filtered magnesium is reabsorbed in the proximal tubule. Modulation of renal magnesium excretion occurs primarily in the ascending loop of Henle, with some contribution of the distal convoluted tubule. Magnesium is transported by the paracellular route similar to calcium, as well as through the transcellular route. Although specific magnesium transporters for transcellular absorption have been identified such as TRPM6, the precise mechanisms by which they are regulated remain unclear.

ACIDIFICATION AND CONCENTRATING MECHANISMS

Acidification and concentration are addressed in the sections on renal tubular acidosis and nephrogenic diabetes insipidus, respectively (see Chapters 569 and 570).

DEVELOPMENTAL CONSIDERATIONS

The tubular transport capabilities of neonates (especially premature infants) and young infants are less than those of adults. Although nephrogenesis (the formation of new glomerular/tubular units) is complete by about 36 weeks of gestation, significant tubular maturation occurs during infancy. Renal tubular immaturity, a reduced glomerular filtration rate, a decreased concentrating gradient, and a diminished responsiveness to antidiuretic hormone are characteristic of young infants. These factors can contribute to impaired regulation of water, solute, and electrolyte and acid-base homeostasis, particularly during times of acute illness.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

Chapter 569

Renal Tubular Acidosis

Melisha G. Hanna and Bradley P. Dixon

Renal tubular acidosis (RTA) is a disease state characterized by a non–anion gap (hyperchloremic) metabolic acidosis in the setting of a normal or near-normal glomerular filtration rate. There are four main types of RTA: proximal (type II), classic distal (type I), hyperkalemic (type IV), and a combined proximal and distal (type III). Proximal RTA (pRTA) results from impaired bicarbonate reabsorption and distal RTA (dRTA) from failure to secrete acid. These defects may be inherited and persistent from birth or acquired, as is seen more commonly in clinical practice.

NORMAL URINARY ACIDIFICATION

Kidneys contribute to the acid-base balance by reabsorption of filtered bicarbonate (HCO_3^-) and excretion of hydrogen ion (H^+) produced every day. Hydrogen ion secretion from tubule cells into the lumen is key in the reabsorption of HCO_3^- and the formation of titratable acid (H^+ bound to buffers such as HPO_4^{2-}) and ammonium ions (NH_4^+). Because loss of filtered HCO_3^- is equivalent to the addition of H^+ to the body, all filtered bicarbonate should be absorbed before dietary H^+ can be excreted. Approximately 90% of filtered bicarbonate is absorbed in the proximal tubule and the remaining 10% in the distal segments, mostly the thick ascending limb and outer medullary collecting tubule (Fig. 569.1). In the proximal tubule and thick ascending limb of the loop of Henle, H^+ from water is secreted by the Na^+-H^+ exchanger on the luminal membrane. H^+ combines with filtered bicarbonate, resulting in the formation of H_2CO_3, which decomposes into water and CO_2 in the presence of carbonic anhydrase IV. CO_2 diffuses freely back into the cell, combines with OH^- (from H_2O) to form HCO_3^- in the presence of carbonic anhydrase II, and returns to the systemic circulation via a Na^+-HCO_3^- co-transporter situated at the basolateral membrane of the cell. In the collecting tubule, H^+ is secreted into the lumen by H^+ATPase (adenosine triphosphatase), and HCO_3^- is returned to the systemic circulation by the HCO_3^--Cl^- exchanger located on the basolateral membrane. The H^+ secreted proximally and distally in excess of the filtered HCO_3^- is excreted in the urine either as titratable acid ($H_2PO_4^-$) or as NH_4^+.

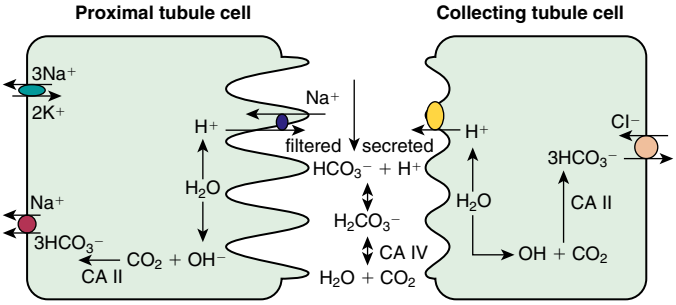

Fig. 569.1 Major cellular luminal events in acid-base regulation in the proximal and collecting tubule cells. In the proximal tubule, H^+, split from H_2O, is secreted into the lumen via the Na^+/H^+ exchanger, and HCO_3^-, formed by a combination of OH^- (split from H_2O) with CO_2 in the presence of carbonic anhydrase (CA) II, is returned to the systemic circulation by an Na^+-$3HCO_3^-$ co-transporter. Similarly, in the collecting tubule, H^+ is secreted into the lumen by an active H^+-ATPase (adenosine triphosphatase), and HCO_3^- is returned to the systemic circulation via an HCO_3^--Cl^- exchanger. H^+ secreted into the lumen combines with filtered HCO_3^- to form carbonic acid (H_2CO_3) and then CO_2 and H_2O in the presence of CA IV, which can be passively reabsorbed. *(Modified from Rose BD, Post TW. Clinical Physiology of Acid-Base and Electrolyte Disorders, 5th ed. New York: McGraw-Hill; 2001.)*

569.1 Proximal (Type II) Renal Tubular Acidosis

Melisha G. Hanna and Bradley P. Dixon

pRTA can be inherited and persistent from birth or occur as a transient phenomenon during infancy. Although rare, it may be primary and isolated. Typically, however, pRTA occurs as a component of global proximal tubular dysfunction or **Fanconi syndrome,** which is characterized by low molecular weight proteinuria, glycosuria, phosphaturia, aminoaciduria, and pRTA. Table 569.1 outlines the causes of pRTA and Fanconi syndrome. Many of these causes are inherited disorders. In addition to **cystinosis** and **Lowe syndrome,** autosomal recessive and dominant pRTA are addressed further in this section. Other inherited forms of Fanconi syndrome include galactosemia (see Chapter 107.2), hereditary fructose intolerance (see Chapter 107.3), tyrosinemia (see Chapter 105.2), and Wilson disease (see Chapter 405.2). Dent disease, or X-linked nephrolithiasis, is discussed in Chapter 571.3. In children, an important form of secondary Fanconi syndrome is exposure to medications such as the chemotherapy agents ifosfamide and cisplatin.

AUTOSOMAL RECESSIVE DISEASE

Isolated autosomal recessive pRTA is caused by pathogenic variants in *SLC4A4* encoding the sodium bicarbonate co-transporter NBC1. It manifests with ocular abnormalities (band keratopathy, cataracts, and glaucoma, often leading to blindness), short stature, enamel defects of the teeth, intellectual impairment, and occasionally basal ganglia calcification along with pRTA. An autosomal dominant pattern of inheritance has also been identified but is rare; these patients present with hyperchloremic metabolic acidosis, a normal ability to acidify urine, normal renal function, and growth retardation.

CLINICAL MANIFESTATIONS OF PROXIMAL RTA AND FANCONI SYNDROME

Patients with isolated, sporadic, or inherited pRTA present with growth failure in the first year of life. Additional symptoms can include polyuria, dehydration (from sodium loss), anorexia, vomiting, constipation, and hypotonia. Patients with primary Fanconi syndrome have additional symptoms, secondary to phosphate wasting, such as rickets. Those with systemic diseases present with additional signs and symptoms specific to their underlying disease. Urinalysis in patients with isolated pRTA is generally unremarkable. The urine pH is acidic (<5.5) because distal acidification mechanisms are intact in these patients. Urinary studies in patients with Fanconi syndrome demonstrate varying degrees of phosphaturia, aminoaciduria, glycosuria, uricosuria, and elevated urinary sodium or potassium. Depending on the nature of the underlying disorder, laboratory evidence of chronic kidney disease (CKD), including elevated serum creatinine, may be present.

Cystinosis

Cystinosis is an autosomal recessive, systemic lysosomal storage disease caused by a defect in the transport of cystine out of lysosomes resulting in the accumulation of cystine crystals in most of the major organs of the body, notably the kidney, liver, eye, and brain. It occurs at an incidence of 1:100,000 to 1:200,000. At least three clinical patterns have been described. The most severe form of the disease, infantile or nephropathic cystinosis, presents in the first or second

year of life with severe tubular dysfunction and growth failure. If the disease is not treated, the children develop end-stage kidney disease by the end of their first decade. A milder form of the disease manifests by adolescence called juvenile or intermediate nephropathic cystinosis, and it is characterized by less severe tubular abnormalities and a slower progression to renal failure. A nonnephropathic adult form also exists called ocular cystinosis and has isolated ocular involvement.

Cystinosis is caused by pathogenic variants in *CTNS,* which encodes the protein cystinosin, a lysosomal cystine transporter. Genotype-phenotype studies demonstrate that patients with severe nephropathic cystinosis carry variants that lead to complete loss of cystinosin function. Patients with milder clinical disease have variants that lead to the expression of partially functional protein. Patients with nephropathic cystinosis present with clinical manifestations reflecting their pronounced tubular dysfunction and Fanconi syndrome, including polyuria and polydipsia, growth failure, and rickets. Fever, caused by dehydration or diminished sweat production, is common. Patients are typically fair skinned and blond because of diminished pigmentation. Ocular presentations include photophobia, retinopathy, and impaired visual acuity. Patients also can develop hypothyroidism, hepatosplenomegaly, and delayed sexual maturation. With progressive tubulointerstitial fibrosis, CKD is invariant.

The diagnosis of cystinosis is suggested by the detection of cystine crystals in the cornea and confirmed by measurement of increased leukocyte cystine content and genetic testing for biallelic pathogenic variants in the *CTNS* gene. Prenatal testing is available for at-risk families.

Treatment of cystinosis is directed at correcting the metabolic abnormalities associated with Fanconi syndrome. In addition, lifelong therapy is required with cysteamine, a therapy which converts cystine to cysteine and a cysteine-cysteamine heterodimer. This facilitates lysosomal transport and decreases tissue cystine. Oral cysteamine does not achieve adequate levels in ocular tissues, so additional therapy with cysteamine eyedrops is required. Early initiation of cysteamine can prevent or delay deterioration of renal function and the need for renal replacement therapy. Patients with growth failure that does not improve with cysteamine may benefit from treatment with growth hormone. Kidney transplantation is a viable option in patients with renal failure. With prolonged survival, additional complications may become evident, including central nervous system abnormalities, muscle weakness, swallowing dysfunction, and pancreatic insufficiency. It is unclear whether long-term cysteamine therapy will decrease these complications.

Lowe Syndrome

Lowe syndrome (oculocerebrorenal syndrome of Lowe) is a rare X-linked disorder characterized by congenital cataracts, developmental delay, and Fanconi syndrome. The disease is caused by pathogenic variants in *OCRL1,* which encodes the phosphatidylinositol polyphosphate 5-phosphatase protein. The abnormalities seen in Lowe syndrome are thought to be caused by abnormal transport of vesicles within the Golgi apparatus. Kidneys show nonspecific tubulointerstitial changes. Thickening of glomerular basement membrane and changes in proximal tubule mitochondria are also seen.

Patients with Lowe syndrome typically present in infancy with cataracts, progressive growth failure, hypotonia, and Fanconi syndrome. Significant low molecular weight proteinuria is common. Blindness and CKD often develop. Characteristic behavioral abnormalities are also seen, including tantrums, stubbornness, stereotypy (repetitive behaviors), and obsessions. There is no specific therapy for the renal disease or neurologic deficits. Cataract removal is generally required.

569.2 Distal (Type I) Renal Tubular Acidosis

Melisha G. Hanna and Bradley P. Dixon

dRTA can be sporadic or inherited. It can also occur as a complication of inherited or acquired diseases of the distal tubules. Primary or secondary causes of dRTA can result from damaged or impaired

functioning of one or more transporters or proteins involved in the acidification process, including the H^+/ATPase, the HCO_3^-/Cl^- anion exchangers, or the components of the aldosterone pathway. Because of impaired hydrogen ion excretion, the urine pH cannot be reduced to <5.5, despite the presence of severe metabolic acidosis. Loss of sodium bicarbonate distally, due to lack of H^+ to bind to in the tubular lumen (see Fig. 569.1), results in increased chloride absorption and hyperchloremia. Inability to secrete H^+ is compensated for by increased K^+ secretion distally, leading to hypokalemia. **Hypercalciuria** is usually present and can lead to nephrocalcinosis or nephrolithiasis. Chronic metabolic acidosis also impairs urinary citrate excretion. **Hypocitraturia** further increases the risk of calcium deposition in the tubules. Bone disease is common, resulting from mobilization of organic components from bone to serve as buffers to chronic acidosis.

CLINICAL MANIFESTATIONS OF DISTAL RTA

dRTA shares features with those of pRTA, including non–anion gap metabolic acidosis and growth failure; distinguishing features of dRTA include nephrocalcinosis and hypercalciuria. The phosphate and massive bicarbonate wasting characteristic of pRTA is generally absent. Table 569.2 lists the causes of primary and secondary dRTA. Although inherited forms are rare, three specific inherited forms of dRTA have been identified, including an autosomal recessive form associated with sensorineural deafness.

Medullary sponge kidney is a relatively rare sporadic disorder in children, although not uncommon in adults. *HNF1B* pathogenic variants have been implicated in some patients. It is characterized by cystic dilation of the terminal portions of the collecting ducts as they enter the renal pyramids. On ultrasound studies, patients often have medullary nephrocalcinosis. Although patients with this condition typically maintain normal renal function through adulthood, complications include nephrolithiasis, pyelonephritis, hyposthenuria (inability to concentrate urine), and dRTA. Associations of medullary sponge kidney with Beckwith-Wiedemann syndrome or hemihypertrophy have been reported.

569.3 Hyperkalemic (Type IV) Renal Tubular Acidosis

Melisha G. Hanna and Bradley P. Dixon

Type IV RTA occurs as the result of impaired aldosterone production *(hypoaldosteronism)* or impaired renal responsiveness to aldosterone *(pseudohypoaldosteronism)*. Acidosis results because aldosterone has a direct effect on the H^+/ATPase responsible for hydrogen secretion. In addition, aldosterone is a potent stimulant for potassium secretion in the collecting tubule; consequently, lack of aldosterone results in hyperkalemia. This further affects the acid-base status by inhibiting ammoniagenesis and, thus, H^+ excretion. Aldosterone deficiency typically occurs as a result of adrenal gland disorders such as Addison disease or some forms of congenital adrenal hyperplasia. In children, aldosterone unresponsiveness is a more common cause of type IV RTA. This can occur transiently, during an episode of acute pyelonephritis or acute urinary obstruction, or chronically, particularly in infants and children with a history of obstructive uropathy. The latter patients can have significant hyperkalemia, even in instances when renal function is normal or only mildly impaired. Rare examples of inherited forms of type IV RTA have been identified (Table 569.3).

CLINICAL MANIFESTATIONS OF TYPE IV RTA

Patients with type IV RTA can present with growth failure in the first few years of life. Polyuria and dehydration (from salt wasting) are common. Rarely, patients (especially those with pseudohypoaldosteronism type 1) present with life-threatening hyperkalemia.

Table 569.3 Disorders with Dysfunction of Renal Acidification: Generalized Abnormality of Distal Nephron with Hyperkalemia

MINERALOCORTICOID DEFICIENCY

Primary Mineralocorticoid Deficiency

- Combined deficiency of aldosterone, desoxycorticosterone, and cortisol
  - Addison disease
  - Bilateral adrenalectomy
  - Bilateral adrenal destruction
  - Hemorrhage or carcinoma
- Congenital enzymatic defects
  - 21-Hydroxylase deficiency
  - 3β-Hydroxydehydrogenase deficiency
  - Desmolase deficiency
- Isolated (selective) aldosterone deficiency
  - Chronic idiopathic hypoaldosteronism
  - Heparin (low molecular weight or unfractionated) administration in critically ill patient
  - Familial hypoaldosteronism
  - Corticosterone methyl oxidase deficiency types 1 and 2
  - Primary zona glomerulosa defect
  - Transient hypoaldosteronism of infancy
  - Persistent hypotension and/or hypoxemia
- Angiotensin-converting enzyme inhibition
  - Endogenous
  - Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers

Secondary Mineralocorticoid Deficiency

- Hyporeninemic hypoaldosteronism
  - Diabetic nephropathy
  - Tubulointerstitial nephropathies
  - Nephrosclerosis
  - Nonsteroidal antiinflammatory agents
  - Acquired immunodeficiency syndrome
  - Immunoglobulin M monoclonal gammopathy
  - Obstructive uropathy

MINERALOCORTICOID RESISTANCE

- PHA I: autosomal dominant (human mineralocorticoid receptor defect)

Renal Tubular Dysfunction (Voltage Defect)

- PHA I: autosomal recessive
- PHA II: autosomal dominant
- Drugs that interfere with Na^+ channel function in the CCT
  - Amiloride
  - Triamterene
  - Trimethoprim
  - Pentamidine
- Drugs that interfere with Na^+-K^+-ATPase in the CCT
  - Cyclosporine
  - Tacrolimus
- Drugs that inhibit aldosterone effect on the CCT
  - Spironolactone
  - Eplerenone
- Disorders associated with tubulointerstitial nephritis and renal insufficiency
  - Lupus nephritis
  - Methicillin nephrotoxicity
  - Obstructive nephropathy
  - Kidney transplant rejection
  - Sickle cell disease
  - Williams syndrome with uric acid nephrolithiasis

From Hamm LL, DuBose TD Jr. Disorders of acid-base balance. In: Yu AS, Chertow GM, Luyckx VA, et al., eds. *Brenner & Rector's The Kidney,* 11th ed. Philadelphia: Elsevier; 2020: Table 16.11.

Patients with obstructive uropathies can present acutely with signs and symptoms of pyelonephritis, such as fever, vomiting, and foul-smelling urine. Laboratory tests reveal a hyperkalemic non–anion gap metabolic acidosis. Urine may be alkaline or acidic. Elevated urinary sodium levels with inappropriately low urinary potassium levels reflect the absence of aldosterone effect.

DIAGNOSTIC APPROACH TO RENAL TUBULAR ACIDOSIS

The first step in the evaluation of a patient with suspected RTA is to confirm the presence of a normal anion gap metabolic acidosis, identify electrolyte abnormalities, assess renal function, and rule out other causes of bicarbonate loss such as diarrhea (Table 569.4). Metabolic acidosis associated with diarrheal dehydration is extremely common, and acidosis generally improves with correction of volume depletion. Patients with protracted diarrhea can deplete their total-body bicarbonate stores and can have persistent acidosis despite apparent restoration of volume status. In instances where a patient has a recent history of severe diarrhea, full evaluation for RTA should be delayed for several days to permit adequate time for reconstitution of total-body bicarbonate stores. If acidosis persists beyond a few days in this setting, additional studies are indicated.

Serum electrolytes, BUN, calcium, phosphorus, creatinine, and venous blood gas for pH should be obtained by venipuncture. Traumatic blood draws (such as heel-stick specimens), small volumes of blood in adult-size specimen collection tubes, or a prolonged specimen transport time at room temperature can lead to falsely low bicarbonate levels, often in association with an elevated serum potassium value. True hyperkalemic acidosis is consistent with type IV RTA, whereas the finding of normal or low potassium suggests type I or II RTA. The **blood anion gap** should be calculated using the formula $[Na^+] - [Cl^- + HCO_3^-]$. Typically, values of <12 demonstrate the absence of an anion gap. Values of >20 indicate the presence of an anion gap and other diagnoses (lactic acidosis, diabetic ketoacidosis, inborn errors of metabolism, ingested toxins) should be investigated. If tachypnea is noted, evaluation of an arterial blood gas may be appropriate to evaluate the possibility of a mixed acid-base disorder primarily involving respiratory and metabolic components. A detailed history, with particular attention to growth and development, recent or recurrent diarrheal illnesses, a family history of developmental delay, failure to thrive, end-stage kidney disease, infant deaths, or miscarriages is essential. The physical examination should determine growth parameters and volume status as well as the presence of any dysmorphic features suggesting an underlying syndrome.

Once the presence of a non–anion gap metabolic acidosis is confirmed, the urine pH can help distinguish distal from proximal causes. A urine pH <5.5 in the presence of acidosis suggests pRTA, whereas patients with dRTA typically have a urine pH >6.0. The **urine anion gap** ([urine Na^+ + urine K^+] – urine Cl^-) is sometimes calculated to confirm the diagnosis of dRTA. A positive gap suggests a deficiency of ammoniagenesis and, thus, the possibility of a dRTA. A negative gap is consistent with proximal tubule bicarbonate wasting (or gastrointestinal bicarbonate wasting). A urinalysis should also be obtained to determine the presence of glycosuria, proteinuria, or hematuria, suggesting more global tubular damage or dysfunction. Random or 24-hour urine calcium and creatinine measurements will identify hypercalciuria. Renal ultrasonography should be performed to identify underlying structural abnormalities such as obstructive uropathies, as well as to determine the presence of nephrolithiasis or nephrocalcinosis (Fig. 569.2).

TREATMENT AND PROGNOSIS

The mainstay of therapy in all forms of RTA is bicarbonate replacement. Patients with pRTA often require large quantities of bicarbonate, up to 20 mEq/kg/24 hr, in the form of sodium bicarbonate or sodium citrate solution (Bicitra or Shohl solution). The base requirement for dRTA is generally in the range of 2-4 mEq/kg/24 hr, although individual patient requirements can vary. Patients with Fanconi syndrome usually require phosphate supplementation. Patients with dRTA should be monitored for the development of hypercalciuria. Those with symptomatic hypercalciuria (recurrent episodes of gross hematuria), nephrocalcinosis, or nephrolithiasis may require

Table 569.4 Contrasting Features and Diagnostic Studies in Renal Tubular Acidosis

	TYPE OF RENAL TUBULAR ACIDOSIS		
FINDING	**PROXIMAL**	**CLASSIC DISTAL**	**GENERALIZED DISTAL DYSFUNCTION**
Plasma [K^+]	Low	Low	High
Urine pH with acidosis	<5.5	>5.5	<5.5 or >5.5
Urine net charge	Negative	Positive	Positive
Fractional bicarbonate excretion	>10–15% during alkali therapy	2–5%	5–10%
U−BPco_2	Normal	Low	Low
Response to therapy	Least responsive	Responsive	Less responsive
Associated features	Fanconi syndrome	Nephrocalcinosis/ hyperglobulinemia	Renal insufficiency

U−BPco_2, urine minus blood CO_2 pressure.

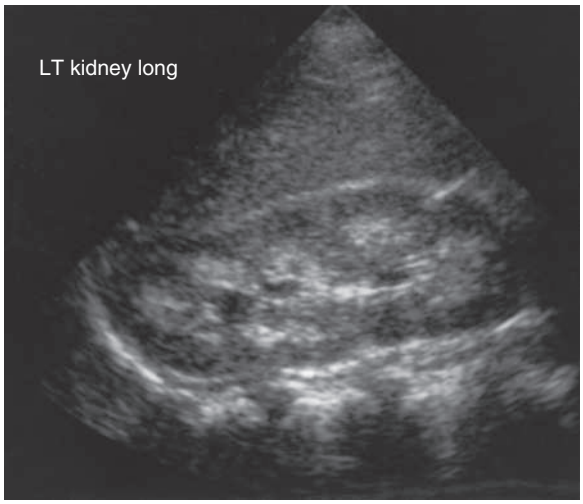

Fig. 569.2 Ultrasound examination of a child with distal RTA, demonstrating medullary nephrocalcinosis.

thiazide diuretics to decrease urine calcium excretion. Patients with type IV RTA can require chronic treatment for hyperkalemia with a sodium-potassium exchange resin (i.e., sodium polystyrene sulfonate or patiromer).

The prognosis of RTA depends to a large extent on the nature of any existing underlying disease. Patients with treated isolated proximal or dRTA generally demonstrate improvement in growth, provided serum bicarbonate levels can be maintained in the normal range. Patients with systemic illness and Fanconi syndrome can have ongoing morbidity with growth failure, rickets, and signs and symptoms related to their underlying disease.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

569.4 Rickets Associated with Renal Tubular Acidosis

Melisha G. Hanna and Bradley P. Dixon

Rickets may be present in primary RTA, *particularly in pRTA,* due to the added features of hypophosphatemia and phosphaturia from generalized proximal tubular dysfunction. Bone demineralization without overt rickets usually is detected in distal (type I) RTA. This metabolic bone disease may be characterized by bone pain, growth retardation, osteopenia, and, occasionally, pathologic fractures. Bone demineralization in dRTA probably relates to dissolution of bone because the calcium carbonate in bone serves as a buffer against the metabolic acidosis due to the hydrogen ions retained by patients with RTA.

Administration of sufficient bicarbonate to reverse acidosis reverses bone dissolution and the hypercalciuria that is common in dRTA. pRTA is treated with both bicarbonate and oral phosphate supplements to heal rickets. Doses of phosphate similar to those used in familial hypophosphatemia or Fanconi syndrome may be indicated. Vitamin D is required to offset the secondary hyperparathyroidism that complicates oral phosphate therapy. Following therapy, growth in patients with type II (proximal) RTA is greater than in patients with primary Fanconi syndrome.

Chapter 570 Nephrogenic Diabetes Insipidus

Margret E. Bock and Bradley P. Dixon

Nephrogenic diabetes insipidus (NDI) is a rare congenital or, more commonly, acquired, disorder of water metabolism characterized by an inability of the kidneys to concentrate urine, even in the presence of antidiuretic hormone (ADH). The most common pattern of inheritance in congenital NDI is as an X-linked recessive disorder (90% of cases of congenital NDI). Rarely, affected females are seen, presumably secondary to nonrandom X-chromosome inactivation. Approximately 10% of cases of congenital NDI are inherited as autosomal dominant or recessive disorders, with males and females affected equally. The clinical phenotype of autosomal recessive forms is similar to that of the X-linked form. Secondary (acquired) forms of NDI, either partial or complete, are not uncommon. They may be seen in many disorders affecting renal tubular function, including obstructive uropathies, acute kidney injury or chronic kidney disease, cystic kidney diseases, interstitial nephritis,

nephrocalcinosis, or toxic nephropathy caused by hypokalemia, hypercalcemia, lithium, or amphotericin B.

PATHOGENESIS

The ability to concentrate urine (and thus absorb water) requires three components: (1) the delivery of urine to the collecting tubule, (2) an intact concentrating gradient in the renal medulla, and (3) the ability to modulate water permeability in the collecting tubule by ADH. ADH (also called arginine vasopressin [AVP]) is synthesized in the hypothalamus and stored in the posterior pituitary. Under basal situations, the collecting tubule is impermeable to water. However, in response to increased serum osmolality (as detected by osmoreceptors in the hypothalamus) and/or severe volume depletion, ADH is released into the systemic circulation. It then binds to its receptor, vasopressin V2R (AVPR2), on the basolateral membrane of the collecting tubule cell. Binding of the hormone to its receptor activates a cyclic adenosine monophosphate–dependent cascade that results in insertion of preformed water channels (aquaporin 2 [AQP2]) into the luminal membrane of the collecting duct, rendering it permeable to water.

Pathogenic variants in *AVPR2* cause the more common X-linked form of NDI. Pathogenic variants in *AQP2* have been identified in patients with the rarer autosomal dominant and recessive forms. Pathogenic variants in *STIM1* (stromal interaction molecular 1) have also been identified in a mouse model exhibiting partial NDI, due to abnormalities in intracellular calcium regulation by the endoplasmic reticulum. Prenatal testing is available for families at risk for X-linked NDI. Patients with secondary forms of NDI can have ADH resistance due to defective aquaporin expression (as seen in lithium intoxication). Most often, secondary ADH resistance occurs as the result of loss of the hypertonic medullary gradient as a result of solute diuresis or tubular damage, resulting in the inability to absorb sodium or urea.

CLINICAL MANIFESTATIONS

Patients with congenital NDI typically present in the newborn period with massive polyuria, volume depletion, hypernatremia, and hyperthermia. Irritability and inconsolability are common features. Constipation and poor weight gain are also seen. After multiple episodes of **hypernatremic dehydration** in infancy, patients may develop intellectual disabilities, although this has become less common with cautious fluid resuscitation and gradual correction of hypernatremia. Toddlers and older children often display a marked thirst and a preference particularly for cold water. Mediated by the intact thirst mechanism, the need to consume large volumes of water during the day is profound, and patients often have diminished appetite and poor food intake, which may contribute to failure to thrive. However, even with adequate caloric supplementation, patients still exhibit growth abnormalities. Daytime and nighttime enuresis, caused by large urine volumes, is common. Patients with congenital NDI also may exhibit behavioral problems, including hyperactivity and short-term memory problems. Patients with the secondary form generally present later in life, primarily with hypernatremia and polyuria. Associated symptoms such as developmental delay and behavioral abnormalities are less common in this latter group.

DIAGNOSIS

The diagnosis is suggested in a male infant with polyuria, hypernatremia, and dilute urine. Simultaneous serum and urine osmolality measurements should be obtained. *If the serum osmolality value is ≥290 mOsm/kg with a simultaneous urine osmolality value of <290 mOsm/kg, a formal water-deprivation test is not necessary.* Because the differential diagnosis includes causes of **central diabetes insipidus,** the inability to respond to ADH (and thus the presence of NDI) should be confirmed by the administration of vasopressin (10-20 μg intranasally) followed by serial urine and serum osmolality measurements hourly for 4 hours. In patients with possible "partial" or secondary diabetes insipidus, in whom the initial serum osmolality value may be <290 mOsm/kg, a water-deprivation test should be considered. Fluids should be withheld and urine and serum osmolalities measured periodically until the serum osmolality value is >290 mOsm/kg; vasopressin is then given as before. Criteria for premature termination of a water-deprivation test include a decrease in body weight of >3%. These evaluations typically require an inpatient admission, given the need for serial laboratory monitoring and prompt intervention/response to results. If NDI is confirmed or suspected, an additional evaluation should include a detailed history to assess possible toxic exposures, determination of renal function by serum creatinine and BUN levels, and renal ultrasonography to identify obstructive uropathies or cystic kidney disease. Because of the massive urine output, patients with congenital NDI can have *nonobstructive hydronephrosis* of varying severity.

TREATMENT AND PROGNOSIS

Treatment of NDI includes maintenance of adequate fluid intake and access to free water, minimizing the urine output by limiting the solute load with a low-osmolar, low-sodium diet, and administering medications directed at decreasing the urine output. For infants, human milk or a low-solute formula, such as Similac PM 60/40, is preferred. Most infants with congenital NDI require gastrostomy or nasogastric feedings to ensure adequate fluid administration throughout the day and night. Sodium intake in older patients should be <0.7 mEq/kg/24 hr**.** Thiazide diuretics (2-3 mg/kg/24 hr of hydrochlorothiazide) effectively induce sodium loss and stimulate proximal tubule reabsorption of water. Potassium-sparing diuretics, in particular, amiloride (0.3 mg/kg/24 hr in three divided doses), are often additionally indicated. Patients who have an inadequate response to diuretics alone might benefit from the addition of prostaglandin synthetase inhibitors such as indomethacin (2 mg/kg/24 hr), which has an additive effect in reducing water excretion in some patients. Renal function must be monitored closely in such patients because indomethacin can cause deterioration in renal function over time. Patients with secondary NDI may not require medications but should have access to free water. Such patients should have the serum electrolytes and volume status monitored closely, particularly during periods of superimposed acute illnesses. Amiloride may also play a role in managing lithium-induced NDI by blocking entry of lithium into the tubular cell through the epithelial sodium channel (ENaC).

Prevention of recurrent dehydration and hypernatremia in patients with congenital NDI has significantly improved the neurodevelopmental outcome of these patients. However, behavioral issues remain a significant problem. In addition, chronic use of nonsteroidal antiinflammatory drugs can predispose patients to chronic kidney disease. The prognosis of patients with secondary NDI generally depends on the nature of the underlying disease.

Chapter 571

Inherited Tubular Transport Abnormalities

571.1 Bartter Syndrome

Danielle E. Soranno and Bradley P. Dixon

Bartter syndrome is a group of disorders characterized by hypokalemic hypochloremic metabolic alkalosis with hypercalciuria and salt wasting (see Chapter 73). These disorders are currently classified by the anatomic site affected by the pathogenic variant (Tables 571.1 and 571.2). **Antenatal Bartter syndrome** (types I, II, and IV; also called hyperprostaglandin E syndrome) typically manifests in infancy and has a more severe phenotype than **classic Bartter syndrome** (type III). The perinatal onset includes maternal polyhydramnios, neonatal salt wasting, and severe episodes of recurrent dehydration. The milder phenotype, classic Bartter syndrome, manifests in childhood with failure to thrive and a history of recurrent episodes of dehydration. A phenotypically related disease, **Gitelman syndrome**, has a distinct genetic defect and is discussed in Chapter 571.2 (see Table 571.1). One distinct variant of antenatal Bartter syndrome is associated with sensorineural deafness (type IV). Bartter-like phenotypes have been noted in other diseases such as Kearns-Sayre syndrome.

PATHOGENESIS

The biochemical features of Bartter syndrome, such as hypokalemic hypochloremic metabolic alkalosis with hypercalciuria, resemble those seen with chronic use of loop diuretics and reflect a defect in sodium, chloride, and potassium transport in the ascending loop of Henle. The urinary loss of sodium and chloride, with resultant volume contraction, stimulates the renin-angiotensin II-aldosterone axis. Aldosterone promotes distal sodium uptake and potassium secretion, exacerbating the hypokalemia. It also stimulates hydrogen ion secretion distally, worsening the metabolic alkalosis. Hypokalemia stimulates prostaglandin synthesis, which further activates the renin-angiotensin II-aldosterone axis. Bartter syndrome has been associated with at least five distinct genetic defects in transporters along the loop of Henle (see Table 571.1). Each contributes, in some manner, to sodium and chloride transport. Pathogenic variants in the genes that encode the $Na^+/K^+/2Cl^-$ transporter (NKCC2, the site of action of furosemide), the luminal potassium channel (ROMK), combined chloride channel (CLC-Ka, CLC-Kb), or subunit of chloride channels (barttin) cause neonatal Bartter syndrome. Isolated defects in the genes that produce a specific basolateral chloride channel (ClC-Kb) cause classic Bartter syndrome.

CLINICAL MANIFESTATIONS

A history of maternal polyhydramnios with or without prematurity may be elicited. Dysmorphic features, including triangular facies, protruding ears, large eyes with strabismus, and drooping mouth may be present on physical examination. Consanguinity suggests the presence of an autosomal recessive disorder. Older children can have a history of recurrent episodes of polyuria with dehydration, failure to thrive, nonspecific fatigue, dizziness, and chronic constipation. Older children may also present with muscle cramps and weakness secondary

Table 571.1 Types of Bartter Syndrome, Gitelman Syndrome, and Related Conditions

DISORDER	OMIM, GENE	GENE PRODUCT	INHERITANCE	FEATURES
BS VARIANTS				
BS I (ABS, HPES)	601678, *SLC12A1*	NKCC2	AR	Polyhydramnios, prematurity, hypokalemic hypochloremic alkalosis, nephrocalcinosis, with or without concentrating defect
BS II (ABS with transient hyperkalemia and acidosis, HPES)	241200, *KCNJ1*	ROMK1	AR	Polyhydramnios, prematurity, transient hyperkalemia and acidosis, then hypokalemic hypochloremic alkalosis, nephrocalcinosis, with or without concentrating defect
BS III (CBS)	607364, *CLCNKB*	ClC-Kb	AR; many sporadic	Variable age at presentation with severity corresponding to type of gene pathogenic variant; hypokalemic hypochloremic alkalosis
BS IVa and BS IVb (ABS or HPES with sensorineural deafness)	602522, *BSND CLCNKA, CLCNKB*	Bartter ClC-Ka and ClC-Kb	AR	Polyhydramnios, prematurity, hypokalemic hypochloremic alkalosis, sensorineural deafness, with or without concentrating defect
BS V (transient ABS)	300971, *MAGED2*	MAGED2	XR	Severe polyhydramnios, hypokalemic hypochloremic alkalosis with symptoms resolving within the first few months of life
AD hypocalcemic hypercalciuria	601199, *L125P*	CaSR	AD	Hypocalcemic hypocalciuria, hypokalemic hypochloremic alkalosis, suppressed PTH
GS VARIANTS				
GS	263800, *SLC12A3*	NCC	AR	Present in later childhood or adulthood with weakness, lethargy, carpopedal spasm, hypokalemic alkalosis, hypomagnesemia, hypermagnesuria and hypocalciuria
EAST syndrome (SeSAME)	612780, *Kir4.1*	KCNJ10	AR	Epilepsy, ataxia, sensorineural deafness, hypokalemic hypochloremic alkalosis
OTHER VARIANTS				
CLDN10 pathogenic variants	617579, *CLDN10*	Claudin-10	AR	Hypokalemic metabolic alkalosis with hypocalciuria but normal to elevated magnesium

to chronic hypokalemia. Blood pressure is usually preserved, although patients with the antenatal form can have severe salt wasting, resulting in dehydration and hypotension. Serum chemistry reveals the classic biochemical abnormalities of a **hypokalemic hypochloremic metabolic alkalosis.** Renal function is typically normal. Urinary calcium levels are typically elevated, as are urinary potassium and sodium levels. Serum renin, aldosterone, and prostaglandin E levels are often markedly elevated, particularly in the more severe antenatal form. Nephrocalcinosis, resulting from hypercalciuria, may be seen on ultrasound examination (types I and II).

DIAGNOSIS

The diagnosis is usually made based on the clinical presentation and laboratory findings. The diagnosis in the neonate or infant is suggested by severe hypokalemia, usually <2.5 mmol/L, with metabolic alkalosis. Hypercalciuria is typical; hypomagnesemia is seen in a minority of patients but is more common in Gitelman syndrome. Because features of Bartter syndrome resemble the chronic use of loop diuretics, diuretic abuse should be considered in the differential diagnosis, even in young children. Chronic vomiting and cystic fibrosis can also present a similar clinical picture but can be distinguished by the measurement of **urinary chloride,** which is elevated in Bartter syndrome and low in patients with chronic vomiting and cystic fibrosis. Kidneys demonstrate hyperplasia of the juxtaglomerular apparatus, although renal biopsy is rarely performed to diagnose this condition.

TREATMENT AND PROGNOSIS

Treatment of Bartter syndrome is directed at preventing dehydration, maintaining nutritional status, and correcting hypokalemia. Potassium supplementation, usually in the form of potassium chloride to correct the concomitant chloride depletion and often at very high doses, is required. Potassium-sparing diuretics (such as spironolactone) are also often used to inhibit distal potassium secretion. Even with appropriate therapy, serum potassium values might not normalize, particularly in patients with the neonatal form. Infants and young children require a high-sodium diet and, at times, sodium supplementation. Indomethacin, a prostaglandin inhibitor, can also be effective. If hypomagnesemia is present, magnesium supplementation is required. With close attention to electrolyte balance, volume status, and growth, the long-term prognosis is generally good. Routine monitoring is necessary, particularly during periods of growth, to ensure that electrolytes are maintained in a safe range. Strict return/call precautions are needed in times of illness with extrarenal volume loss such as vomiting or diarrhea. In a minority of patients, chronic hypokalemia, nephrocalcinosis, and chronic indomethacin therapy can lead to chronic interstitial nephritis and chronic renal failure.

571.2 Gitelman Syndrome

Danielle E. Soranno and Bradley P. Dixon

Gitelman syndrome (often called a *Bartter syndrome variant*) is a rare autosomal recessive cause of hypokalemic hypochloremic metabolic alkalosis, with distinct features of **hypocalciuria** and **hypomagnesemia.** Patients with Gitelman syndrome are typically diagnosed incidentally in late childhood or early adulthood (see Tables 571.1 and 571.2).

PATHOGENESIS

The biochemical features of Gitelman syndrome resemble those of chronic use of thiazide diuretics. Thiazides act on the sodium chloride cotransporter NCCT, present in the distal convoluted tubule. Through linkage analysis and mutational studies, defects in the gene encoding NCCT have been demonstrated in patients with Gitelman syndrome.

CLINICAL MANIFESTATIONS

Patients with Gitelman syndrome typically present at a later age than those with Bartter syndrome and may have symptoms similar to older children with Bartter syndrome (see Chapter 571.1). Patients often have a history of salt craving, recurrent muscle cramps and spasms, presumably caused by low serum magnesium levels, nocturia, polyuria, and occasional hypotension. They usually do not have a history of recurrent episodes of dehydration. Biochemical abnormalities include hypokalemia, metabolic alkalosis, and hypomagnesemia. The urinary calcium level is usually very low (in contrast to the elevated urinary calcium level often seen in Bartter syndrome), and the urinary magnesium level is elevated. Renin and aldosterone levels are usually normal, and prostaglandin E secretion is not elevated. Growth failure is less prominent in Gitelman syndrome than in Bartter syndrome.

DIAGNOSIS

The diagnosis of Gitelman syndrome is suggested in an adolescent or adult presenting with hypokalemic hypochloremic metabolic alkalosis, hypomagnesemia, and hypocalciuria. The diagnosis is often made incidentally after hypokalemia is noted on bloodwork, spurring further evaluation.

TREATMENT

Therapy is directed at correcting hypokalemia and hypomagnesemia with supplemental potassium and magnesium. Sodium supplementation or treatment with prostaglandin inhibitors is generally not necessary because patients typically do not have episodes of volume

depletion or elevated prostaglandin E excretion. Recently, SGLT2 inhibitors have begun to be utilized in adults with refractory hypomagnesemia; however, further studies are needed to investigate their utility in the treatment of Gitelman syndrome.

571.3 Other Inherited Tubular Transport Abnormalities

Danielle E. Soranno and Bradley P. Dixon

Inherited abnormalities in distinct transporters in each segment of the nephron have now been identified and the molecular defects have been characterized. Renal tubular acidosis and nephrogenic diabetes insipidus are discussed in detail in Chapters 569 and 570, respectively. **Cystinuria** is an autosomal recessive disorder seen primarily in patients of Middle Eastern descent and is characterized by recurrent stone formation. The disease is caused by a defective high-affinity transporter for L-cystine and dibasic amino acids present in the proximal tubule; affected females form fewer stones than males. Treatment focuses on stone prevention via hydration, sodium restriction, urine alkalinization, and cystine-binding therapy.

Dent disease is an X-linked proximal tubulopathy with characteristic abnormalities that include low molecular weight proteinuria, hypercalciuria, and variably other features of Fanconi syndrome, such as glycosuria, aminoaciduria, and phosphaturia. Although some patients develop nephrocalcinosis, nephrolithiasis, progressive renal failure, and hypophosphatemic rickets, patients with Dent disease typically do not have proximal renal tubular acidosis or extrarenal manifestations. Loss-of-function pathogenic variants of *CLCN5,* which encodes a renal Cl^-/H^+ antiporter (ClC-5), are reported in ~50–60% of patients with Dent disease. The genetic heterogeneity of Dent disease in some patients who exhibit pathogenic variants in the gene for OCRL1 (responsible for Lowe syndrome) also meet the criteria for Dent disease (~15% of patients) called Dent 2 disease. Dent disease includes X-linked recessive nephrolithiasis with renal failure, X-linked recessive hypophosphatemic rickets, and idiopathic low molecular weight proteinuria seen in Japanese children.

Pathogenic variants in an extracellular basolateral calcium-sensing receptor, normally present in the loop of Henle, can cause a **dominant Bartter syndrome–like picture** (also known as Bartter syndrome type V). These patients' predominant symptoms are hypocalcemia and suppressed parathyroid hormone function, which differentiates them from patients with Bartter syndrome.

In the distal convoluted tubule, gain-of-function pathogenic variants in *WNK1* and loss-of-function pathogenic variants in *WNK4,* both serine threonine kinases, lead to excessive NCCT-mediated salt reabsorption with the clinical picture of pseudohypoaldosteronism type 2 (familial hyperkalemic hypertension, or **Gordon syndrome**), including volume expansion with hypertension, hyperkalemia, hyperchloremic metabolic acidosis, and hypercalciuria. Due to the excessive activation of the thiazide-sensitive NCCT, this disorder can be effectively treated with thiazide diuretics.

In the collecting duct, gain-of-function pathogenic variants of the gene that encodes the epithelial sodium channel (ENaC) cause an inherited form of hypertension, **Liddle syndrome.** Patients with this disorder have constitutive sodium uptake in the collecting duct, with hypokalemia and suppressed aldosterone. Due to the excessive activation of ENaC, potassium-sparing diuretics (specifically amiloride) are an effective treatment for Liddle syndrome. Conversely, loss-of-function pathogenic variants cause **pseudohypoaldosteronism,** characterized by severe sodium wasting and hyperkalemia as well as a distal (type IV) RTA (also discussed in Chapter 569.3). A variant of the latter disorder is associated with systemic abnormalities, including defects in sweat chloride, and can resemble cystic fibrosis.

Renal hypouricemia, a defect in *SLC22A12,* presents with low serum uric acid levels and is complicated by exercise-induced acute kidney injury. Patients have elevated urine uric acid levels and present with loin pain, nausea, and vomiting after exercise. Treatment is for acute kidney injury and reducing the intensity of exercise.

Chapter 572 Renal Failure

572.1 Acute Kidney Injury

Prasad Devarajan

Acute kidney injury (AKI) has been traditionally defined as an abrupt loss of kidney function leading to a rapid decline in the glomerular filtration rate (GFR), accumulation of waste products such as blood urea nitrogen (BUN) and creatinine, and dysregulation of extracellular volume and electrolyte homeostasis. The term AKI has replaced acute renal failure (ARF); AKI embodies a continuum of renal dysfunction that ranges from a small increase in serum creatinine to complete anuric renal failure. The incidence of AKI varies from 5–10% of all hospitalizations to >25% in critically ill infants and children. The etiology of AKI varies widely according to age, geographic region, and clinical setting. Functional AKI induced by dehydration is usually reversible with early fluid therapy. However, the prognosis for patients with structural AKI in the intensive care setting with multiorgan failure remains guarded.

A classification system proposed by the Kidney Disease Improving Global Outcomes (KDIGO) AKI Consensus Conference takes both serum creatinine and urine output criteria into account to define and stage AKI (Table 572.1). Thus AKI is defined as

Increase in serum creatinine by ≥0.3 mg/dL from baseline within 48 hours, *or*

Increase in serum creatinine to ≥1.5 times baseline within the prior 7 days, *or*

Urine volume ≤0.5 mL/kg/hr for 6 hours

PATHOGENESIS

AKI has been conventionally classified into three categories: prerenal, intrinsic renal, and postrenal (Table 572.2 and Fig. 572.1).

Prerenal AKI, also called *prerenal azotemia,* is characterized by a diminished effective circulating arterial volume, which leads to inadequate kidney perfusion and a decreased GFR. Evidence of structural kidney damage is largely absent. Common causes of prerenal AKI include dehydration, sepsis, hemorrhage, severe hypoalbuminemia, and cardiac failure. If the underlying cause of the kidney hypoperfusion is reversed promptly, kidney function returns to normal. If hypoperfusion is sustained, intrinsic kidney parenchymal damage can develop.

Intrinsic renal AKI includes a variety of disorders characterized by kidney parenchymal damage, including sustained hypoperfusion and ischemia. Ischemic/hypoxic injury and nephrotoxic insults are the most common causes of intrinsic AKI in high-resource countries and are more common with an underlying comorbid condition; most are associated with cardiac, oncologic, urologic, kidney, and genetic disorders or prematurity (Table 572.3). Many forms of **glomerulonephritis,**

Table 572.1 Kidney Disease Improving Global Outcomes Staging of Acute Kidney Injury

STAGE	SERUM CREATININE	URINE OUTPUT
1	1.5-1.9 times baseline, OR ≥0.3 mg/dL increase	<0.5 mL/kg/hr for 6-12 hr
2	2.0-2.9 times baseline	<0.5 mL/kg/hr for ≥12 hr
3	3.0 times baseline, OR SCr ≥4.0 mg/dL, OR Initiation of renal replacement therapy, OR eGFR <35 mL/min per 1.73 m^2 (<18 yr)	<0.3 mL/kg/hr for ≥24 hr, OR Anuria for ≥12 hr

including postinfectious glomerulonephritis, lupus nephritis, IgA vasculitis nephritis (formerly Henoch-Schönlein purpura nephritis), membranoproliferative glomerulonephritis, and anti–glomerular basement membrane nephritis, can also cause intrinsic AKI. Severe and prolonged ischemic/hypoxic injury and nephrotoxic insult lead to **acute tubular**

necrosis (ATN), seen most often in critically ill infants and children. Mechanisms leading to ischemic AKI include hypotension/intravascular volume depletion (hemorrhage, third-space fluid losses, diarrhea), decreased effective intravascular volume (heart failure, cirrhosis, hepatorenal syndrome, peritonitis, abdominal compartment syndrome), vasodilation/vasoconstriction (sepsis, hepatorenal syndrome), renal artery obstruction (thrombosis, embolization, stenosis), intrarenal artery disease (vasculitis, hemolytic uremic syndrome [HUS], sickle cell anemia, transplant rejection), and impaired renal blood flow (cyclosporine, tacrolimus, angiotensin-converting enzyme [ACE] inhibitors, angiotensin-receptor blocking agents, radiocontrast agents).

The typical pathologic feature of ATN is tubular cell necrosis, although significant histologic changes are not consistently seen in patients with clinical ATN. The mechanisms of injury in ATN can include alterations in intrarenal hemodynamics, tubular obstruction, and passive back leak of the glomerular filtrate across injured tubular cells into the peritubular capillaries.

Tumor lysis syndrome is a specific form of AKI related to spontaneous or chemotherapy-induced cell lysis in patients with lymphoproliferative malignancies. This disorder is primarily caused by obstruction of the tubules by uric acid crystals (see Chapters 544 and 545). **Acute interstitial nephritis** is another common cause of AKI and is usually a result of a hypersensitivity reaction to a therapeutic agent or various infectious agents (see Chapter 561.2).

Postrenal AKI includes a variety of disorders characterized by obstruction of the urinary tract. In neonates and infants, congenital conditions, such as posterior urethral valves and bilateral ureteropelvic junction obstruction, account for most cases of AKI. Other conditions, such as urolithiasis, tumor (intraabdominal lesion or within the urinary tract), hemorrhagic cystitis, and neurogenic bladder, can cause AKI in older children and adolescents. In a patient with two functioning kidneys, obstruction must be bilateral to result in AKI. Relief of the obstruction usually results in recovery of renal function, except in patients with associated renal dysplasia or prolonged urinary tract obstruction.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

A carefully taken history is critical in defining the cause of AKI. An infant with a three day history of vomiting and diarrhea most likely has prerenal AKI caused by volume depletion, but hemolytic-uremic syndrome (HUS) must also be a consideration. A 6-year-old child with a recent pharyngitis who presents with periorbital edema, hypertension, and gross hematuria most likely has intrinsic AKI related to acute postinfectious glomerulonephritis. A critically ill child with a history of protracted hypotension or with exposure to nephrotoxic medications most likely has ATN. A neonate with a history of hydronephrosis seen on prenatal ultrasound studies and a palpable bladder most likely has congenital urinary tract obstruction, probably related to posterior urethral valves.

The physical examination must be thorough, with careful attention to volume status. Tachycardia, dry mucous membranes, and poor peripheral perfusion suggest an inadequate circulating volume and the possibility of prerenal AKI. Hypertension, peripheral edema, rales, and a cardiac gallop suggest volume overload and the possibility of intrinsic AKI from glomerulonephritis or ATN. The presence of a rash and arthritis might indicate systemic lupus erythematosus (SLE) or IgA vasculitis nephritis. Palpable flank masses may be seen with renal vein thrombosis, tumors, cystic disease, or urinary tract obstruction.

LABORATORY FINDINGS

Laboratory abnormalities can include anemia (the anemia is usually dilutional or hemolytic, as in SLE, renal vein thrombosis, HUS); leukopenia (SLE, sepsis); thrombocytopenia (SLE, renal vein thrombosis, sepsis, HUS); hyponatremia (dilutional); metabolic acidosis; elevated serum concentrations of blood urea nitrogen (BUN), creatinine, uric acid, potassium, and phosphate (diminished kidney function); and hypocalcemia (hyperphosphatemia).

The serum C3 level may be depressed (postinfectious glomerulonephritis, SLE, or membranoproliferative glomerulonephritis), and antibodies may be detected in the serum to streptococcal (poststreptococcal glomerulonephritis), nuclear (SLE), neutrophil cytoplasmic (granulomatosis with polyangiitis, microscopic polyarteritis), or glomerular basement membrane (Goodpasture disease) antigens.

The presence of hematuria, proteinuria, and red blood cell or granular urinary casts suggests intrinsic AKI, in particular glomerular disease and ATN. The presence of white blood cells and white blood cell casts with low-grade hematuria and proteinuria suggests tubulointerstitial disease. Urinary eosinophils may be present in some children with drug-induced tubulointerstitial nephritis.

Urinary indices may be useful in differentiating prerenal AKI from intrinsic AKI (Table 572.4). Patients whose urine shows an elevated specific gravity (>1.020), elevated urine osmolality (UOsm >500 mOsm/kg), low urine sodium (UNa <20 mEq/L), and fractional excretion of sodium <1% (<2.5% in neonates) most likely have prerenal AKI. Those with a specific gravity of <1.010, low urine osmolality (UOsm <350 mOsm/kg), high urine sodium (UNa >40 mEq/L), and fractional excretion of sodium >2% (>10% in neonates) most likely have intrinsic AKI.

Table 572.4 Urinalysis, Urine Chemistries, and Osmolality in Acute Kidney Injury

	HYPOVOLEMIA	ACUTE TUBULAR NECROSIS	ACUTE INTERSTITIAL NEPHRITIS	GLOMERULONEPHRITIS	OBSTRUCTION
Sediment	Bland, may have hyaline casts	Broad, brownish granular casts	White blood cells, eosinophils, cellular casts	Red blood cells, red blood cell casts	Bland or bloody
Protein	None or low	None or low	Minimal but may be increased with NSAIDs	Increased, >100 mg/dL	Low
Urine sodium (mEq/L)*	<20	>40	>30	<20	<20 (acute) >40 (few days)
Urine osmolality (mOsm/kg)	>400	<350	<350	>400	<350
Fractional excretion of sodium %†	<1	>2‡	Varies	<1	<1 (acute) >1 (few days)

*The sensitivity and specificity of urine sodium of <20 mEq/L in differentiating prerenal azotemia from acute tubular necrosis are 90% and 82%, respectively.
†Fractional excretion of sodium is the urine:plasma (U:P) ratio of sodium divided by U:P of creatinine × 100. The sensitivity and specificity of fractional excretion of sodium of <1% in differentiating prerenal azotemia from acute tubular necrosis are 96% and 95%, respectively.
‡The fractional excretion of sodium may be <1% in acute tubular necrosis secondary to radiocontrast material or rhabdomyolysis.
NSAIDs, Nonsteroidal antiinflammatory drugs.
From Singri N, Ahya SN, Levin ML. Acute renal failure. *JAMA*. 2003;289:747–751.

Chest radiography may reveal cardiomegaly, pulmonary congestion (fluid overload), or pleural effusions. Renal ultrasonography can reveal hydronephrosis and/or hydroureter, which suggest urinary tract obstruction, or nephromegaly, consistent with intrinsic renal disease. Renal biopsy may ultimately be required to determine the precise cause of AKI in patients who do not have clearly defined prerenal or postrenal AKI.

Although serum creatinine is used to measure kidney function, it is an insensitive and delayed measure of decreased kidney function following AKI. Tissue inhibitor of metallopritinase-2 (TIMP2) and insulin-like growth factor binding protein-7 (IGFBP7) are biomarkers for early tubular injury and the risk for the development of AKI used mostly in critically ill adult patients.

TREATMENT

Medical Management

Complications of AKI are noted in Table 572.5. In infants and children with urinary tract obstruction, such as in a newborn with suspected posterior ureteral valves, a bladder catheter should be placed immediately to ensure adequate drainage of the urinary tract. The placement of a bladder catheter may also be considered in nonambulatory older children and adolescents to accurately monitor urine output during AKI; however, precautions to prevent iatrogenic infection should be taken.

Determination of the volume status is of critical importance when initially evaluating a patient with AKI. If there is no evidence of volume overload or cardiac failure, the intravascular volume should be expanded by intravenous (IV) administration of isotonic saline, 20 mL/kg over 30 minutes. In the absence of blood loss or hypoproteinemia, colloid-containing solutions are not required for volume expansion. Severe hypovolemia may require additional fluid boluses (see Chapters 74, 75, and 85). Determination of the central venous pressure may be helpful if adequacy of the blood volume is difficult to determine. After volume resuscitation, hypovolemic patients generally void within 2 hours; failure to do so suggests intrinsic or postrenal AKI. Hypotension caused by sepsis requires vigorous fluid resuscitation followed by a continuous infusion of vasopressors.

Diuretic therapy should be considered only after the adequacy of the circulating blood volume has been established. Furosemide (2-4 mg/kg) may be administered as a single IV dose. Bumetanide (0.1 mg/kg) may be given as an alternative to furosemide. If urine output is not improved, then a continuous diuretic infusion may be considered. To increase renal cortical blood flow, many clinicians administer dopamine (2-3 μg/kg/min) in conjunction with diuretic therapy, although no controlled data support this practice. *There is little evidence that diuretics or dopamine can prevent AKI or hasten recovery*. Mannitol may be effective in the prevention of pigment (myoglobin, hemoglobin)-induced renal failure. Atrial natriuretic peptide may be of value in preventing or treating AKI, although there is little pediatric evidence to support its use.

If there is no response to a diuretic challenge, diuretics should be discontinued and fluid restriction is essential. Patients with a relatively normal intravascular volume should initially be limited to 400 mL/m^2/24 hr (insensible losses) plus an amount of fluid equal to the urine output for that day. Extrarenal (blood, GI tract) fluid losses should be replaced, milliliter for milliliter, with appropriate fluids. Markedly hypervolemic patients can require further fluid restriction, omitting the replacement of insensible fluid losses, urine output, and extrarenal losses to diminish the expanded intravascular volume. Fluid intake, urine and stool output, body weight, and serum chemistries should be monitored daily.

In AKI, rapid development of **hyperkalemia** (serum potassium level >6 mEq/L) can lead to cardiac arrhythmia, cardiac arrest, and death. The earliest electrocardiographic change seen in patients with developing hyperkalemia is the appearance of peaked T waves. This may be followed by widening of the QRS intervals, ST segment depression, ventricular arrhythmias, and cardiac arrest (see Chapter 472.2). Procedures to deplete body potassium stores should be initiated when the serum potassium value rises to >6.0 mEq/L. Exogenous sources of potassium (dietary, IV fluids, total parenteral nutrition) should be eliminated. Sodium polystyrene sulfonate (SPS) resin (Kayexalate), 1 g/kg, should be given orally or by retention enema. This resin exchanges sodium for potassium and can take several hours to take effect. A single dose of 1 g/kg can be expected to lower the serum potassium level by about 1 mEq/L. Resin therapy may be repeated every 2 hours, the frequency being limited primarily by the risk of sodium overload.

More severe elevations in serum potassium (>7 mEq/L), especially if accompanied by electrocardiographic changes, require emergency measures in addition to Kayexalate. The following agents should be administered:

- Calcium gluconate 10% solution, 100 mg/kg/dose (maximum 3,000 mg/dose)
- Sodium bicarbonate, 1-2 mEq/kg IV, over 5-10 minutes
- Regular insulin, 0.1 units/kg, with glucose 50% solution, 1 mL/kg, over 1 hour

Calcium gluconate counteracts the potassium-induced increase in myocardial irritability but does not lower the serum potassium level. Administration of sodium bicarbonate, insulin, or glucose lowers the serum potassium level by shifting potassium from the extracellular to the intracellular compartment. A similar effect has been reported with the acute administration of β-adrenergic agonists in adults, but there are no controlled data in pediatric patients. Because the duration of action of these emergency measures is just a few hours, persistent hyperkalemia should be managed by dialysis.

Mild **metabolic acidosis** is common in AKI because of the retention of hydrogen ions, phosphate, and sulfate, but it rarely requires treatment. If acidosis is severe (arterial pH <7.15; serum bicarbonate <8 mEq/L) or contributes to significant hyperkalemia, treatment is indicated. The acidosis should be corrected partially by the IV route, generally by giving enough bicarbonate to raise the arterial pH to 7.20 (which approximates a serum bicarbonate level of 12 mEq/L). The remainder of the correction may be accomplished by oral administration of sodium bicarbonate after normalization of the serum calcium and phosphorus levels. Correction of metabolic acidosis with IV bicarbonate can precipitate tetany in patients with renal failure because rapid correction of acidosis reduces the ionized calcium concentration.

Hypocalcemia is primarily treated by lowering the serum phosphorus level. Calcium should not be given IV, except in cases of tetany, to avoid deposition of calcium salts into tissues. Patients should

From Weisbord SD, Palevsky PM. Acute kidney injury. In: Yu AS, Chertow GM, Luyckx VA, et al, eds. *Brenner & Rector's The Kidney,* 11th ed. Philadelphia: Elsevier; 2020: Table 29.6.

be instructed to follow a low-phosphorus diet, and phosphate binders should be orally administered to bind any ingested phosphate and increase the GI phosphate excretion. Common agents include sevelamer (Renagel), calcium carbonate (Tums tablets or Titralac suspension), and calcium acetate (PhosLo). Aluminum-based binders, commonly employed in the past, should be avoided because of the risk of aluminum toxicity.

Hyponatremia is most commonly a dilutional disturbance that must be corrected by fluid restriction rather than sodium chloride administration. Administration of hypertonic (3%) saline should be limited to patients with symptomatic hyponatremia (seizures, lethargy) or those with a serum sodium level <120 mEq/L. Acute correction of the serum sodium to 125 mEq/L (mmol/L) should be accomplished using the following formula:

$$\text{mEq sodium required} = 0.6 \times \text{weight in kg} \times (125 - \text{serum sodium in mEq/L}).$$

AKI patients are predisposed to **GI bleeding** because of uremic platelet dysfunction, increased stress, and heparin exposure if treated with hemodialysis (HD) or continuous renal replacement therapy (CRRT). Oral or IV H_2 blockers such as ranitidine are commonly administered to prevent this complication.

Hypertension can result from hyperreninemia associated with the primary disease process and/or expansion of the extracellular fluid volume and is most common in AKI patients with acute glomerulonephritis or HUS. Salt and water restriction is critical, and diuretic administration may be useful (see Chapter 494). Isradipine (0.05-0.15 mg/kg/dose, maximum dose 5 mg 4 times per day) may be administered for a relatively rapid reduction in blood pressure (BP). Longer-acting oral agents such as calcium channel blockers (amlodipine, 0.1-0.6 mg/kg/24 hr daily or divided twice daily) or β blockers (labetalol, 4-40 mg/kg/24 hr divided 2 or 3 times daily) may be helpful in maintaining control of the BP. Children with severe symptomatic hypertension (hypertensive urgency or emergency) should be treated with continuous infusions of nicardipine (0.5-5.0 μg/kg/min), sodium nitroprusside (0.5-10.0 μg/kg/min), labetalol (0.25-3.0 mg/kg/hr), or esmolol (150-300 μg/kg/min) and converted to intermittently dosed antihypertensives when more stable.

Neurologic symptoms in AKI can include headache, seizures, lethargy, and confusion (encephalopathy). Potential etiologic factors include hypertensive encephalopathy, hyponatremia, hypocalcemia, cerebral hemorrhage, cerebral vasculitis, and the uremic state. Benzodiazepines are the most effective agents in acutely controlling seizures, and subsequent therapy should be directed toward the precipitating cause.

The **anemia** of AKI is generally mild (hemoglobin 9-10 g/dL) and primarily results from volume expansion (hemodilution). Children with HUS, SLE, active bleeding, or prolonged AKI can require transfusion of packed red blood cells if their hemoglobin level falls below 7 g/dL. In hypervolemic patients, blood transfusion carries the risk of further volume expansion, which can precipitate hypertension, heart failure, and pulmonary edema. Slow (4- to 6-hour) transfusion with packed red blood cells (10 mL/kg) diminishes the risk of hypervolemia. The use of fresh, washed red blood cells minimizes the acute risk of hyperkalemia, and the chronic risk of sensitization if the patient becomes a future candidate for renal replacement therapy. In the presence of severe hypervolemia or hyperkalemia, blood transfusions are most safely administered during dialysis or ultrafiltration.

Nutrition is of critical importance in children who develop AKI. In most cases, sodium, potassium, and phosphorus should be restricted. Protein intake should be moderately restricted while maximizing the caloric intake to minimize the accumulation of nitrogenous wastes. In critically ill patients with AKI, parenteral hyperalimentation with essential amino acids should be considered.

Dialysis

Indications for dialysis in AKI include the following:

- Anuria/oliguria with fluid overload
- Volume overload with evidence of hypertension and/or pulmonary edema refractory to diuretic therapy
- Persistent hyperkalemia
- Severe metabolic acidosis unresponsive to medical management
- Uremia (encephalopathy, pericarditis, neuropathy)
- Calcium:phosphorus imbalance, with hypocalcemic tetany that cannot be controlled by other measures

An additional important practical indication for dialysis is the inability to provide adequate nutritional intake because of the need for severe fluid restriction. In patients with AKI, dialysis support may be necessary for days or for up to 12 weeks. Many patients with AKI require dialysis support for 1-3 weeks. Table 572.6 lists the advantages and disadvantages of the three types of dialysis.

Intermittent HD is useful in patients with a relatively stable hemodynamic status. This highly efficient process accomplishes both fluid and electrolyte removal in sessions of 3-4 hours using a pump-driven extracorporeal circuit and large central venous catheter. Intermittent HD may be performed 3-7 times per week based on the patient's fluid and electrolyte balance.

Peritoneal dialysis (PD) is most employed in neonates and infants with AKI, although this modality may be used in children and adolescents of all ages. Hyperosmolar dialysate is infused into the peritoneal cavity via a surgically or percutaneously placed PD catheter. The fluid is allowed to dwell for 45-60 minutes and is then drained from the patient by gravity (manually or with the use of machine-driven cycling), accomplishing fluid and electrolyte removal. Cycles are repeated for 8-24 hours per day based on the patient's fluid and electrolyte balance. Anticoagulation is not necessary. PD is contraindicated in patients with significant abdominal pathology.

Continuous renal replacement therapy (CRRT) is useful in patients with an unstable hemodynamic status, increased intracranial pressure, cerebral edema, concomitant sepsis, or multiorgan failure (including

hepatic failure) in the intensive care setting. CRRT is an extracorporeal therapy in which fluid, electrolytes, and small- and medium-size solutes are continuously removed from the blood (24 hours/day) using a specialized pump-driven machine. Usually, a double-lumen catheter is placed into the internal jugular or femoral vein. The patient is then connected to the pump-driven CRRT circuit, which continuously passes the patient's blood across a highly permeable filter.

CRRT may be performed in three basic fashions. In continuous venovenous **hemofiltration**, a large volume of fluid is driven by systemic or pump-assisted pressure across the filter, bringing with it by *convection* other molecules, such as urea, creatinine, phosphorus, and uric acid. The blood volume is reconstituted by an IV infusion of a replacement fluid having a desirable electrolyte composition similar to that of blood. Continuous venovenous **HD** uses the principle of diffusion by circulating dialysate in a countercurrent direction on the ultrafiltrate side of the membrane. No replacement fluid is used. Continuous **hemodiafiltration** employs both replacement fluid and dialysate, offering the most effective solute removal of all forms of CRRT.

Table 572.6 compares the relative risks and benefits of the various renal replacement therapies. CRRT has similar outcomes for recovery of renal function when compared with intermittent HD.

PROGNOSIS

The mortality rate in children with AKI is variable and depends entirely on the nature of the underlying disease process rather than on the renal failure itself. Children with AKI caused by a kidney-limited condition such as postinfectious glomerulonephritis have a very low mortality rate (<1%); those with AKI related to multiorgan failure have a very high mortality rate (>50%).

The prognosis for recovery of kidney function depends on the disorder that precipitated AKI. Recovery is likely after AKI resulting from prerenal causes, ATN, acute interstitial nephritis, or tumor lysis syndrome. Complete recovery of renal function is unusual when AKI results from most types of rapidly progressive glomerulonephritis, bilateral renal vein thrombosis, or bilateral cortical necrosis. Medical management may be necessary for a prolonged period to treat the sequelae of AKI, including chronic renal insufficiency, hypertension, renal tubular acidosis, and urinary concentrating defect.

572.2 Chronic Kidney Disease

Donna J. Claes

Chronic kidney disease (CKD) is determined by the presence of kidney damage and level (or severity) of kidney function (GFR; Tables 572.7 and 572.8). **End-stage kidney disease (ESKD)** is an administrative term in the United States; it is used to define patients who are treated with dialysis or kidney transplantation and is a subset of patients with stage 5 CKD.

Table 572.7 Criteria for Definition of Chronic Kidney Disease (NKF KDOQI Guidelines)

Patient has chronic kidney disease (CKD) if either of the following criteria are present:

1. Kidney damage for ≥3 mo, as defined by structural or functional abnormalities of the kidney, with or without decreased GFR, manifested by one or more of the following features:
   - Abnormalities in the composition of the blood or urine
   - Abnormalities in imaging tests
   - Abnormalities on kidney biopsy
2. GFR < 60 mL/min/1.73 m^2 for ≥3 mo, with or without the other signs of kidney damage described previously

GFR, Glomerular filtration rate; NKF KDOQI, National Kidney Foundation Kidney Disease Outcomes Quality Initiative.

Table 572.8 Standardized Terminology for Stages of Chronic Kidney Disease (NKF KDOQI Guidelines)

STAGE	DESCRIPTION	GFR (ML/MIN/1.73 M²)
1	Kidney damage with normal or increased GFR	≥90
2	Kidney damage with mild decrease in GFR	60-89
3	Moderate decrease in GFR	30-59
4	Severe decrease in GFR	15-29
5	Kidney failure	<15 or on dialysis

GFR, Glomerular filtration rate; NKF KDOQI, National Kidney Foundation Kidney Disease Outcomes Quality Initiative.

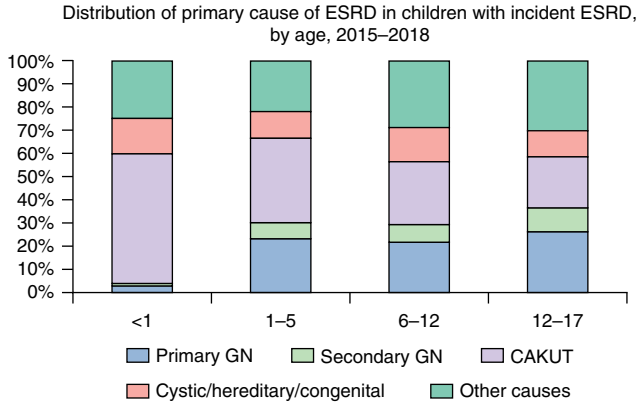

Fig. 572.2 Distribution of primary cause of end-stage renal disease (ESRD), by age, in incident pediatric dialysis patients reported to United States Renal Data System (USRDS) in 2016–2020. CAKUT, Congenital anomalies of the kidney and urinary tract; GN, glomerulonephritis. *(Adapted from the United States Renal Data System. 2022 USRDS Annual Data Report: Epidemiology of kidney disease in the United States. National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, 2022. Fig. 8.4. https://usrds-adr.niddk.nih.gov/2022/end-stage-renal-disease/8-esrd-among-children-and-adolescents)*

Pediatric CKD prevalence is approximately 18 per 1 million children. The prognosis for the infant, child, or adolescent with CKD has improved secondary to improved medical management, dialysis techniques, and kidney transplantation. Childhood-onset ESKD still carries significant morbidity and a 30-fold increased mortality rate as compared with healthy peers.

ETIOLOGY

The etiology of pediatric CKD may be the result of congenital, acquired, inherited, or metabolic renal disease; however, the common etiology is having a reduction in nephron mass (Fig. 572.2). Causes of kidney disease in children are typically subdivided as being non-glomerular vs glomerular in origin (Table 572.9). The underlying cause correlates with the age at the time of diagnosis. **Congenital anomalies of the kidney and urinary tract** (CAKUT; i.e., renal hypoplasia, dysplasia, obstructive uropathy) are predominantly diagnosed in children less than 5 years of age; in many cases, CAKUT is diagnosed with prenatal ultrasonography. Cystic kidney disease (due to single gene pathogenic variants associated with cilia function, or ciliopathies) can be diagnosed prenatally, during childhood, or as a young adult depending on the underlying genetic variant and disease phenotype. After 5 years of age, acquired or inherited forms of glomerulonephritis predominate.

Table 572.9 Etiologies of Pediatric Chronic Kidney Disease

NONGLOMERULAR	GLOMERULAR
Aplastic, hypoplastic, and dysplastic kidneys	Chronic glomerulonephritis (including focal segmental glomerulonephritis [FSGS])
Cystinosis	Congenital nephrotic syndrome (CNS)
Medullary cystic kidney disease/ juvenile nephronophthisis	Hemolytic uremic syndrome (HUS)
Obstructive uropathy (e.g., PUV, cloaca, neurogenic bladder)	Idiopathic crescentic glomerulonephritis
Oxalosis	IgA nephritis
Autosomal dominant and autosomal recessive polycystic kidney disease (ADPKD, ARPDK)	IgA nephropathy (IGAN)
Pyelonephritis/interstitial nephritis/reflux nephropathy	Membranoproliferative glomerulonephritis (MPGN)
Renal infarct	Membranous nephropathy
Syndrome of agenesis of abdominal musculature (Eagle-Barrett syndrome)	Sickle cell nephropathy
Wilms tumor	Systemic immunologic disease (e.g., SLE, granulomatosis with polyangiitis)
	Hereditary nephritis (Alport syndrome)

PUV, Posterior urethral valve; SLE, systemic lupus erythematosus.

PATHOGENESIS

In addition to progressive injury with ongoing structural or metabolic genetic diseases, renal injury can progress despite removal of the original insult.

Hyperfiltration injury may be an important final common pathway of glomerular destruction, independent of the underlying cause of renal injury. As nephrons are lost, the remaining nephrons undergo structural and functional hypertrophy characterized by an increase in glomerular blood flow. The driving force for glomerular filtration is thereby increased in the surviving nephrons. Although this compensatory hyperfiltration temporarily preserves total renal function, it can cause progressive damage to the surviving glomeruli, possibly by a direct effect of the elevated hydrostatic pressure on the integrity of the capillary wall and/or the toxic effect of increased protein traffic across the capillary wall. Over time, the remaining nephrons suffer an increased excretory burden, resulting in a vicious cycle of increasing glomerular blood flow and hyperfiltration injury.

Other pathologic etiologies of CKD include proteinuria, hypertension, hyperphosphatemia, and hyperlipidemia. **Proteinuria**, secondary to either damage to the glomerular capillary wall and/or decreased tubular reabsorption, contributes to renal functional decline. Proteinuria can exert a direct toxic effect on tubular cells and initiate many inflammatory and pro-fibrotic cellular pathways that recruit monocytes and macrophages, enhancing the process of glomerular sclerosis and tubulointerstitial fibrosis. Podocyte injury can also result from proteinuria, although the mechanism is less understood. Uncontrolled **hypertension** can exacerbate disease progression by causing arteriolar nephrosclerosis and by increasing the hyperfiltration injury. **Hyperphosphatemia** can increase progression of disease by leading to calcium phosphate deposition in the renal interstitium and blood vessels. **Hyperlipidemia,** a common condition in CKD patients, can adversely affect glomerular function through oxidant-mediated injury.

CKD is viewed as a continuum of disease, with increasing biochemical and clinical manifestations as renal function deteriorates (Fig. 572.3). Regardless of etiology, the progression of tubulointerstitial fibrosis is the primary determinant of CKD progression.

CLINICAL MANIFESTATIONS

Table 572.10 outlines the pathophysiologic manifestations of CKD. The clinical presentation of CKD is varied and depends on the underlying etiology and CKD stage (Fig. 572.4). CAKUT and some genetic forms of renal disease (i.e., familial nephronophthisis) demonstrate growth failure, vomiting, and polyuria with associated polydipsia. Patients with cystic kidney disease due to a ciliopathy can have a wide range of extrarenal anomalies of the kidneys, liver, pancreas, skeletal system, eyes, central nervous system, and/or cardiac system that can assist with disease diagnosis. Urinary tract infection can also be common in those with urologic abnormalities. Glomerular forms of CKD often present with edema, hypertension, hematuria, and proteinuria; in severe forms of glomerulonephritis, malnutrition can be seen. As renal deterioration advances in severity, patients can develop uremic symptoms (i.e., worsening fatigue, weakness, nausea, vomiting, anorexia, and poor sleep patterns) and edema, hypertension, and other findings of fluid overload, regardless of CKD etiology.

Physical examination in CKD should focus on overall growth and development, with special attention and/or evaluation of BP, as well as the skin (pallor) and the extremities (edema; bony abnormalities of rickets seen in untreated renal osteodystrophy).

LABORATORY FINDINGS

Laboratory findings can include elevations in BUN and serum creatinine in addition to hyperkalemia, hyponatremia (secondary to either renal salt wasting vs volume overload), hypernatremia (loss of free water), acidosis, hypocalcemia, hyperphosphatemia, and an elevation in uric acid. Patients with heavy proteinuria can have hypoalbuminemia. A complete blood cell count may show a normochromic, normocytic anemia. Dyslipidemia is commonly seen. In children with glomerulonephritis, the urinalysis (UA) shows hematuria and proteinuria, whereas, in children with congenital lesions such as renal dysplasia, the UA often has a low specific gravity with minimal other abnormalities.

Renal function can be measured or estimated by GFR. Inulin clearance is the gold standard to measure GFR, but it is no longer readily available. Other methods to measure GFR in clinical practice include using iohexol or various radioisotopes (^{99m}Tc-DTPA, ^{51}Cr-EDTA, or ^{125}Iothalamate). However, estimating GFR by endogenous markers (such as creatinine and/or cystatin C) is the most utilized method to understand severity of renal disease. A "bedside" creatinine-based estimating equation [estimated GFR (mL/min/1.73 m^2) = 0.413 × height (cm)/serum creatinine (mg/dL)] has been validated in a pediatric CKD population of children age 1-16 years whose GFR was between 15 and 90 mL/min/1.73 m^2; however, this formula has less accuracy in the very young (<5 years of age) and young adults (18-25 years of age). Newer estimation formulas ("Chronic Kidney Disease in Children [CKID] study under 25," or U25) have been developed that allow for age- and gender-based corrections of creatinine and cystatin C with improved accuracy of GFR estimation. Although these newer formulas are more complex in regard to the mathematical corrections of age and gender for both creatinine and cystatin C, they are accessible by an online calculator, which allows for ease in their clinical use.

TREATMENT/MANAGEMENT

CKD treatment is supportive, with an aim to screen for and treat various metabolic complications of CKD in hopes of improving quality of life and potentially slowing the progression of renal dysfunction. Children with CKD should be treated at a pediatric center capable of supplying multidisciplinary services, including medical, nursing, social service, nutritional, and psychologic support.

CKD management requires close monitoring of blood studies, urine studies (including quantitative measurement for proteinuria using either a spot urine protein/urine creatinine ratio or 24-hour urine collection), and overall clinical symptomatology. Ambulatory blood pressure monitoring (ABPM) over 24 hours, the gold standard of BP evaluation, is recommended in patients with renal disease to diagnose and treat hypertension, especially masked hypertension. **Masked hypertension** (defined as a normal office BP but abnormal ABPM) is seen in up to 35% of pediatric predialysis CKD patients and carries a fourfold increased risk of having left ventricular hypertrophy (LVH).

Nutrition

Nutritional management by a dietician experienced in pediatric renal patients is recommended by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF KDOQI). Patients should

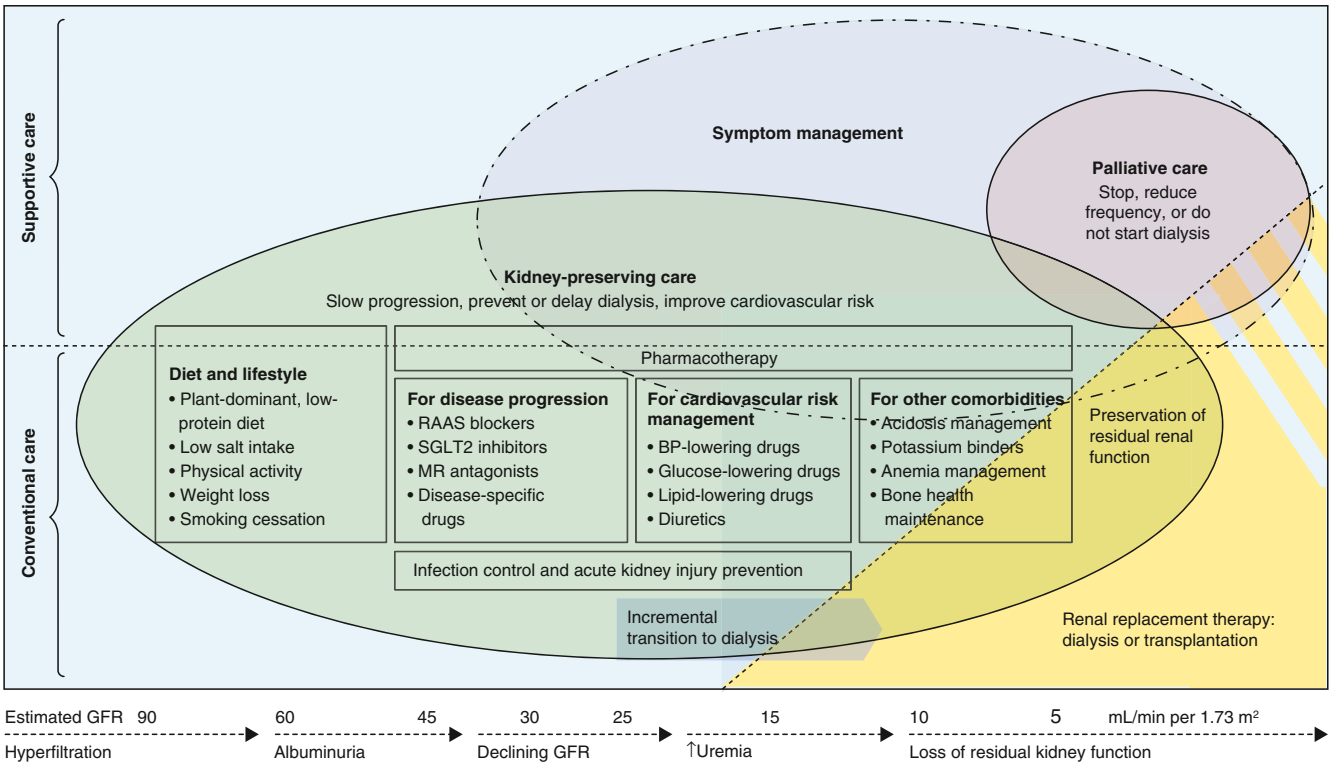

Fig. 572.3 Conservative and preservative management of chronic kidney disease without dialysis or renal transplantation. This chart highlights the role of preservative management and its goals *(green domain)* within the overall conservative management of chronic kidney disease without dialysis *(blue zone)*, juxtaposing renal replacement therapy including dialysis and kidney transplantation *(yellow zone)*. The X-axis (showing chronic kidney disease progression) should be read exclusively from left to right. The bottom half of the chart represents conventional (life-prolonging and kidney-prolonging) strategies, whereas the top half represents supportive care, including palliative and hospice care, in which dialysis is often avoided or withdrawn *(violet domain)*. The *oblique dotted line* between the two main zones (conservative management vs renal replacement therapy) suggests that there is variability in transitioning to dialysis therapy (moving from bottom left to top right), including timing (early vs late vs never), level of care (life-prolonging vs supportive care), and type of dialysis (conventional vs incremental). The symptom management *(purple)* domain provides wide ranges of interventions to encompass the goals of care under both kidney-preserving care and palliative and hospice care. Preservative management can preserve residual kidney function for longer, especially after incremental transition to dialysis. BP, Blood pressure; GFR, glomerular filtration rate; MR, mineralocorticoid receptor; RAAS, renin-angiotensin-aldosterone system. *(From Kalantar-Zadeh K, Jafar TH, Nitsch D, et al. Chronic kidney disease. Lancet. 2021;398:786–798. Fig. 1, p. 787.)*

receive 100% of estimated energy requirement for age, individually adjusted for physical activity level, body mass index, and response in the rate of weight gain or loss. When oral supplemental nutrition with increased calories or fluid volume is insufficient, tube feeding (by nasogastric tubes or gastrostomy tubes) should be considered. Calories should be balanced between carbohydrate, unsaturated fat in physiologic ranges (per dietary reference intake [DRI]), and protein. Dietary protein restriction is not suggested for children with CKD because of the concern about adverse effects on growth and development; in fact, recommended protein intake is often 100% (or more for those receiving dialysis) of the DRI for ideal weight for children. Children with CKD stages 2-5 should receive 100% of DRI of vitamins and trace elements; water-soluble vitamin supplements are often required for patients receiving dialysis.

CKD Mineral and Bone Disorder (CKD-MBD)

CKD is characterized by systemic disorders of calcium, phosphorus, parathyroid hormone (PTH), and vitamin D metabolism that can lead to bone disorders (**renal osteodystrophy**) but also *vascular and soft tissue calcification* (Fig. 572.5). Efforts have focused on the role of the hormone fibroblast growth factor 23 (FGF-23) and its cofactor, Klotho, in CKD-mineral and bone disorder (MBD). Elevated FGF-23 results in increased urinary phosphate excretion and suppression of 1-α-hydroxylase activity, leading to reduced 1,25-dihydroxycholecalciferol ($1,25OH_2D$) values and increased PTH secretion. Elevated FGF-23 is the first sign of altered osteocyte function in pediatric and adult CKD, is seen as early as CKD stage 2 (GFR 60-90 mL/min/1.73 m^2), and occurs despite normal calcium, phosphorus, PTH, and $1,25OH_2D$ levels. With continued loss of renal function, further FGF-23 elevation results in the development of secondary hyperparathyroidism (low $1,25OH_2D$ with hypocalcemia, hyperphosphatemia, and elevated PTH values).

Renal osteodystrophy is characterized by abnormalities in *bone turnover* (high vs low), *mineralization,* and *bone volume.* High-turnover bone disease, or **osteitis fibrosa cystica**, is the most common condition seen in advanced pediatric CKD, with characteristic laboratory (hypocalcemia, hyperphosphatemia, and elevated alkaline phosphatase and PTH values) and radiographic (subperiosteal bone resorption, metaphyseal widening) findings. Clinical manifestations may include bone pain, fractures with minor trauma, and various bony abnormalities (rachitic changes, varus and valgus deformities of the long bones, and slipped capital femoral epiphyses [SCFE]). In contrast, low-turnover bone disease **(adynamic renal osteodystrophy)** is associated with PTH over-suppression, hypercalcemia, and low alkaline phosphatase activity; it is more commonly seen in pediatric dialysis patients receiving treatment for secondary hyperparathyroidism. Defective bone mineralization occurs in states of either high bone turnover (mixed lesion) or low to normal bone turnover (osteomalacia). In terms of bone volume, most pediatric CKD patients have normal to high bone volume on bone histomorphometry unless they were exposed to prolonged corticosteroid use.

Vascular calcification in CKD-MBD typically occurs within the vascular media, which is in contrast to the atherosclerotic plaques that form within the vascular intima in patients with traditional cardiovascular risk factors (hypertension, diabetes/obesity, cigarette smoking,

Table 572.10 Pathophysiology of Chronic Kidney Disease

MANIFESTATION	MECHANISMS
Accumulation of nitrogenous waste products	Decrease in glomerular filtration rate
Acidosis	Decreased ammonia synthesis Impaired bicarbonate reabsorption Decreased net acid excretion
Sodium wasting	Solute diuresis Tubular damage
Urinary concentrating defect	Solute diuresis Tubular damage
Hyperkalemia	Decrease in glomerular filtration rate Metabolic acidosis Excessive potassium intake Hyporeninemic hypoaldosteronism
Renal osteodystrophy	Impaired renal production of 1,25-dihydroxycholecalciferol ($1,25OH_2D$) Hyperphosphatemia Hypocalcemia Secondary hyperparathyroidism
Growth retardation	Inadequate caloric intake Renal osteodystrophy Metabolic acidosis Anemia Growth hormone resistance
Anemia	Decreased erythropoietin production Iron, folate, and/or vitamin B_{12} deficiency Decreased erythrocyte survival
Bleeding tendency	Defective platelet function
Infection	Defective granulocyte function Impaired cellular immune functions Indwelling dialysis catheters
Decreased academic achievement, attention regulation, or executive functioning	Hypertension Low birth weight
Gastrointestinal symptoms (feeding intolerance, abdominal pain)	Gastroesophageal reflux Decreased gastrointestinal motility
Hypertension	Volume overload Excessive renin production
Hyperlipidemia	Decreased plasma lipoprotein lipase activity Abnormal HDL-C
Cardiomyopathy	Hypertension Anemia Fluid overload
Glucose intolerance	Tissue insulin resistance

HDL-C, High-density lipoprotein cholesterol.

and dyslipidemia). Vascular calcification in CKD has been associated with hypercalcemia, hyperphosphatemia, and an elevated calcium-phosphorus product ($Ca \times PO_4$); yet, studies of adult and pediatric patients with mild to moderate CKD have noted findings of vascular calcification despite normal serum calcium and phosphorus values. The cause of vascular calcification in CKD is not completely understood and is being actively studied. The proposed pathophysiologic etiology involves the transition of vascular smooth muscle cells to osteoblast-like cells in response to trigger(s) that are currently unknown.

Treatment for CKD-MBD is guided by clinical assessment of calcium, phosphorus, 25OH vitamin D, and PTH. The goals of treatment are to normalize mineral metabolism with the goal of improving growth, reducing bone deformities and fragility, and reducing vascular and other soft tissue calcification. This is typically accomplished with reduced phosphorus intake, normalization of 25OH vitamin D, and use of active vitamin D sterols.

CKD patients of all ages should typically follow a low-phosphorus diet with the goal to maintain age-appropriate serum phosphorus values. Infants should be provided with a low-phosphorus formula (Similac PM 60/40). **Phosphate binders** (given with meals) are used to enhance GI phosphate excretion, and at present are recommended to be started at the onset of hyperphosphatemia. Phosphate binders should be adjusted to maintain normal serum calcium and phosphorus levels and to ensure that the recommended total daily intake of calcium is not exceeded. Phosphate binders can be either calcium based (calcium carbonate, calcium acetate) or non–calcium based (sevelamer). Because aluminum may be absorbed from the GI tract and can lead to aluminum toxicity (manifested by anemia, various bony abnormalities, and neurologic abnormalities including seizures), aluminum-based binders should be avoided.

Correcting 25OH vitamin D insufficiency can delay the onset of secondary hyperparathyroidism in predialysis CKD patients and improves bone mineralization. 25OH vitamin D provides a substrate for the formation of $1,25OH_2D$ and has been shown to directly suppress PTH production at the level of the parathyroid gland. U.S.-based pediatric CKD treatment guidelines define 25OH vitamin D sufficiency as a serum value of ≥30 ng/mL; **ergocalciferol** or **cholecalciferol** are typically recommended to treat insufficient 25OH vitamin D.

Active vitamin D sterols have been traditionally indicated when (1) $1,25OH_2D$ levels fall below the established goal range for the child's particular stage of CKD, (2) PTH levels increase above the established goal range for CKD stage (after correcting for insufficient 25OH vitamin D), or (3) patients have elevated PTH levels and hypocalcemia. Vitamin D sterols increase calcium and phosphorus absorption from the GI tract and are effective in reducing PTH values. Calcitriol is the most well-known and studied active vitamin D sterol; other agents such as paricalcitol and doxercalciferol have less intestinal calcium and phosphorus reabsorption and are used in CKD patients predisposed to hypercalcemia. The ideal PTH target to initiate and monitor active vitamin D sterol therapy is debated, particularly in the predialysis CKD population.

Fluid and Electrolyte Management

Infants and children with renal dysplasia may be polyuric with significant urinary sodium and free water losses. These children benefit from high-volume, low-caloric-density feedings with sodium supplementation. Children with high BP or edema benefit from sodium restriction and diuretic therapy. Fluid restriction is necessary in severe cases of nephrotic syndrome or when renal function worsens to the point of requiring dialysis.

Hyperkalemia can develop with severe deterioration in renal function, as well as in patients with moderate renal insufficiency who have excessive dietary potassium intake, severe acidosis, or hyporeninemic hypoaldosteronism (related to destruction of the renin-secreting juxtaglomerular apparatus). Hyperkalemia may be treated by restriction of dietary potassium intake, administration of oral alkalinizing agents, and/or use of **cation exchange resins**. The most commonly utilized cation exchange resin, SPS (Kayexalate) has many severe adverse drug events, including but not limited to GI abnormalities (including intestinal necrosis), hypernatremia, hypocalcemia, and hypomagnesemia, that can limit its use or result in significant morbidity. Newer cation exchange resins (such as sodium zirconium cyclosilicate and patiromer) are more selective for potassium ion exchange and have a more favorable side effect profile compared with SPS. Patiromer is approved for ages ≥12 years in the United States, and sodium cyclosilicate is currently approved for adults; pediatric studies are ongoing.

Metabolic acidosis develops as a result of decreased net acid excretion by the failing kidneys. Either Bicitra (1 mEq sodium citrate/mL) or sodium bicarbonate tablets (650 mg = 7.7 mEq of sodium and 7.7 mEq of bicarbonate) may be used to maintain the serum bicarbonate level ≥22 mEq/L.

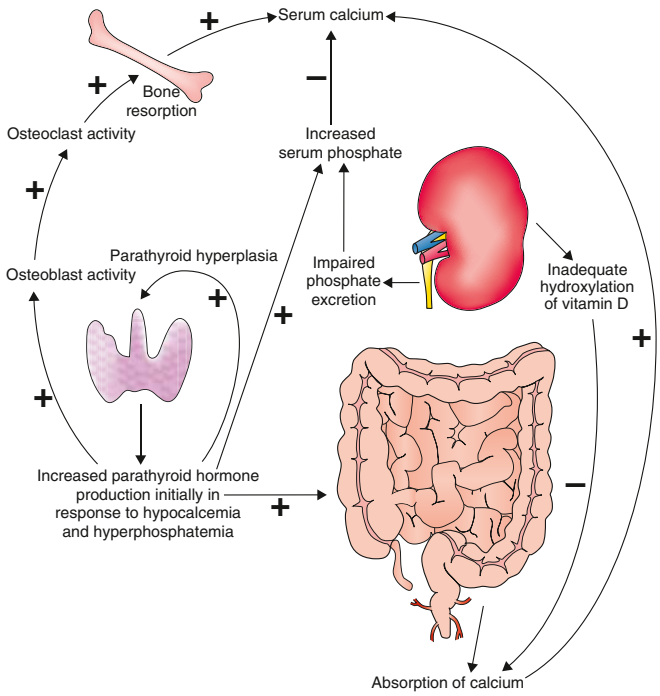

Fig. 572.5 Pathophysiology of CKD mineral bone disease. *(From Webster AC, Navler EV, Morton RL, et al. Chronic kidney disease. Lancet. 2017;389:1238–1252. Fig. 4.)*

Linear Growth

Short stature is a significant long-term sequela of childhood CKD. CKD results in an apparent growth hormone–resistant state, with elevated growth hormone levels but decreased insulin-like growth factor-1 levels and abnormalities of insulin-like growth factor–binding proteins.

Children with CKD who remain less than −2 SD for height and/or have a growth velocity of <25% over a minimum of 6 months despite optimal medical support (adequate caloric intake and effective treatment of renal osteodystrophy, anemia, and metabolic acidosis) may benefit from treatment with recombinant human growth hormone (rHuGH). rHuGH is given by daily, subcutaneous injections and continues until the patient reaches the 50th percentile for mid-parental height, achieves a final adult height, or undergoes kidney transplantation (with the caveat that rHuGH can be restarted 1 year after kidney transplantation if there are concerns for ongoing short stature despite kidney transplantation). Long-term rHuGH treatment significantly improves final adult height and induces persistent catch-up growth; some patients are able to achieve normal adult height.

Anemia

Anemia in patients with CKD is primarily the result of inadequate erythropoietin production by the peritubular interstitial cells of the kidneys and typically manifests when renal function falls below 40 mL/min/1.73 m^2. Other contributory factors for anemia in CKD include iron, folic acid, and/or vitamin B_{12} deficiency, and decreased erythrocyte survival secondary to uremia.

Anemia in pediatric CKD patients is defined when the hemoglobin falls to <5% for age and gender; alternatively, anemia can also be defined when the hemoglobin falls to <11g/dL (ages 0.5-5 years of age), <11.5 g/dL (5-12 years of age), <12 g/dL (females >12 years of age, males 12-15 years of age), and <13 g/dL (males >15 years of age). Once anemia is diagnosed, the recommendation is to investigate for deficiencies in iron and/or other vitamins (i.e., vitamin B_{12}, folate). Iron supplementation (oral or IV) is recommended for patients who demonstrate a transferrin saturation (TSAT) ≤20% and ferritin ≤100 ng/mL.

Erythropoiesis-stimulating agents (ESAs) have decreased the need for transfusions in CKD patients, especially those receiving HD. Erythropoietin and darbepoetin alfa are commonly prescribed ESAs. All patients receiving ESA therapy should be provided with either oral or IV iron supplementation. Patients who appear to be resistant to ESA should be evaluated for iron deficiency, occult blood loss, a chronic infection or inflammatory state, vitamin B_{12} or folate deficiency, or bone marrow fibrosis related to secondary hyperparathyroidism.

Emerging therapies for anemia of CKD are being directed toward the hypoxia-inducible signaling factor (HIF) pathway. HIF stabilizers prevent degradation of the HIF alpha subunit and allow for erythropoietin production. These agents are currently being studied for clinical use in adult CKD patients.

Hypertension and Proteinuria

Hypertension in pediatric CKD can be secondary to volume overload and/or excessive renin production due to glomerular disease. Both hypertension and proteinuria have been independently associated with more rapid CKD progression in various pediatric CKD observational studies. The ESCAPE trial demonstrated that more aggressive BP control delays CKD progression. In this study, participants with 24-hour mean arterial pressure (MAP) <50th percentile for age and sex by ABPM had a 35% lower risk of reaching the composite outcome (doubling of serum creatinine, estimated GFR (eGFR) of <10 mL/min/1.73 m^2, or need for dialysis or kidney transplant) compared with those randomized to a conventional BP target (MAP of 50–95% by ABPM); this effect was more notable in those with significant proteinuria.

Therapy for hypertension involves both dietary interventions and often pharmacologic agents. **Dietary sodium restriction** (<2 g of sodium/24 hr) and lifestyle modifications that promote achieving a healthy weight are both important aspects of achieving good BP control. Treatment guidelines recommend initiating pharmacologic antihypertensive therapy when systolic or diastolic BPs are >90% for age, gender, and height. Once therapy is started, it is recommended to titrate medications to achieve a systolic and diastolic BP <50% for age, gender, and height, especially in those patients with proteinuria. **ACE inhibitors** (such as enalapril, lisinopril) and **angiotensin II receptor blockers** (ARBs; such as losartan) are the antihypertensive medications of choice in all children with pediatric CKD, irrespective of the level of proteinuric renal disease, because of their potential ability to slow CKD and their superiority in controlling BP as noted in various observational and research studies. It is important to closely monitor renal function and electrolyte balance while using ACE inhibitors or ARBs, particularly in those with advanced CKD. **Thiazide** (hydrochlorothiazide, chlorothiazide, metolazone, and chlorthalidone) or **loop diuretics** (furosemide) can be helpful to control hypertension related to salt and fluid retention. Historical guidelines recommend the cessation of thiazide diuretics when a patient's eGFR falls below 30 mL/min/1.73 m^2 due to concerns of decreased efficacy; however, many adult studies support continued thiazide use either alone or in conjunction with loop diuretics for BP control in advanced (non-ESKD) CKD. Calcium channel blockers (amlodipine), β blockers (propranolol, atenolol), and centrally acting agents (clonidine) may be useful as adjunctive agents in children with CKD whose BP cannot be controlled using dietary sodium restriction, ACE inhibitors, and diuretics.

Immunizations

Children with CKD should receive all standard immunizations according to the schedule used for healthy children, with an exception to withhold live virus vaccines (such as measles, mumps, rubella, varicella) from those receiving immunosuppressive medications (i.e., kidney transplant recipients, and in some patients with glomerulonephritis). It is critical to make every attempt to administer live virus vaccines before kidney transplantation. All children with CKD should receive a yearly influenza vaccine; children with CKD are also eligible for pneumococcal vaccination with PPSV-23. Data from a number of studies suggest that children with CKD might respond suboptimally to immunizations.

Adjustment in Drug Dose

Drugs excreted by the kidneys may need to be dose adjusted in CKD patients to maximize effectiveness and minimize the risk of toxicity. Strategies in dosage adjustment include lengthening of the interval between doses, decreasing the absolute dose, or both.

Progression of Disease

The timing of CKD progression from minimal renal injury to onset of ESKD is variable. The median loss of GFR in children enrolled in the CKID study is 1.5 (non-glomerular CKD etiology) vs 4.3 (glomerular CKD etiology) mL/min/1.73 m^2/year. Nonmodifiable risk factors associated with more rapid CKD progression include older age, glomerular etiology of renal disease, CKD severity, and onset of puberty. In terms of potential modifiable risk factors, in addition to elevated BP, persistent nephrotic range proteinuria, anemia, dyslipidemia, and no ACE inhibitor/ARB use were important predictors of CKD progression.

In addition to addressing and treating the risk factors as noted previously, prompt treatment of infectious complications (especially urinary tract infection [UTI]) and episodes of dehydration can minimize additional loss of renal parenchyma. Other potentially beneficial recommendations include tobacco avoidance; prevention of obesity; and avoidance of potential nephrotoxic medications, which includes over-the-counter medications (such as nonsteroidal antiinflammatory medicines), pharmacologic agents, various illegal street drugs, and herbal and/or homeopathic medications or supplements.

572.3 End-Stage Kidney Disease

Donna J. Claes

Kidney failure, also termed end-stage kidney disease (ESKD), represents the state in which a patient's kidney dysfunction has progressed to the point at which homeostasis and survival can no longer be sustained despite maximal medical management. At this point, kidney replacement therapy (KRT; which is either dialysis or kidney transplantation) becomes necessary. The ultimate goal for children with ESKD is successful kidney transplantation (see Chapter 573) because it provides the most normal lifestyle and improved mortality and morbidity.

In the United States, 75% of children with ESKD require dialysis before transplantation. It is recommended discussions and plans for eventual KRT be initiated when a child reaches stage 4 CKD (GFR <30 mL/min/1.73 m^2). Indications for initiating maintenance dialysis include diuretic-resistant fluid overload, severe fluid restrictions that inhibit the ability to provide appropriate nutrition sufficient for linear growth, uncontrolled electrolyte abnormalities (hyperkalemia, hyperphosphatemia, metabolic acidosis), and subjective findings of uremia (fatigue, weakness, nausea, vomiting, anorexia, and poor sleep patterns), especially if these symptoms are negatively affecting academic performance. Although dialysis initiation should be considered as the GFR approaches 10-15 mL/min/1.73m^2, multiple adult and pediatric studies have indicated increased risk of mortality in those who start dialysis with a higher GFR compared to a lower GFR. Thus it is recommended to maximize medical management of CKD for as long as possible until concerns of severe fluid and electrolyte abnormalities, malnutrition, and uremic symptoms make medical management unsafe and/or impossible. Dialysis modality selection must be individualized to fit the needs of each child.

In the United States, peritoneal dialysis (PD) is still the most utilized dialysis modality (55.7%) compared to hemodialysis (44.3%); however, there is a temporal trend toward greater use of hemodialysis (HD) as the initial maintenance dialysis therapy. Age is a defining factor in dialysis modality selection: 85% of infants and children from birth to 5 years of age initiate maintenance dialysis treatment using PD, whereas 50% of children ≥13 years of age initiate maintenance dialysis treatment with HD.

Peritoneal dialysis utilizes the patient's peritoneal membrane to transport fluid and solutes. Excess body water is removed by an osmotic gradient created by the relatively high dextrose concentration in the dialysis fluid; wastes are removed by diffusion from the peritoneal capillaries into the dialysis fluid. Access to the peritoneal cavity is achieved by a surgically inserted tunneled catheter. PD may be provided either as continuous ambulatory peritoneal dialysis (CAPD) or as an automated therapy using a cycler (APD), which allows exchanges of peritoneal fluid to be performed automatically during sleep by a cycler machine. APD is the PD modality of choice in countries without cost restraints. Cycler-driven PD therapy allows the child and family an

uninterrupted day of activities (including decreased school interruption), a reduction in the number of dialysis catheter connections and disconnections (which decreases the risk of peritonitis), often less strict fluid and dietary restrictions, and a reduction in the time required by patients and parents to perform dialysis, reducing the risk of caregiver fatigue and burnout. Because PD is not as efficient as HD, it must often be performed 6-7 days per week. Contraindications to PD use include anatomic abnormalities (e.g., significant surgical adhesions, omphalocele, gastroschisis, or bladder exstrophy), peritoneal injury (including injury secondary to previous severe peritoneal infections), or lack of an appropriate caregiver who can reliably perform PD in the home.

Hemodialysis, unlike PD, is usually performed in a hospital or outpatient clinic setting; home pediatric HD programs or programs that provide intensified HD are available but uncommon. Access to the child's circulation is achieved by a surgically created arteriovenous fistula (AVF), arteriovenous graft (AVG), or tunneled dual lumen catheter. The internal jugular vein is the preferred catheter site because indwelling subclavian catheters can cause subclavian stenosis that limits that ability to utilize future AVF and AVG in the ipsilateral arm. Each HD treatment is typically prescribed to provide appropriate solute clearance and fluid removal. HD has historically been provided 3 times per week; however, more frequent dialysis treatments (up to 4-5 times per week) are seen in the United States. Intensified HD programs (such as short daily HD, intermittent nocturnal HD, and daily nocturnal HD) have demonstrated improved control of BP, fluid overload, phosphorus, anemia, and improved growth. Contraindications to HD include inadequate vascular access.

Pediatric patients on dialysis have a death rate 30 times higher than the general pediatric population, with cardiovascular disease and infections as the leading causes of mortality. Dialysis-associated infections (peritonitis, HD-related bloodstream infections) are also the leading causes of hospitalization in pediatric dialysis patients.

Chapter 573

Renal Transplantation

David K. Hooper and Charles D. Varnell Jr.

Kidney transplantation is the optimal therapy for children with end-stage kidney disease (ESKD). The life expectancy in children who receive a kidney transplant has steadily increased and is substantially better than for those who remain on dialysis (Fig. 573.1). Children and adolescents with ESKD have special needs that differ from adults, including the need to achieve normal growth and cognitive development. Successful transplantation leads to accelerated linear growth, allows for regular school attendance, and often eliminates the need for dietary restrictions. Improvements in surgical techniques and a reduction in the early complications such as thrombosis have given young children the best long-term outcomes of all age-groups among transplant recipients. Following kidney transplantation, the most commonly encountered complications include acute or chronic allograft rejection, an increased risk for infections with both community-acquired and opportunistic organisms, and cardiovascular disease (hypertension, obesity, dyslipidemia). Providers must also be aware of the risks for malignancy and sequelae of chronic kidney disease (CKD).

INCIDENCE AND ETIOLOGY OF ESKD

The incidence of ESKD in pediatric patients in the United States varies by age-group (Table 573.1), with an adjusted incident rate of 11 per million population in 2020. The etiology of ESKD in children also varies

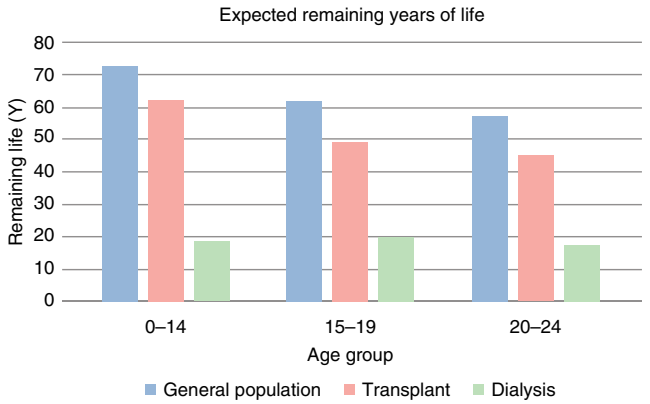

Fig. 573.1 Expected remaining years of life by end-stage renal disease treatment modality. Patients on dialysis or with a kidney transplant are compared to healthy children by age. *(Adapted from United States Renal Data System. 2020 USRDS annual data report: epidemiology of kidney disease in the United States. National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, 2020.)*

Table 573.1 Incident Rates of Reported ESKD in the United States

AGE RANGE (YEAR)	ADJUSTED INCIDENT RATES PER MILLION POPULATION
<1	26
1-5	7
6-12	8
13-17	16

Data from United States Renal Data System. 2022 USRDS annual data report: epidemiology of kidney disease in the United States. National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, 2022. Fig. 8.2. https://usrds-adr.niddk.nih.gov/2022/end-stage-renal-disease/8-esrd-among-children-and-adolescents.

by age (Table 573.2; see Fig. 572.2 in Chapter 572). **Cystic or hereditary diseases** account for more than 24% of children wait-listed for a kidney transplant, whereas **congenital anomalies of the kidney and urinary tract (CAKUT)** account for 18% of such children. In 2020, there were 710 kidney transplants performed in children <18 years of age in the United States, with 184 performed in children ≤5 years old, 129 in children ages 6-10 years, and 397 in children ages 11-17 years. That same year, of the 6,177 children in the United States with ESKD, 4,577 (74.1%) had a functioning kidney transplant.

INDICATIONS FOR RENAL TRANSPLANTATION

Renal transplantation is generally considered for any child when chronic renal replacement therapy is indicated. There are few absolute contraindications for pediatric kidney transplantation, yet relative contraindications arise when the combined risks of the transplant procedure itself and lifelong immunosuppression outweigh the benefits of improved health, longevity, and/or quality of life. Such relative contraindications include preexisting malignancy, primary or secondary immunodeficiency, chronic severe infection, inability to receive appropriate posttransplant care, or severe neurologic dysfunction where improvement in the quality of life and/or longevity is unlikely. In each scenario, the multidisciplinary team must weigh the risks and benefits of transplantation while accounting for the values of patients and caregivers. For instance, patients who have remission of malignancy for a minimum of 1-2 years may be considered on an individual basis for kidney transplantation. Similarly, patients with autoimmune diseases resulting in ESKD (e.g., systemic lupus erythematosus) are candidates for transplantation after a period of immunologic quiescence of the primary disease.

Table 573.2 Characteristics of Children with Incident End-Stage Kidney Disease, by Primary Cause of End-Stage Kidney Disease, 2016–2020

PRIMARY CAUSES OF ESKD	%
All Etiologies	100
Primary Glomerular Disease	21.5
Glomerulonephritis (GN) (histologically not examined)	5.4
Focal glomerulosclerosis, focal sclerosing	11.4
Membranous nephropathy	0.4
Membranoproliferative GN (MPGN) type 1, diffuse MPGN	0.4
Dense deposit disease, MPGN type 2	0.3
IgA nephropathy, Berger's disease (proven by immunofluorescence)	0.5
With lesion of rapidly progressive GN	0.8
Other proliferative GN	2.5
Secondary Glomerular Disease	8.3
Systemic lupus erythematosus (SLE nephritis)	2.6
Hemolytic uremic syndrome	1.9
Polyarteritis and other vasculitis	1.5
Associated vasculitis	1.8
CAKUT1	28.1
Congenital obstructive uropathies	10.1
Renal hypoplasia, dysplasia, oligonephronia	15.0
Chronic pyelonephritis, reflux nephropathy	3.0
Cystic/Hereditary/Congenital Diseases	11.9
Polycystic kidneys, adult type (dominant)	0.5
Polycystic, infantile (recessive)	3.0
Medullary cystic disease, including nephronophthisis	1.7
Hereditary nephritis, Alport syndrome	1.2
Cystinosis	1.0
Primary oxalosis	0.4
Congenital nephrotic syndrome	2.0
Other (congenital malformation syndromes)	1.9
Tubulointerstitial Diseases	4.9
Chronic interstitial nephritis	2.3
Acute interstitial nephritis	0.4
Tubular necrosis	2.1
Transplant Complications	1.5
Other transplant complication	1.4
Diabetes	0.6
Neoplasms/Tumors	0.8
Renal tumor	0.7
Hypertensive/Large Vessel Disease	1.6
Renal artery stenosis	0.3
Renal artery occlusion	1.2
Miscellaneous Conditions	14.0
Acquired obstructive uropathy	4.5
Unspecified with renal failure	2.3
Traumatic or surgical loss of kidney(s)	1.1
Other renal disorders	5.1
Nephropathy caused by other agents	0.9
Etiology Uncertain	4.0
Etiology Missing	2.9

IgA, Immunoglobulin A; CAKUT, congenital anomalies of the kidney and urinary tract. Modified from the United States Renal Data System. 2022 *USRDS* Annual Data Report: Epidemiology of kidney disease in the United States. National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, 2022. Table 8.1. https://usrds-adr.niddk.nih.gov/2022/end-stage-renal-disease/8-esrd-among-children-and-adolescents.

In children, dialysis may be required before transplantation to optimize the nutritional and metabolic conditions, allow for quiescence of an underlying autoimmune disorder, achieve an appropriate size, or keep a patient stable until a suitable donor is available. Although successful transplantation with an adult-sized kidney has occurred in children <10 kg and <6 months of age, recipients usually must weigh at least 8-10 kg to minimize the risk for vascular thrombosis and accommodate an adult-size kidney. This may require a period of dialysis support until the child is 12-18 months of age.

Preemptive transplantation (i.e., transplantation without prior dialysis) accounts for ~25% of all pediatric renal transplants. It is the preferred approach when possible because of a small but incremental decrease in patient and allograft survival for every year spent on dialysis before transplant. Preemptive renal transplantation can and should therefore be considered in any child with stage 4 or 5 CKD who is likely to require dialysis within 6-12 months and/or has evidence of the adverse effects of CKD on their health or neurocognitive development. This requires early referral to a transplant center for evaluation of the candidate and potential donors. The transplant team must work with the recipient and caregivers to determine the optimal time for transplantation considering the risks and benefits posed to the recipient.

CHARACTERISTICS OF KIDNEY DONORS AND RECIPIENTS

Approximately 30–40% of pediatric kidney transplants come from **living donors.** Because the Organ Procurement and Transplantation Network (OPTN) gives preference to children waiting for a **deceased-donor** renal transplant, children have a higher rate of transplantation than adults. In 2020, children less than 17 years of age on dialysis were transplanted at a rate of 43.7 transplants per 100 patient-years (29.9 deceased donor, 13.8 living donor), whereas adults were transplanted at a rate of 8.3 transplant per 100 patient-years. The current allocation policy was implemented to allocate priority to children based on projected organ survival using the **Kidney Donor Profile Index (KDPI),** which computes the projected allograft survival from 12 important donor characteristics. Under this system, the top 35% of kidneys (KDPI <35%) are preferentially allocated to children. Additional factors that determine the allocation include the time on dialysis or since listing (whichever is longest), a zero human leukocyte antigen (HLA)-antigen mismatch, calculated panel-reactive antibody (cPRA), prior living donor, and 0 or 1 HLA-DR (HLA–antigen D–related) mismatch. In 2021, a new allocation system was implemented based on a 250-nautical mile radius rather than allocation based on local organ procurement organizations, and children were given even higher priority on the wait-list. Because of such policies, the time on the wait-list for children is shorter than that for adults. Median wait time is approximately 7-8 months for children nationally compared with 4-5 years or more for adults.

EVALUATION AND PREPARING FOR KIDNEY TRANSPLANTATION

A comprehensive transplant evaluation includes a transplant surgeon, nephrologist, dietitian, social worker, psychologist, pharmacist, financial counselor, pretransplant nurse coordinator, and anesthesiologist. A urologist familiar with transplantation is also essential for patients with lower urinary tract anomalies. Important considerations for the transplant evaluation include considering the primary diagnosis and risk of recurrence; ensuring an adequate lower urinary tract for drainage of the transplanted kidney; diagnosing and treating infections; the presence of cardiovascular disease, anemia, and other sequelae of ESKD; and preparing the patient with immunizations before starting lifelong immunosuppression.

Understanding the primary renal disease is essential before kidney transplantation. For instance, a number of primary renal diseases can recur in a transplanted kidney, but this is not a contraindication to transplantation. Recurrent disease accounts for graft loss in almost 7% of primary transplantations and 10% of repeat transplants. **Primary focal segmental glomerulosclerosis (FSGS)** is known to recur in 30–60% of cases and substantially decreases allograft survival. Because **primary hyperoxaluria** is caused by enzymatic defects in the liver, traditionally kidney transplantation has been accompanied by liver transplantation to prevent recurrent disease in the kidney allograft. However, advancements in pharmacotherapy have led to development of **lumasiran**, the first medication approved by the U.S.

Food and Drug Administration (FDA) to treat primary hyperoxaluria. It is not yet known how these medications will affect progression to ESKD in children and/or the need for liver transplantation. Primary **membranoproliferative glomerulonephritis (MPGN)** carries a high risk of disease recurrence (>50%) and decreased allograft survival. Attempts to classify MPGN into immune vs complement-mediated disease may facilitate research that provides insight into prognosis and options for prevention and treatment, but data are still limited. Histologic recurrence with mesangial immunoglobulin (Ig) A deposits is common and occurs in about half of the patients with **IgA nephropathy** and in approximately 30% of patients with **IgA vasculitis** (formerly Henoch-Schönlein purpura), yet it may not necessarily lead to premature allograft failure. **Congenital nephrotic syndrome** rarely recurs after transplantation, although patients can develop **antinephrin antibodies** and present with nephrotic syndrome. **Membranous nephropathy** occurs very rarely in children. The recurrence rate after kidney transplantation for patients who have been treated for **Wilms tumor** is approximately 13%. Although **Alport syndrome** does not recur following transplantation, approximately 3–4% of patients with Alport syndrome can develop de novo **anti–glomerular basement membrane (anti-GBM) glomerulonephritis** that may lead to graft loss. Certain forms of **complement-mediated thrombotic microangiopathy (TMA)** (commonly referred to as **atypical hemolytic uremic syndrome**) caused by inherited defects in complement regulation can recur posttransplant with devastating consequences for the new allograft. These conditions must be evaluated with genetic testing and analysis of the complement system before transplant so appropriate monitoring and therapy with complement inhibition can be applied to prevent recurrent disease.

Due to the high risk of developing Wilms tumor, patients with **Denys-Drash syndrome** should undergo bilateral nephrectomy before transplantation. Other indications for unilateral or bilateral native nephrectomies include hyposthenuria with polyuria, significant proteinuria leading to coagulopathy, recurrent infection of the native kidneys, and severe hypertension resistant to medical management. Nephrectomies are also indicated in cases such as **polycystic kidney disease,** where the native kidneys may become so large that they cause feeding intolerability in infants or prevent space for a transplanted kidney. Finally, it is important to perform bilateral native nephrectomy or ureteral ligation in patients with **primary FSGS** who produce significant amounts of urine protein to allow for surveillance of proteinuria and early identification and treatment of **recurrent FSGS.**

Urologic problems, such as **vesicoureteral reflux, posterior urethral valves,** and/or abnormal bladders as seen in **Eagle-Barrett syndrome**, should be addressed before surgery. Malformations and voiding abnormalities (e.g., neurogenic bladder, bladder dyssynergia, remnant posterior urethral valves, and urethral strictures) should be identified and repaired if possible. Children with urologic disease and renal dysplasia often require multiple operations to optimize the urinary tract anatomy and function. Such procedures include ureteric reimplantation to correct vesicoureteral reflux, bladder augmentation or reconstruction, urinary diversion (vesicostomy, ureterostomy, ileal conduit, continent appendicovesicostomy), and excision of ureteroceles. Good outcomes have been achieved in posterior urethral valve bladders by following a staged procedure of initial valve resection and bladder rehabilitation by a process of regimented double voiding and/or bladder cycling before transplantation. Following transplantation, bladder function in these patients should be followed for the long term because they can become less compliant over time and lead to premature failure of the transplanted allograft.

A comprehensive nutritional assessment should be performed to ensure that an optimal nutritional status is achieved before transplant. Many children with ESKD require nutritional supplements to provide them with sufficient protein and calories. Infants and young children on dialysis often require nasogastric or gastrostomy tube feedings to overcome decreased oral intake from nausea and anorexia due to uremia.

Bone disease should be evaluated for and bone health optimized before transplantation. Uncontrolled secondary hyperparathyroidism may lead to urinary phosphate wasting, hypercalcemia, hypercalciuria, and/or nephrolithiasis posttransplant. A high calcium phosphorus product before transplantation leads to vascular stiffness and calcifications, increasing the risk for cardiovascular disease and difficult-to-control hypertension in the perioperative and posttransplant period.

In the United States, >25% of the deaths in children on maintenance dialysis are a result of cardiovascular disease. Cardiac death is the leading cause of mortality in young adults after transplant in childhood. Therefore evaluation of cardiac function, including echocardiography and electrocardiography, is required before kidney transplantation to ensure sufficient cardiac function to tolerate the large fluid load that accompanies kidney transplantation. Hypertension is common in ESKD and should be treated before transplant. If medical management is insufficient, bilateral nephrectomy may be considered to control the hyperreninemic response from the failing kidneys. Finally, patients with a history of obstructive uropathy and oligohydramnios in utero who survive to kidney transplant may have undiagnosed/unrecognized pulmonary hypertension, which should be evaluated before transplantation.

Anemia needs to be treated before transplantation. Most patients receive erythropoietin, folate, and iron to maintain goals for hemoglobin levels between 11 and 13 g/dL. Blood transfusions should be avoided if possible due to concerns about sensitizing the patient to HLAs before transplant. If a blood transfusion is required, patients should receive leukoreduced red blood cells.

Evaluation for hypercoagulable states is important before renal transplantation because venous thrombosis is an important cause of graft failure. Risk factors for graft thrombosis include history of prior thrombosis, surgical technique, perfusion and reperfusion injury of the graft, young donor age (<6 years), young recipient (<5 years), cold ischemia time >24 hours, arterial hypotension, prior history of peritoneal dialysis, and/or hypoperfusion of an adult allograft transplanted into a small child. Particularly in the young recipient, there must be an evaluation for thrombosis of the iliac vessels and inferior vena cava, especially if there is a history of previous surgery or central line placement. Children who have large protein losses, such as from nephrotic syndrome and/or peritoneal dialysis, can be at an increased risk for thrombosis because of protein loss, such as protein S, protein C, and antithrombin III. Doppler ultrasound, CT angiography, and MR angiography have all been used to evaluate vessels. To minimize the risk of contrast-induced nephropathy associated with CT contrast, patients with advanced CKD or ESKD not yet on dialysis should receive intravenous hydration before and after the study and acidosis should be corrected before giving contrast medium. While MR angiography has traditionally been avoided in patients with CKD or ESKD because of the risk of nephrogenic systemic fibrosis from early forms of gadolinium, the more recent broad availability of newer, more stable gadolinium preparations makes contrast-enhanced MRI a valid and reasonably safe option. Collaboration between radiology and nephrology is important when determining which gadolinium agents to use and when contrast MRI is appropriate in children with CKD and ESKD.

Infections must be identified, prevented, and treated before transplantation. Infectious disease screening includes obtaining a complete history of the following: current or previous infections, all vaccinations, any occupational risks among family members (e.g., healthcare worker), household or other contacts with treatment for tuberculosis, travel within the past 2 years or significant time spent in another country, bacille Calmette-Guérin administration, animal and/or insect exposure, sexual activity, and consumption of high-risk foods such as unpasteurized products. Screening includes a tuberculosis skin test (purified protein derivative) or interferon gamma release assay, cytomegalovirus IgG, Epstein-Barr virus (EBV) antibody panel, varicella titer, measles antibody, hepatitis B serologies, hepatitis C antibody, HIV, and toxoplasmosis. Additional testing for patients who live in or have visited endemic areas might include *Coccidioides* immunodiffusion, serology for *Strongyloides,* and/or antibody for *Histoplasma* antibody. Sexually active patients should also be screened for syphilis, gonorrhea, and *Chlamydia.*

It is recommended that all immunizations be current before transplantation. All live vaccines (measles, mumps, rubella [MMR] and varicella) should be given before transplantation, and antibody titers should be checked for a response because these vaccines should not be given to immunosuppressed patients. MMR may be given as early as 6 months of age. Inhaled (live-attenuated virus) influenza vaccine should not be given to transplant patients, family members, or healthcare providers.

Psychiatric evaluation should be performed before transplantation to evaluate the ability of patients and families to cope with the substantial stressors that accompany caring for a child with a kidney transplant. This evaluation should include screening for depression, substance abuse, and adherence so that problems can be identified and managed before kidney transplantation. If nonadherence is identified or anticipated, interventions should be in place before transplantation.

The ABO blood type must be confirmed twice before a patient is listed for kidney transplantation. Donors and recipients are currently matched for HLA-A, HLA-B, and HLA-DR antigens. In general, better matched organs have improved survival times following kidney transplantation. Matching at the DR locus appears to be especially advantageous, though in the modern era of immunosuppression, successful six-antigen mismatched transplants are performed routinely. All patients must be screened for preformed anti-HLA antibodies before kidney transplantation. The most common, sensitive, and specific method uses flow cytometry and single HLA-antigen beads. In this manner, a patient's PRA can be assessed and is reported as the percentage of the population against which a recipient has anti-HLA antibodies. Patients can become sensitized by a prior transplant, blood transfusions, and/or pregnancy. Highly sensitized patients (PRA >80%) may undergo desensitization with plasmapheresis, anti-CD 20 antibody, and/or proteasome inhibitors to expand the donor pool from which they can safely receive an organ.

IMMUNOSUPPRESSION

Most pediatric kidney transplant centers employ induction immunosuppression at the time of transplant followed by lifelong maintenance immunosuppression with a calcineurin inhibitor and an antiproliferative agent with or without steroids.

Induction Therapy

Induction therapy is used in nearly all pediatric renal transplants to prevent early acute rejection. The OPTN Scientific Registry of Transplant Recipients (OPTN/SRTR) 2020 Annual Report indicates that 60% of patients receive T-cell–depleting induction therapy (rabbit antithymocyte globulin). Use of an interleukin (IL)-2 receptor antagonist (basiliximab) has been stable at between 30% and 40% for the past 5 years, and the rates of no induction therapy have declined to below 10%.

T-Cell Antibodies

Antithymocyte globulin is comprised of rabbit- or horse-derived polyclonal antibodies against human T-lymphocyte antigens that results in a rapid depletion of T lymphocytes. The infusion is generally started in the operating room before reperfusion of the transplant kidney. Most centers use this for standard induction therapy, but some limit its use to induction of sensitized high-risk patients or patients who have concerns for delayed graft function and want to avoid high calcineurin inhibitor levels in the early postoperative period. The standard dosage is 1.5 mg/kg/dose for three to five doses, with daily monitoring of lymphocyte, neutrophil, and platelet counts. Some centers monitor $CD3^+$ subsets and hold the dose if the $CD3^+$ count is below 20 cells/mm^3.

Interleukin-2 Receptor Antibodies

Basiliximab is currently the only monoclonal anti-CD25 antibody on the market. This chimeric (murine/human) anti-CD25 antibody prevents T-cell proliferation but does not cause T-cell depletion. Basiliximab is given in two doses of 10 mg for patients <35 kg and 20 mg for patients ≥35 kg. The first dose should be given within 2 hours before the transplant surgery and the second dose on day 4. Patients tend to tolerate IL-2 receptor antagonists well with few side effects.

Other Induction Therapies

Alemtuzumab (Campath-1H) is a monoclonal antibody against CD52 present on T and B cells, monocytes, and natural killer cells. Some centers have used this induction antibody in steroid and calcineurin inhibitor-sparing protocols, but pediatric data are limited as has been its use.

Other induction therapies for highly sensitized patients include targeting B cells and/or removing neutralizing antibodies by using rituximab against the CD20 epitope on early-lineage and intermediate-lineage B cells, proteasome inhibitors, and plasmapheresis and/or high-dose intravenous immunoglobulin for removing donor-specific antibodies.

Maintenance Immunosuppression

Lifelong maintenance immunosuppression is required in nearly all patients following kidney transplantation. The most common regimens include a calcineurin inhibitor (predominantly tacrolimus vs cyclosporine) and an antiproliferative agent (predominantly mycophenolate mofetil [MMF] vs azathioprine) with or without corticosteroids. The mammalian target of rapamycin (mTOR) inhibitors sirolimus and everolimus are sometimes used in place of the calcineurin inhibitor or antiproliferative agent. The rationale for combination therapy in children is to provide effective immunosuppression while minimizing the toxicity of any single drug.

Calcineurin Inhibitors

Despite the search for immunosuppression regimens that minimize calcineurin inhibitor exposure, **tacrolimus** remains the centerpiece of maintenance immunosuppression for most pediatric patients in North America. According to OPTN/SRTR in 2020, >90% of children in the United States were placed on tacrolimus-based immunosuppression at the time of transplant. The increasing use of tacrolimus in place of **cyclosporine** can be attributed to studies demonstrating better efficacy (fewer rejections and less reliance on steroids) and less severe cosmetic side effects, such as hypertrichosis, gingival hyperplasia, and coarsening of facial features. This is especially relevant for adolescents for whom unwanted cosmetic side effects can become a barrier to immunosuppression adherence. Tacrolimus also appears to cause less dyslipidemia, though other side effects such as **new-onset diabetes after transplant (NODAT),** tremor, seizure, alopecia, and sleep disturbance seem to be more common in patients treated with tacrolimus. Despite the nearly complete replacement of cyclosporine with tacrolimus, there are select cases when cyclosporine is the preferred agent (e.g., to treat posttransplant recurrence of FSGS or conversion therapy in patients who develop NODAT).

Unfortunately, both calcineurin inhibitors have a narrow therapeutic index and can cause acute and chronic kidney injury. Additionally, many foods and drugs interact with the calcineurin inhibitor metabolism, requiring frequent therapeutic drug monitoring. A usual starting dose of tacrolimus is 0.1-0.15 mg/kg twice a day on the day of the transplant, targeting trough levels above 10 ng/mL for the first month and then tapering down to trough levels of 4-8 ng/mL by 6 months. Patients with CYP3A5 expression (80–90% of patients from African descent vs 20–30% of patients with Caucasian ancestry) often require doses nearly twice as high. Pharmacogenetic testing of CYP3A5 polymorphisms is available and may assist with personalized dosing. The recent development of long-acting tacrolimus preparations (Envarsus XR and Astagraf XL) have provided the opportunity for a simplified, once daily medication regimen. Most long-term immunosuppressive regimens attempt to limit calcineurin inhibitor dosing as much as possible, and the search for calcineurin inhibitor–sparing drug regimens remains an area of intense research.

Antiproliferative Agents

Most immunosuppression regimens for children following kidney transplantation include an antiproliferative agent. **MMF** is the

morpholinoethyl ester prodrug of mycophenolic acid, an inhibitor of de novo purine synthesis, and is part of the initial maintenance immunosuppression regimen in at least two thirds of U.S. pediatric renal transplant recipients. The absence of nephrotoxicity, cardiovascular risk (hypertension, dyslipidemia), and hepatotoxicity make it an attractive option for immunosuppression, and the fact that it has greater efficacy than azathioprine has enabled the use of lower doses of corticosteroids and/or calcineurin inhibitors. Primary toxicities include diarrhea and upset stomach, as well as leukopenia and anemia, affecting up to 40% of patients. These side effects are often transient and can be treated with a temporary dosage reduction, but persistent dose reductions have been associated with an increased risk of rejection. MMF is also associated with a high risk for birth defects, so its use in adolescent females necessitates two forms of birth control and regular pregnancy screening. The usual dose of MMF is 600 mg/m^2 in patients treated with cyclosporine. MMF metabolism is slower in patients treated concomitantly with tacrolimus, allowing for lower doses (450 mg/m^2) to be used.

Azathioprine, an analog of **6-mercaptopurine**, is an alternative to MMF that also inhibits de novo purine synthesis and contributes to cell cycle arrest. It was the first medication approved for immunosuppression in kidney transplantation, yet in the past 2 decades, its use has declined because of the advent of newer immunosuppressive medications with purported greater efficacy. It is inexpensive and, unlike MMF, it can be administered once daily, so it is an attractive alternative for patients who struggle to take twice-daily medications. Usual dosage is 1.5-3 mg/kg once daily. Bone marrow suppression is the primary toxicity, but gastrointestinal side effects are less common than with MMF, with the exception of pancreatitis, which has rarely been reported. Unlike MMF, it is not associated with birth defects and is an important alternative in pregnant patients. Enteric-coated mycophenolic acid is another alternative to MMF that may decrease upper gastrointestinal side effects in some patients.

Mammalian Target of Rapamycin (mTOR) Inhibitors

mTOR inhibitors (sirolimus more commonly than everolimus) are used primarily as adjunctive immunosuppression in combination with MMF to avoid tacrolimus toxicity or with tacrolimus and MMF to spare steroids. However, they are used in only 5–10% of pediatric kidney transplant recipients 1 year posttransplant, perhaps due to evidence suggesting a high rate of donor-specific antibodies and antibody-mediated rejection (AMR) in patients taking mTOR inhibitors. Other toxicities, including a high rate of aphthous ulcers, dyslipidemia, poor wound healing, proteinuria, and diarrhea, have limited their use.

Corticosteroids

Corticosteroids remain integral to most immunosuppressive protocols despite their multifaceted toxicities. According to the 2020 OPTN/SRTR report, 54% of patients are treated with steroids at the time of transplant. The adverse effects of steroids are especially pronounced in children, for whom retarded skeletal growth, hypertension, obesity, diabetes mellitus, hyperlipidemia, osteopenia, and aseptic necrosis of bone (particularly the femoral heads) can have dire long-term consequences. Cosmetic side effects, such as cushingoid facies and acne, also become barriers to adolescents taking their medication. For these reasons, steroid-based regimens in children seek to minimize steroid exposure by starting with high-dose steroids as induction therapy and tapering down over several months to a lowest dose of 5-10 mg or 0.1 mg/kg daily. Other protocols call for a more rapid steroid taper lasting from 1 week to several months before stopping them altogether.

Several well-designed randomized controlled trials in children and adults have demonstrated that complete steroid avoidance can be safely achieved in patients with a low immunologic risk by using induction therapy with dual-maintenance immunosuppression comprised of tacrolimus and MMF. In general, steroid avoidance is associated with higher rates of rejection but also carries significant benefits for growth, hypertension, and dyslipidemia with no decrease in long-term allograft survival. Importantly, this approach appears to be safe and without increases in the generation of donor-specific antibody or histologic injury. Despite this evidence, data from the OPTN network suggest that steroid use is largely dependent on the center where the transplant is performed rather than the characteristics of the patient.

Other Agents

Belatacept is a fusion protein composed of the Fc fragment of a human IgG_1 linked to the extracellular domain of CTLA-4 (a molecule crucial for T-cell costimulation), which selectively blocks the process of T-cell activation. Belatacept is attractive for maintenance immunosuppression because it is a quick monthly infusion rather than a daily oral medication, and it does not have many of the untoward side effects associated with calcineurin inhibitors, including and especially nephrotoxicity. Adult studies of belatacept have demonstrated similar rejection rates but significantly improved kidney function up to 10 years following kidney transplantation compared with cyclosporine. Unfortunately, there is an unacceptably high rate of **posttransplant lymphoproliferative disorder (PTLD)** in EBV-naïve patients, which are most of the children receiving a kidney transplant.

FLUID MANAGEMENT IN INFANTS AND SMALL CHILDREN AFTER KIDNEY TRANSPLANTATION

Maintenance of adequate blood flow to an adult-sized kidney in an infant or small child is crucial to avoid acute tubular necrosis (ATN) and graft loss from vascular thrombosis. The recipient aortic blood flow early after transplantation of an adult-size kidney more than doubles from the pretransplantation aortic blood flow. The maximum blood flow that can be obtained in an adult-size kidney transplanted into a small child is approximately 65% of what was in the donor. Low blood flow states, such as those with hypovolemia or hypotension, increase the risk for ATN, graft thrombosis, and graft nonfunction. Thus, in the postoperative period, patients are maintained on high fluid volumes.

Close attention is paid to the blood pressure and hydration status in the operating room in an attempt to reduce the incidence of delayed graft function. Typically, a central venous catheter is inserted to monitor the central venous pressure throughout the operation. A central venous pressure of 12-15 cm H_2O should be achieved before removing the vascular clamps; a higher central venous pressure may be desirable in the case of a small infant receiving an adult-size kidney. Dopamine may be started in the operating room and continued for 24-48 hours postoperatively to maintain a mean arterial blood pressure (MAP) >55 mm Hg. A blood transfusion with packed red blood cells may be required in very small recipients because the hemoglobin can drop as a result of sequestration of approximately 150-250 mL of blood in the transplanted kidney. Because an adult kidney transplanted into a small child can produce enormous amounts of urine, a fluid strategy that provides a constant rate for insensible losses (D10W at a rate of 400 mL/m^2/day) and urine replacements helps to ensure adequate hydration of the adult kidney. Some transplant centers continue to provide infants with aggressive fluid management by nasogastric or gastrostomy tube feedings of at least 2,500 mL/m^2/day for up to 6 months following transplant if the child is unable to take in sufficient volume by mouth.

REJECTION OF KIDNEY TRANSPLANT

Hyperacute rejection, caused by preformed antibodies against the donor HLA, ABO, or other antigens, occurs immediately on reperfusion of the allograft. The practice of prospective cross matching using complement-dependent cytotoxicity has virtually eliminated hyperacute rejection.

Acute T-cell-mediated rejection (TCMR) must be identified and treated promptly, although this may not be straightforward in the very young transplant recipient. Because most small children receive adult-size kidneys with a large renal reserve compared with their body mass, significant allograft dysfunction may be present with little or no increase in serum creatinine. Therefore even subtle findings such as hypertension or new proteinuria can indicate acute TCMR and must be investigated. Late diagnosis and treatment of rejection are associated with a higher incidence of resistant rejections and graft loss. Most cases of acute TCMR can be treated if detected early by using a short course (3-5 days) of high-dose intravenous steroids

(10-30 mg/kg) followed by an oral steroid taper over the next several weeks and either increased maintenance immunosuppression or improved adherence, whichever is most appropriate. Steroid-resistant or high-grade rejection can be treated with thymoglobulin (1.5 mg/kg/day) for 7-14 days, high-dose tacrolimus (trough levels >20 ng/dL for 1-2 weeks), or local allograft irradiation. Following treatment for rejection, it is important to consider 3-12 months of prophylaxis with trimethoprim/sulfamethoxazole to prevent *Pneumocystis jirovecii* pneumonia (PJP pneumonia), valganciclovir/valacyclovir to prevent cytomegalovirus/herpes reactivation, and nystatin or fluconazole to prevent oral candidiasis.

Active AMR consisting of anti-HLA donor-specific antibodies is an important cause of kidney function decline and allograft loss. It can present acutely in the few weeks following transplantation in previously sensitized patients or may develop chronically due to inadequate immunosuppression or poor adherence. Unlike acute TCMR, acute AMR is much more difficult to treat and may require plasmapheresis, intravenous immunoglobulin (IVIG), anti-CD20 antibody infusions, and/or proteasome inhibitors. Treatment is most likely to be successful if initiated within a few months of identifying new donor-specific antibodies.

Chronic rejection (T-cell mediated or antibody mediated) is the leading cause of graft loss. Children often have a gradual decline in their renal function and often have fixed proteinuria and hypertension. Despite initial excitement about the potential of MMF and sirolimus mitigating chronic graft injury, this has not translated readily into observable clinical benefits. Chronic TCMR, chronic AMR, and the impact of non-HLA antibodies are areas of active investigation.

Kidney Biopsy

Kidney biopsy is the gold standard for the diagnosis of TCMR or AMR. Despite attempts to develop noninvasive biomarker panels, none has proven sensitive enough to rule out rejection. Many centers perform **surveillance biopsies** at specific time points following transplantation to detect **subclinical rejection**, which has been reported in <10% of such surveillance biopsies.

GRAFT SURVIVAL OF KIDNEYS

Survival rates for live-donor kidney allografts are superior to those for deceased-donor allografts. Living-donor kidneys generally have fewer HLA mismatches, lower cold ischemia time, and require less immunosuppression than deceased-donor kidneys. Furthermore, deceased-donor transplant requires children to wait several weeks to a few years on the deceased-donor wait-list before receiving an organ. The OPTN/SRTR 2021 annual report showed that the death-censored, 5-year allograft survival rate was 85.2% for deceased-donor kidney transplants performed in 2014–2016, whereas the death-censored, 5-year allograft survival rate for living-donor transplants was 93.1% over the same time period. For these reasons and because it expands the donor pool, living donation should be advocated at every opportunity.

Children <10 years of age have the best long-term graft and patient survival rates of all age-groups, and adolescents and young adults have the worst. Among patients with at least 1 year of graft function, graft failure rates are stable at around 1.4 per 100 person-years until 10 years of age, when rates increase, peaking at a maximum of 6.3 per 100 person-years at age 19 years, regardless of the age at transplantation. A variety of factors likely account for such poor outcomes in adolescents and young adults, including the patient's changing physiology, a transition from pediatric to adult care, and a greater number of barriers to taking immunosuppressives.

COMPLICATIONS OF IMMUNOSUPPRESSION

Since the mid-1990s, the incidence of acute rejection has decreased, but the incidence of infection after transplantation has increased.

Pneumonia and urinary tract infection are the most common post-transplant bacterial infections. Urinary tract infections can progress rapidly to urosepsis and may be confused with episodes of acute rejection. Trimethoprim-sulfamethoxazole is used for urinary tract infection antibiotic prophylaxis as well as PJP prophylaxis for 3-6 months after transplant (see Chapter 290).

The herpesviruses (cytomegalovirus, herpesvirus, varicella-zoster virus, and EBV) pose a special problem in view of their common occurrences in childhood (see Chapters 299-302). Many young children have not yet been exposed to these viruses, and because they lack protective immunity, their predisposition to serious primary infection is high. The incidence of cytomegalovirus seropositivity is approximately 30% in children >5 years of age and rises to approximately 60% in teenagers. Thus the younger child is at a greater potential risk for serious infection when a cytomegalovirus-positive donor kidney is transplanted. About half of children are seronegative for EBV; most of them will become infected shortly after transplant. Most EBV infections are clinically silent but put transplant recipients at risk for PTLD in the presence of immunosuppression. The incidence of these infections is higher in children who receive antibody induction therapy and after treatment of acute rejection. Antiviral prophylaxis with ganciclovir or valganciclovir for 3-12 months after transplantation, especially in the higher-risk groups (recipient-negative, donor-positive), has been effective in reducing the incidence of clinical cytomegalovirus disease. Serial surveillance for these viruses by quantitative polymerase chain reaction (PCR) for the viral load in the peripheral blood has also allowed educated minimization of immunosuppression with a resultant reduction in the viral burden. It is important to monitor for PTLD with routine examinations for lymphadenopathy, hepatosplenomegaly, and EBV screening.

Polyomavirus nephropathy is an important cause of allograft dysfunction; almost 30% of children have BK viruria (see Chapter 321), although allograft dysfunction occurs only in a small subset of patients (~5%). Early protocols focusing on screening for BK virus in the urine have proven ineffective at distinguishing patients who will develop BK nephropathy; rather, plasma BK monitoring has become the standard of care. Ultimately, a renal biopsy, with identification of BK virus by immunoperoxidase staining, is required to make the diagnosis of BK virus nephropathy with certainty. Reducing immunosuppression when plasma BK PCR levels start to rise is the main form of therapy. Cidofovir, leflunomide, and IVIG have all been used as adjunctive therapies.

Oral candidiasis is another important infection following kidney transplantation and can be prevented with oral nystatin 4 times daily or fluconazole once daily for the first 3 months after transplant. Careful monitoring of calcineurin inhibitor levels is important when starting or stopping treatment with fluconazole as it interferes with calcineurin inhibitor metabolism.

Pediatric solid organ transplant patients are generally considered to be at increased risk for infections and worse outcomes compared with their nonimmunosuppressed peers. This concern was brought to the forefront during the global COVID-19 pandemic. Despite their immunosuppressed state, studies have not shown that children with a solid organ transplant are at increased risk for complications from COVID-19 infection. Early studies indicate that short-term outcomes from COVID-19 in pediatric kidney transplant recipients are generally favorable, without increased risk of graft loss, respiratory failure, or death compared with nonimmunosuppressed peers. Nonetheless, COVID-19 vaccination is recommended before transplantation to minimize risk of complications and spread.

Hypertension, dyslipidemia, obesity, and posttransplant diabetes mellitus are other complications of immunosuppression and kidney transplantation that have been underrecognized and undertreated. Cardiovascular disease is the primary cause of premature death in young adults who had a kidney transplant in childhood, and uncontrolled blood pressure leads to premature allograft failure. Up to 80% of children have hypertension and up to 60% are uncontrolled despite multiple available therapies. The 24-hour ambulatory blood pressure monitoring (ABPM) is the gold standard for assessing blood pressure control because isolated nocturnal hypertension and masked hypertension are common following kidney transplantation and can only be diagnosed with ABPM. Guidelines for CKD recommend treating blood pressure to achieve a MAP below the 50th percentile for age, gender, and height on ABPM, though recommendations for children with a kidney transplant have not been as aggressive. Blood pressure

should be treated to at least below the 90th percentile for age, gender, and height and below 130/80 mm Hg. Angiotensin-converting enzyme (ACE) inhibitors are the preferred first-line agents in patients with proteinuria; otherwise, either calcium channel blockers or ACE inhibitors can be used with other agents added as needed to achieve blood pressure control.

Although growth improves after transplantation, chronic steroid use does not allow a child to reach their full potential height. The use of recombinant human growth hormone in pediatric renal transplant recipients significantly improves the growth velocity and standard deviation score (SDS). Steroid minimization and withdrawal protocols have demonstrated growth benefits, and the steroid-avoidance data in children show significant catch-up growth at 5 years after transplantation. It is thus likely that with a well-functioning kidney and no maintenance steroids, children might now be able to realize their full height potential.

Malignancy is an important problem following kidney transplantation for children. Lifelong immunosuppression confers at least a twofold lifetime risk of developing cancer for solid-organ transplant recipients compared with the general population. The most common cancer to develop within 10 years following kidney transplantation in children is **PTLD.** It occurs in 1–5% of pediatric kidney transplant recipients and is the most likely cancer to be encountered in childhood. Over the long term, skin cancers (basal cell carcinoma, cutaneous squamous cell carcinoma) are the most common malignancies, with an incidence of close to 15% by 15 years posttransplant and increasing from there. Carcinomas other than skin carcinomas also arise at a rate far higher than in the general population. The prognosis is generally good for most of these malignancies when they are diagnosed early and treated appropriately. Any kidney transplant recipient must be assessed regularly for signs of malignancy and practice preventative measures such as using appropriate sunscreen products.

Developing good adherence behaviors with immunosuppressive medications is one of the most important challenges facing children and adolescents following kidney transplantation. Up to 43% of adolescents display some decreased adherence to their immunosuppressive regimen, which is thought to contribute to decreased allograft survival rates compared with other age-groups. A child's normal development, which includes establishing more independence, spending more time away from home, feeling invincible, and being vulnerable to cosmetic medication side effects, increases the barriers to taking immunosuppression medications. Systems-based approaches, in which clinicians partner with patients to identify and address adherence barriers, are most likely to improve adherence over the long term.

LONG-TERM OUTCOME OF KIDNEY TRANSPLANTATION

With advances in transplant care and treatment modalities and with diligent attention to the pediatric patient's psychosocial, educational, vocational, and developmental rehabilitation, the social and emotional functioning of the child and the child's family appears to return to the same level as before the illness within 1 year of successful transplantation. Renal transplantation leads to improvement in linear growth in children. School function tests improve after renal transplantation. Most patients can reenter school and social activities after a short recovery time of 6-12 weeks following surgery. Surveys of 10-year survivors of pediatric kidney transplants report that most patients consider their health to be good, and they engage in appropriate social, educational, and sexual activities while experiencing a very good to excellent quality of life.

Urologic Disorders in Infants and Children

PART XXII

Chapter 574

Congenital Anomalies and Dysgenesis of the Kidneys

Heather N. Di Carlo and Chad B. Crigger

EMBRYONIC AND FETAL DEVELOPMENT

The kidney is derived from reciprocal interaction between the ureteral bud and the metanephric blastema. During the fifth week of gestation, the ureteral bud arises from the mesonephric (Wolffian) duct and penetrates the metanephric blastema, which is an area of undifferentiated mesenchyme on the nephrogenic ridge. The ureteral bud undergoes a series of approximately 15 generations of divisions and by the 20th week of gestation forms the entire collecting system, including the ureter, renal pelvis, calyces, papillary ducts, and collecting tubules. Signals from the mesenchymal cells induce ureteric bud formation from the Wolffian duct as well as ureteric bud branching. Reciprocal signals from the ureteric bud and, later, from its branching tips induce mesenchymal cells to condense, proliferate, and convert into epithelial cells. Under the inductive influence of the ureteral bud, nephron differentiation begins during the seventh week of gestation.

By the 20th week of gestation, when the collecting system is developed, approximately 30% of the nephrons are present. Nephrogenesis continues at a nearly exponential rate and is complete by the 36th week of gestation. During nephrogenesis, the kidneys ascend to a lumbar site just below the adrenal glands. At least 16 signaling agents have been identified that regulate renal development. Defects in any of the signaling activities could cause a kidney not to form **(renal agenesis)** or to differentiate abnormally **(renal dysgenesis)**. Dysgenesis of the kidney includes **aplasia, dysplasia, hypoplasia,** and certain forms of **renal cystic disease.**

The fetal kidneys play a minor role in the maintenance of fetal salt and water homeostasis. The rate of urine production increases throughout gestation; at term, volumes have been reported to be 50 mL/hr. The glomerular filtration rate is 25 mL/min/1.73 m^2 at term and triples by 3 months postpartum. The increase in the glomerular filtration rate is caused by a reduction in intrarenal vascular resistance and redistribution of intrarenal blood flow to the cortex, where more nephrons are located.

RENAL AGENESIS

Renal agenesis, or absent kidney development, can occur secondary to a defect of the Wolffian duct, ureteric bud, or metanephric blastema. Unilateral renal agenesis has an incidence of 1 in 450-1,000 births. Unilateral renal agenesis often is discovered during the course of an evaluation for other congenital anomalies such as VACTERL association (vertebral defects, anal atresia, congenital heart disease, tracheoesophageal fistula, renal and limb defects; see Chapter 100.1). Its incidence is increased in newborns with a single umbilical artery. In true agenesis, the ureter and the ipsilateral bladder hemitrigone are absent. The contralateral kidney undergoes compensatory hypertrophy to some degree prenatally, but primarily after birth. Approximately 15% of these children have contralateral vesicoureteral reflux, and most males have an ipsilateral absent vas deferens because the Wolffian duct is absent. Because the Wolffian and müllerian ducts are contiguous, müllerian abnormalities in females also are common.

The **Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome** (1 in 4,000 to 1 in 5,000 female births) is a group of associated findings that may include vaginal aplasia, uterine maldevelopment, and normal ovaries. Two types are described. In **type I**, only müllerian aplasia occurs, whereas in **type II**, there are associated anomalies, most commonly unilateral renal agenesis, or a horseshoe kidney, with skeletal anomalies present in 10% (see Chapter 591). **Zinner syndrome** is considered the male counterpart of MRKH syndrome (Fig. 574.1). In this condition, males with unilateral renal agenesis (or a regressed **multicystic dysplastic kidney** [MCDK]) have an ipsilateral seminal vesicle cyst and a possible epididymal cyst and dilated distal ureteral segment. These patients typically present in adolescence. Expectant management is usually followed with interim ultrasonography unless symptoms develop, including hematuria, hematospermia, or dysuria.

Renal agenesis is distinguished from aplasia, in which a nubbin of nonfunctioning tissue is seen capping a normal or abnormal ureter. This distinction may be difficult but usually is clinically insignificant. Unilateral renal agenesis is diagnosed in some patients based on the finding of an absent kidney on ultrasonography or renal scintigraphy (renal scan). Some of these patients were born with a hypoplastic kidney or a MCDK that underwent complete cyst regression. Although the specific diagnosis is not critical, if the finding of an absent kidney is based on an ultrasound, a functional imaging study such as a renal scan should be considered because some of these patients have an ectopic kidney in the pelvis. If there is a normal contralateral kidney, long-term renal function usually remains normal.

Bilateral renal agenesis is incompatible with extrauterine life and produces **Potter syndrome.** Death occurs shortly after birth from pulmonary hypoplasia. The newborn has a characteristic facial appearance, termed **Potter facies** (Fig. 574.2). The eyes are widely separated with epicanthal folds, the ears are low set, the nose is broad and compressed flat, the chin is receding, and there are limb anomalies. Bilateral renal agenesis should be suspected when maternal ultrasonography demonstrates **oligohydramnios,** nonvisualization of the bladder, and absent kidneys. The incidence of this

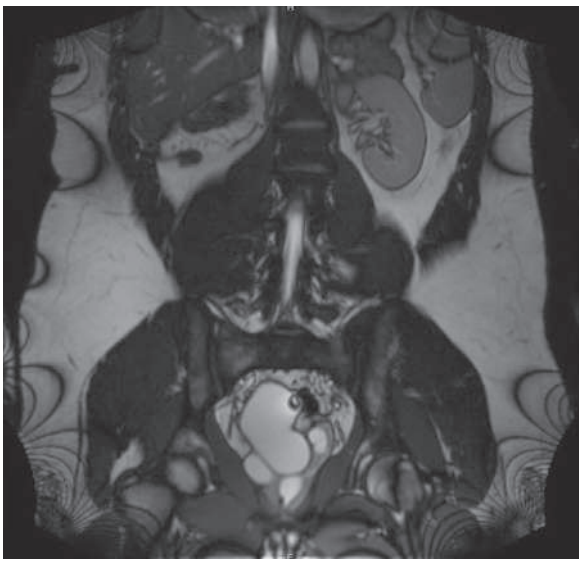

Fig. 574.1 Zinner syndrome. A 17-yr-old male with regressed right multicystic dysplastic kidney and dilated ectopic distal ureter draining into seminal vesicle cyst.

Fig. 574.2 Stillborn infant with renal agenesis exhibiting characteristic Potter facies.

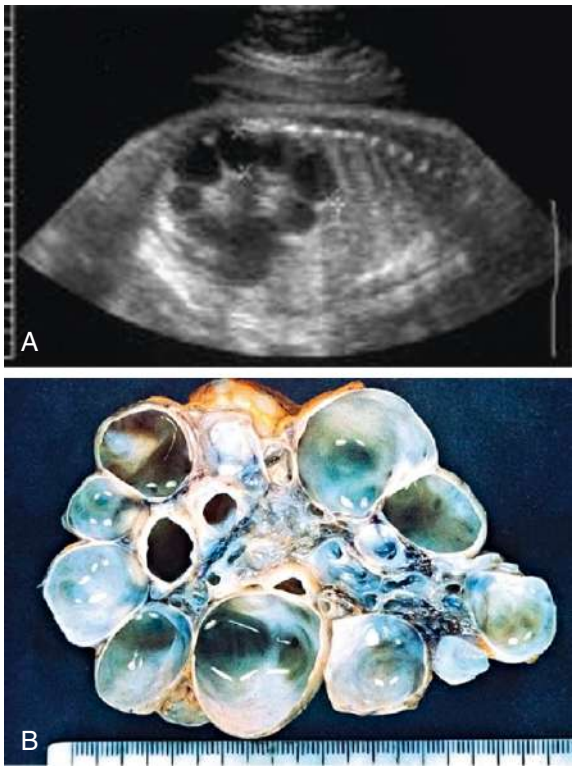

Fig. 574.3 A, Prenatal sonogram demonstrating multicystic dysplastic kidney. B, Surgical specimen.

disorder is 1 in 5,000 births, with a male predominance, and represents 20% of newborns with the Potter phenotype. Other common causes of neonatal renal failure associated with the Potter phenotype include cystic renal dysplasia and obstructive uropathy. Less common causes are autosomal recessive polycystic kidney disease (infantile), renal hypoplasia, and medullary dysplasia. Neonates with bilateral renal agenesis die of pulmonary insufficiency from pulmonary hypoplasia rather than renal failure (see Chapter 444).

The term **familial renal adysplasia** describes families in which renal agenesis, renal dysplasia, multicystic kidney (dysplasia), or a combination occurs in a single family. This disorder has an autosomal dominant inheritance pattern with a penetrance of 50–90% and variable expression. Because of this association, many clinicians advise screening first-degree relatives of persons who have renal agenesis or dysplasia.

The American Academy of Pediatrics recommends that children with a single kidney or single functioning kidney be allowed to play most sports. In fact, sports are less likely to cause kidney injury than motor vehicle crashes, horseback riding, or bicycle accidents. Children with one kidney are not at higher risk for renal injury during contact sports. Despite this, families should be made aware of the potential complications of injury to the patient's single kidney including potential need for dialysis or a renal transplant. Protective padding may be worn during sports, but there is no evidence that this prevents renal injury.

RENAL DYSGENESIS: DYSPLASIA, HYPOPLASIA, AND CYSTIC ANOMALIES

Renal dysgenesis refers to maldevelopment of the kidney that affects its size, shape, or structure. The three principal types of dysgeneses are dysplastic, hypoplastic, and cystic. Although dysplasia always is accompanied by a decreased number of nephrons (hypoplasia), the converse is not true: hypoplasia can occur in isolation. When both conditions are present, the term **hypodysplasia** is preferred. The term **dysplasia** is technically a histologic diagnosis and refers to focal, diffuse, or segmentally arranged primitive structures, specifically primitive ductal structures, resulting from abnormal metanephric differentiation. Nonrenal elements, such as cartilage, may also be present. The condition can affect all or only part of the kidney. If cysts are present, the condition is termed **cystic dysplasia.** If the entire kidney is dysplastic with a preponderance of cysts, the kidney is referred to as a **MCDK** (Fig. 574.3).

The pathogenesis of dysplasia is multifactorial. The "bud" theory proposes that if the ureteral bud arises in an abnormal location, such as an ectopic ureter, there is abnormal penetration and induction of the metanephric blastema, which causes abnormal kidney differentiation, resulting in dysplasia. Renal dysplasia also can occur with severe obstructive uropathy early in gestation, as with the most severe cases of posterior urethral valves or in a MCDK, in which a portion of the ureter is absent or atretic.

MCDK is a congenital condition in which the kidney is replaced by cysts and does not function; it can result from ureteral atresia. Kidney size is highly variable. The incidence is approximately 1 in 2,000. Some clinicians incorrectly use the terms *multicystic kidney* and *polycystic kidney* interchangeably. However, polycystic kidney disease is an inherited disorder that may be autosomal recessive or autosomal dominant and affects both kidneys (see Chapter 563). MCDK usually is unilateral and generally is not inherited. Bilateral MCDKs are incompatible with life.

MCDK is the most common cause of an abdominal mass in the newborn, but the vast majority are nonpalpable at birth. In most cases, it is discovered incidentally during prenatal ultrasound. In some patients, the cysts are identified prenatally, but the cysts regress in utero, and no kidney is identified on imaging at birth. Contralateral hydronephrosis is present in 5–10% of patients. Sonography shows the characteristic appearance of a kidney replaced by multiple cysts of varying sizes that do not communicate, and no identifiable parenchyma is present. In some patients, usually males, a small nonobstructing ureterocele is present in the bladder (see Chapter 577). Although 15% have contralateral vesicoureteral reflux, it is

usually low grade, and obtaining a voiding cystourethrogram is unnecessary unless there is significant contralateral hydronephrosis or the child develops an upper urinary tract infection. *Management is controversial.* Complete cyst regression occurs in nearly half of MCDKs by age 7 years. The risk of associated hypertension is 0.2–1.2%, and the risk of Wilms tumor arising from a MCDK is approximately 1 in 1,200. Because neoplasms arise from the stromal rather than the cystic component, even if the cysts regress completely, the likelihood that the kidney could develop a neoplasm is not altered.

Because of the occult nature of these potential problems, many clinicians advise follow-up with ultrasound and blood pressure measurement every 6 months to a year. The most important aspect of follow-up is being certain that the solitary kidney is functioning normally. *If there is an abdominal mass, the cysts enlarge, the stromal core increases in size, or hypertension develops, nephrectomy is recommended.* In lieu of follow-up screening, laparoscopic nephrectomy may be performed.

Renal hypoplasia refers to a small nondysplastic kidney that has fewer than the normal number of calyces and nephrons. The term encompasses a group of conditions with an abnormally small kidney and should be distinguished from aplasia, in which the kidney is rudimentary. If the condition is unilateral, the diagnosis usually is made incidentally during evaluation for another urinary tract problem or hypertension. Bilateral hypoplasia usually manifests with signs and symptoms of chronic renal failure and is a leading cause of end-stage renal disease during the first decade of life. A history of polyuria and polydipsia is common. Urinalysis results may be normal. In a rare form of bilateral hypoplasia called **oligomeganephronia,** the number of nephrons is markedly reduced, and those present are markedly hypertrophied.

The **Ask-Upmark kidney,** also termed **segmental hypoplasia,** refers to small kidneys, usually weighing less than 35 g, with one or more deep grooves on the lateral convexity, underneath which the parenchyma consists of tubules resembling those in the thyroid gland. It is unclear whether the lesion is congenital or acquired. Most patients are 10 years or older at diagnosis and have severe hypertension. *Nephrectomy usually controls the hypertension.*

Table 574.1 Cystic Diseases of the Kidney

INHERITABLE
Autosomal recessive (infantile) polycystic kidney disease (ARPKD)
Autosomal dominant (adult) polycystic kidney disease (ADPKD)
Juvenile nephronophthisis and medullary cystic disease complex
Juvenile nephronophthisis (autosomal recessive)
Medullary cystic disease (autosomal dominant)
Congenital nephrosis (familial nephrotic syndrome) (autosomal recessive)
Familial hypoplastic glomerulocystic disease (autosomal dominant)
Multiple malformation syndromes with renal cysts (e.g., tuberous sclerosis, von Hippel-Lindau disease)
Glomerulocystic kidney disease
Familial
Meckel-Gruber syndrome
Tuberous sclerosis
Zellweger syndrome
Trisomy 13
Jeune syndrome
Lissencephaly
Nephronophthisis
Orofacialdigital syndrome
NONHERITABLE
Multicystic kidney (multicystic dysplastic kidney)
Benign multilocular cyst (cystic nephroma)
Simple cysts
Medullary sponge kidney
Sporadic glomerulocystic kidney disease
Acquired renal cystic disease
Calyceal diverticulum (pyelogenic cyst)

Modified from Glassberg KI, Stephens FD, Lebowitz RL, et al. Renal dysgenesis and cystic disease of the kidney: a Report of the Committee on Terminology, Nomenclature and Classification, Section on Urology, American Academy of Pediatrics. *J Urol.* 1987;138:1085–1092. Table 2.

RENAL CYSTS IN CHILDREN

Although rare, there are many renal cystic disorders in children (Table 574.1). The most common is the **simple renal cyst** with a mean incidence of 0.22%. They are usually discovered incidentally during urinary tract imaging. Most are small and asymptomatic and do not require treatment, although follow-up imaging is recommended. If there are septations, irregular margins, calcifications, or a cluster of cysts, further evaluation may be indicated. The **Bosniak classification** of simple and complex renal cysts places various cystic lesions into four risk categories and helps guide a decision on whether removal of a lesion is necessary. A **calyceal diverticulum** is an outpouching of the collecting system into the corticomedullary region of the kidney, and it usually arises from the fornix of a calyx, usually in the upper or lower pole. Typically, the infundibulum between the diverticulum and renal pelvis is narrow. Occasionally, calculi form within the lesion, or it causes symptoms of flank pain, necessitating removal of the diverticulum.

A **multilocular cyst (multilocular cystic nephroma)** is a lesion in the kidney that falls in a spectrum of diseases, along with multilocular cyst with partially differentiated Wilms tumor, multilocular cyst with nodules of Wilms tumor, or cystic Wilms tumor. The multilocular cyst is considered benign and is unrelated to the MCDK. More than 95% occur in children <4 years, and most are discovered during evaluation for an abdominal or flank mass. The lesion should be removed.

ANOMALIES IN SHAPE AND POSITION

During renal development, the kidneys normally ascend from the pelvis into their normal position within the retroperitoneum. The normal process of ascent and rotation of the kidney may be incomplete,

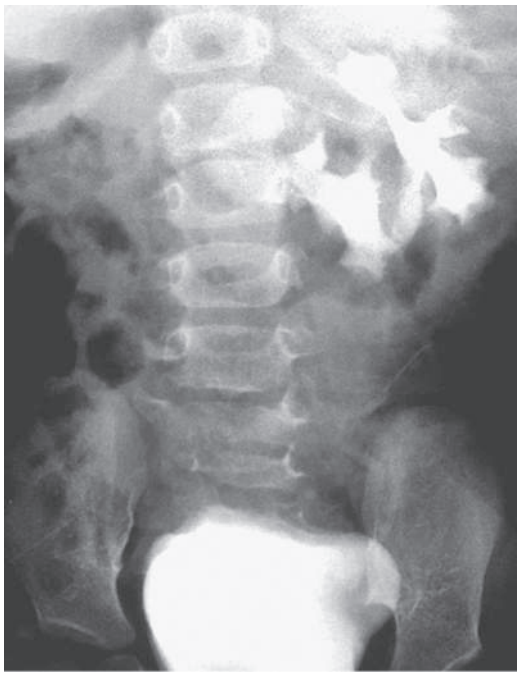

Fig. 574.4 Crossed renal ectopia. Intravenous urography shows both renal collecting systems to the left of the spine. Segmentation anomalies of the sacrum, which are subtle in this child, are one of the skeletal anomalies associated with renal ectopia. *(From Slovis T, ed. Caffey's Pediatric Diagnostic Imaging, 11th ed. Philadelphia: Elsevier; 2008. Fig. 145-23A, p. 2244.)*

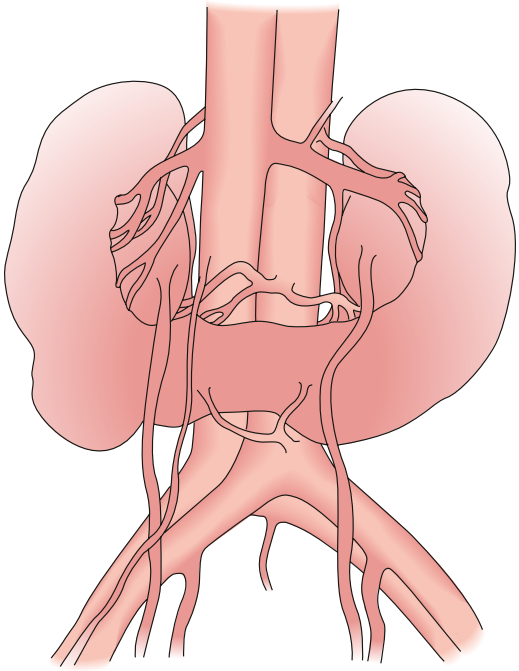

Fig. 574.5 Horseshoe kidney.

resulting in renal ectopia or malrotation. The ectopic kidney may be in a pelvic, iliac, thoracic, or contralateral position. Ectopia may be bilateral; the kidneys fuse in 90% of these cases. The incidence of renal ectopia is approximately 1 in 900 (Fig. 574.4).

Renal fusion anomalies are more common. The lower poles of the kidneys can fuse in the midline, resulting in a horseshoe kidney (Fig. 574.5); the fused portion is termed the *isthmus* and may be thick functioning parenchyma or a thin fibrous strand. Horseshoe kidneys occur in 1 in 400-500 births and are seen in 14–20% of patients with Turner syndrome (see Chapter 626); horseshoe kidneys are also associated with VACTERL and caudal regression syndromes, as well as trisomies 18 and 21. Wilms tumors are four times more common in children with horseshoe kidneys than in the general population. Stone disease, hydronephrosis secondary to ureteropelvic junction obstruction, and vesicoureteral reflux are other potential complications. The incidence of MCDK affecting one of the two sides of a horseshoe kidney also is increased. With crossed fused ectopia, one kidney crosses over to the other side, and the parenchyma of the two kidneys is fused. Renal function usually is normal. Most commonly, the left kidney crosses over and fuses with the lower pole of the right kidney. The insertion of the ureter to the bladder does not change, and the adrenal glands remain in their normal positions. The clinical significance of this anomaly is that if renal surgery is necessary, the blood supply is variable and can make partial nephrectomy more difficult.

ASSOCIATED PHYSICAL FINDINGS

Upper urinary tract anomalies are more common in children with certain physical findings. The incidence of renal anomalies is increased if there is a single umbilical artery and an abnormality of another organ system (e.g., congenital heart disease). External ear anomalies, imperforate anus, and scoliosis are also associated with renal anomalies. Infants with these physical findings should undergo a renal ultrasound.

Chapter 575

Urinary Tract Infections

Marie E. Wang and Pearl W. Chang

PREVALENCE AND ETIOLOGY

Urinary tract infections (UTIs) commonly occur in children of all ages, though the prevalence varies with age. UTIs are most common in children under 1 year of age. The prevalence in *febrile* infants and children less than 24 months is 7%, and the prevalence in older children less than 19 years presenting with urinary symptoms and/or fever is 8%. During the first 3 months of life, UTIs are most common in uncircumcised febrile males with a prevalence of 20%, which is eight times higher than circumcised males and 2-3 times higher than females. After 6 months of age, UTIs are much more likely in females, with peaks during infancy, toilet training, and onset of sexual activity.

UTIs are caused primarily by colonic bacteria. *Escherichia coli* (see Chapter 246) causes the majority of UTIs, followed by *Klebsiella* spp. and *Proteus* spp., *Enterococcus,* and *Pseudomonas* (see Chapter 148). Other bacteria known to cause UTIs include *Staphylococcus saprophyticus,* group B streptococcus, and, less commonly, *Staphylococcus aureus, Candida* spp., and *Salmonella* spp.

CLINICAL MANIFESTATIONS AND CLASSIFICATION

The two basic forms of UTIs are **pyelonephritis** and **cystitis.** Focal pyelonephritis (lobar nephronia) and renal abscesses are less common.

Pyelonephritis

Pyelonephritis is characterized by any or all of the following: abdominal, back, or flank pain; fever; malaise; nausea; vomiting; and, occasionally, diarrhea. *Fever may be the only manifestation, especially in young children; particular consideration should occur for a temperature ≥39°C (102.2°F) without another source lasting more than 48 hours in infants*. Newborns can also show nonspecific symptoms, such as poor feeding, irritability, jaundice, or weight loss. Pyelonephritis is the most common bacterial infection in infants younger than 24 months of age who have fever without an obvious focus (see Chapters 220 and 221). Involvement of the renal parenchyma is termed acute pyelonephritis (Figs. 575.1 and 575.2), whereas if there is no parenchymal involvement, the condition may be termed **pyelitis**. Acute pyelonephritis can result in renal injury, termed **pyelonephritic scarring**.

Acute lobar nephronia (acute focal bacterial nephritis) is a localized renal parenchymal mass caused by acute focal infection without liquefaction; it more commonly occurs in older children. It may be an early stage in the development of a renal abscess (Fig. 575.3). Manifestations are identical to those of pyelonephritis and include fever and flank pain. The epidemiology of the causative organism is also similar to that of pyelonephritis. **Renal abscess** can occur following a pyelonephritic infection caused by the usual uropathogens or less commonly following hematogenous spread with *S. aureus.* Most abscesses are unilateral and right-sided and can affect children of all ages (Fig. 575.4). Both acute lobar nephronia and renal abscess are associated with an increased risk of renal scarring. **Perinephric abscess** can occur secondary to contiguous infection in the perirenal area (e.g., vertebral osteomyelitis, psoas abscess) or pyelonephritis that dissects to the renal capsule. It differs from renal abscess in that it is diffuse throughout the capsule and is not walled off, although it can develop septations. As with renal abscesses, the most common organisms are *S. aureus* and *E. coli.* A perinephric abscess may not communicate with the collecting system, and, thus, abnormal findings may not be seen on urinalysis or culture.

Xanthogranulomatous pyelonephritis is a rare type of chronic renal infection characterized by granulomatous inflammation with

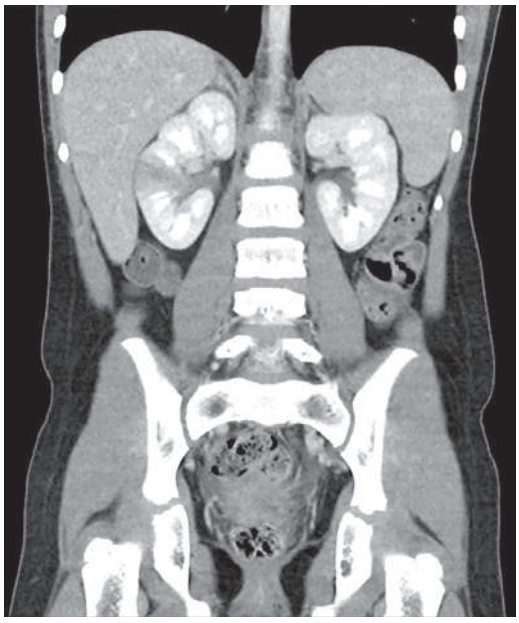

Fig. 575.1 Acute pyelonephritis seen as an area of decreased perfusion by CT scan done for abdominal pain and fever in a child who subsequently was shown to have no reflux by VCUG.

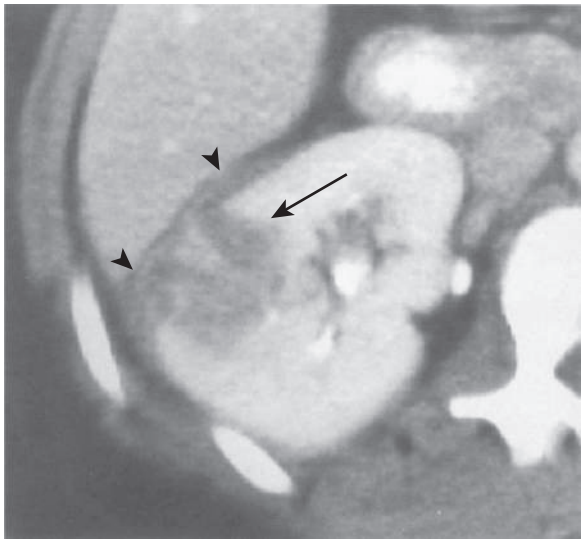

Fig. 575.2 Acute pyelonephritis with focal mass formation. The kidney shows a rounded heterogeneous mass *(arrow)* with a poorly defined margin. Inflammatory changes in the adjacent perinephric fat and renal fascial thickening *(arrowheads)* are also present. *(From Haaga JR, Boll DT, eds. CT and MRI of the Whole Body, 6th ed. Philadelphia: Elsevier; 2017. Fig. 54-131, p. 1833.)*

giant cells and foamy histiocytes. It can manifest clinically with a renal mass and nonspecific symptoms including fever, flank pain, weight loss, and malaise. Dysuria and other urinary symptoms are less common. Renal calculi, obstruction, and infection with *Proteus* spp. or *E. coli* contribute to the development of this lesion, which usually requires total or partial nephrectomy.

Alkaline encrusted pyelitis/cystitis is a rare chronic obstruction UTI caused by *Corynebacterium urealyticum*. The organism creates an alkaline urine (converting urea to ammonia), precipitating struvite and calcium phosphate resulting in stone formation and pyuria with

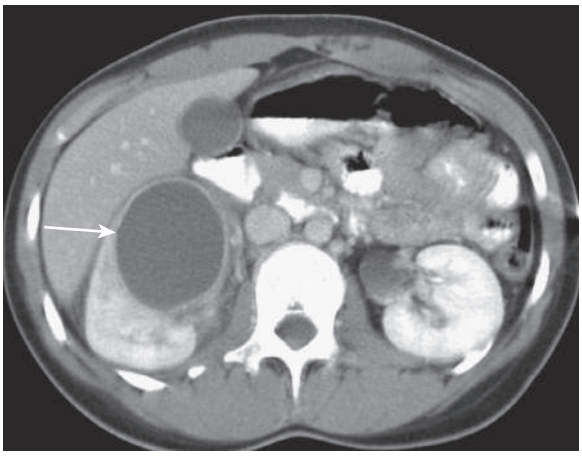

Fig. 575.3 Right renal abscess *(arrow)* shows a thick wall and low density (30 HU). Inflammatory stranding is present in the perinephric fat. *(From Haaga JR, Boll DT, eds. CT and MRI of the Whole Body, 6th ed. Philadelphia: Elsevier; 2017. Fig. 55.3, p. 1834.)*

hematuria. Risk factors include urinary tract instrumentation, congenital uropathies/anomalies, chronic illness, and immune suppression.

Cystitis

Cystitis indicates that there is only bladder involvement; symptoms include dysuria, urgency, frequency, suprapubic pain, incontinence, and possibly malodorous urine. Cystitis does not cause high fever and does not result in renal injury. Malodorous urine is suggestive but not specific for a UTI.

Acute hemorrhagic cystitis, though uncommon in immunocompetent children, is often caused by *E. coli;* it also has been attributed to adenovirus types 11 and 21. It is self-limiting, with hematuria lasting approximately 4 days. Patients receiving immunosuppressive therapy (e.g., solid-organ or bone marrow transplantation) are at higher risk for hemorrhagic cystitis; adenoviruses and polyomaviruses (i.e., JC virus and BK virus) are important causes in immunocompromised populations (see Chapter 321). Other rare types of cystitis that may be confused with infection include *eosinophilic cystitis* or *interstitial cystitis.* Eosinophilic cystitis may present with hematuria, whereas interstitial cystitis may present with irritative voiding symptoms but a negative urine culture.

PATHOGENESIS AND PATHOLOGY

Nearly all UTIs are ascending infections. The bacteria arise from the fecal flora, colonize the perineum, and enter the bladder via the urethra. In uncircumcised males, the bacterial pathogens arise from the flora beneath the prepuce. In some cases, the bacteria causing cystitis ascend to the kidney to cause pyelonephritis. Rarely, renal infection occurs by hematogenous spread, as in endocarditis or in bacteremic neonates.

If bacteria ascend from the bladder to the kidney, acute pyelonephritis can occur. Normally, the simple and compound papillae in the kidney have an antireflux mechanism that prevents urine in the renal pelvis from entering the collecting tubules. However, some compound papillae, typically in the upper and lower poles of the kidney, allow intrarenal reflux. Infected urine stimulates an immunologic and inflammatory response that can cause renal injury and scarring (Figs. 575.5 and 575.6).

Table 575.1 and Figure 575.7 outline the host risk factors for UTI. Vesicoureteral reflux (VUR) is discussed in Chapter 576. If there is grade III, IV, or V VUR and a febrile UTI, 90% of patients have evidence of acute pyelonephritis on renal scintigraphy or other imaging studies. In females, UTIs often occur at the onset of toilet training because of bowel-bladder dysfunction that occurs at that age. The child is trying to retain urine to stay dry, yet the bladder may have uninhibited contractions forcing urine out. The resulting high-pressure, turbulent urine flow and incomplete bladder emptying both increase

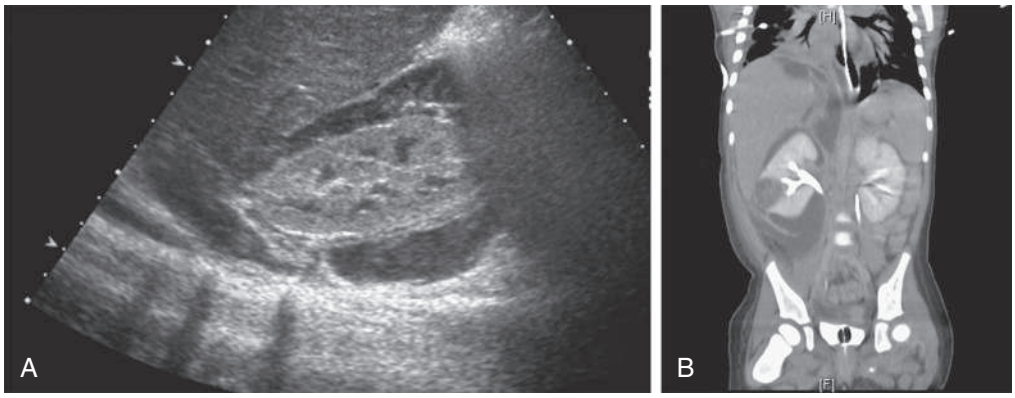

Fig. 575.4 A, Renal sonogram, 19-mo-old infant with perirenal abscess secondary to methicillin-resistant *Staphylococcus aureus*. B, CT scan demonstrates extensive perinephric and focal intrarenal abscess. Patient underwent incision and drainage.

Table 575.1 Risk Factors for Urinary Tract Infection

Female anatomy	Obstructive uropathy
Uncircumcised male	Urethral instrumentation
Age ≤1 years	Constipation
Vesicoureteral reflux	Anatomic abnormality (labial adhesion)
Toilet training	Neurogenic bladder
Voiding dysfunction	Sexual activity
Sources of external irritation (such as tight clothing, pinworm infestation)	Pregnancy

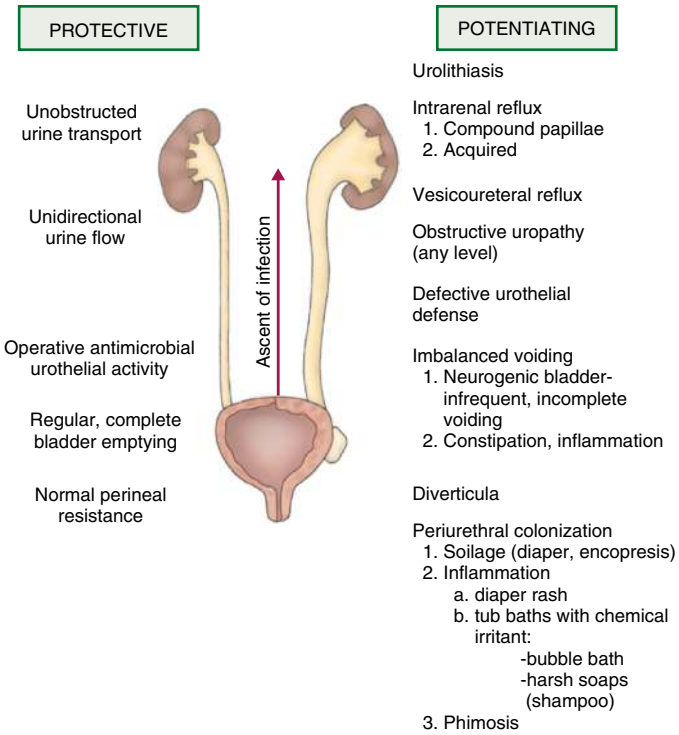

Fig. 575.7 Host factors that protect the urinary tract from infection and abnormalities that potentiate the establishment of invasive bacterial infection. *(From Holcomb III GW, Murphy JP, Ostlie DJ, eds. Holcomb and Ashcraft's Pediatric Surgery, 7th ed. Philadelphia: Elsevier; 2020. Fig. 55-3, p. 855.)*

Table 575.2 Sensitivity and Specificity of Components of Urinalysis, Alone and in Combination

TEST	SENSITIVITY (RANGE) %	SPECIFICITY (RANGE) %
Leukocyte esterase test	83 (67–94)	78 (64–92)
Nitrite test	53 (15–82)	98 (90–100)
Leukocyte esterase or nitrite positive	93 (90–100)	72 (58–91)
Microscopy (white blood cells)	73 (32–100)	81 (45–98)
Microscopy (bacteria)	81 (16–99)	83 (11–100)
Leukocyte esterase test, nitrite, or microscopy positive	99.8 (99–100)	70 (60–92)

From Finnell SM, Carroll AE, Downs SM, Subcommittee on Urinary Tract Infection. Technical report—diagnosis and management of an initial UTI in febrile infants and young children. *Pediatrics.* 2011;128:e749–e770.

the likelihood of bacteriuria. *Bowel-bladder dysfunction* can arise in school-age children who refuse to use the school bathroom, creating a state of urinary retention. Obstructive uropathy resulting in hydronephrosis increases the risk of UTI because of urinary stasis. Constipation with fecal impaction can increase the risk of UTI because it can cause bladder dysfunction.

Other host factors for UTI include anatomic abnormalities precluding normal micturition, such as a labial adhesion. This lesion acts as a barrier and causes vaginal voiding. A neurogenic bladder can predispose to UTI if there is incomplete bladder emptying and/or detrusor-sphincter dyssynergia or a resultant need for frequent catheterization. Sexual activity is associated with UTI in females due to introduction of bacteria near the urinary tract, which can be exacerbated in part because of urethral irritation and incomplete bladder emptying following intercourse.

The pathogenesis of UTI is based in part on the presence of bacterial pili or fimbriae on the bacterial surface, which allow for attachment to the uroepithelial cells. For *E. coli,* this attachment occurs through the type 1 fimbriae and P-fimbriae, which may result in bacterial uptake and replication and formation of intracellular bacterial communities. These intracellular organisms may evade the immune response, form quiescent reservoirs protected from antibiotics, and be a source of recurrent infections. Current research is attempting to prevent the initial attachment of bacteria to the bladder wall that can lead to intracellular bacterial communities and quiescent reservoirs.

DIAGNOSIS

Among children 2-24 months of age, risk factors for UTI include age younger than 12 months, being a female or uncircumcised male, temperature ≥39°C (102.2°F), fever for at least 2 days, and absence of another source of infection. Urine testing is recommended when the pretest probability of a UTI is ≥2%, and an online UTI calculator can provide probability estimates (https://uticalc.pitt.edu/). In older verbal children, urine testing should be considered when there are UTI symptoms. A positive urinalysis suggestive of infection (i.e., presence of pyuria) plus a urine culture with ≥50,000 colony-forming units (CFU)/mL of a single uropathogen are recommended for diagnosis of a UTI in a symptomatic child. In the appropriate clinical context, ≥10,000 CFU/mL may be sufficient for diagnosis, especially if the laboratory does not categorize counts between 10,000 and 100,000 CFU/mL.

There are several ways to obtain a urine sample; some are more accurate than others. In toilet-trained children, a midstream urine sample usually is satisfactory; the introitus should be cleaned before obtaining the specimen. In uncircumcised males, the prepuce must be retracted; if the prepuce is not retractable, a voided sample may be unreliable and contaminated with skin flora. For children 2-24 months who are not toilet trained, a catheterized urine sample should be obtained. Alternatively, the application of an adhesive, sealed, sterile collection bag after disinfection of the skin of the genitals can be useful only if the urinalysis and culture are negative; the negative predictive value for urinalysis from a "bag" specimen is 99%. However, a positive culture can result from skin contamination, particularly in females and uncircumcised males. If treatment is planned immediately after obtaining the urine sample, a bagged specimen *should not* be the method because of a high rate of contamination, often with mixed organisms. A suprapubic aspirate generally is unnecessary.

Inclusion of pyuria in the diagnostic criteria along with a positive urine culture helps to distinguish true UTI from asymptomatic bacteriuria or contamination. **Pyuria** is defined as ≥5 white blood cells (WBCs)/high-power field on a centrifuged specimen, ≥10 WBC/mm^3 on an enhanced urinalysis, or any **leukocyte esterase** on a dipstick. Additional urinalysis findings that support a UTI diagnosis include presence of **nitrites**. Bacteria generally require 4 hours for metabolism of nitrates to nitrites. Thus nitrites may not be detected in cases of UTI where the organism does not convert nitrates to nitrites (most notably *Enterococcus*) or if the child has urinary frequency, where there may not be enough time for the conversion to nitrites. Findings of leukocyte esterase, WBC on microscopy, or nitrites has a high sensitivity for UTI, including in febrile infants <60 days of age (Table 575.2). Microscopic hematuria is common in acute cystitis, but microhematuria alone does not suggest UTI. WBC casts in the urinary sediment suggest renal involvement, but in practice these are rarely seen.

Sterile pyuria (positive leukocytes, negative culture) may occur in partially treated bacterial UTI, viral infections, urolithiasis, renal tuberculosis, renal abscess, UTI in the presence of urinary obstruction, urethritis as a consequence of a sexually transmitted infection (see Chapter 163), inflammation near the ureter or bladder (appendicitis, Crohn disease), Kawasaki disease (see Chapter 493.1), COVID-19–associated multisystem inflammatory syndrome in children (MIS-C; see Chapter 311), schistosomiasis, neoplasm, renal transplant rejection, or interstitial nephritis (eosinophils). Prompt plating of the urine sample for culture is important, because if the urine sits at room temperature for more than 60 minutes, overgrowth of a minor contaminant can suggest a UTI when the urine might not be infected. Refrigeration is a reliable method of storing the urine until it can be cultured.

With acute renal infection, leukocytosis and neutrophilia are noted on the CBC; an elevated ESR, procalcitonin level, and CRP are common. However, these are all nonspecific markers of inflammation; thus their elevation does not prove that the child has acute pyelonephritis, and they do not need to be routinely obtained. Bacteremia in the setting of pyelonephritis is reported to occur in 3–20% of patients and is most common in infants <60 days old (with rates decreasing with increasing age in the first 60 days). For infants <60 days old or ill-appearing patients at presentation, blood cultures should be drawn before starting antibiotics, if possible.

IMAGING FINDINGS

Imaging is not needed to make the diagnosis of UTI. If there is concern about acute lobar nephronia or renal abscess (e.g., patient not responding to appropriate antibiotics), imaging should be considered. Ultrasound is the first-line imaging for screening and will likely demonstrate an enlarged kidney with a possible mass in the case of acute lobar nephronia or renal abscess. CT scan is more sensitive and specific for lobar nephronia and will typically show a wedge-shaped, lower-density area after contrast administration.

TREATMENT

Acute cystitis should be treated promptly to prevent possible progression to pyelonephritis. If the symptoms are severe, and the urinalysis shows pyuria, presumptive treatment should be started while awaiting urine culture results. If the symptoms are mild or the diagnosis is doubtful, treatment can be delayed until the results of culture are known, and the urinalysis and culture can be repeated if the results are uncertain. In **acute febrile UTI**, the clinical symptoms of cystitis and pyelonephritis are difficult to differentiate. Given the presence of systemic symptoms, it is reasonable to consider that the infection has likely progressed to the kidneys and treat for pyelonephritis. A UTI can be treated safely and effectively with oral antibiotics in the outpatient setting, including in younger children. Thus route of therapy should be based on practical considerations. Parenteral therapy should be used in children who are dehydrated, are vomiting, are unable to drink fluids, have complicated infection, or in whom urosepsis is a possibility. Infants less than 1 month of age with suspected febrile UTI are typically hospitalized and started on parenteral antibiotics while awaiting results of a sepsis evaluation and can be converted to oral therapy if there is no concern for meningitis and they are otherwise clinically well. Infants 1-2 months of age can be managed as an outpatient unless hospitalization is indicated for other reasons (e.g., emesis, dehydration). Although infants with bacteremic UTI are often treated with longer parenteral courses, duration of therapy has not been associated with UTI relapse.

Local antimicrobial sensitivity patterns should be considered when selecting empiric antibiotic treatment. For oral treatment, cephalexin is a commonly used narrow-spectrum empiric option, as overall rates of *E. coli* resistance to first-generation cephalosporins are low. In areas with high rates of *E. coli* resistance to first-generation cephalosporins, oral third-generation cephalosporins such as cefixime can be appropriate empiric options and are effective against a variety of gram-negative organisms. Trimethoprim-sulfamethoxazole (TMP-SMX) may also be used, though resistance is increasing in some areas. Nitrofurantoin can be used for cystitis but should not be used routinely in children with a febrile UTI, because it does not achieve significant renal tissue levels. The oral fluoroquinolone ciprofloxacin can be considered for UTI caused by *P. aeruginosa* or resistant microorganisms when there are no other oral antibiotic options. However, clinical treatment with fluoroquinolones in young children should be used with caution because of potential cartilage damage. For parenteral treatment in hospitalized children 1 month and older, ceftriaxone is a reasonable choice until culture results are available to determine whether a narrower-spectrum antibiotic can be used. Ampicillin plus either gentamicin or a third-generation cephalosporin are often used empirically in neonates. If prior urine culture results have grown resistant or atypical organisms, other antibiotic choices may be prudent on a case-by-case basis.

A repeat urine culture after the termination of UTI treatment is not routinely needed. Urine cultures are typically negative within 24 hours of initiation of antibiotic therapy; therefore a urine culture during treatment is almost invariably negative. Most children exhibit clinical improvement (afebrile) within 48-72 hours of antibiotic initiation. Recommended duration of therapy is generally 3-5 days for cystitis and 7-10 days for uncomplicated pyelonephritis. Atypical features include failure to respond within 48-72 hours of appropriate antibiotics; poor urine flow; an abdominal, flank, or suprapubic mass; sepsis; or an elevated creatinine level. Atypical features should prompt further evaluation.

Acute Lobar Nephronia, Renal Abscess, and Perinephric Abscess

Acute lobar nephronia is treated with the same antibiotics as pyelonephritis. The recommended duration of treatment is 14-21 days; one study suggested higher treatment failure in the group treated for shorter duration. Children with a renal or perirenal abscess or with infection in obstructed urinary tracts can require percutaneous or surgical drainage in addition to antibiotic therapy and other supportive measures (see Fig. 575.4). Percutaneous drainage is typically attempted prior to surgical intervention. Medical management alone has been successful in treating small-to-moderate renal abscesses. Although some studies have commented that resolution with antibiotics alone are more likely in abscesses 3 cm or less, some patients with abscesses >3 cm have been managed successfully with IV antibiotics only. Thus a 48-hour trial of IV antibiotics prior to percutaneous drainage may be warranted in otherwise stable children. Few studies address the role of oral antibiotic therapy for renal abscess. Traditionally, patients received 10-14 days of IV antibiotics, followed by 2-4 weeks of oral antibiotic therapy targeted against the known organism (or the likely causes of *E. coli* and *S. aureus* if the organism was unknown). The increasing use of oral antibiotics for other serious infections (e.g., osteomyelitis) suggests that an earlier transition to oral therapy for renal abscess is likely feasible. Kidney loss is reported to occur in 10–20% of cases of renal abscess. Perinephric abscesses may be managed with IV antibiotics alone or with percutaneous drainage if the area is large or causing impaired kidney function. Identification of a causative organism can be an additional advantage of percutaneous drainage of a perinephric abscess because the infection may remain isolated from the collecting system based on the location.

Other Potential Treatment or Prevention Options

There is interest in probiotic therapy as well as cranberry juice to *prevent* UTIs. Studies are ongoing and a probiotic containing a non-uropathogenic *E. coli* called Nissle 1917 is available in Europe and other parts of the world. These bacteria may inhibit growth of other bacteria. Cranberry juice may prevent bacterial adhesion and biofilm formation, hypothesized to be via proanthocyanidin (PAC). Currently there is insufficient evidence regarding the use of these therapies in children to reduce UTIs.

The main consequences of chronic renal damage caused by pyelonephritis are arterial hypertension and end-stage renal insufficiency; when they are found, they should be treated appropriately (see Chapters 494 and 572). Even without chronic renal damage, the consequences of infections include lost days from school and work, uncomfortable symptoms, and exposure to antibiotics that change the healthy microbiome.

IMAGING STUDIES IN CHILDREN WITH A FEBRILE UTI

The primary goal of imaging studies in children with a febrile UTI is to identify anatomic abnormalities that predispose to future infection, such as high-grade VUR, posterior urethral valves, or other obstructive uropathy. Imaging is usually unnecessary in children with afebrile cystitis. Historically, children either underwent a renal sonogram plus a voiding cystourethrogram (VCUG) in a "bottom-up" approach, or a dimercaptosuccinic acid (DMSA) renal scan first to identify areas of acute pyelonephritis (Fig. 575.8) in a "top-down" approach. If the DMSA scan was positive, then a VCUG was performed (Fig. 575.9) because up to 90% of children with dilating reflux have a positive DMSA scan. In the past decade, with increasing evidence that most children with first-time UTI have normal genitourinary tracts and the unclear benefit of early detection of VUR, most national guidelines recommend selective imaging for children with UTI. Though the sensitivity of renal-bladder ultrasounds for detecting VUR is poor, there is no established harm of nondetection of VUR after a first UTI.

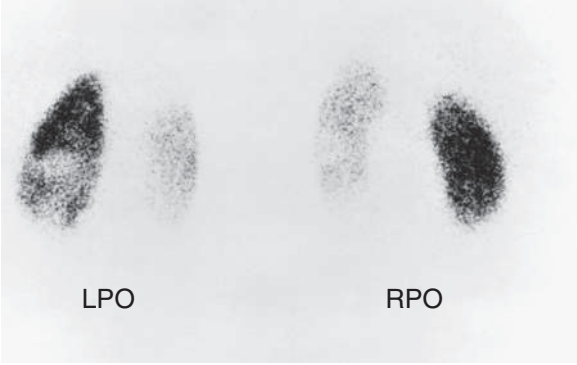

Fig. 575.8 DMSA renal scan showing bilateral photopenic areas indicating acute pyelonephritis and renal scarring. LPO, left posterior oblique; RPO, right posterior oblique.

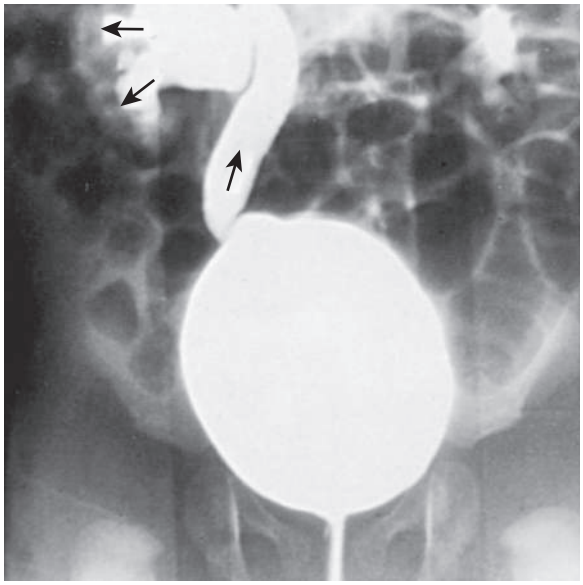

Fig. 575.9 Intrarenal reflux. VCUG in an infant boy with a history of a UTI. Note the right VUR with ureteral dilation, with opacification of the renal parenchyma representing intrarenal reflux.

Most experts still recommend initial ultrasound of the kidneys, ureters, and bladder for children 2-24 months with a first febrile UTI. VCUG should be obtained if the ultrasound study indicates hydronephrosis, scarring, or other findings suggestive of high-grade (e.g., grades IV-V) reflux or obstructive uropathy, or if the patient has other atypical complex features. Further, a VCUG should be obtained if the child has a recurrent febrile UTI (Table 575.3). The rate of renal scarring increases between days 2 and 3 of fever; this makes the prompt evaluation and appropriate treatment of a recurrent UTI important. The risk of scarring also increases with the number of episodes of pyelonephritis and with higher grades of reflux.

The NICE (National Institute for Health and Care Excellence, UK) guidelines for diagnosis, management, and imaging after UTI were released in 2022 (Table 575.4). These recommendations divided children into those younger than 6 months, 6 months to younger than 3 years, and 3 years and older. An initial renal-bladder ultrasound is recommended for all children younger than 6 months, and a VCUG only if atypical features (including non–*E. coli* infection, sepsis or bacteremia, failure to respond to antibiotics within 48 hours), recurrent UTI, or abnormal ultrasound findings. For children age 6 months to younger than 3 years who have a UTI with atypical features or recurrent UTI, an ultrasound is recommended, and if risk factors are present, then also a VCUG should also be obtained (see Table 575.4). No imaging is suggested for otherwise first-time, typical UTI in this age group. When ultrasound is recommended, the optimal timing for obtaining it is unclear. Most national guidelines recommend an ultrasound during the acute infection if there is concern for obstruction (e.g., not responding to antibiotics, elevated creatinine, poor urine flow) but otherwise nonurgently within 2-6 weeks after the UTI as routine ultrasound during the acute infection rarely changes management.

PREVENTION OF RECURRENCES

In a child with recurrent UTIs, identification of predisposing factors is beneficial. Bowel and bladder dysfunction is a very important contributor to recurrent UTIs and is one of the main reasons for an increase in UTIs around the time of toilet training. Bladder dysfunction is manifested by urgency, wetting, and especially "Vincent's curtsy" (children squat on their heels in response to an uninhibited bladder contraction) (see Chapter 580). In toilet-trained children, a thorough history and use of urodynamic studies and measurement of postvoid residual volumes may be helpful in

Table 575.3 Guideline Recommendations for Diagnostic Evaluation Following a Febrile Urinary Tract Infection in Infants

GUIDELINE	ULTRASONOGRAPHY	VCUG	LATE DMSA SCAN
National Institute for Health and Care Excellence (NICE)	See Table 575.4		
American Academy of Pediatrics (retired)	Yes	If abnormal ultrasonogram or febrile recurrence	No
Italian Society for Paediatric Nephrology (ISPN)	Yes	If abnormal ultrasonogram, non-*Escherichia coli* infection, or febrile recurrence	If grade IV-V VUR
Spanish Association of Paediatrics	Yes, if age <6 months, atypical infection,* or recurrence	If abnormal ultrasonogram, atypical infection,* or recurrence	If atypical infection* or recurrence
Swiss consensus recommendations	Yes	If abnormal ultrasonogram, atypical infection,† or febrile recurrence	No

*Defined as fever >48 hours after appropriate antibiotics, sepsis, non–*E. coli* infection, acute kidney injury, or abdominal or vesical mass.
†Defined as failure to respond to appropriate antibiotics within 48 hours, non–*E. coli* infection, increased creatinine, abnormal electrolytes, hypertension, or poor urine flow.
VCUG, Voiding cystourethrogram; DMSA, dimercaptosuccinic acid; VUR, vesicoureteral reflux.

Table 575.4 NICE Recommended Imaging Schedule for Children with Urinary Tract Infection

CHILD AGE AND TESTS	TYPE OF INFECTION		
	RESPONDS WELL TO TREATMENT WITHIN 48 HR	ATYPICAL INFECTION*	RECURRENT INFECTION
CHILDREN YOUNGER THAN 6 MO OLD			
Ultrasound scan during acute infection	No	Yes	Yes
Ultrasound scan within 6 wk of infection	Yes	No	No
DMSA scan 4-6 mo after acute infection	No	Yes	Yes
VCUG	Consider if ultrasound scan abnormal	Yes	Yes
CHILDREN 6 MO TO YOUNGER THAN 3 YR OLD			
Ultrasound scan during acute infection	No	Yes	No
Ultrasound scan within 6 wk of infection	No	No	Yes
DMSA scan 4-6 mo after acute infection	No	Yes	Yes
VCUG	No	Not routine; consider if dilation on ultrasound, poor urine flow, non–*E. coli* infection, or family history of vesicoureteral reflux	
CHILDREN 3 YR OR OLDER			
Ultrasound scan during acute infection	No	Yes	No
Ultrasound scan within 6 wk of infection	No	No	Yes
DMSA scan 4-6 mo after acute infection	No	No	Yes
VCUG	No	No	No

*Defined as seriously ill, poor urine flow, abdominal or bladder mass, raised creatinine, sepsis or bacteriemia, failure to respond to appropriate antibiotics within 48 hours, or infection with non–*E. coli* organisms.

identifying children with bladder dysfunction that may contribute to UTI. Tightening the pelvic floor during urination can sometimes be seen on a VCUG as a **spinning-top urethra** (Fig. 575.10). An ultrasound may document residual urine and possibly a thick bladder wall. Urodynamics may show an intermittent stream with increased activity in the pelvic floor muscles. Some children with UTI may also have constipation (see Chapter 378.3). Behavioral modification, with treatment of constipation as described in Chapter 580, often is effective at reducing recurrent UTI from constipation.

Routine use of antibiotic prophylaxis is not recommended for children with a first episode of pyelonephritis and an otherwise anatomically normal urinary tract. Urologic conditions that can cause recurrent UTIs that might benefit from long-term antibiotic prophylaxis include neurogenic bladder, urinary tract stasis and obstruction, severe VUR (see Chapter 576), and urinary calculi. The RIVUR study was a randomized trial of TMP-SMX prophylaxis for patients with a history of UTI and diagnosed grades I-IV VUR. Although the UTI recurrence rate was decreased by half from 30% in the group not receiving prophylaxis to 15% in those receiving prophylaxis, rates of renal scarring were the same in both groups. Additionally, the rates of UTI caused by resistant organisms increased in the group receiving prophylaxis. Although the use of prophylaxis can decrease rates of recurrence, routine prophylaxis is not recommended for children with VUR (especially lower-grade VUR) due to the increase in antibiotic resistance, need for daily medication in children, and lack of change in renal scarring.

Chapter 576

Vesicoureteral Reflux

Heather N. Di Carlo and Chad B. Crigger

Vesicoureteral reflux (VUR) describes the retrograde flow of urine from the bladder to the ureter and kidney. The ureteral attachment to the bladder normally is oblique, between the bladder mucosa and detrusor muscle, creating a flap-valve mechanism that prevents VUR (Fig. 576.1). VUR occurs when the submucosal tunnel between the mucosa and detrusor muscle is short or absent. Affecting 1–2% of children, VUR usually is congenital and often is familial. VUR is present in approximately 30% of females who had a urinary tract infection and in 5–15% of infants with antenatal hydronephrosis.

VUR predisposes to kidney infection **(pyelonephritis)** by facilitating the transport of bacteria from the bladder to the upper urinary tract (see Chapter 575). The inflammatory reaction caused by pyelonephritis can result in renal injury or scarring, also termed **reflux-related renal injury** or **reflux nephropathy.** In children with a febrile urinary tract infection, those with VUR are three times more likely to develop renal injury compared with those without VUR. Extensive **renal scarring** impairs renal function and can result in renin-mediated hypertension (see Chapter 494), renal insufficiency or end-stage renal disease (see Chapter 572), impaired somatic growth, and morbidity during pregnancy. Scarring associated with reflux may be present at birth or develop in the absence of infection if there is significant bladder-sphincter discoordination during voiding.

In the past, reflux nephropathy accounted for as much as 15–20% of end-stage renal disease in children and young adults. With greater attention to the management of UTIs and a better understanding of VUR, end-stage renal disease secondary to reflux nephropathy is uncommon. Reflux nephropathy remains a common cause of hypertension in children. VUR in the absence of infection or elevated bladder pressure (e.g., neuropathic bladder, posterior urethral valves) rarely causes renal injury.

CLASSIFICATION

VUR severity is graded using the International Reflux Study (IRS) classification of I-V and is based on the appearance of the urinary tract on a contrast **voiding cystourethrogra**m (VCUG) (Figs. 576.2 and 576.3). The higher the VUR grade the greater the likelihood of renal injury. VUR severity is an indirect indication of the degree of abnormality of the ureterovesical junction.

VUR may be primary or secondary (Table 576.1). **Bladder-bowel dysfunction (BBD)** can worsen preexisting VUR if there is a marginally competent ureterovesical junction. In the most severe cases, there is such massive VUR into the upper tracts that the bladder becomes overdistended. This condition, the **megacystis-megaureter syndrome,** occurs primarily in males and may be unilateral or bilateral (Fig. 576.4). Reimplantation of the ureters into the bladder to correct VUR corrects the condition.

Primary VUR appears to be an autosomal dominant inherited trait with variable penetrance. Approximately 35% of siblings of children with VUR also have VUR, and VUR is found in nearly half of newborn siblings. The likelihood of a sibling having VUR is independent of the grade of VUR or sex of the index child. Approximately 12% of asymptomatic siblings with VUR have evidence of renal scarring. In addition, 50% of children born to women with a history of VUR also have VUR. The American Urological Association Vesicoureteral Reflux Guidelines Panel stated that, *in siblings of individuals with VUR, a VCUG or radionuclide cystogram is recommended if there is evidence of a renal cortical abnormality or renal size asymmetry on sonography, or if the sibling has a history of febrile UTI*. Otherwise, screening is optional. VUR may be suggested on a prenatal ultrasound that demonstrates hydronephrosis or hydroureteronephrosis.

Approximately 1 in 125 children has a **duplication** of the upper urinary tract, in which two ureters rather than one drain the kidney. Duplication may be partial or complete. In partial duplication, the

Table 576.1 Classification of Vesicoureteral Reflux

TYPE	CAUSE
Primary	Congenital incompetence of the valvular mechanism of the vesicoureteral junction
Primary associated with other malformations of the ureterovesical junction	Ureteral duplication Ureterocele with duplication Ureteral ectopia Paraureteral diverticula
Secondary to increased intravesical pressure	Neuropathic bladder Nonneuropathic bladder dysfunction Bladder outlet obstruction
Secondary to inflammatory processes	Severe bacterial cystitis Foreign bodies Vesical calculi Clinical cystitis
Secondary to surgical procedures involving the ureterovesical junction	Surgery

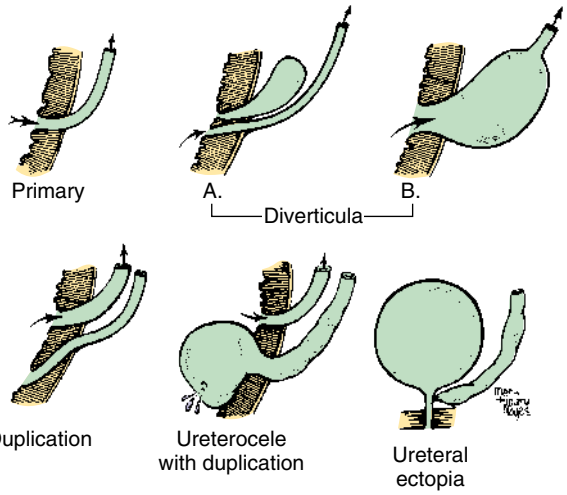

Fig. 576.5 Various anatomic defects of the ureterovesical junction associated with VUR.

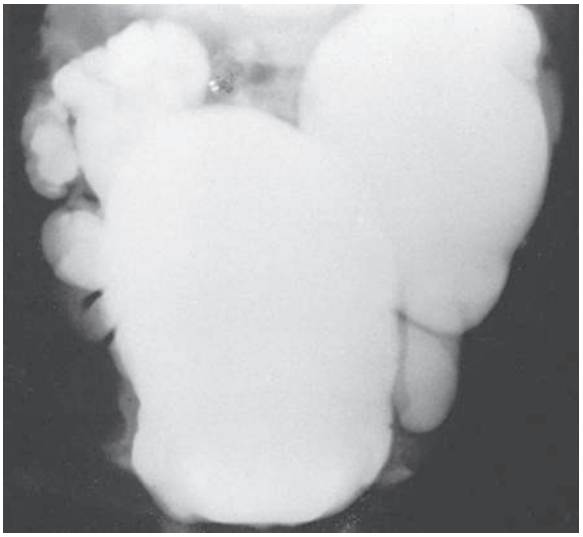

Fig. 576.4 VCUG in a newborn with megacystis-megaureter syndrome. Note the massive ureteral dilation caused by high-grade VUR. The bladder is very distended. There was no urethral obstruction or neuropathic dysfunction.

Fig. 576.6 VUR and bladder diverticulum. The VCUG demonstrates left VUR and a paraureteral diverticulum.

ureters join above the bladder, and there is one ureteral orifice. In complete duplication, the attachment of the lower pole ureter to the bladder is superior and lateral to the upper pole ureter. The valvelike mechanism for the lower pole ureter often is marginal, and VUR into the lower ureter occurs in as many as 50% of cases (Fig. 576.5). VUR occurs into both the lower and upper systems in some persons. With a duplication anomaly, some patients have an **ectopic ureter**, in which the upper pole ureter drains outside the bladder (see Chapter 577 and Figs. 577.6 and 577.7). If the ectopic ureter drains into the bladder neck, typically it is obstructed and refluxes. Duplication anomalies also are common in children with a **ureterocele**, which is a cystic swelling of the intramural portion of the distal ureter. These patients often have VUR into the associated lower pole ureter or the contralateral ureter. In addition, generally VUR is present when the ureter enters a bladder diverticulum (Fig. 576.6).

VUR is present at birth in 25% of children with **neuropathic bladder,** as occurs in myelomeningocele (see Chapters 579 and 631.4), sacral agenesis, and many cases of high imperforate anus. VUR is seen in 50% of males with posterior urethral valves. VUR with increased intravesical pressure (as in detrusor-sphincter discoordination or bladder outlet obstruction) can result in renal injury because of increased intravesical pressure transmitted to the upper urinary tract, even in the absence of infection.

Primary VUR occurs in association with several congenital urinary tract abnormalities. Of children with a multicystic dysplastic kidney or renal agenesis (see Chapter 574), 15% have VUR into the contralateral kidney, and 10–15% of children with a ureteropelvic junction obstruction have VUR into either the hydronephrotic kidney or the contralateral kidney. As such, a diagnosis of VUR should prompt complete investigation to rule out concomitant pathology contralaterally.

CLINICAL MANIFESTATIONS

VUR usually is discovered during evaluation for a UTI (see Chapter 575). Among these children, 80% are female, with an average age at diagnosis of 2-3 years. In other children, a VCUG is performed during evaluation of BBD, renal insufficiency, hypertension, or other suspected pathologic process of the urinary tract. Primary VUR also may be discovered during evaluation for antenatal hydronephrosis. In this select population, 80% of affected children are male, and the VUR

grade usually is higher than in females whose VUR is diagnosed following a UTI. The UTI may be symptomatic, an isolated febrile event, or more often both febrile and symptomatic (abdominal pain, dysuria). BBD (constipation) may be present in 50% of children with reflux and a UTI.

DIAGNOSIS

Diagnosis of VUR requires catheterization of the bladder, instillation of a solution containing iodinated contrast or a radiopharmaceutical, and radiologic imaging of the lower and upper urinary tract (a contrast VCUG or radionuclide cystogram, respectively). The bladder and upper urinary tracts are imaged during bladder filling and voiding. VUR occurring during bladder filling is termed *low-pressure* VUR; VUR during voiding is termed *high-pressure* VUR. *VUR in children with low-pressure VUR is significantly less likely to resolve spontaneously than in children who exhibit only high-pressure VUR.* Radiation exposure during a radionuclide cystogram is significantly less than that from a contrast VCUG. Low-dose radiation contrast VCUG provides more anatomic information, such as demonstration of a duplex collecting system, ectopic ureter, paraureteral (bladder) diverticulum, bladder outlet obstruction in males, upper urinary tract stasis, and signs of voiding dysfunction, such as a **spinning-top** urethra in females. The VUR grading system is based on the appearance on contrast VCUG, and the grade reported is the maximum grade observed during the study. For follow-up evaluation, some prefer the radionuclide cystogram because of the lower radiation exposure (Fig. 576.7), although it is difficult to determine whether the VUR severity has changed and the grading system for the radionuclide study is different than the standard IRS grading system.

Fig. 576.7 Radionuclide cystogram shows bilateral VUR.

Children undergoing cystography may be psychologically traumatized by the catheterization. Careful preparation by caregivers, use of Child Life specialists, or administration of oral or nasal midazolam (for sedation and amnesia) or propofol before the study can result in a less-distressing experience.

Indirect cystography is a technique of detecting VUR without catheterization that involves injecting an intravenous radiopharmaceutical that is excreted by the kidneys, waiting for it to be excreted into the bladder, and imaging the lower urinary tract while the patient voids. This technique detects only 75% of VUR cases. Another technique, which avoids radiation exposure, involves instilling sonographic contrast medium through a urethral catheter. The kidneys are imaged sonographically to determine whether any of the material refluxes. This technique is currently investigational only.

After VUR is diagnosed, assessment of the upper urinary tract is important. The goal of upper tract imaging is to assess whether renal scarring and associated urinary tract anomalies are present. Renal imaging typically is performed with a renal sonogram and/or renal scintigraphy (Fig. 576.8; see Chapter 575).

The child should be evaluated for BBD, including urgency, frequency, diurnal incontinence, infrequent voiding, or a combination of these (see Chapter 575). Children with an overactive bladder often undergo a regimen of behavioral modification with timed voiding, treatment of constipation, and, on occasion, anticholinergic therapy.

After diagnosis, the child's height, weight, and blood pressure should be measured and monitored. If upper tract imaging shows renal scarring, a serum creatinine measurement should be obtained. The urine should be assessed for infection and proteinuria.

NATURAL HISTORY

The incidence of reflux-related renal scarring increases with VUR grade. With bladder growth and maturation, the VUR grade often resolves or improves. *Lower grades of VUR are much more likely to resolve than are higher grades.* For grade I and II VUR, the likelihood of resolution is similar regardless of age at diagnosis and whether it is unilateral or bilateral. For grade III, a younger age at diagnosis and unilateral VUR usually are associated with a higher rate of spontaneous resolution (Fig. 576.9). Bilateral grade IV VUR is much less likely to resolve than is unilateral grade IV VUR. Grade V VUR rarely resolves. The mean age at VUR resolution is 6 years. *BBD and grade III-V VUR are the most common risk factors for recurrent febrile UTI and new renal scarring.*

Sterile VUR does not usually cause renal injury in the absence of infection, but in situations with high-pressure VUR, as in children with posterior urethral valves, neuropathic bladder, and nonneurogenic neurogenic bladder (i.e., **Hinman syndrome**), sterile VUR can cause significant renal damage. Children with high-grade VUR who acquire

Fig. 576.8 A, VCUG in a 3-yr-old child with two febrile UTIs shows bilateral grade III VUR. B, At 5 years, repeat VCUG shows worsening VUR and calyceal clubbing, indicating renal scarring. C, At 11 years, renin-mediated hypertension has developed. Dimercaptosuccinic acid (DMSA) renal scan shows significant VUR-related renal scarring.

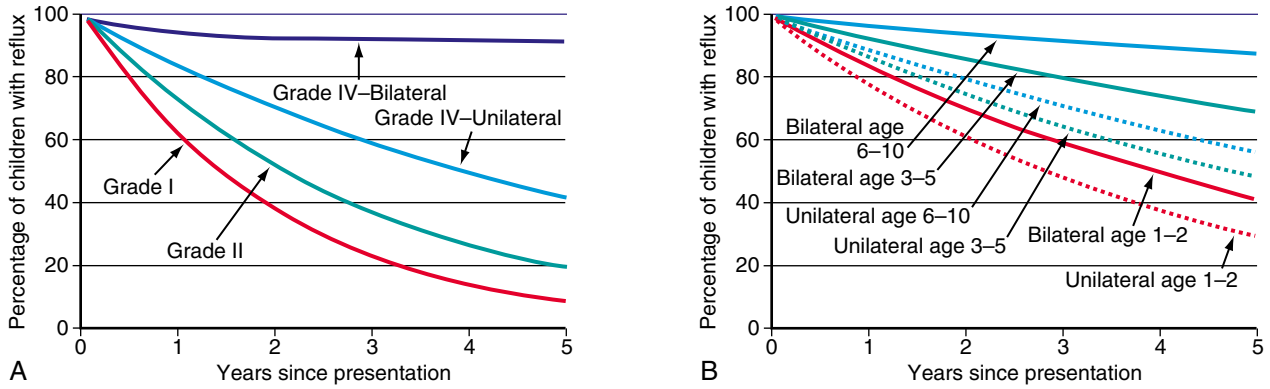

Fig. 576.9 A, Percentage chance of VUR persistence, grades I, II, and IV, for 1-5 years after presentation. B, Percentage chance of VUR persistence by age at presentation, grade III, for 1-5 years after presentation. *(From Elder JS, Peters CA, Arant BS Jr, et al. Pediatric Vesicoureteral Reflux Guidelines Panel summary report on the management of primary vesicoureteral reflux in children. J Urol. 1997;157:1846–1851.)*

a UTI are at significant risk for acute and recurrent pyelonephritis and new renal scarring (see Fig. 576.8).

TREATMENT

The goals of treatment are to prevent pyelonephritis, VUR-related renal injury, and other complications of VUR. Medical therapy is based on the principle that VUR often resolves over time and that if UTIs can be prevented, the morbidity or complications of VUR may be avoided without surgery. Medical therapy includes observation with behavioral modification or behavioral modification with antimicrobial prophylaxis in some patients. The basis for surgical therapy is that in selected children, ongoing VUR has caused or has significant potential for causing renal injury or other VUR-related complications, and that elimination of VUR minimizes the risk of these problems. Therapy for VUR should be individualized based on a particular patient's risk factors.

Observation

In children undergoing observation, therapeutic emphasis is directed at minimizing the risk of UTI by behavioral modification. These methods include timed voiding during the day, ensuring regular fecal elimination, increased fluid intake, periodic assessment of satisfactory bladder emptying, and prompt assessment and treatment of UTIs, particularly febrile UTIs. This approach is most appropriate for children with grade I and II VUR, and perhaps older children with persistent VUR and normal kidneys who have not experienced clinical pyelonephritis.

Antimicrobial Prophylaxis

In the past, daily antimicrobial prophylaxis was recommended as an initial approach to most children with VUR. However, several prospective clinical trials question the benefit of prophylaxis in children with VUR. The risk of recurrent UTI is highest in patients with grade III or IV reflux, those with BBD, and those whose first reflux-associated UTI was *febrile* rather than just symptomatic without fever. Antibiotic prophylaxis after a reflux-associated UTI decreases the risk of recurrent UTI but may increase the risk of developing resistant bacteria. In one study, antibiotic prophylaxis reduced the risk of new renal scars in children with grade III or IV reflux, while in another larger study, antibiotic prophylaxis did not affect the incidence of new renal scars in those with severe reflux (approximately 10% developed new scars regardless of prophylaxis).

Surgery

The purpose of surgical therapy is to minimize the risk of febrile UTI from ongoing VUR and nonsurgical therapy (observation or prophylaxis with follow-up testing). VUR can be corrected through a lower abdominal or inguinal incision (open), laparoscopically (with or without robotic assistance), or endoscopically with subureteral injection of a bulking agent.

Surgical management involves modifying the abnormal ureterovesical attachment. The operation can be performed from either outside (extravesical) or inside the bladder (intravesical). When VUR is associated with severe ureteral dilation (i.e., megaureter), the ureter must be tailored or narrowed to a more normal size to allow a smaller length:width ratio for the intramural tunnel, and a corner of the bladder is attached to the psoas tendon, forming a *psoas hitch.* Most children can be discharged 1-2 days following the surgical procedure. If the refluxing kidney is poorly functioning, nephrectomy or nephroureterectomy is indicated. Minimally invasive approaches with **laparoscopic** and **robotic-assisted laparoscopic ureteral reimplantation** offer alternatives to open surgical management; as experience with these procedures grows, success rates are approaching that of open surgery.

The success rate of conventional open ureteral reimplantation in children with primary VUR is >95–98% for grades I-IV, with 2% experiencing persistent VUR and 1% having ureteral obstruction that requires correction. The success rate is so high that many pediatric urologists do not perform a postoperative VCUG unless the child develops clinical pyelonephritis. For grade V VUR, the success rate is approximately 80%. In lower grades of VUR, a failed reimplantation is most likely to occur in children with undiagnosed BBD. In children with secondary VUR (posterior urethral valves, neuropathic bladder), the success rate is slightly lower than with primary VUR. The risk of pyelonephritis in children with grade III and IV VUR is significantly lower following open surgical correction compared with medical management. *Surgical repair will not reverse renal scarring or lead to improvement in renal function.*

Endoscopic repair of VUR involves injection of a bulking agent through a cystoscope just beneath the ureteral orifice, creating an effective flap-valve (Figs. 576.10 and 576.11). In 2001, the US Food and Drug Administration (FDA) approved the use of a biodegradable material, dextranomer microspheres suspended in hyaluronic acid (Dx-HA) (Deflux), for subureteral injection. The advantage of subureteral injection is that it is a noninvasive outpatient procedure (performed under general anesthesia) with no recovery time. The success rate is 70–80% and is highest for lower grades of VUR. If the first injection is unsuccessful, one or two repeat injections can be performed. The VUR recurrence rate is approximately 10–20%. In other areas of the world, a polyacrylamide hydrogel is used for endoscopic injection. The success rate with this product, which is not approved in the United States, is similar to Dx-HA, but the risk of reflux recurrence is significantly less.

CURRENT VESICOURETERAL REFLUX GUIDELINES

The long-standing belief regarding the benefit of antibiotic prophylaxis in children with VUR has been questioned. Multiple randomized, controlled prospective trials suggested that the risk of UTI in children with VUR is not reduced by prophylaxis. Most of the children in these trials had grade I-III VUR, and few younger than 1 year of age were studied.

In contrast, the PRIVENT (Prevention of Recurrent Urinary Tract Infection in Children with Vesicoureteric Reflux and Normal Renal Tracts) trial from Australia showed significant benefit to prophylaxis in children with VUR. The Swedish VUR Trial in Children studied children younger than 2 years of age with grades III and IV VUR; they compared antibiotic prophylaxis (nitrofurantoin) with observation and endoscopic injection therapy. Females in the surveillance group had a significantly higher incidence of febrile UTI and new renal scarring compared with the other treatment groups. The largest randomized trial (RIVUR [Randomized Intervention for Children with Vesicoureteral Reflux]) enrolled more than 600 children and demonstrated a reduction in the recurrence rate of UTIs with no reduction in the occurrence of renal scarring with antibiotic prophylaxis, but the prevalence of renal scarring at study entry was low.

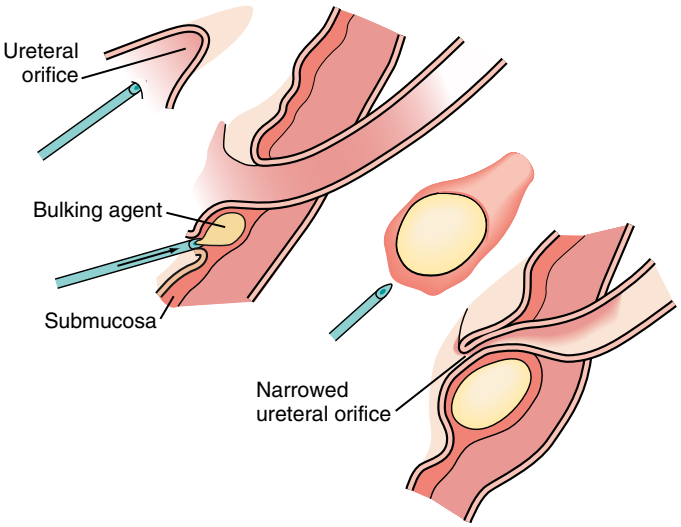

Fig. 576.10 Endoscopic correction of VUR. Through a cystoscope, a needle is inserted into the submucosal plane deep to the ureteral orifice, and a bulking agent is injected, creating a flap-valve to prevent VUR. *(Adapted from Ortenberg J. Endoscopic treatment of vesicoureteral reflux in children. Urol Clin North Am. 1998;25:151–156.)*

Prophylaxis is recommended by the American Urologic Association (AUA) in children at greatest risk for VUR-related renal injury (i.e., those <1 year of age). In addition, evaluation for bladder and bowel dysfunction is considered a standard part of initial and ongoing patient evaluation in children with VUR. Because children with BBD and VUR are much more likely to have recurrent UTIs and renal scarring, prophylaxis is recommended for these children. In children with VUR who are being managed by surveillance, if a febrile UTI occurs, prophylaxis is recommended. The decision whether to recommend observation, medical therapy, or surgery is based on the risk of VUR to the patient, the likelihood of spontaneous resolution, and the parents' and patient's preferences; the family should understand the risks and benefits of each treatment approach.

Another aspect of VUR management pertains to screening. VUR is known to be a familial disorder with autosomal dominant transmission with variable penetrance. The advantage of early VUR detection is to implement treatment before a potentially damaging episode of clinical pyelonephritis. In siblings of an index patient with VUR, optional management includes screening of asymptomatic siblings or offspring with a renal ultrasound or VCUG. The AUA recommends that a VCUG should be obtained if a screening ultrasound demonstrated a renal abnormality or if the sibling had a UTI.

The AUA also determined that female newborns with renal pelvic dilation were more likely than male newborns to have VUR. The AUA recommends that a VCUG be performed in neonates with grade III-IV *antenatal* hydronephrosis (moderate to severe pelvicalyceal dilation), hydroureter, or an abnormal bladder. In children with less severe renal pelvic dilation, an observational approach without screening for VUR, with prompt treatment of any UTI, is appropriate. However, the AUA also indicated that obtaining a VCUG is considered an appropriate option for neonates with lesser grades of hydronephrosis.

Chapter 577

Obstruction of the Urinary Tract

Heather N. Di Carlo and Chad B. Crigger

Most childhood obstructive lesions are congenital, although urinary tract obstruction can be caused by trauma, neoplasia, calculi, inflammatory processes, or surgical procedures. Obstructive lesions occur at any level from the urethral meatus to the calyceal infundibula (Table 577.1). The pathophysiologic effects of obstruction depend on its level, the extent of involvement, the child's age at onset, and whether it is acute or chronic.

ETIOLOGY

Severe ureteral obstruction early in fetal life results in renal dysplasia, ranging from multicystic kidney, which is associated with ureteral or ureteropelvic junction (UPJ) atresia (see Fig. 574.3), to various degrees of histologic renal cortical dysplasia that are seen with less severe obstruction. **Chronic ureteral obstruction** in late fetal life or after birth results in dilation of the ureter, renal pelvis, and calyces with alterations of renal parenchyma ranging from minimal tubular changes to dilation of Bowman's space, glomerular fibrosis, and interstitial fibrosis. After birth, infection can complicate obstruction and worsen renal damage.

Prenatal screening with ultrasonography (US) may detect **antenatal hydronephrosis** (ANH), which is graded by the trimester and the anterior-posterior diameter of the renal pelvis (Table 577.2); most are mild. Table 577.3 notes the eventual etiology. Risk stratification for prenatal (Fig. 577.1) and postnatal (Fig. 577.2) urinary tract dilation (UTD) helps plan for further evaluation and treatment.

CLINICAL MANIFESTATIONS

Obstruction of the urinary tract generally causes **hydronephrosis,** which typically is asymptomatic in its early phases. An obstructed kidney secondary to a **ureteropelvic junction (UPJ) obstruction** or **ureterovesical junction obstruction** can manifest as a unilateral mass or cause upper abdominal or flank pain on the affected side. Pyelonephritis can occur because of urinary stasis. An upper urinary tract stone can occur, causing abdominal and flank pain and hematuria. With bladder outlet obstruction, the urinary stream may be weak; urinary tract infection (UTI; see Chapter 575) is common. Many of these lesions are identified by antenatal US; an abnormality involving the genitourinary tract is suspected in as many as 1 in 50 fetuses (see Table 577.3).

Obstructive renal insufficiency can manifest itself by failure to thrive, vomiting, diarrhea, or other nonspecific signs and symptoms. In older children, **infravesical obstruction** can be associated with overflow urinary incontinence or a poor urine stream. **Acute ureteral obstruction** causes flank or abdominal pain; there may be nausea and vomiting. Chronic ureteral obstruction can be silent or can cause vague abdominal or typical flank pain with increased fluid intake (such as in Dietl's crisis).

DIAGNOSIS

Urinary tract obstruction may be diagnosed prenatally by US, which typically shows hydronephrosis and occasionally a distended bladder. More complete evaluation, including imaging studies, should be undertaken in these children in the neonatal period.

A multidisciplinary consensus group has standardized the fetal evaluation and early postnatal management of babies with ANH. The US parameters include the anterior-posterior renal pelvic diameter (APRPD), **calyceal dilation,** whether the ANH involves the major and/or minor calyces, the parenchymal thickness and appearance, whether the ureter is normal or abnormal, and whether the bladder is normal or abnormal. Normal values for UTD are based on the APRPD:

Antenatal	16-27 weeks	<4 mm
	≥28 weeks	<7 mm
Postnatal	(>48 hours)	<10 mm

Assuming there is no calyceal dilation, the kidneys have a normal appearance, and the ureter and bladder are normal, the study is considered normal.

The consensus group then categorized ANH into antenatal and postnatal risk groups. For antenatal ANH, there are two risk groups: low and high (see Fig. 577.1). For postnatal ANH, there are three risk groups: low,

Moderate	7–10 mm	10–15 mm
Severe	>10 mm	>15 mm

From Nguyen HT, Herndon CDA, Cooper C, et al. The Society for Fetal Urology consensus statement on the evaluation and management of antenatal hydronephrosis. *J Pediatr Urol.* 2010;6:212–231. Table 2.

Table 577.3 Etiology of Antenatal Hydronephrosis

ETIOLOGY	INCIDENCE
Transient hydronephrosis	41–88%
Ureteropelvic junction obstruction	10–30%
Vesicoureteral reflux	10–20%
Ureterovesical junction obstruction/ megaureters	5–10%
Multicystic dysplastic kidney	4–6%
Posterior urethral valve/urethral atresia	1–2%
Ureterocele/ectopic ureter/duplex system	5–7%
Others: prune-belly syndrome, cystic kidney disease, congenital ureteric strictures, megalourethra	Uncommon

From Nguyen HT, Herndon CDA, Cooper C, et al. The Society for Fetal Urology consensus statement on the evaluation and management of antenatal hydronephrosis. *J Pediatr Urol.* 2010;6:212–231. Table 5.

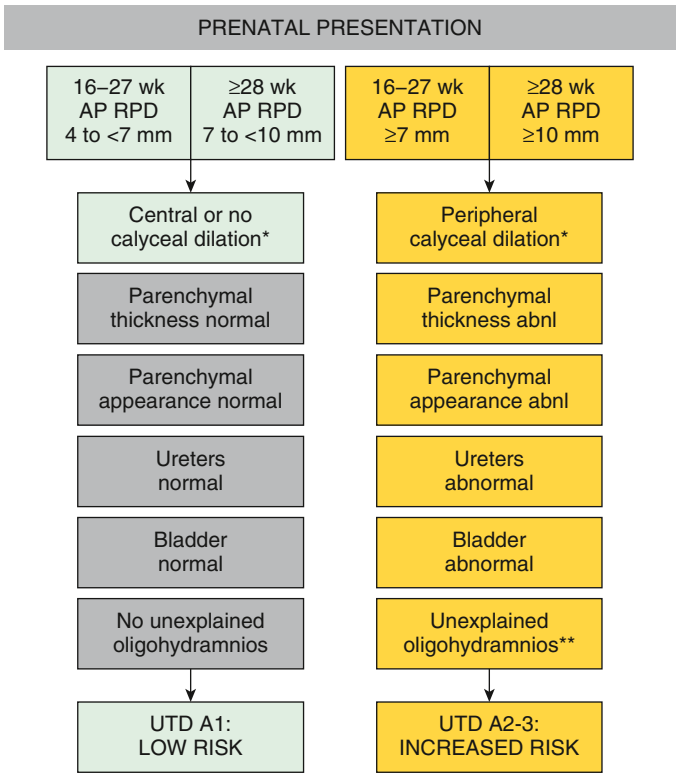
intermediate, and high (see Fig. 577.2). The panel recommended that all seven urinary tract parameters be described in a written report.

For antenatal presentation, if the APRPD is 4-7 mm at 16-27 weeks or 7-10 mm at ≥28 weeks and there is central or no calyceal dilation, the fetus is categorized as having **UTD A1**, **Low Risk**. In follow-up for UTD A1, the panel suggested one additional antenatal US at ≥32 weeks, and after birth, a renal US at >48 hours to 1 month of age and a second renal US 6 months later. Genetic screening is not indicated unless there are associated congenital malformations.

If the APRPD is ≥7 mm at 16-27 weeks or ≥10 mm at ≥28 weeks, with any peripheral calyceal dilation or any other upper urinary tract abnormality, the fetus is classified as having **UTD A2-3,** or **Increased Risk**. The assigned risk is based on the most concerning feature. For UTD A2-3, the panel recommends a follow-up US in 4-6 weeks, although with suspected **posterior urethral valves** (PUVs) or severe bilateral hydronephrosis, more frequent follow-up was recommended until delivery. Following delivery, a renal US after 48 hours but before 1 month is suggested, again with more immediate evaluation if PUV is suspected or there is significant bilateral hydronephrosis. In addition, specialist consultation with pediatric urology or nephrology is recommended.

For postnatal presentation, at >48 hours an APRPD <10 mm is **Normal.** If the APRPD is 10-15 mm and there is central calyceal dilation, but all other parameters are normal, the infant is classified as having **UTD P1, Low Risk**. Society of Fetal Urology (SFU) hydronephrosis grades 1 and 2 correspond to UTD P1. The panel recommends a follow-up renal US in 1-6 months. *A voiding cystourethrogram (VCUG) and antibiotic prophylaxis are optional and at the discretion of the clinician. A renal scan is not recommended.*

If the postnatal APRPD is ≥15 mm and there is peripheral calyceal dilation and/or abnormal ureters, the infant is classified as having **UTD P2, Intermediate Risk**. SFU hydronephrosis grade 3 corresponds to UTD P2. The panel recommends a follow-up renal US in 1-3 months.



*Central and peripheral calyceal dilation may be difficult to evaluate early in gestation

**Oligohydramnios is suspected to result from a GU cause

Fig. 577.1 Urinary tract dilation (UTD) risk stratification: prenatal presentation for UTD A1 (low risk) and UTD A2-3 (increased risk). Note: Classification is based on the presence of the most concerning feature. For example, a fetus with an APRPD within the UTD A1 range but with peripheral calyceal dilation would be classified as UTD A2-3. GU, Genitourinary. *(From Nguyen HT, Benson CB, Bromley B, et al. Multidisciplinary consensus on the classification of prenatal and postnatal urinary tract dilation [UTD classification system]. J Pediatr Urol. 2014;10:982–998. Fig. 3.)*

VCUG, antibiotic prophylaxis, and a functional renal scan are optional and at the discretion of the clinician.

If the APRPD is ≥15 mm and there is peripheral calyceal dilation, abnormal parenchymal thickness, abnormal parenchymal appearance, abnormal ureters, and/or abnormal bladder, the infant is classified as having **UTD P3, High Risk**. SFU hydronephrosis grade 4 corresponds to UTD P3. The panel recommends a follow-up renal US in 1 month. *A VCUG and antibiotic prophylaxis are recommended. A functional renal scan is optional and at the discretion of the clinician (but is virtually always recommended).*

PHYSICAL FINDINGS

Urinary tract obstruction is often silent. In the newborn infant, a palpable abdominal mass most commonly is a hydronephrotic or multicystic dysplastic kidney. With PUVs, which constitute an infravesical obstructive lesion in males, a walnut-sized mass representing the bladder is palpable just above the pubic symphysis. A **patent draining urachus** also can suggest urethral obstruction. **Urinary ascites** in the newborn usually is caused by renal or bladder urinary extravasation secondary to PUVs. Infection and sepsis may be the first indications of an obstructive lesion of the urinary tract. The combination of infection and obstruction poses a serious threat to infants and children and generally requires parenteral administration of antibiotics and drainage of the obstructed kidney. Renal US should be performed in all children during the acute stage of an initial febrile UTI.

IMAGING STUDIES

Renal Ultrasound

Hydronephrosis is the most common characteristic of obstruction (Fig. 577.3). Upper UTD is not diagnostic of obstruction and often

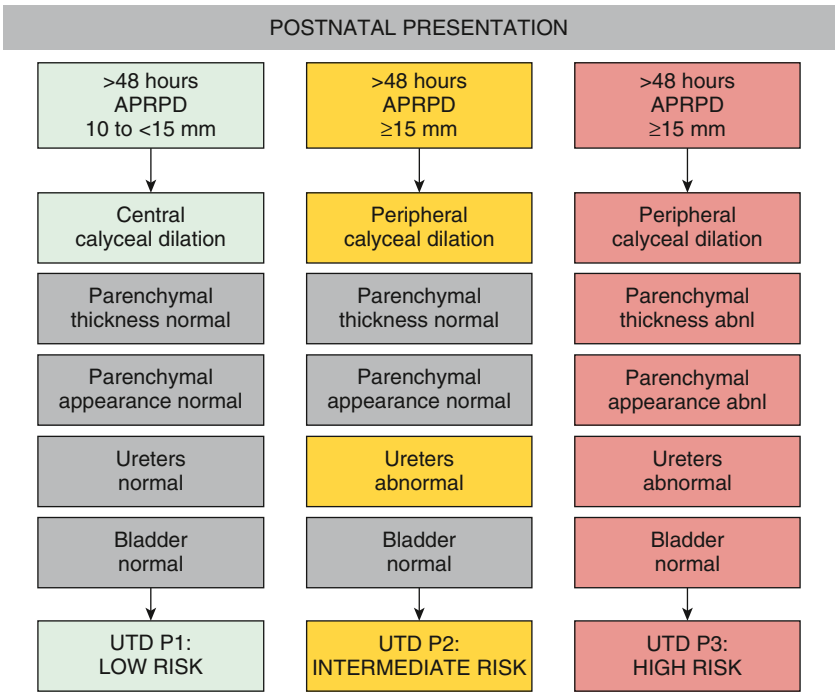


Fig. 577.2 Urinary tract dilation (UTD) risk stratification: postnatal presentation for UTD P1 (low risk), UTD P2 (intermediate risk), and UTD P3 (high risk). Note: Stratification is based on the most concerning ultrasound finding. For example, if the APRPD is in the UTD P1 range but there is peripheral calyceal dilation, the classification is UTD P2. Similarly, the presence of parenchymal abnormalities (abnl) denotes a UTD P3 classification, regardless of APRPD measurement. *(From Nguyen HT, Benson CB, Bromley B, et al. Multidisciplinary consensus on the classification of prenatal and postnatal urinary tract dilation [UTD classification system]. J Pediatr Urol. 2014;10:982–998. Fig. 6.)*

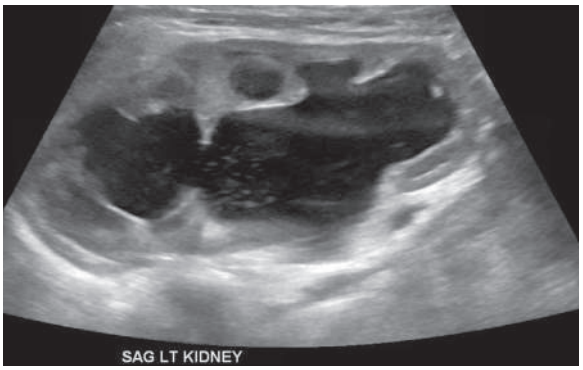

Fig. 577.3 US image of the left kidney with marked pelvic and calyceal dilation (grade 4 hydronephrosis) in a newborn with ureteropelvic junction obstruction.

persists after surgical correction of a significant obstructive lesion. Dilation can result from vesicoureteral reflux (VUR), or it may be a manifestation of abnormal development of the urinary tract, even when there is no obstruction. Renal length, degree of caliectasis and parenchymal thickness, and presence or absence of ureteral dilation should be assessed. In addition to the UTD system, most pediatric urologists also grade the severity of hydronephrosis from 1-4 using the SFU grading scale (Table 577.4). The clinician should ascertain that the contralateral kidney is normal, and the bladder should be imaged to see whether the bladder wall is thickened, the lower ureter is dilated, and bladder emptying is complete. In acute or intermittent obstruction, the dilation of the collecting system may be minimal, and US may be misleading.

Voiding Cystourethrogram

In neonates and infants with congenital grade 3 or 4 hydronephrosis and in any child with ureteral dilation, a **contrast VCUG** should be obtained, because the dilation is secondary to VUR in 15% of cases.

Table 577.4 Society for Fetal Urology Grading System for Hydronephrosis

GRADE OF HYDRONEPHROSIS	RENAL IMAGE	
	CENTRAL RENAL COMPLEX	RENAL PARENCHYMAL THICKNESS
0	Intact	Normal
1	Slight splitting	Normal
2	Evident splitting, complex confined within renal border	Normal
3	Wide splitting, pelvis dilated outside renal border, calyces uniformly dilated	Normal
4	Further dilation of pelvis and calyces (calyces may appear convex)	Thin

After Maizels M, Mitchell B, Kass E, et al. Outcome of nonspecific hydronephrosis in the infant: a report from the registry of the Society for Fetal Urology. *J Urol.* 1994;152:2324–2327.

In males, the VCUG also is performed to rule out urethral obstruction, particularly in cases of suspected PUVs. In older children, the urinary flow rate can be measured noninvasively with a urinary flowmeter. Decreased flow with a normal bladder contraction suggests infravesical obstruction (e.g., PUVs, urethral stricture). When the urethra cannot be catheterized to obtain a VCUG, the clinician should suspect a urethral stricture or an obstructive urethral lesion. Retrograde urethrography with contrast medium injected into the urethral meatus helps delineate the anatomy of the urethral obstruction.

Radioisotope Studies

Renal scintigraphy is used to assess renal anatomy and function. The two most commonly used radiopharmaceuticals are mercaptoacetyl triglycine (MAG-3) and technetium-99m–labeled dimercaptosuccinic acid (DMSA). MAG-3, which is excreted by renal tubular secretion, is used to assess differential renal function, and when furosemide is administered, drainage also can be measured. DMSA is a renal cortical imaging agent and is used to assess differential renal function and to demonstrate whether renal scarring is present. It is used infrequently in children with obstructive uropathy.

In a MAG-3 diuretic renogram, a small dose of technetium-labeled MAG-3 is injected intravenously (Figs. 577.4 and 577.5). During the first 2-3 minutes, renal parenchymal uptake is analyzed and compared, allowing computation of differential renal function.

Subsequently, excretion is evaluated. After 20 minutes, furosemide 1 mg/kg is injected intravenously, and the rapidity and pattern of drainage from the kidneys to the bladder are analyzed. If no obstruction is present, half of the radionuclide should be cleared from the renal pelvis within 10-15 minutes, termed the half-time ($t_{1/2}$). If there is significant upper tract obstruction, the $t_{1/2}$ usually is longer than 20 minutes. A $t_{1/2}$ of 15-20 minutes is indeterminate. An elevated $t_{1/2}$ is suggestive but not diagnostic of obstruction. The images generated usually provide an accurate assessment of the site of obstruction. Numerous variables affect the outcome of the diuretic renogram. Newborn kidneys are functionally immature, and, in the first month of life, normal kidneys might not demonstrate normal drainage after diuretic administration. Patient dehydration prolongs parenchymal transit and can blunt the diuretic response. As such, renal scintigraphy is usually performed after 8 weeks of life in an appropriately hydrated infant. Giving an insufficient dose of furosemide can result in slow drainage. If VUR is present, continuous bladder drainage is mandatory to prevent the radionuclide from refluxing from the bladder into the dilated upper tract, which would prolong the washout phase.

Magnetic Resonance Urography

Magnetic resonance (MR) urography is also used to evaluate suspected upper urinary tract pathology. The child is hydrated and given intravenous furosemide. Gadolinium-diethylene tetrapentaacetic acid is injected, and routine T1 weighted and fat-suppressed fast spin-echo T2 weighted imaging is performed through the kidneys, ureters, and bladder. This study provides superb images of the pathology, and methodology permits assessment of differential renal function and drainage (Fig. 577.6). There is no radiation exposure; however, young children need sedation or anesthesia. It is used primarily when renal US and radionuclide imaging fail to delineate complex pathology.

Computed Tomography

In children with a suspected ureteral calculus (see Chapter 584), noncontrast, low-dose spiral CT of the abdomen and pelvis is a standard method of demonstrating whether a calculus is present, its location, and whether there is significant proximal hydronephrosis. This study may be ordered when a renal/bladder US is inconclusive. The disadvantage of CT is the significant radiation exposure, and it should be used only when the results will direct management decisions.

Ancillary Studies

In unusual cases, an **antegrade pyelogram** (insertion of a percutaneous nephrostomy tube and injection of contrast agent) can be performed to assess the anatomy of the upper urinary tract. This procedure usually requires general anesthesia. In addition, an **antegrade pressure-perfusion flow study** (Whitaker test) may be performed, in which fluid is infused at a measured rate, usually 10 mL/min. The pressures

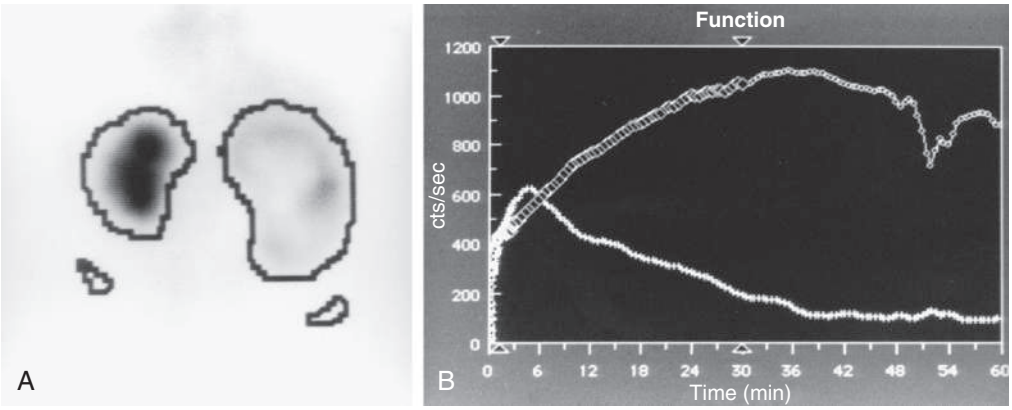

Fig. 577.4 MAG-3 diuretic renogram of a 6-wk-old infant with severe right hydronephrosis. The right kidney is on the *right* side of the image. A, Differential renal function: left kidney 70%, right kidney 30%. B, After administration of furosemide, drainage from the left kidney was normal and drainage from the right kidney was slow, consistent with right UPJ obstruction. Pyeloplasty was performed on the right kidney.

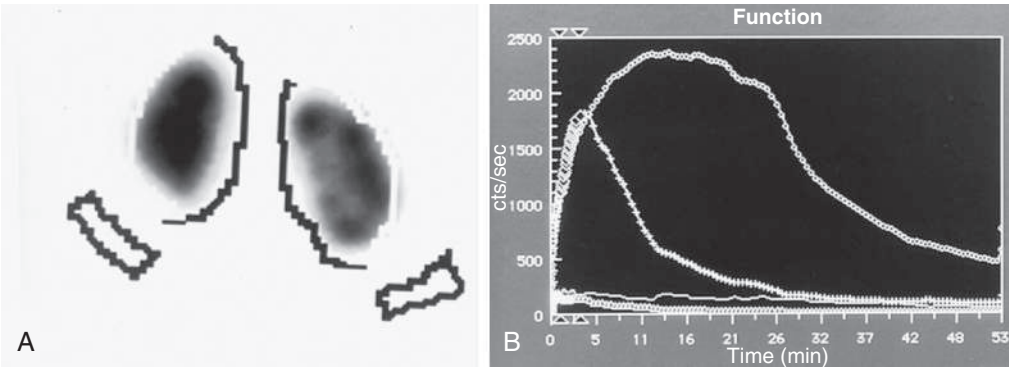

Fig. 577.5 A, MAG-3 diuretic renogram at 14 mo of age shows equal function in the two kidneys. B, Prompt drainage after the administration of furosemide.

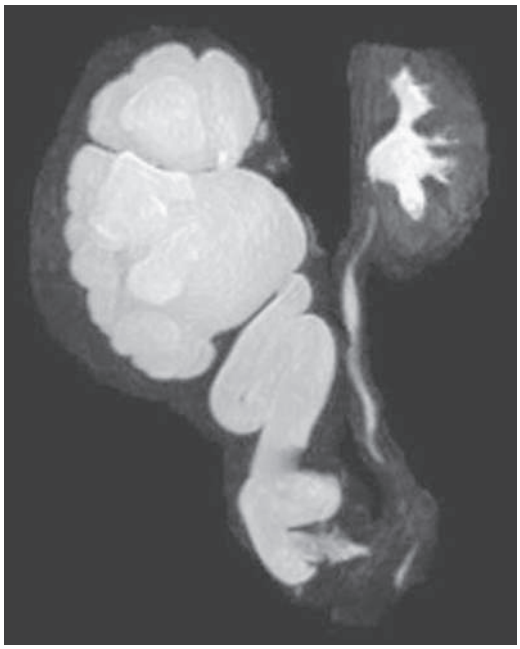

Fig. 577.6 MR urogram in boy with distal ureterovesical obstruction.

in the renal pelvis and the bladder are monitored during this infusion, and pressure differences exceeding 20 cm H_2O suggest obstruction. In other cases, cystoscopy with retrograde pyelography provides excellent images of the upper urinary tract (Fig. 577.7).

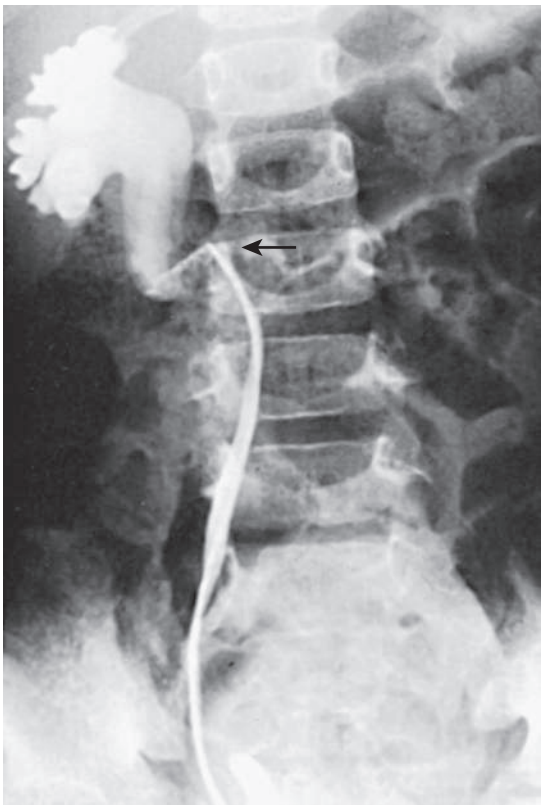

Fig. 577.7 Retrograde pyelogram showing medial deviation of a dilated upper ureter to the level of the third lumbar vertebra *(arrow)*, characteristic of a retrocaval ureter.

SPECIFIC TYPES OF URINARY TRACT OBSTRUCTION AND THEIR TREATMENT

Hydrocalycosis

Hydrocalycosis refers to a localized dilation of the calyx caused by obstruction of its infundibulum, termed **infundibular stenosis.** This condition can be developmental in origin or secondary to inflammatory processes, such as UTI. It usually is discovered during evaluation for pain or UTI. The diagnosis of infundibular stenosis is usually established by sonograph and CT scan or MR urography.

Ureteropelvic Junction Obstruction

UPJ obstruction is the most common obstructive lesion in childhood and usually is caused by intrinsic stenosis (see Figs. 577.3-577.5). An accessory artery to the lower pole of the kidney can also cause extrinsic obstruction. The typical appearance on US is grade 3 or 4 hydronephrosis without a dilated ureter and a clear transition point. UPJ obstruction may present on antenatal sonography revealing fetal hydronephrosis; as a palpable renal mass in a newborn or infant; as abdominal, flank, or back pain; as a febrile UTI; or as hematuria after minimal trauma. Approximately 60% of cases occur on the left side; the male:female ratio is 2:1. *UPJ obstruction is bilateral in only 10% of cases*. In kidneys with UPJ obstruction, renal function may be significantly impaired from pressure atrophy, but approximately half of affected kidneys have relatively normal glomerular function. The anomaly is corrected by performing a **pyeloplasty**, in which the stenotic segment is excised, and the normal ureter and renal pelvis are reattached. Success rates are 91–98%. Pyeloplasty can be performed using laparoscopic techniques, often robotic assisted using the da Vinci robot.

Lesser degrees of UPJ narrowing might cause mild hydronephrosis, which usually is nonobstructive, and typically these kidneys function normally. The spectrum of UPJ abnormalities has been referred to as **anomalous UPJ**. Another cause of mild hydronephrosis is fetal folds of the upper ureter, which also are nonobstructive.

The diagnosis can be difficult to establish in an asymptomatic infant in whom dilation of the renal pelvis is found incidentally in a prenatal US. After birth, the sonographic study is repeated to confirm the prenatal finding. A VCUG is necessary because 10–15% of patients have ipsilateral vesicoureteral reflux. Because neonatal oliguria can cause temporary decompression of a dilated renal pelvis, it is ideal to perform the first postnatal US after the third day of life. Delaying the US may be impractical. *If no dilation is found on the initial US, a repeat study should be performed at 1 month of age*. If the kidney shows grade 1 or 2 hydronephrosis and the renal parenchyma appears normal, a period of observation usually is appropriate, with sequential renal US studies to monitor the severity of hydronephrosis, and the hydronephrosis usually disappears. Antibiotic prophylaxis is *not* indicated for children with mild hydronephrosis. If the hydronephrosis is grade 3 or 4, spontaneous resolution is less likely, and obstruction is more likely to be present, particularly if the renal pelvic diameter is 3 cm. A diuretic renogram with MAG-3 is performed at 4-6 weeks of age. If there is poor upper tract drainage or the differential renal function is poor, pyeloplasty is recommended. After pyeloplasty the differential renal function often improves, and improved drainage with furosemide stimulation is expected.

If the differential function on renography is normal and drainage is satisfactory, the infant can be followed with serial US studies, even with grade 4 hydronephrosis. If the hydronephrosis remains severe with no improvement, a repeat diuretic renogram after 6-12 months can help in the decision between continued observation and surgical repair. Prompt surgical repair is indicated in infants with an abdominal mass, bilateral severe hydronephrosis, a solitary kidney, or diminished function in the involved kidney. In unusual cases in which the differential renal function is <10% but the kidney has some function, insertion of a percutaneous nephrostomy tube allows drainage of the hydronephrotic kidney for a few weeks to allow reassessment of renal function. In older children who present with symptoms, the diagnosis of UPJ obstruction usually is established by US and diuretic renography.

The differential diagnosis includes megacalycosis, a congenital nonobstructive dilation of the calyces without pelvic or ureteric dilation; VUR with marked dilation and kinking of the ureter; midureteral or

distal ureteral obstruction when the ureter is not well visualized on the urogram; and retrocaval ureter.

Midureteral Obstruction

Congenital ureteral stenosis or a ureteral valve in the midureter is rare. It is corrected by excision of the strictured segment and reanastomosis of the normal upper and lower ureteral segments. A **retrocaval ureter** is an anomaly in which the upper right ureter travels posterior to the inferior vena cava. In this anomaly, the vena cava can cause extrinsic compression and obstruction. A retrograde pyelogram or MR urogram shows the right ureter to be medially deviated at the level of the third lumbar vertebra (see Fig. 577.7). Surgical treatment consists of transection of the upper ureter, moving it anterior to the vena cava, and reanastomosing the upper and lower segments. Repair is necessary only when obstruction is present. Retroperitoneal tumors, fibrosis caused by surgical procedures, inflammatory processes (as in chronic granulomatous disease), and radiation therapy can cause acquired midureteral obstruction.

Ectopic Ureter

A ureter that drains outside the bladder is referred to as an ectopic ureter. This anomaly is three times as common in females as in males and usually is detected prenatally. The ectopic ureter typically drains the upper pole of a duplex collecting system (two ureters).

In females, approximately 35% of these ureters enter the urethra at the bladder neck; 35% enter the urethrovaginal septum; 25% enter the vagina; and a few drain into the cervix, uterus, Gartner duct, or a urethral diverticulum. Often the terminal aspect of the ureter is narrowed, causing **hydroureteronephrosis**. Apart from the ectopic ureter entering the bladder neck, in females an ectopic ureter causes continuous urinary incontinence from the affected renal moiety. UTI is common because of urinary stasis.

In males, ectopic ureters enter the posterior urethra (above the external sphincter) in 47%, the prostatic utricle in 10%, the seminal vesicle in 33%, the ejaculatory duct in 5%, and the vas deferens in 5%. Consequently, in males, an ectopic ureter does not cause incontinence, and most patients present with a UTI or epididymitis.

Evaluation includes a renal US, VCUG, and renal scan, which demonstrates whether the affected segment has significant function. The US shows the affected hydronephrotic kidney or dilated upper pole and ureter down to the bladder (Fig. 577.8). If the ectopic ureter drains into the bladder neck (female), a VCUG usually shows reflux into the ureter. Otherwise, there is no reflux into the ectopic ureter, but there may be reflux into the ipsilateral lower pole ureter or contralateral collecting system.

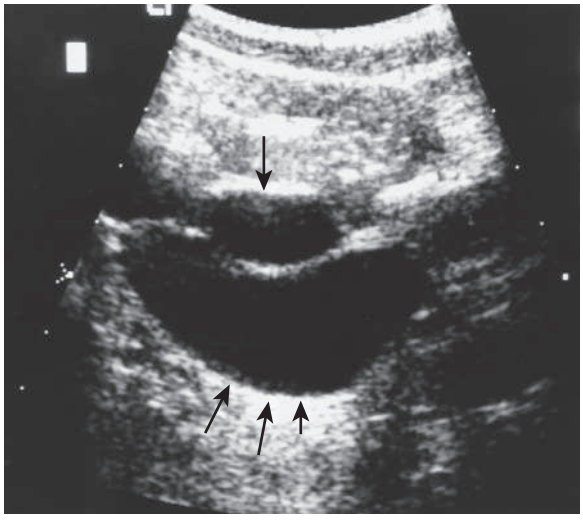

Fig. 577.8 US image of the right dilated ureter *(bottom arrows)* extending behind and caudal to a nearly empty bladder *(top arrow)* in a female with urinary incontinence and ectopic ureter draining into the vagina.

Treatment depends on the status of the renal unit drained by the ectopic ureter. If there is satisfactory function, ureteral reimplantation into the bladder or **ureteroureterostomy** (anastomosing the ectopic upper pole ureter into the normally inserting lower pole ureter) is indicated. If function is poor, partial or total nephrectomy is indicated. In many centers this procedure is done laparoscopically, often with robotic assistance.

Ureterocele

A ureterocele is a cystic dilation of the terminal ureter and is obstructive because of a pinpoint ureteral orifice. Ureteroceles are much more common in females than in males. Affected children usually are discovered by prenatal US, but some present with a febrile UTI. Ureteroceles may be ectopic, in which case the cystic swelling extends through the bladder neck into the urethra, or orthotopic, in which case the ureterocele is entirely within the bladder. Both orthotopic and ectopic ureteroceles can be bilateral.

In females, ureteroceles nearly always are associated with ureteral duplication (Fig. 577.9), whereas in 50% of affected males there is only one ureter. When associated with a duplication anomaly, the ureterocele drains the upper renal moiety, which commonly functions poorly or is dysplastic because of congenital obstruction. The lower pole ureter drains into the bladder superior and lateral to the upper pole ureter and may reflux.

An **ectopic ureterocele** extends submucosally through the bladder neck into the urethra. Rarely, large ectopic ureteroceles can cause bladder outlet obstruction and retention of urine with bilateral hydronephrosis. In females, the ureterocele can prolapse from the urethral meatus. US is effective in demonstrating the ureterocele and whether the associated obstructed system is duplicated or single. VCUG usually shows a filling defect in the bladder, sometimes large, corresponding to the ureterocele, and it often shows reflux into the adjacent lower pole collecting system with typical findings of a "drooping lily" appearance to the kidney. Nuclear renal scintigraphy is most accurate in demonstrating whether the affected renal moiety has significant function.

Treatment of ectopic ureteroceles depends on whether the upper pole functions on renal scan and whether there is reflux into the lower pole ureter. If there is nonfunction of the upper pole of the kidney and there is no reflux, treatment usually involves laparoscopic, robotic, or open excision of the obstructed upper pole and most of the associated ureter. If there is function in the upper pole or significant reflux into the lower pole ureter, or if the patient is septic from infection of the hydronephrotic kidney, then transurethral incision with cautery is appropriate initial therapy to decompress the ureterocele. Reflux into the incised ureterocele is common, and subsequent excision of the ureterocele and ureteral reimplantation usually is necessary. An alternative method is to perform an upper-to-lower ureteroureterostomy, allowing the obstructed upper pole ureter to drain through the normal lower ureter; this procedure often is performed with minimally invasive laparoscopic (robotic) technique or through a small incision.

Orthotopic ureteroceles are associated with duplicated or single collecting systems, and the orifice is in the expected location in the bladder (Fig. 577.10). These anomalies usually are discovered during an investigation for prenatal hydronephrosis or a UTI. US is sensitive for detecting the ureterocele in the bladder and hydroureteronephrosis. Transurethral incision of the ureterocele effectively relieves the obstruction, but it can result in VUR, necessitating ureteral reimplantation later. Some prefer open excision of the ureterocele and reimplantation as the initial form of treatment. Small, simple ureteroceles discovered incidentally without upper tract dilation generally do not require treatment. Rarely, a large ureterocele occupying much of the bladder lumen can result in bilateral hydronephrosis by obstructing drainage of the contralateral ureteral orifice.

Megaureter

Table 577.5 presents a classification of megaureters (dilated ureter). Numerous disorders can cause ureteral dilation, and many are nonobstructive.

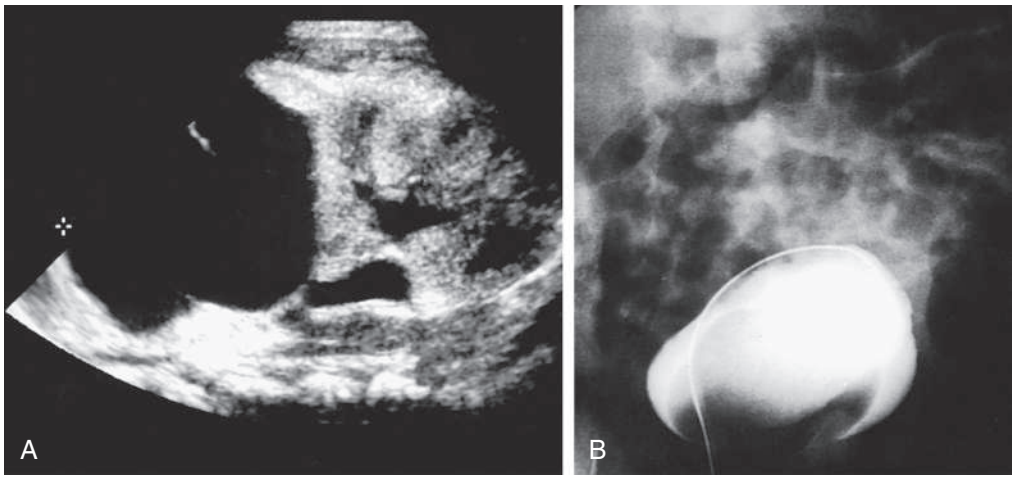

Fig. 577.9 A, Infant with ectopic ureterocele. US of the left kidney shows massive dilation of the upper pole and a normal lower pole. B, VCUG shows large ureterocele, draining the left upper pole, in the bladder. No reflux is present.

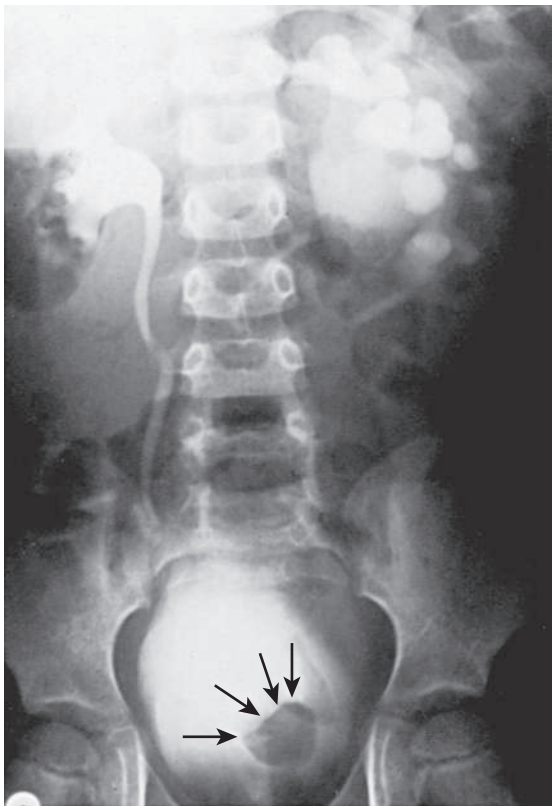

Fig. 577.10 Simple intravesical ureterocele. The excretory urogram shows left hydronephrosis and a round filling defect *(arrows)* on the left side of the bladder corresponding to a simple ureterocele causing left ureteral obstruction. This lesion was treated by transurethral incision and drainage of the ureterocele.

Megaureters usually are discovered during antenatal US or during workup for postnatal UTI, hematuria, or abdominal pain. A careful history, physical examination, and VCUG identify causes of secondary megaureters and refluxing megaureters, as well as the prune-belly syndrome. Primary obstructed megaureters and nonobstructed megaureters represent varying degrees of severity of the same anomaly.

The **primary obstructed nonrefluxing megaureter** results from abnormal development of the distal ureter, with collagenous tissue replacing the muscle layer. Normal ureteral peristalsis is disrupted, and the proximal ureter widens. In most cases there is not a true stricture. On intravenous pyelogram or an MR urogram, the distal ureter is more dilated in its distal segment and tapers abruptly at or above the junction of the bladder (Fig. 577.11). The lesion may be unilateral or bilateral. Significant hydroureteronephrosis suggests obstruction. Megaureter predisposes to UTI, urinary stones, hematuria, and flank pain because of urinary stasis. In most cases, diuretic renography and sequential sonographic studies can reliably differentiate obstructed from nonobstructed megaureters. In most nonobstructed megaureters, the hydroureteronephrosis diminishes gradually (Fig. 577.12). Truly obstructed megaureters require surgical treatment, with excision of the narrowed segment, ureteral tapering, and reimplantation of the ureter. The results of surgical reconstruction usually are good, but the prognosis depends on preexisting renal function and whether complications develop.

If differential renal function is normal (>45%) and the child is asymptomatic, it is safe to manage the patient with observation with serial US and periodic diuretic renography to monitor renal function and drainage. In children with grade 4 hydroureteronephrosis, prophylactic antimicrobial therapy should be prescribed, as these children are prone to upper UTI. If renal function deteriorates, upper urinary tract drainage slows, or UTI occurs, ureteral reimplantation is recommended. Approximately 25% of children with a nonrefluxing megaureter undergo ureteral reimplantation.

Prune-Belly Syndrome

Prune-belly syndrome, also called **triad syndrome** (lax abdominal wall muscles, urinary tract distention, intrabdominal testis) or **Eagle-Barrett syndrome,** occurs in approximately 1 in 40,000 births; 95% of affected children are male. The characteristic association occurs in a wide spectrum with deficient (hypoplastic) abdominal muscles, undescended testes, and urinary tract abnormalities (Fig. 577.13 and Table 577.6). Oligohydramnios and pulmonary hypoplasia are common complications in the perinatal period. Urinary tract abnormalities include massive (usually unobstructed) dilation of the ureters and upper tracts and a very large hypotonic bladder, with a patent urachus or a urachal diverticulum. Most patients have VUR. The prostatic urethra is usually dilated, and the prostate is hypoplastic. The anterior urethra may be dilated, resulting in a **megalourethra**. In severe cases, there is urethral stenosis or atresia. The kidneys show various degrees of dysplasia, and the testes are typically intraabdominal. Malrotation of the bowel is often present. Cardiac abnormalities occur in 10% of cases; >50% have abnormalities of the musculoskeletal system, including limb abnormalities and scoliosis. In the females, rare anomalies of the urethra, uterus, and vagina usually are present. Pathogenic variants in *FLNA* and possibly *MYOCD* or *HNF1β* have been reported; the disorder is usually sporadic, although rare instances of familial cases occur.

Many neonates with prune-belly syndrome have difficulty with effective bladder emptying because the bladder musculature is poorly

Table 577.5 Classification of Megaureter

REFLUXING		OBSTRUCTED		NONREFLUXING AND NONOBSTRUCTED	
PRIMARY	**SECONDARY**	**PRIMARY**	**SECONDARY**	**PRIMARY**	**SECONDARY**
Primary reflux	Neuropathic bladder	Intrinsic (primary obstructed megaureter)	Neuropathic bladder	Nonrefluxing, nonobstructive	Diabetes insipidus
Megacystic-megaureter syndrome	Hinman syndrome	Ureteral valve	Hinman syndrome		Infection
Ectopic ureter	Posterior urethral valves	Ectopic ureter	Posterior urethral valves		Persistent after relief of obstruction
Prune-belly syndrome	Bladder diverticulum Postoperative	Ectopic ureterocele	Ureteral calculus Extrinsic Postoperative		

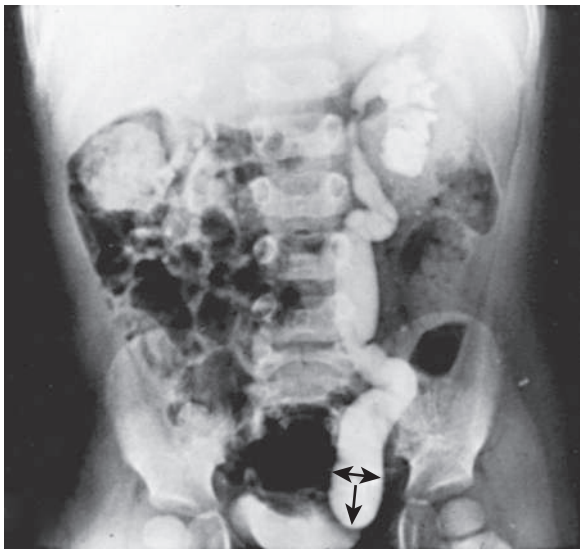

Fig. 577.11 Obstructed nonrefluxing megaureter. Excretory urogram in a female with a history of a febrile UTI. The right side is normal. The left side reveals hydroureteronephrosis with predominant dilation of the distal ureter. Note the characteristic appearance of the distal ureter. There was no vesicoureteral reflux. The diagnosis of obstruction was confirmed by diuretic renography.

developed, and the urethra may be narrowed. When no obstruction is present, the goal of treatment is the prevention of UTI with antibiotic prophylaxis. When obstruction of the ureters or urethra is demonstrated, temporary drainage procedures, such as a vesicostomy, can help to preserve renal function until the child is old enough for surgical reconstruction. Some children with prune-belly syndrome have been found to have classic or atypical PUVs. UTIs occur often and should be treated promptly. Correction of the undescended testes by orchidopexy can be difficult in these children because the testes are located high in the abdomen and surgery is best accomplished in the first 6 months of life. Reconstruction of the abdominal wall offers cosmetic and functional benefits.

The prognosis depends on the degree of pulmonary hypoplasia and renal dysplasia. One third of children with prune-belly syndrome are stillborn or die in the first few months of life because of pulmonary hypoplasia. As many as 30% of the long-term survivors develop end-stage renal disease from dysplasia or complications of infection or reflux and eventually require renal transplantation. Renal transplantation in these children offers good results.

Megacystis-microcolon-intestinal hypoperistalsis syndrome manifests with a dilated unobstructed bladder in the context of the more dominant gastrointestinal manifestations of intestinal pseudoobstruction (see Table 378.11 and Figs. 378.6 and 378.7). The abdominal muscles are normal, but abdominal distention is prominent. Associated pathogenic gene variants include *ACTG2* (~45%) as well as *MYH11*, *LOMD1*, *MYL9*, and *MYLK*; ~20% are unknown. Hydronephrosis is common, and most patients are female.

Bladder Neck Obstruction

Bladder neck obstruction usually is secondary to ectopic ureterocele, bladder calculi, or a tumor of the prostate (rhabdomyosarcoma). The manifestations include difficulty voiding, urinary retention, UTI, and bladder distention with overflow incontinence. Apparent bladder neck obstruction is common in cases of PUVs, but it seldom has any functional significance. Primary bladder neck obstruction is extremely rare.

Posterior Urethral Valves

The most common cause of severe obstructive uropathy in children is PUVs, affecting 1 in 8,000 males. The urethral valves are tissue leaflets fanning distally from the prostatic urethra to the external urinary sphincter. A slitlike opening usually separates the leaflets. Valves are of unclear embryologic origin and cause varying degrees of obstruction. Approximately 30% of patients experience end-stage renal disease or chronic renal insufficiency. The prostatic urethra dilates, and the bladder muscle undergoes hypertrophy. VUR occurs in 50% of patients, and distal ureteral obstruction can result from a chronically distended bladder or bladder muscle hypertrophy. Renal changes range from mild hydronephrosis to severe renal dysplasia; their severity depends on the severity of the obstruction and its time of onset during fetal development. As in other cases of obstruction or renal dysplasia, there may be oligohydramnios and pulmonary hypoplasia.

Affected males with PUVs often are discovered prenatally when maternal US reveals bilateral hydronephrosis, a distended bladder, and, if the obstruction is severe, oligohydramnios. Prenatal bladder decompression by percutaneous vesicoamniotic shunt or open fetal surgery has been reported. Experimental and clinical evidence of the possible benefits of fetal intervention is lacking, and few affected fetuses are candidates. Prenatally diagnosed PUVs, particularly when discovered in the second trimester, carry a poorer prognosis than those detected in the third trimester following a normal second-trimester fetal US. In the male neonate, PUVs are suspected when there is a palpably distended bladder and the urinary stream is weak. If the obstruction is severe and goes unrecognized during the neonatal period, infants can present later in childhood with failure to thrive because of uremia or sepsis caused by infection in the obstructed urinary tract. With lesser degrees of obstruction, children present later in life with difficulty in achieving diurnal urinary continence or with UTI. The diagnosis is established with a VCUG (Fig. 577.14) or by perineal US.

After the diagnosis is established, renal function and the anatomy of the upper urinary tract should be carefully evaluated. In the healthy neonate, a small polyethylene feeding tube (No. 5 or No. 8 French) is inserted in the bladder and left for several days. Passing the feeding tube may be difficult because the tip of the tube can coil in the prostatic

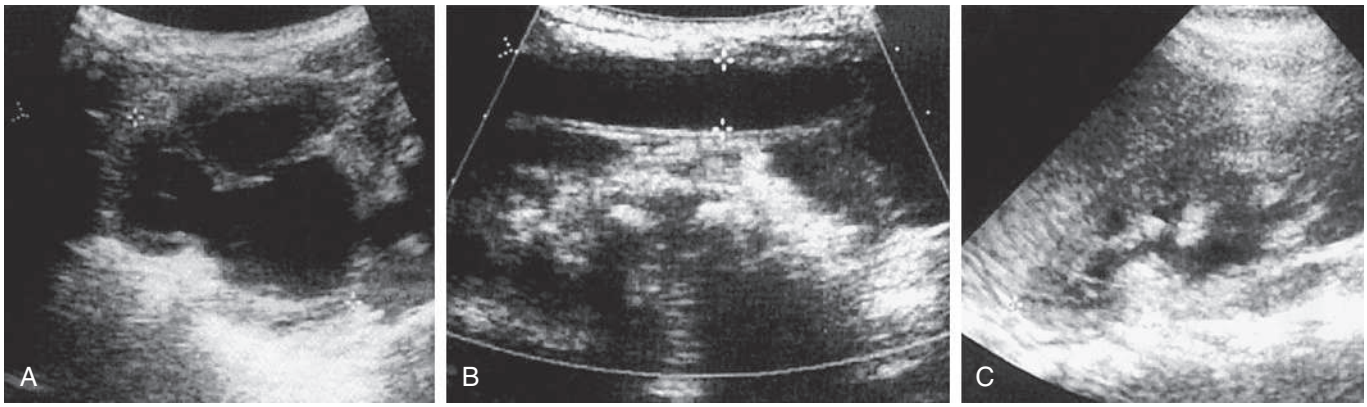

Fig. 577.12 Neonate with primary nonrefluxing megaureter. **A,** Renal US shows grade 4 hydronephrosis. **B,** Dilated ureter. urethra. A sign of this problem is that urine drains around the catheter rather than through it. A Foley (balloon) catheter *should not be used*, because the balloon can cause severe bladder spasm, which can produce severe ureteral obstruction.

If the serum creatinine level remains normal or returns to normal, treatment consists of transurethral ablation of the valve leaflets, which is performed endoscopically under general anesthesia. If the urethra is too small for transurethral ablation, temporary vesicostomy is preferred, in which the dome of the bladder is exteriorized on the lower abdominal wall. When the child is older, the valves may be ablated and the vesicostomy closed.

If the serum creatinine level remains high or increases despite bladder drainage by a small catheter, secondary ureteral obstruction, irreversible renal damage, or renal dysplasia should be suspected. In such cases, a vesicostomy should be considered. Cutaneous pyelostomy rarely affords better drainage compared with cutaneous vesicostomy, and the latter also allows continued bladder growth and gradual improvement in bladder wall compliance.

In the septic and uremic infant, lifesaving measures must include prompt correction of the electrolyte imbalance and control of the infection by appropriate antibiotics. Drainage of the upper tracts by percutaneous nephrostomy and hemodialysis may be necessary. After the patient's condition becomes stable, evaluation and treatment may be undertaken. PUVs are diagnosed in some older males because of a poor stream, diurnal incontinence, or a UTI; these males are treated by primary valve ablation.

Favorable prognostic factors include a normal prenatal US between 18 and 24 weeks of gestation, a serum creatinine level <0.8-1.0 mg/dL after bladder decompression, and visualization of the corticomedullary junction on renal sonography. In several situations, a "popoff valve" can occur during urinary tract development, which preserves the integrity of one or both kidneys. For example, 15% of males with PUVs have unilateral reflux into a nonfunctioning dysplastic kidney, termed the **VURD syndrome** (valves, unilateral reflux, dysplasia). In these males, the high bladder pressure is dissipated into the nonfunctioning kidney, allowing normal development of the contralateral kidney. In newborn males with urinary ascites, the urine leaks out from the obstructed collecting system through the renal fornices, allowing normal development of the kidneys. Unfavorable prognostic factors include the presence of oligohydramnios in utero, identification of hydronephrosis before 24 weeks of gestation, a serum creatinine level >1.0 mg/dL after bladder decompression, identification of cortical cysts in both kidneys, and persistence of diurnal incontinence beyond 5 years of age.

The prognosis in the newborn is related to the child's degree of pulmonary hypoplasia and potential for recovery of renal function. Severely affected infants often are stillborn. Of those who survive the neonatal period, approximately 30% eventually require kidney transplantation, and 15% have renal insufficiency. In some series, kidney transplantation in children with PUVs has a lower success rate than does transplantation in children with normal bladders, presumably because of the adverse influence of altered bladder function on graft function and survival.

After valve ablation, antimicrobial prophylaxis is beneficial in preventing UTI, because hydronephrosis to some degree often persists for many years. These males should be evaluated annually with a renal US, physical examination including assessment of somatic growth and blood pressure, urinalysis, and determination of serum levels of electrolytes. Many individuals have significant polyuria resulting from a concentrating defect secondary to prolonged obstructive uropathy. If these children acquire a systemic illness with vomiting and/or diarrhea, urine output cannot be used to assess their hydration status. They

can become dehydrated quickly, and there should be a low threshold for hospital admission for intravenous rehydration. Some of these patients have renal tubular acidosis, requiring oral bicarbonate therapy. If there is any significant degree of renal dysfunction, growth impairment, or hypertension, the child should be followed closely by a pediatric nephrologist. When VUR is present, expectant treatment and prophylactic doses of antibacterial drugs are advisable. If breakthrough UTI occurs, surgical correction should be undertaken.

After treatment, males with PUVs often do not achieve diurnal urinary continence as early as other males. Incontinence can result from a combination of factors, including uninhibited bladder contractions, poor bladder compliance, bladder atonia, bladder neck dyssynergia, or polyuria. Often these males require urodynamic evaluation with urodynamics or videourodynamics to plan therapy. Individuals with a poorly compliant bladder are at significant risk for ongoing renal damage, even in the absence of infection. Overnight catheter drainage has been shown to be beneficial in males with polyuria and can help preserve renal function. Urinary incontinence usually improves with age, particularly after puberty. Meticulous attention to bladder compliance, emptying, and infection can improve results in the future.

Urethral Atresia

The most severe form of obstructive uropathy in males is urethral atresia, a rare condition. In utero there is a distended bladder, bilateral hydroureteronephrosis, and oligohydramnios. In most cases, these infants are stillborn or succumb to pulmonary hypoplasia. Rare males with prune-belly syndrome also have urethral atresia. If the urachus is patent, oligohydramnios is unlikely, and the infant usually survives.

Urethral reconstruction is difficult, and most patients are managed with continent urinary diversion.

Urethral Hypoplasia

Urethral hypoplasia is a rare form of obstructive uropathy in males that is less severe than urethral atresia. In urethral hypoplasia, the urethral lumen is extremely small. Neonates with urethral hypoplasia typically have bilateral hydronephrosis and a distended bladder. Passage of a small pediatric feeding tube through the urethra is difficult or impossible. Usually a cutaneous vesicostomy must be performed to relieve upper urinary tract obstruction, and the severity of renal insufficiency is variable. The most severely affected males have end-stage renal disease. Treatment includes urethral reconstruction, gradual urethral dilation, or continent urinary diversion.

Urethral Stricture

Urethral strictures in males usually result from urethral trauma, either iatrogenic (catheterization, endoscopic procedures, previous urethral reconstruction) or accidental (straddle injuries, pelvic fractures). Because these lesions can develop gradually, the decrease in force of the urinary stream is seldom noticed by the child or the parents. More commonly, the obstruction causes symptoms of bladder instability, hematuria, or dysuria. Catheterization of the bladder usually is impossible. The diagnosis is made by a **retrograde urethrogram,** in which contrast is injected toward the bladder through a catheter inserted into the distal urethra. US also has been used to diagnose urethral strictures. Endoscopy is confirmatory. Endoscopic treatment of short strictures by direct vision urethrotomy is often successful initially and results in a profoundly improved urinary stream, but strictures are prone to recur. Longer strictures surrounded by periurethral fibrosis often require urethroplasty. Repeated endoscopic procedures should be avoided as they cause additional urethral damage. Noninvasive measurement of the urinary flow rate and pattern is useful for diagnosis and follow-up.

In females, true urethral strictures are rare because the female urethra is protected from trauma, particularly in childhood.

Anterior Urethral Valves and Urethral Diverticula in the Male

Anterior urethral valves are rare. The obstruction is not obstructing valve leaflets, as occurs in the posterior urethra. Rather, it is a urethral diverticulum in the penile urethra that expands during voiding. Distal extension of the diverticulum causes extrinsic compression of the distal penile urethra, causing urethral obstruction. There is usually a soft mass on the ventral surface of the penis at the penoscrotal junction. In addition, the urinary stream is typically weak, and the physical findings associated with PUVs are often present. The diverticulum may be small and minimally obstructive or, in other cases, may be severely obstructive and cause renal insufficiency. The diagnosis is suspected on physical examination and is confirmed by VCUG. Treatment involves open excision of the diverticulum or transurethral excision of the distal urethral cusp. Urethral diverticula occasionally occur after extensive hypospadias repair.

Fusiform dilation of the urethra or megalourethra can result from underdevelopment of the corpus spongiosum and support structures of the urethra. This condition is commonly associated with prune-belly syndrome.

Male Urethral Meatal Stenosis

See Chapter 581 for information on urethral meatal stenosis in males.

Chapter 578

Anomalies of the Bladder

Heather N. Di Carlo and Chad B. Crigger

BLADDER EXSTROPHY

Exstrophy of the urinary bladder occurs in approximately 1 in 35,000-40,000 births with a male:female ratio of 2:1. The severity ranges from simple **epispadias** (in males) to complete exstrophy of the cloaca involving exposure of the entire hindgut and the bladder **(cloacal exstrophy)**.

Considering the range of defects associated with exstrophy, prenatal diagnosis is challenging. Accurately diagnosing exstrophy (and its subtypes) is paramount in properly counseling families. Proper prenatal diagnosis allows for planning that may optimize postnatal medical and surgical management. Classically, the diagnosis was suspected on prenatal ultrasound. For instances in which the diagnosis remains uncertain, as for midline abdominal defects such as exstrophy versus gastroschisis or omphalocele, fetal magnetic resonance imaging (fMRI) may help elucidate the correct diagnosis.

Clinical Manifestations

Anomalies of the bladder are hypothesized to result when the mesoderm fails to invade the cephalad extension of the cloacal membrane; the timing and extent of this failure determines the degree of the anomaly. In classic bladder exstrophy (Fig. 578.1), the bladder protrudes from the abdominal wall, and its mucosa is exposed. The umbilicus is displaced downward, the pubic rami are widely separated in the midline, and the rectus muscles are separated. In males, there is complete epispadias with dorsal chordee, and the overall penile length is approximately half that of unaffected males. The scrotum typically is separated slightly from the penis and is wide and shallow. Undescended testes and inguinal hernias are common. Females may also have epispadias, with separation of the two halves of the clitoris and wide separation of the labia. The anus is displaced anteriorly in both sexes, and there may be rectal prolapse. The pubic rami are widely separated.

The consequences of untreated bladder exstrophy are total urinary incontinence and an increased incidence of bladder cancer, usually adenocarcinoma. The external and internal genital deformities cause sexual disability in both sexes, particularly in males. The wide separation of the pubic rami causes a characteristic broad-based gait but no significant lasting disability. In classic bladder exstrophy, the upper urinary tracts usually are normal at birth.

Fig. 578.1 Classic bladder exstrophy in a newborn male. The bladder is exposed in the midline, the umbilical cord is displaced caudad, the penis is epispadiac, and the scrotum is broad.

Treatment

Management of bladder exstrophy should start at birth. The bladder should be covered with plastic wrap to keep the bladder mucosa moist. Saline may be gently irrigated as needed to moisten the bladder template. *Application of gauze or petroleum-gauze to the bladder mucosa should be avoided, because significant inflammation will result.* The infant should be transferred promptly to a center with pediatric urology and pediatric anesthetic support for newborns with complex anomalies. These children are prone to *latex allergy,* and latex precautions should be practiced from birth, both in the nursery and in the operating room.

There are two surgical approaches: staged reconstruction and total single-stage reconstruction. Most babies also undergo bilateral iliac osteotomy, which allows the pubic symphysis to be approximated, which supports the bladder closure. In a staged reconstruction, the initial stage is bladder closure, the second stage (in males) is epispadias repair, and the final stage is bladder neck reconstruction. The single-stage reconstruction attempts to reconstruct the entire malformation in a single procedure. When this operation is performed in the newborn, there is an increased risk of intraoperative penile injury and postoperative hydronephrosis compared with the staged reconstruction. The complication rate is high with both approaches, and there is no consensus on which is better.

Although bladder closure within the first 48 hours of life has been the historical standard, many centers of excellence now defer the procedure until 1-2 weeks of life to ensure that the appropriate multidisciplinary surgical and anesthetic teams are available. During bladder exstrophy closure, the abdominal wall is mobilized and the pubic rami are brought together in the midline following pelvic osteotomy. Early bladder closure can be performed in almost all neonates with classic bladder exstrophy. Treatment should be deferred in select situations including when surgical therapy would be excessively risky or complex, such as a premature baby, or if performed by inexperienced surgeons. In the staged approach, in males, epispadias repair usually is performed around age 1 or 2 years. At this point the child has total urinary incontinence because there is no functional external urinary sphincter. Most infants with bladder exstrophy have vesicoureteral reflux and should receive antibiotic prophylaxis. Typically, the bladder capacity is monitored every 12-24 months using cystoscopy with cystogram under anesthesia. The final stage of reconstruction involves creation of a sphincter muscle for bladder control and correction of vesicoureteral reflux. This is usually performed when the child is 3-6 years old with a bladder capacity of at least 80-90 mL, and the child must have gained rectal sphincter control.

Total single-stage reconstruction includes newborn closure of the bladder and bladder neck narrowing, abdominal wall closure, and, in males, correction of epispadias using a technique of penile disassembly. This involves separating the two corpora cavernosa and the midline urethra into three parts via radical mobilization. Postoperatively, the infant's upper urinary tract is monitored closely for possible development of hydronephrosis and infection. Comparison of outcomes between the multistage and single-stage approaches is ongoing.

At puberty pubic hair is often distributed to the sides of the external genitals. A monsplasty can be performed during adolescence to provide a normal escutcheon.

Long-Term Prognosis

Long-term management of individuals born with bladder exstrophy includes monitoring the upper urinary tract appearance and function for any deterioration and infection, as well as assessing continence. As these patients age, erectile function is assessed in males, and, later on in adults, sexual function and fertility are evaluated.

The previously described plan of treatment has yielded a continence rate of 60–70% in a few centers, with <15% risk of deterioration of the upper urinary tract. This continence rate reflects not only successful reconstruction but also the quality and size of the bladder. From a functional standpoint, the reconstructed bladder neck does not relax during voiding as in a normal child; instead the patient must void by assisted techniques such as the Valsalva maneuver or Credé maneuver.

Children who remain incontinent for more than 1 year after bladder neck reconstruction or those who are ineligible for bladder neck reconstruction because of small bladder capacity are candidates for an alternative reconstructive procedure to achieve dryness. In select cases, cystoscopic injection of bulking agents such as dextranomer or polydimethylsiloxane microspheres into the bladder neck can provide sufficient bladder neck coaptation and resistance to establish continence. Alternatively, if the child is not a candidate for endoscopic therapy, options include:

- Augmentation cystoplasty, in which the bladder is enlarged with a patch of small or large bowel to increase its capacity.
- Creation of a neobladder out of a small or large bowel segment with placement of a continent abdominal stoma through which clean, intermittent catheterization can be performed.
- Placement of an artificial urinary sphincter, with possible combined augmentation cystoplasty.
- Ureterosigmoidostomy, in which the ureters are detached from the bladder and sutured to the sigmoid colon; individuals void urine and stool from the rectum and rely on their anal sphincter for continence. This approach does not require many resources in surgical technique or long-term care (such as ostomy supplies).
- Mainz II procedure, in which the sigmoid colon is reconfigured into a "bladder" into which the ureters are connected; the patient voids 3-6 times daily through the rectum, and the stool tends to be more solid.

Ureterosigmoidostomy carries a significant risk of chronic pyelonephritis (see Chapter 575), upper urinary tract damage, metabolic acidosis resulting from absorption of hydrogen ion and chloride in the intestine, and at least a 15–22% long-term risk of colon carcinoma. Patients from less-developed countries often undergo the Mainz II procedure because the continence rate is high and pyelonephritis and upper tract changes are relatively uncommon.

Late follow-up has shown that although adult males with exstrophy have a penis that is half the normal length, they usually experience satisfactory sexual function. Fertility has been low, possibly because of iatrogenic injury to the secondary sexual organs during reconstruction. With artificial reproductive technology, nearly all affected men can be fertile. In adult females, fertility is not affected, but uterine prolapse during pregnancy is a problem. In adult females who have undergone a continent urinary diversion, delivery by cesarean section is usually necessary.

OTHER EXSTROPHY ANOMALIES

More rarely, children have a more severe form of exstrophy, cloacal exstrophy, which occurs in 1 in 400,000 live births. In addition to an exposed bladder, gastrointestinal manifestations typically include omphalocele, an imperforate anus, and a short bowel, resulting in short bowel syndrome (see Chapter 385.6). It is the most devastating anomaly managed by pediatric urologists. Approximately 50% of patients have an upper urinary tract anomaly, and 50% have spina bifida (see Chapter 631.2). Children with cloacal exstrophy do not achieve normal urine or stool continence. Reconstructive techniques result in a satisfactory outcome in most patients with permanent urinary diversion (either ileal conduit or continent urinary diversion) and a colostomy. Because the penis in males with cloacal exstrophy usually is diminutive, genital reconstruction in males with cloacal exstrophy has been unsatisfactory. Until recently, many specialists recommended assigning a female gender to such infants, but currently there is debate as to whether these children, who have a 46,XY karyotype and brain androgen imprinting in utero, can have a satisfactory female gender identity (see Chapter 153). Decisions regarding gender assignment should be made jointly by the physicians caring for the infant (surgical team, pediatric endocrinologist, child psychiatrist, and ethicist) and the family. Current practice by pediatric urologists is to reconstruct genitalia in a manner congruent with the genotype when at all possible, and after extensive counseling with the patient's family.

Epispadias is at the less severe end of the spectrum of exstrophy anomalies, affecting approximately 1 in 117,000 males and 1 in 480,000 females. In males, the diagnosis is obvious because the prepuce is distributed primarily on the ventral aspect of the penile shaft and the urethral meatus is on the dorsum of the penis. Distal epispadias in males (Fig. 578.2) usually is associated with normal urinary control and normal upper urinary tracts and should be repaired by 6-12 months of age. In females, the clitoris is bifid, and the urethra is split dorsally (Fig. 578.3). In more severely affected males and in all females with

Fig. 578.2 Adolescent male with penopubic epispadias.

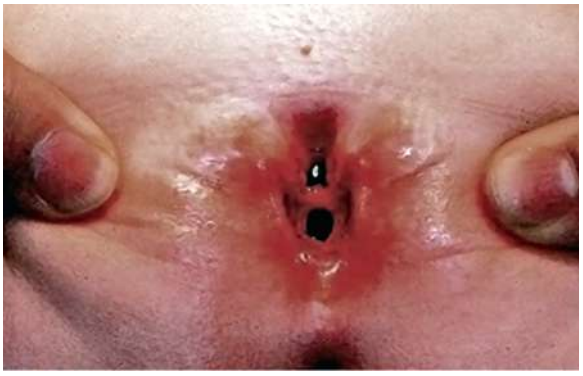

Fig. 578.3 Female with complete epispadias. *(From Gearhart JP, Rink RC, Mouriquand PDE, eds. Pediatric Urology, 2nd ed. Philadelphia: Saunders; 2010.)*

epispadias, there is total urinary incontinence because the sphincter is incompletely formed along with a wide separation of the pubic rami. These children require surgical reconstruction of the bladder neck, similar to the final management stage in children with classic bladder exstrophy.

BLADDER DIVERTICULA

Bladder diverticula develop as herniations of the bladder mucosa between defects of bladder smooth muscle fibers. Primary bladder diverticula usually develop at the ureterovesical junction and may be associated with vesicoureteral reflux, because the diverticulum interferes with the normal flap-valve attachment between the ureter and bladder. In rare circumstances, the diverticulum is so large that it interferes with normal micturition by obstructing the bladder neck. Bladder diverticula also commonly are associated with distal urethral obstructions such as posterior urethral valves or neurogenic bladder dysfunction. They occur commonly in children with connective tissue disorders, including Williams syndrome, Ehlers-Danlos syndrome, and Menkes syndrome (Fig. 578.4). Small diverticula require no treatment other than that of the primary disease, whereas large diverticula can contribute to inefficient voiding, residual urine, urinary stasis, and urinary tract infections and should be excised.

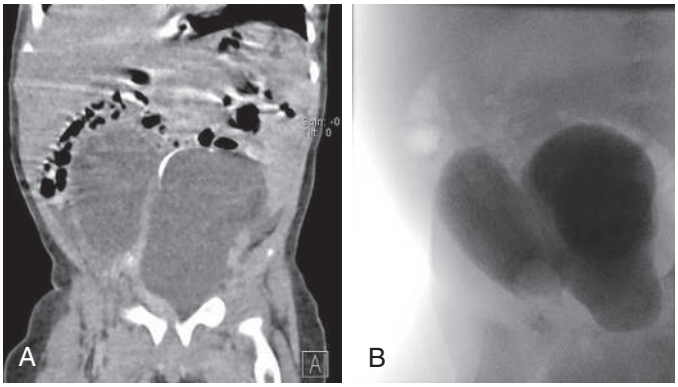

Fig. 578.4 Six-mo-old male with abdominal mass. Ultrasound showed a large fluid-filled mass and normal kidneys. **A,** CT scan shows large bladder diverticulum on right side with ureter coursing between the diverticulum and the bladder. **B,** Voiding cystourethrogram demonstrates no reflux and large diverticulum on left side. Managed with diverticulectomy.

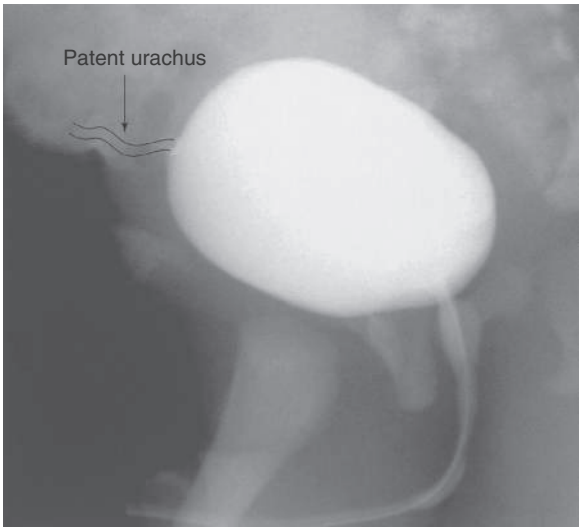

Fig. 578.5 Patent urachus. Vesicourethrogram image of patent urachus in a newborn. Philadelphia: Elsevier; 2021. Fig. 30-7.)*

URACHAL ANOMALIES

The urachus is an embryologic canal connecting the dome of the fetal bladder with the allantois, a structure that contributes to the formation of the umbilical cord. The lumen of the urachus is normally obliterated during embryonic development, transforming the urachus into a solid cord. Urachal abnormalities are more common in males than in females. A **patent urachus** can occur as an isolated anomaly, or it may be associated with prune-belly syndrome or posterior urethral valves (see Chapter 577; Fig. 578.5). A patent urachus results in continuous urinary drainage from the umbilicus and treatment involves excising the tract. Another urachal anomaly is the **urachal cyst,** which can become infected. Typical symptoms and physical findings include suprapubic pain, fever, irritative voiding symptoms, and an infraumbilical mass, which can be erythematous. Diagnosis is made by ultrasonography or CT (Fig. 578.6). Treatment is intravenous antibiotic therapy and drainage and excision. Other urachal anomalies include the **vesicourachal diverticulum,** which is a diverticulum of the bladder dome, and **umbilical-urachal sinus,** which is a blind external sinus that opens at the umbilicus. These lesions should be excised.

Chapter 579

Neuropathic Bladder

Heather N. Di Carlo and Chad B. Crigger

Neuropathic bladder dysfunction in children is usually congenital, generally resulting from neural tube defects or other spinal abnormalities (see Chapter 754). Acquired diseases and traumatic lesions of the spinal cord are less common (see Chapter 751). Central nervous system tumors, sacrococcygeal teratoma, spinal abnormalities associated with imperforate anus (see Chapter 392), and spinal cord trauma also can result in abnormal innervation of the bladder and/or sphincter (Table 579.1).

NEURAL TUBE DEFECTS

Neural tube defects, resulting from failure of the neural tube to close spontaneously between the third and fourth week in utero, result in abnormalities of the vertebral column that affect spinal cord function, including **spina bifida occulta**, **myelomeningocele,** and **meningocele**

Table 579.1 Causes of Neuromuscular Dysfunction of the Lower Urinary Tract

(see Chapters 631.2, 631.3, and 631.4). Specialized medical centers in the United States have performed antenatal myelomeningocele closure. Long-term results from one large clinical trial of **in utero closure** have not shown a definite improvement in lower urinary tract function, although some children have demonstrated nearly normal bladder function. Overall, this trial has demonstrated a significant reduction in the need for ventriculoperitoneal shunting and improved performance on measures of self-care, motor function, and mobility.

Clinical Manifestations and Diagnosis

The most important urologic consequences of neuropathic bladder dysfunction associated with neural tube defects are urinary incontinence (see Chapter 580), urinary tract infections (UTIs; see Chapter 575), and hydronephrosis from vesicoureteral reflux (see Chapter 576) or detrusor-sphincter dyssynergia (see Chapter 580). Pyelonephritis and renal functional deterioration (see Chapter 575) are common causes of premature death in affected patients.

In the neonate, renal ultrasonography, assessment of postvoiding residual urine volumes, and a voiding cystourethrogram are performed after closure of the myelomeningocele as approximately 10–15% of newborns with myelomeningocele have hydronephrosis, and renal malformations are common; 25% have vesicoureteral reflux. A **urodynamic** study also should be performed. In this study, the bladder is filled with saline, and the bladder volume, bladder pressure, abdominal pressure, and sphincter tone are measured until the patient voids. During bladder filling, the bladder might show (1) uninhibited (premature) contractions (termed hyperreflexia) at low volumes, (2) normal bladder volume with contraction at an appropriate volume, or (3) atonia (lack of bladder contraction). Bladder compliance or elasticity also may be abnormal (i.e., abnormally high bladder pressure during bladder filling). The sphincter can show (1) normal tonicity with relaxation during bladder contraction, (2) reduced or absent tonicity, or (3) normal or increased tonicity that increases significantly during a bladder contraction (termed **detrusor-sphincter dyssynergia**; Fig. 579.1).

Renal Damage

Renal damage usually results from detrusor-sphincter dyssynergia. This dyssynergia causes functional obstruction of the bladder outlet, leading to bladder muscle hypertrophy and trabeculation, high intravesical pressure, and transmission of this high pressure into the upper urinary tracts, causing hydronephrosis (Fig. 579.2). Vesicoureteral reflux and UTI compound this problem, but severe hydronephrosis can result without reflux. Treatment includes reduction of bladder pressure with anticholinergic drugs (e.g., oxybutynin, 0.2 mg/kg/dose up to three times per day) and **clean intermittent catheterization** every 3-4 hours. If the child has vesicoureteral reflux or UTI, antimicrobial prophylaxis also is prescribed.

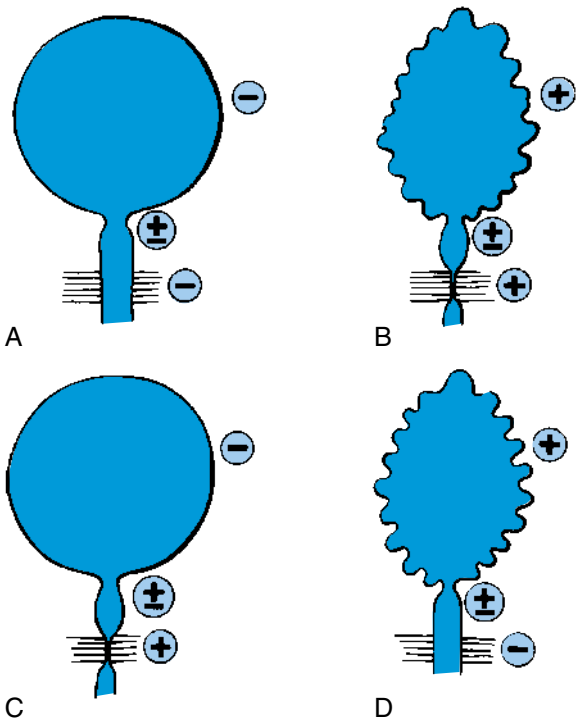

Fig. 579.1 Grouping of neuropathic bladder dysfunction according to the innervation, tonicity, and coordination of the detrusor and sphincters described by Guzman. This grouping is based on data from imaging studies, cystometrography, and electromyography of the sphincters. Patients in group B are at risk of developing reflux and hydronephrosis. For guidance in the treatment of incontinence, group A patients benefit from procedures that increase outlet resistance, group B patients from anticholinergics or bladder augmentation surgery, and group C patients from intermittent catheterization. Group D patients require both increased outlet resistance and pharmacologic or surgical bladder enlargement. Most patients require intermittent catheterization to empty. *(Modified from Gonzalez R. Urinary incontinence. In Kelalis PK, King LR, Belman AB, eds. Clinical Pediatric Urology. Philadelphia: Saunders; 1992. p. 387.)*

Fig. 579.2 Voiding cystourethrogram in an infant with myelodysplasia shows a severely trabeculated bladder with multiple diverticula and grade V (out of V) right vesicoureteral reflux. Evaluation showed severe detrusor-sphincter dyssynergia.

Temporary urinary diversion by cutaneous vesicostomy is an alternative in the newborn or infant with severe reflux, if intermittent catheterization is difficult, or if anticholinergic medications are not well tolerated. Another option for treating the severely trabeculated bladder is transurethral injection of botulinum toxin (Botox) into the detrusor muscle, which reduces bladder hypertonicity for approximately 6 months and often needs to be repeated. A different approach in these children is to temporarily inactivate the tight sphincter by urethral overdilation or transurethral injection of botulinum toxin into the sphincter. In children with upper tract changes, continuous overnight bladder drainage allows significant bladder relaxation and can reduce bladder wall thickening and lessen hydronephrosis.

Clean intermittent catheterization and anticholinergic therapy cure reflux in up to 80% of children with grade I or II reflux. Children with more severe reflux often require subureteral endoscopic injection therapy (see Chapter 576) or open antireflux surgery followed by intermittent catheterization and anticholinergic drugs. In older children with myelomeningocele with high-grade reflux, UTI, and hydronephrosis, augmentation enterocystoplasty (enlarging the bladder with a patch of intestine) with intermittent catheterization may be necessary. This intervention allows a normal-capacity bladder with low bladder pressure and effective drainage of the bladder.

Urinary Incontinence

Incontinence in the child with neuropathic bladder can result from total or partial denervation of the sphincter, bladder hyperreflexia, poor bladder compliance, chronic urinary retention, or a combination of these factors.

Incontinence is often addressed at 4-5 years of age and is tailored to the individual child. Nearly all children require clean intermittent catheterization to stay dry. This technique allows efficient bladder emptying with minimal risk of symptomatic UTI. *The urinary tract should be reevaluated with renal ultrasonography, a voiding cystourethrogram, and a urodynamic study (including bladder capacity) prior to initiation of an intermittent catheterization regimen*. If the external sphincter tone is sufficient and the bladder has adequate compliance, intermittent catheterization every 3-4 hours is often successful in keeping the child socially dry. If there are unstable bladder contractions, an anticholinergic medication such as oxybutynin chloride, hyoscyamine, or tolterodine is prescribed to increase bladder capacity. If there is sphincteric incompetence, α-adrenergic medications are prescribed to enhance outlet resistance. Bacteriuria is seen in up to 50% of children using intermittent self-catheterization, but it seldom causes symptoms. In the absence of reflux, there seems to be little cause for concern. Performing intermittent catheterization with a new catheter (hydrophilic or standard silicone) each time is also quite effective in preventing bacteriuria and avoids the need for antibiotic prophylaxis. With this treatment plan, 40–85% of patients are dry, depending on the definition of continence; some children wear a pad in their underwear or a diaper for security but feel that they are dry.

If there is persistent incontinence despite medical therapy, reconstructive urinary tract surgery nearly always provides complete or satisfactory continence. If urethral resistance is low, bladder neck reconstructive procedures such as a periurethral sling are often successful. Alternatively, implantation of an artificial sphincter is usually successful. This sphincter consists of an inflatable cuff that is placed around the bladder neck, a pressure-regulating balloon implanted in the extraperitoneal space, and a pump mechanism that is implanted in the scrotum of boys and in the labia majora of girls. Squeezing the pump 3-4 times moves the fluid out of the inflatable urethral cuff, and then the cuff slowly refills over the next 2-3 minutes.

If the bladder capacity or bladder compliance is low, or if there are persistent uninhibited contractions despite anticholinergic therapy, enlargement of the bladder with a patch of small or large intestine,

termed augmentation cystoplasty or **enterocystoplasty**, is effective. These patients still need to perform clean intermittent catheterization. If urethral catheterization is difficult, a continent urinary stoma may be incorporated into the urinary tract reconstruction. A common method is the **Mitrofanoff procedure** (appendicovesicostomy), in which the appendix is isolated from the cecum on its vascular pedicle and is interposed between the bladder and abdominal wall to allow intermittent catheterization through a dry stoma. An ileal conduit with a bag on the abdominal wall is rarely used.

Complications of Augmentation Cystoplasty

Urinary Tract Infection

The urine may be colonized with gram-negative bacteria, and attempts to sterilize the urine for prolonged periods usually fail. There is no evidence that chronic bacteriuria in patients who have had enterocystoplasty is associated with renal damage; therefore only symptomatic UTIs should be treated.

Metabolic Acidosis

The enteric mucosal surface in contact with the urine absorbs ammonium, chloride, and hydrogen ions and loses potassium. *Hyperchloremic metabolic acidosis can result, possibly requiring medical treatment* (see Chapter 73). Chronic acidosis can compromise skeletal growth. This condition is common with colocystoplasty but is uncommon with ileocystoplasty. Metabolic acidosis is also common in patients with compromised renal function. To overcome this limitation of enterocystoplasty in patients with chronic renal insufficiency, a composite augmentation using the stomach and a small or large bowel gastric segment can be used. The stomach secretes chloride and hydrogen ions; thus preexisting metabolic acidosis remains stable or improves. However, augmentation with a gastric segment remains rare.

Spontaneous Perforation

Perforation of the augmented bladder is a life-threatening complication that results most often from acute or chronic overdistention of the augmented bladder. Patients with this complication typically present with severe abdominal pain and signs of peritonitis. Prompt diagnosis and treatment with exploratory laparotomy and bladder closure are necessary. Meticulous adherence to the prescribed program of intermittent catheterization to avoid bladder overdistention is important.

Bladder Calculi

Bladder calculi have developed in as many as 70% of children followed for 10 years after enterocystoplasty. The calculi develop in response to mucus that accumulates in the bladder and serves as a nidus for stone formation. This complication can be prevented by daily irrigation of the bladder with sterile saline.

Malignant Neoplasm

Invasive transitional cell carcinoma has been reported in nearly 4.6% of patients undergoing enterocystoplasty (compared with a 2.6% risk in spina bifida patients without enterocystoplasty). The pathogenesis is uncertain, but there is speculation that it is related to bacteriuria and the bowel-bladder contact. The risk is highest following gastrocystoplasty. The risk increases 10 years following enterocystoplasty. Although there are no formal guidelines or recommendations regarding screening, it seems appropriate to advise yearly endoscopic examinations or urine cytologic studies beginning in the tenth postoperative year.

ASSOCIATED DISORDERS

Constipation

Many patients with spina bifida also have bowel problems with constipation, and a vigorous bowel regimen is important. Some benefit from the **Malone antegrade continence enema (MACE) procedure**, in which the appendix is brought out to the skin to allow a catheter to be inserted into the cecum for antegrade enema. The stoma is continent, and an antegrade enema can be performed with tap water each day. This form of management allows the patient to be continent of stool and be more self-sufficient. An alternative to the MACE procedure is a percutaneous cecostomy, in which a button is placed into the cecum to allow an antegrade flush. The MACE and percutaneous cecostomy procedures can be performed laparoscopically.

Latex Allergy

Latex allergy is a very serious problem encountered by as many as half of patients with spina bifida and other urologic conditions who require clean intermittent catheterization and urinary tract reconstructive procedures. This immunoglobulin E–mediated allergy is acquired and is secondary to repeated exposure to the latex allergen. Latex allergy can manifest as watery eyes, sneezing, itching, hives, or anaphylaxis when blowing up a balloon or if an examiner is using latex gloves. Intraoperatively, a sensitized patient can experience anaphylactic shock. A latex-free environment should be provided for all children with spina bifida in the office, during hospitalization, and during operative procedures. Affected children also should wear a medical alert bracelet.

Occult Spinal Dysraphism

Approximately 1 in 4,000 patients have occult spinal dysraphism, a category that includes lipomeningocele, intradural lipoma, diastematomyelia, tight filum terminale, dermoid cyst-sinus, aberrant nerve roots, anterior sacral meningocele, and cauda equina tumor. More than 90% of patients have a cutaneous abnormality overlying the lower spine, including a **sacral dimple**, tuft of hair, dermal vascular malformation, or subcutaneous lipoma (Fig. 579.3). Often these children have high-arched feet, discrepancy in muscle size and strength between the legs,

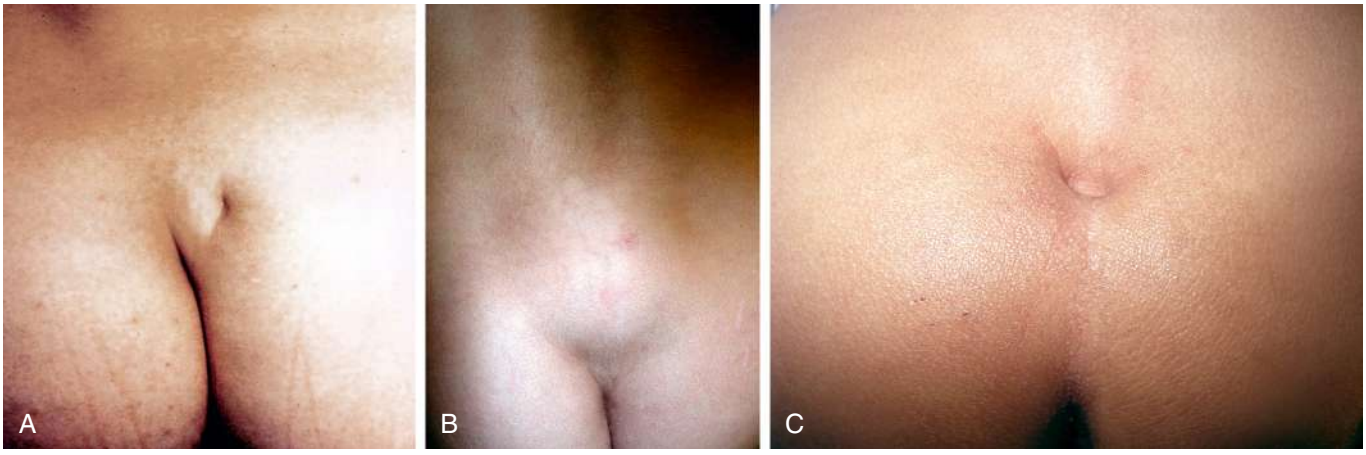

Fig. 579.3 A, Buttocks of teenage boy with tethered cord secondary to lipomeningocele. Note sacral dimple and deviation of gluteal fold to the left. B, Fat deposit over sacrum in girl with tethered cord secondary to lipomeningocele. C, Deep sacral pit in child with neuropathic bladder.

and a gait abnormality. Newborns and young infants often have a normal neurologic examination. Older children often have absent perineal sensation and back pain. Lower urinary tract function is abnormal in 40% of patients, including incontinence, recurrent UTI, and fecal soiling. The likelihood of a normal examination is inversely related to the child's age at surgical correction of the spinal lesion. In infants with abnormal urodynamics, 60% revert to normal; in older children, only 27% become normal. Management of the urinary tract in other children is similar to that described earlier for neural tube defects.

Sacral Agenesis

Sacral agenesis is defined as the absence of part or all of two or more lower vertebral bodies. *This condition is more common in the offspring of women with diabetes.* These children have a flattened buttock and a low, short gluteal cleft but usually have no orthopedic deformity, although some have high-arched feet. Palpation of the coccygeal area detects the absent vertebrae. Approximately 20% of cases are undetected until the age of 3-4 years; many are diagnosed after unsuccessful toilet training. Urodynamic studies in these children show a variety of patterns, and most need clean intermittent catheterization and pharmacotherapy to stay dry.

Imperforate Anus

Approximately 30–45% of children with a high imperforate anus have a neuropathic bladder, often because of sacral agenesis. Newborns with imperforate anus should undergo a spinal ultrasound during their initial evaluation, and if these children have difficulty with toilet training, complete urologic evaluation with upper and lower urinary tract imaging and urodynamics should be performed (see Chapter 392).

Cerebral Palsy

Children with cerebral palsy (see Chapter 638.1) often have reasonable bladder control. However, they achieve continence at a later age than unaffected children. Overall, 25–50% are incontinent, and the risk is directly related to the severity of physical impairment. Their upper urinary tracts are usually normal. Urodynamic studies have shown that most have uninhibited bladder contractions. Timed voiding and anticholinergic therapy are usually effective. Upper urinary tract deterioration is uncommon, and clean intermittent catheterization is rarely necessary.

Chapter 580

Enuresis and Voiding Dysfunction

Heather N. Di Carlo and Chad B. Crigger

NORMAL VOIDING AND TOILET TRAINING

Fetal voiding occurs by reflex bladder contraction in concert with simultaneous contraction of the bladder and relaxation of the sphincter. Urine storage results from sympathetic and pudendal nerve-mediated inhibition of detrusor contractile activity accompanied by closure of the bladder neck and proximal urethra with increased activity of the external sphincter. The infant has coordinated reflex voiding as often as 15-20 times/day. Over time, bladder capacity increases. In children up to the age of 14 years, the mean bladder capacity in milliliters is equal to the ([age (in years) + 2] times 30) (e.g., the bladder capacity of a 6 year old should be [6 + 2] × 30 or 240 mL).

At 2-4 years, the child is developmentally ready to begin toilet training. To achieve conscious bladder control, several conditions must be present: awareness of bladder filling, cortical inhibition (suprapontine modulation) of reflex (unstable) bladder contractions, ability to consciously tighten the external sphincter to prevent incontinence, normal bladder growth, and motivation by the child to stay dry. The transitional phase of voiding refers to the period when children are acquiring bladder control. *Females typically acquire bladder control before males, and bowel control typically is achieved before bladder control.*

DIURNAL INCONTINENCE

Daytime incontinence not secondary to neurologic abnormalities is common in children. At 5 years of age, 95% have been dry during the day at some time and 92% are dry consistently. At 7 years of age, 96% are dry, although 15% have significant **urgency** at times. At 12 years, 99% are dry consistently during the day. The most common causes of daytime incontinence are **overactive bladder (urge incontinence)** and bladder-bowel dysfunction (BBD). Table 580.1 lists the causes of diurnal incontinence in children; Table 580.2 categorizes four types of voiding dysfunction.

The patient history should assess the pattern of incontinence, including the frequency of voiding, frequency of day and night urinary leakage, volume of urine lost during incontinent episodes, whether the incontinence is associated with urgency or giggling, whether it occurs after voiding, and whether the incontinence is continuous. In addition, whether the patient has a strong continuous urinary stream and sensation of incomplete bladder emptying should be assessed. A diary of when the child voids and whether the child is wet or dry is helpful. Other urologic problems, such as urinary tract infections (UTIs), vesicoureteral reflux, neurologic disorders, or a family history of renal duplication anomalies, should be assessed. Bowel habits also should be evaluated because incontinence is common in children with constipation and/or encopresis. Diurnal incontinence can occur in children with a history of sexual abuse or following bullying. Physical examination is directed at identifying signs of organic causes of incontinence. Short stature, hypertension, enlarged kidneys and/or bladder, constipation, labial adhesion, ureteral ectopy, back or sacral anomalies (see Fig. 579.4), and neurologic abnormalities should be documented.

Assessment tools include urinalysis, with culture if indicated; bladder diary (recorded times and volumes voided, whether wet or dry); postvoid residual urine volume (generally obtained by bladder scan); and the **Dysfunctional Voiding Symptom Score** (Fig. 580.1). An alternative to the Dysfunctional Voiding Symptom Score is the **Vancouver Nonneurogenic Lower Urinary Tract Dysfunction/Dysfunctional Elimination Syndrome** questionnaire. This questionnaire is a validated tool that consists of 14 questions scored on a 5-point Likert scale to assess lower urinary tract and bowel dysfunction. In most cases, a

Table 580.2 Symptoms and Signs of Four Main Subtypes of Lower Urinary Tract Dysfunction

	SYMPTOMS	SIGNS
Overactive bladder	(Cystometric) detrusor overactivity, frequency, voiding urgency, incontinence, constipation, enuresis	Holding maneuvers, normal flow pattern, thick bladder wall, low-volume voids
Dysfunctional voiding	Failure to relax the sphincter during voiding, normal micturition frequency, incontinence, constipation, urinary tract infections, enuresis	Post-void residue, staccato or interrupted flow pattern, normal frequency of voids
Underactive bladder	(Cystometric) weak detrusor contractions, low micturition frequency incontinence, constipation, urinary tract infections	Post-void residue, staccato or interrupted flow pattern, frequent large volume voids
Voiding postponement	Low micturition frequency, incontinence	Normal flow pattern

Classification of daytime lower urinary tract dysfunction, assessment, and documentation should be based on the following parameters: incontinence (presence or absence and symptom frequency), voiding frequency, voiding urgency, voided volumes, and fluid intake.

*Females with a score ≥6 and males with a score ≥9 are most likely to have dysfunctional voiding.

Fig. 580.1 Dysfunctional Voiding Symptom Score questionnaire. *(From Farhat W, Bagli DJ, Capolicchio G, et al. The dysfunctional voiding scoring system: quantitative standardization of dysfunctional voiding symptoms in children. J Urol. 2000;164:1011–1015.)*

uroflow study with electromyography (noninvasive assessment of urinary flow pattern and measurement of external sphincter activity) is indicated. Another item that may be useful in children older than age 5 years is the **Pediatric Symptom Checklist (PSC)**, a brief screening questionnaire that may reveal psychosocial stressors contributing to incontinence (see Chapter 32).

Bowel function should also be assessed. The **Bristol Stool Form Score** (Fig. 580.2) should be recorded. In addition, the clinician should utilize the Rome III diagnostic criteria, which classify functional gastrointestinal disorders that do not have underlying structural or tissue-based causes. Children 4 years of age or older are diagnosed as being constipated if they fulfill two or more of the following criteria over a period of 2 months: two or fewer defecations in the toilet per week, at least one episode of fecal incontinence per week, a history of retentive posturing or excessive volitional stool retention, a history of painful or hard bowel movements, the presence of a large fecal mass in the rectum, and a history of large-diameter stools that obstruct the toilet.

Imaging (renal-bladder ultrasound with or without a voiding cystourethrogram) is indicated in children with diurnal incontinence who have significant physical findings, those who have a family history of urinary tract anomalies or UTIs, and those who do not respond to therapy appropriately. Urodynamics should be performed if there is evidence of neurologic disease and may be helpful if empirical therapy is ineffective. *If there is any evidence of a neurologic disorder or if there is a sacral abnormality on physical examination, an MRI of the lower spine should be obtained.*

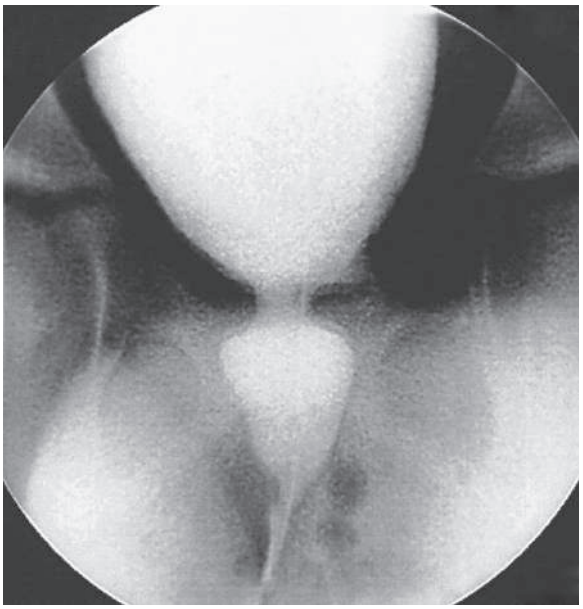

Fig. 580.3 Spinning-top deformity. Voiding cystourethrogram demonstrating dilation of the urethra with distal urethral narrowing and contraction of the bladder neck.

OVERACTIVE BLADDER (DIURNAL URGE SYNDROME)

Children with an overactive bladder typically exhibit urinary frequency, urgency, and urge incontinence. Often a female will squat down on her foot to try to prevent incontinence (termed *Vincent's curtsy*). The bladder in these children is functionally, but not anatomically, smaller than normal and exhibits strong uninhibited contractions. Approximately 25% of children with nocturnal enuresis also have symptoms of an overactive bladder. Many children indicate they do not feel the need to urinate, even just before they are incontinent. In females, a history of recurrent UTI is common, but incontinence can persist long after infections are brought under control. It is unclear if the voiding dysfunction is a sequela of the UTIs or if the voiding dysfunction predisposes to recurrent UTIs. In some females, voiding cystourethrography shows a dilated urethra (**spinning-top deformity**; Fig. 580.3) and narrowed bladder neck with bladder wall hypertrophy. The urethral finding results from inadequate relaxation of the external urinary sphincter.

The overactive bladder nearly always resolves, but the time to resolution is highly variable, occasionally not until the teenage years. Initial therapy is timed voiding, every 1.5-2 hours. Treatment of constipation and UTIs is important. Another treatment is **biofeedback**, in which children are taught pelvic floor exercises **(Kegel exercises),** because daily performance of these exercises can reduce or eliminate unstable bladder contractions. Biofeedback often consists of 8-10 1-hour sessions and may include participation with animated computer games. Biofeedback also may include periodic uroflow studies with sphincter electromyography to be certain that the pelvic floor relaxes during voiding, and assessment of postvoid residual urine volume by sonography. **Anticholinergic** therapy often is helpful if bowel function is normal. **Oxybutynin chloride** and **tolterodine** are the only U.S. Food and Drug Administration (FDA)-approved medications in children, but hyoscyamine, trospium, solifenacin, and mirabegron have also demonstrated safety in this population; these medications reduce bladder overactivity and may help the child achieve dryness. Adequate hydration should be emphasized to combat constipation as oxybutynin can induce constipation in some patients. Treatment with an α-adrenergic blocker such as terazosin or doxazosin can aid in bladder emptying by promoting bladder neck relaxation; these medications also have mild anticholinergic properties. If pharmacologic therapy is successful, the dosage should be tapered periodically to determine its continued need. Children who do not respond to therapy should be evaluated with urodynamic studies to rule out other possible forms of bladder or sphincter dysfunction. In refractory cases, other procedures such as **sacral neuromodulation** (InterStim), percutaneous tibial nerve stimulation, and intravesical botulinum toxin injection have been effective in children.

If the child has constipation based on the criteria described earlier, treatment generally is initiated with polyethylene glycol powder, which has been shown to be safe in children and is generally more effective than other laxative preparations (see Chapter 378.3).

NONNEUROGENIC NEUROGENIC BLADDER (HINMAN SYNDROME)

Hinman syndrome is a very serious but uncommon disorder involving failure of the external sphincter to relax during voiding in children without neurologic abnormalities. Children with this syndrome, also called **nonneurogenic neurogenic bladder**, typically exhibit a staccato stream, day and night wetting, recurrent UTIs, constipation, and encopresis. Evaluation of affected children often reveals vesicoureteral reflux, a trabeculated bladder, and a decreased urinary flow rate with an intermittent pattern (Fig. 580.4). In severe cases, hydronephrosis, renal insufficiency, and end-stage renal disease can occur. The pathogenesis of this syndrome is thought to involve learning abnormal voiding habits during toilet training; the syndrome is rarely seen in infants. Urodynamic studies and MRI of the spine are indicated to rule out a neurologic cause for the bladder dysfunction.

The treatment usually is complex and can include anticholinergic and α-adrenergic blocker therapy, timed voiding, treatment of constipation, behavioral modification, and encouragement of relaxation during voiding. Biofeedback has been used successfully in older children to teach relaxation of the external sphincter. Botulinum toxin injection into the external sphincter can provide temporary sphincteric paralysis and thereby reduce outlet resistance. In severe cases, intermittent catheterization is necessary to ensure bladder emptying. In selected patients, external urinary diversion is necessary to protect the upper urinary tract. These children require long-term treatment and careful follow-up.

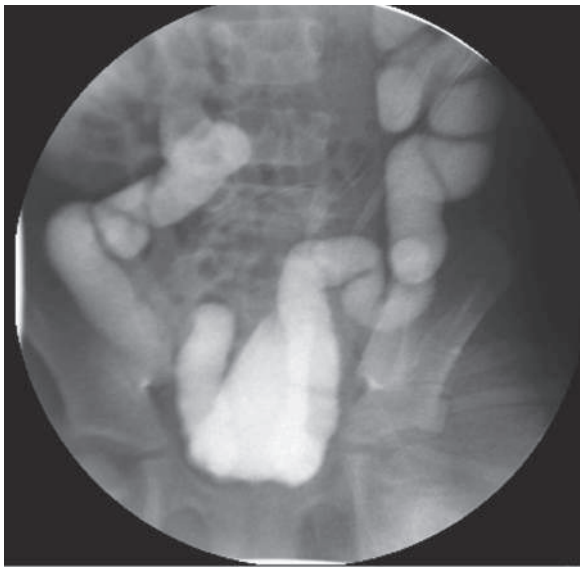

Fig. 580.4 Voiding cystourethrogram demonstrating severe bladder trabeculation and vesicoureteral reflux in a 12-yr-old male with Hinman syndrome. The patient presented with day and night incontinence, had chronic renal failure, and underwent kidney transplantation.

INFREQUENT VOIDING (UNDERACTIVE BLADDER)

Infrequent voiding is a common disorder of micturition. Affected children, usually females, often void only 1-2 times a day rather than the normal 4-7 times. Poor detrusor contraction strength and/or duration lead to bladder overdistention and prolonged retention of urine and ultimately bacterial growth that can lead to recurrent UTIs. Some of these children are constipated. Some also have occasional episodes of incontinence from overflow or urgency. The disorder is behavioral. If the child has UTIs, treatment includes antibacterial prophylaxis and encouragement of frequent voiding and complete emptying of the bladder by double voiding until a normal pattern of micturition is reestablished.

VAGINAL VOIDING

In females with vaginal voiding, incontinence typically occurs after urination after the female stands up. The volume is usually minimal, about 5-10 mL, and characterized as dribbling. One of the most common causes is **labial adhesion** (Fig. 580.5). This lesion, typically seen in young females, can be managed either by topical application of estrogen or steroid cream to the adhesion or manual separation (this should only be done after ensuring adequate anesthesia and potentially sedation; see Chapter 586). Some females experience vaginal voiding because they do not separate their legs widely during urination. These females typically are overweight and/or do not pull their underwear down to their ankles when they urinate. Management involves encouraging the female to separate the legs as widely as possible during urination. The most effective way to do this is to have the child sit backward on the toilet seat during micturition.

OTHER CAUSES OF INCONTINENCE IN FEMALES

Ureteral ectopia, usually associated with a duplicated collecting system in females, refers to a ureter that drains outside the bladder, often into the vagina or distal urethra. It can produce urinary incontinence characterized by constant urinary dribbling all day, even though the child voids regularly. Sometimes the urine production from the renal segment drained by the ectopic ureter is small, and urinary drainage is confused with watery vaginal discharge. Children with a history of vaginal discharge or incontinence and an abnormal voiding pattern require careful study. The ectopic orifice is usually difficult to find. On ultrasonography or intravenous urography, one may suspect duplication of the collecting system (Fig. 580.6), but the upper collecting system drained by the ectopic ureter usually has poor or delayed function.

Fig. 580.5 A, Labial adhesion. Note the inability to visualize the urethral meatus and vagina. B, Normal female external genitals following lysis of labial adhesion.

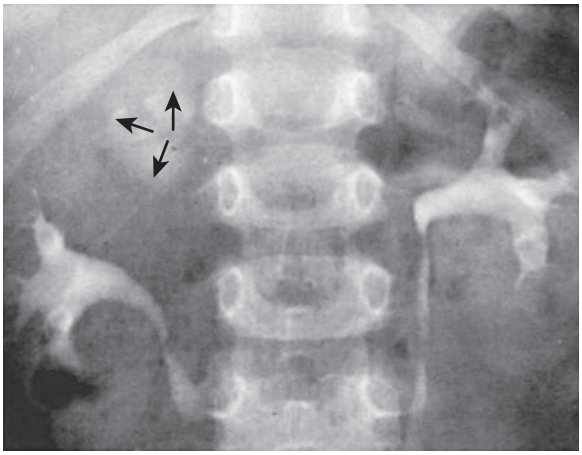

Fig. 580.6 Duplication of the right collecting system with ectopic ureter. Excretory urogram in a female presenting with a normal voiding pattern and constant urinary dribbling. The left kidney is normal, and the right side, well visualized, is the lower collecting system of a duplicated kidney. On the upper pole opposite the first and second vertebral bodies, note the accumulation of contrast material *(arrows)* corresponding with a poorly functioning upper pole drained by a ureter opening in the vestibule.

CT scanning of the kidneys or an MR urogram should demonstrate subtle duplication anomalies. Examination under anesthesia for an ectopic ureteral orifice in the vestibule or the vagina may be necessary (Fig. 580.7). Treatment in these cases is either partial nephrectomy, with removal of the upper pole segment of the duplicated kidney and its ureter down to the pelvic brim, or ipsilateral ureteroureterostomy, in which the upper pole ectopic ureter is anastomosed to the normally positioned lower pole ureter. These procedures often are performed by minimally invasive laparoscopy with or without robotic assistance.

Giggle incontinence typically affects females 7-15 years of age. The incontinence occurs suddenly during giggling, and the entire bladder volume is lost. The pathogenesis is thought to be sudden relaxation of the urinary sphincter. Anticholinergic medication and timed voiding occasionally are effective. The most effective treatment is low-dose methylphenidate, which seems to stabilize the external sphincter.

Total incontinence in females may be secondary to **epispadias** (see Fig. 578.2). This condition, which affects only 1 in 480,000 females, is characterized by separation of the pubic symphysis, separation of the right and left sides of the clitoris, and a patulous urethra. Treatment is bladder neck reconstruction; an alternative surgical therapy is

Fig. 580.7 An ectopic ureter entering the vestibule next to the urethral meatus. The thin ureteral catheter with transverse marks has been introduced into this ectopic ureter. This female had a normal voiding pattern and constant urinary dribbling.

Table 580.3 Nocturnal Enuresis

CAUSES
Delayed maturation of the cortical mechanisms that allow voluntary control of the micturition reflex
Defective sleep arousal
Reduced antidiuretic hormone production at night, resulting in an increased urine output (nocturnal polyuria)
Genetic factors, with chromosomes 12 and 13q the likely sites of the gene for enuresis
Bladder factors (lack of inhibition, reduced capacity, overactive)
Constipation
Organic factors, such as urinary tract infection, obstructive uropathy, or sickle cell anemia nephropathy
Sleep disorders
Sleep-disordered breathing secondary to enlarged adenoids
Psychologic factors more often implicated in secondary enuresis
OTHER FEATURES
Enuresis can occur in any stage of sleep (but usually non–rapid eye movement sleep)
All children are most difficult to arouse in the first third of the night and easiest to awaken in the last third, but enuretic children are more difficult to arouse than those with normal bladder control
Enuretic children often are described as "soaking the bed"
Family history in enuretic children often positive for enuresis
Risk increased with developmental delay, attention-deficit/hyperactivity disorder, autism spectrum disorders

placement of an artificial urinary sphincter to repair the incompetent urethra.

A short, incompetent urethra may be associated with certain urogenital sinus malformations. The diagnosis of these malformations requires a high index of suspicion and a careful physical examination of all incontinent females. In these cases, urethral and vaginal reconstruction often restores continence.

VOIDING DISORDERS WITHOUT INCONTINENCE

Some children have abrupt onset of severe urinary frequency, voiding as often as every 10-15 minutes during the day, without dysuria, UTI, daytime incontinence, or nocturia. The most common age for these symptoms to occur is 4-6 years, after the child is toilet trained; males are more often affected. This condition is termed the **daytime frequency syndrome of childhood,** or **pollakiuria**. The condition is functional without associated anatomic problems. Often the symptoms occur just before a child starts kindergarten or if the child is having emotional family stress-related problems. These children should be checked for UTIs, and the clinician should ascertain that the child is emptying the bladder satisfactorily. Another contributing cause is constipation. Occasionally, pinworms cause these symptoms. The condition is self-limited, and symptoms generally resolve within 2-3 months. Anticholinergic therapy is rarely effective.

Some children have **dysuria-hematuria syndrome,** in which the child has dysuria without UTI but with microscopic or total gross hematuria (blood throughout the stream). This condition affects children who are toilet-trained and is often secondary to hypercalciuria. A 24-hour urine sample should be obtained and calcium and creatinine excretion assessed. A 24-hour calcium excretion of >4 mg/kg is abnormal and deserves treatment with thiazides, because some of these children are at risk for urolithiasis. **Terminal hematuria** (blood at the end of the stream) occurs in males and typically is secondary to BBD or urethral meatal stenosis. Cystoscopy is not indicated, and the condition usually resolves with treatment for constipation.

NOCTURNAL ENURESIS

By 5 years of age, 90–95% of children are nearly completely continent during the day, and 80–85% are continent at night. Nocturnal enuresis refers to the occurrence of involuntary voiding at night after 5 years old, the age when volitional control of micturition is expected. Enuresis may be **primary** (estimated 75–90% of children with enuresis; nocturnal urinary control never achieved) or **secondary** (10–25%; the child was dry at night for at least a few months and then enuresis developed). Overall, 75% of children with enuresis are wet only at night, and 25% are incontinent day and night. This distinction is important, because children with both forms are more likely to have an abnormality of the urinary tract. *Monosymptomatic enuresis* is more common than *polysymptomatic enuresis* (associated urgency, hesitancy, frequency, daytime incontinence).

Epidemiology

Approximately 60% of children with nocturnal enuresis are males. The family history is positive in 50% of cases. Although primary nocturnal enuresis may be polygenetic, candidate genes have been localized to chromosomes 6, 12, and 13. If one parent was enuretic, each child has a 44% risk of enuresis; if both parents were enuretic, each child has a 77% likelihood of enuresis. Nocturnal enuresis without overt daytime voiding symptoms affects up to 20% of children at the age of 5 years; it ceases spontaneously in approximately 15% of involved children every year thereafter. Its frequency among adults is <1%.

Pathogenesis

The pathogenesis of primary nocturnal enuresis (normal daytime voiding habits) is multifactorial (Table 580.3).

Clinical Manifestations and Diagnosis

A careful history should be obtained, especially with respect to fluid intake at night and the pattern of nocturnal enuresis. Children with diabetes insipidus (see Chapter 596), diabetes mellitus (see Chapter 629), and chronic renal disease (see Chapter 572) can have a high obligatory urinary output and a compensatory polydipsia. The family should be asked whether the child snores loudly at night. Many children with enuresis sleepwalk or talk in their sleep. A complete physical examination should include palpation of the abdomen and possibly a rectal examination after voiding to assess the possibility of a chronically distended bladder and constipation. The child with nocturnal enuresis should be examined carefully for neurologic and spinal abnormalities. There is an increased incidence of bacteriuria in enuretic females, and, if found, it should be investigated and treated (see Chapter 575), although this does not always lead to resolution of bed-wetting. A urine sample should be obtained after an overnight fast and evaluated

for specific gravity or osmolality to exclude polyuria as a cause of frequency and incontinence and to ascertain that the concentrating ability is normal. The absence of glycosuria should be confirmed. If there are no daytime symptoms, the physical examination and urinalysis are normal, and the urine culture is negative, further evaluation for urinary tract pathology generally is not warranted. A renal ultrasound is reasonable in an older child with enuresis or in children who do not respond appropriately to therapy.

Treatment

The best approach to treatment is to reassure the child and parents that the condition is self-limited and to avoid punitive measures that can affect the child's psychologic development adversely. Fluid intake should be restricted to 2 oz after 6 or 7 PM. The parents should be certain that the child voids at bedtime. Avoiding extraneous sugar and caffeine after 5 PM is also beneficial. If the child snores and the adenoids are enlarged, referral to an otolaryngologist should be considered, because adenoidectomy can cure the enuresis in some cases.

Active treatment should be avoided in children younger than 6 years of age, because enuresis is extremely common in younger children. Treatment is more likely to be successful in children approaching puberty compared with younger children. In addition, treatment is most likely to be effective in children who are motivated to stay dry and is less successful in children who are overweight. Treatment should be viewed as a facilitator that requires active participation by the child (e.g., a coach and an athlete).

The simplest initial measure is **motivational therapy** and includes a star chart for dry nights. Waking children a few hours after they go to sleep to have them void often allows them to awaken dry, although this measure is not curative. Some have recommended that children try holding their urine for longer periods during the day, but there is no evidence that this approach is beneficial. **Conditioning therapy** involves use of a loud auditory or vibratory alarm attached to a moisture sensor in the underwear. The alarm activates when voiding occurs and is intended to awaken children and alert them to void. This form of therapy has a reported success of 30–60%, although the relapse rate is significant. Often the auditory alarm wakes up other family members and not the enuretic child; persistent use of the alarm for several months often is necessary to determine whether this treatment is effective. Conditioning therapy tends to be most effective in older children. Another form of therapy to which some children respond is self-hypnosis. The primary role of psychologic therapy is to help the child deal with enuresis psychologically and help motivate the child to void at night if he or she awakens with a full bladder.

Pharmacologic therapy is intended to treat the symptom of enuresis and thus is regarded as second line and is not curative. Direct comparisons of the moisture alarm with pharmacologic therapy favor the former because of lower relapse rates, although initial response rates are equivalent.

One form of pharmacologic treatment is **desmopressin acetate,** a synthetic analog of antidiuretic hormone that reduces urine production overnight. This medication is FDA-approved in children and is available as a tablet, with a dosage of 0.2-0.6 mg orally 2 hours before bedtime. A nasal spray formulation is available but is no longer recommended for nocturnal enuresis due to increased risk of hyponatremia and convulsions. Hyponatremia has not been reported in children using oral tablets. Fluid restriction at night is important, and the drug should not be used if the child has a systemic illness with vomiting or diarrhea or if the child has polydipsia. Desmopressin acetate is effective in as many as 40% of children and is most effective in those approaching puberty. If effective, it should be used for 3-6 months, and then an attempt should be made to taper the dosage. Some families use it intermittently (sleepovers, school trips, vacations) with success. If tapering results in recurrent enuresis, the child should return to the higher dosage. Few adverse events have been reported with the long-term use of desmopressin acetate.

For therapy-resistant enuresis or children with symptoms of an overactive bladder, anticholinergic therapy is indicated. Oxybutynin 5 mg or tolterodine 2 mg at bedtime is often prescribed. If the medication is ineffective, the dosage may be doubled. The clinician should monitor constipation as a potential side effect.

A third-line treatment is **imipramine,** which is a tricyclic antidepressant. This medication has mild anticholinergic and α-adrenergic effects, reduces the urine output slightly, and might alter the sleep pattern. The dosage of imipramine is 25 mg in children age 6-8 years, 50 mg in children age 9-12 years, and 75 mg in teenagers. Reported success rates are 30–60%. Side effects include anxiety, insomnia, dry mouth, and heart rhythm changes. If there is any history of palpitations or syncope in the child, or sudden cardiac death or unstable arrhythmia in the family, long QT syndrome in the patient needs to be excluded prior to prescribing imipramine. The drug is one of the most common causes of poisoning by prescription medication, so it is also important to emphasize safe storage.

In unsuccessful cases, combining therapies often is effective. Alarm therapy plus desmopressin is more successful than either alone. The combination of oxybutynin chloride and desmopressin is more successful than a single agent. Desmopressin and imipramine also may be combined.

Chapter 581

Anomalies of the Penis and Urethra

Heather N. Di Carlo and Chad B. Crigger

HYPOSPADIAS

Hypospadias is a urethral opening on the ventral surface of the penile shaft affecting 1 in 200 male newborns. Typically an isolated defect, its incidence is increased in many males with chromosomal abnormalities, anorectal malformation, and congenital heart disease. Usually, there is incomplete development of the prepuce, called a **dorsal hood,** in which the foreskin is on the sides and dorsal aspect of the penile shaft and deficient or absent ventrally. Some males with hypospadias, particularly those with proximal hypospadias, have **chordee,** in which there is ventral penile curvature during erection. The incidence of hypospadias appears to be increasing, possibly because of in utero exposure to estrogenic or antiandrogenic endocrine-disrupting chemicals (e.g., polychlorobiphenyls, phytoestrogens).

Clinical Manifestations

Hypospadias is classified according to the position of the urethral meatus after considering whether chordee is present (Fig. 581.1). The deformity is described as distal (further broken down into glanular [on the glans penis], coronal, or subcoronal), midpenile (distal penile, midshaft, or proximal penile), or proximal (penoscrotal, scrotal, or perineal). Approximately 65% of cases are distal, 25% are subcoronal or midpenile, and 10% are proximal. In the most severe cases, the scrotum is bifid, and sometimes there is moderate **penoscrotal transposition.** As many as 10% of affected males have a **megameatal variant of hypospadias** in which the foreskin is developed normally (megameatus intact prepuce variant), and there is either glanular or subcoronal hypospadias with a "fish mouth" meatus. These cases might not be diagnosed until after a circumcision is performed.

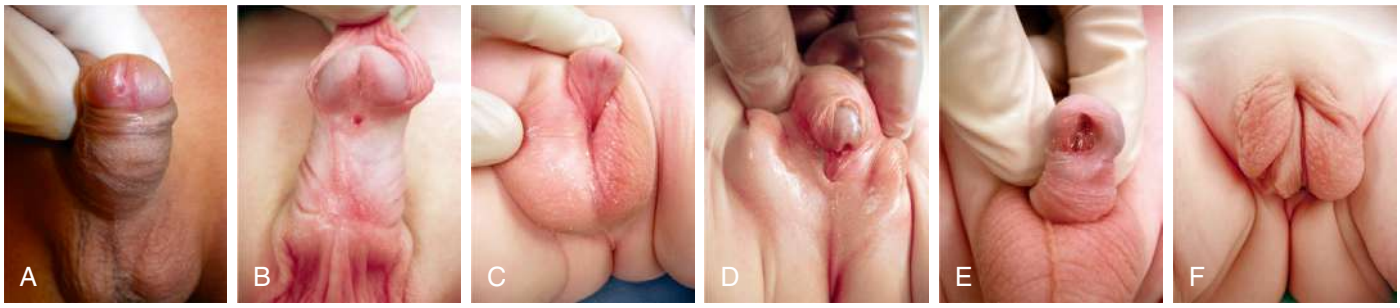

Fig. 581.1 Varying forms of hypospadias. A, Glanular hypospadias. B, Subcoronal hypospadias. Note the dorsal hood of foreskin. C, Penoscrotal hypospadias with chordee. D, Perineal hypospadias with chordee and partial penoscrotal transposition. E, Megameatal variant of hypospadias diagnosed following circumcision; note absence of hooded foreskin. F, Complete penoscrotal transposition with scrotal hypospadias.

Approximately 10% of males with hypospadias have an undescended testis; inguinal hernia(s) also are common. In the newborn, the differential diagnosis of midpenile or proximal hypospadias associated with an undescended testis should include forms of a **disorder of sex development,** particularly mixed gonadal dysgenesis, partial androgen insensitivity, true hermaphroditism, and congenital adrenal hyperplasia in a female (see Chapter 616). In the latter condition, neither gonad is palpable. *A karyotype should be obtained in patients with midpenile or proximal hypospadias and cryptorchidism* (see Chapter 628). In males with proximal hypospadias, a voiding cystourethrogram should be considered because 5–10% of these children have a dilated **prostatic utricle,** which is a remnant of the müllerian system (see Chapter 591). The incidence of upper urinary tract abnormalities is low unless there are abnormalities of other organ systems.

Complications of untreated hypospadias include deformity of the urinary stream, typically ventral deflection or severe splaying; sexual dysfunction secondary to penile curvature; infertility if the urethral meatus is proximal; meatal stenosis (congenital), which is uncommon; and cosmetic appearance. The goal of hypospadias surgery is to correct the functional and cosmetic deformities. Whereas hypospadias repair is recommended for all males with midpenile and proximal hypospadias, some males with distal hypospadias have no functional abnormality and do not need surgical correction.

Treatment

Management begins in the newborn period. *Circumcision should be avoided because the foreskin often is used in the repair in most cases.* The ideal age for repair in a healthy infant is 6-12 months because the risk of general anesthesia at this age is similar to older children; penile growth over the next several years is slow; the child does not remember the surgical procedure; and postoperative analgesic needs are less than in older children. With the exception of proximal hypospadias, virtually all cases are repaired in a single operation on an ambulatory basis. The most common repair involves tubularization of the urethral plate distal to the urethral meatus, with coverage by a vascularized flap from the foreskin, termed a tubularized incised plate repair. Proximal cases might require a two-stage repair.

The complication rate parallels severity: 5% for distal hypospadias, 10% for midpenile hypospadias, and 40% for proximal hypospadias. The most common complications include urethrocutaneous fistula and meatal stenosis. Other complications include a deformed urinary stream, persistent or recurrent penile curvature, and dehiscence of the hypospadias repair. Treatment of these complications generally is straightforward. In complex cases, a buccal mucosa graft from the mouth is used to create urethral mucosa. Repair of hypospadias is a technically demanding operation and should be performed by a surgeon with specialty training in pediatric urology and extensive experience.

CHORDEE WITHOUT HYPOSPADIAS

In some males, there is mild or moderate ventral penile curvature **(chordee)** and incomplete development of the foreskin **(dorsal hood),** but the urethral meatus is at the tip of the glans (Fig. 581.2). In most of these males, the urethra is normal, but there is insufficient ventral penile skin or prominent, inelastic ventral bands of dartos fascia that prevent a straight erection. In some cases, the urethra is hypoplastic, and a formal urethroplasty is necessary for repair. The only sign of this anomaly in the neonate may be the hooded foreskin, and delayed repair under general anesthesia after 6 months of age is recommended. **Lateral penile curvature** usually is caused by overgrowth or hypoplasia of a corporal (erectile) body and usually is congenital. Surgical repair is also recommended at age 6-12 months.

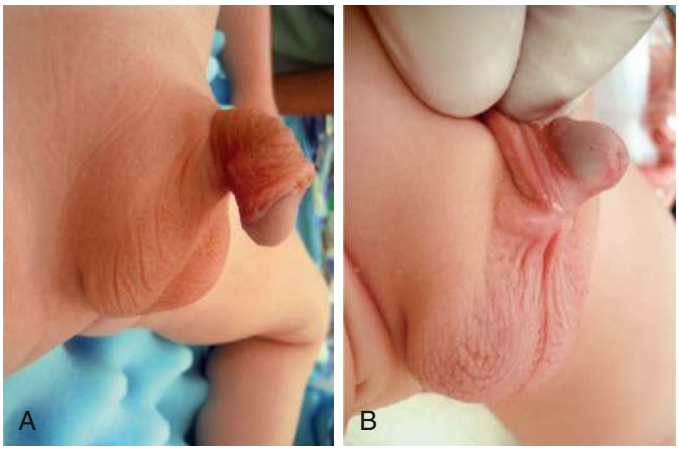

Fig. 581.2 A and B, Two examples of chordee without hypospadias. Note hooded foreskin and normal location of urethral meatus.

PHIMOSIS AND PARAPHIMOSIS

Phimosis refers to the inability to retract the prepuce. At birth, phimosis is physiologic. Over time, the adhesions between the prepuce and glans lyse and the distal phimotic ring loosens. In 80% of uncircumcised males, the prepuce becomes retractable by 3 years of age. Accumulation of epithelial debris under the infant's prepuce is physiologic and does not mandate circumcision. In older males, phimosis may be physiologic or may be pathologic from **lichen sclerosus (balanitis xerotica obliterans)** at the tip of the foreskin (Fig. 581.3A) and can also affect the meatus (see Fig. 581.3B). The prepuce might have been retracted forcefully on one or two occasions in the past, which can result in a cicatricial scar that prevents subsequent retraction of the foreskin. In males with persistent physiologic or pathologic phimosis, application of corticosteroid ointment to the tip of the foreskin twice daily for 1 month loosens the phimotic ring in two thirds of cases. *If there is ballooning of the foreskin during voiding or phimosis beyond 10 years of age and topical corticosteroid therapy is ineffective, circumcision is recommended.*

Paraphimosis occurs when the foreskin is retracted proximal to the coronal sulcus and the prepuce cannot be pulled back over the glans (Fig. 581.4). Painful venous stasis in the retracted foreskin results, with

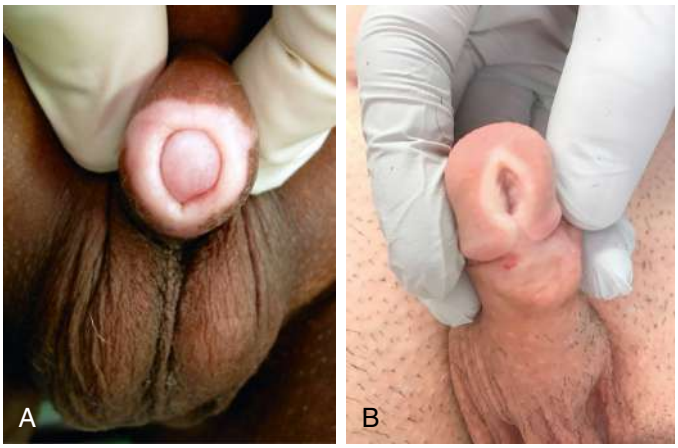

Fig. 581.3 A, Balanitis xerotica obliterans. Note whitish cicatricial plaque. B, Involvement of the urethral meatus necessitated a meatoplasty.

Fig. 581.4 Paraphimosis. The foreskin has been retracted proximal to the glans penis and is markedly swollen secondary to venous congestion.

edema leading to severe pain and inability to reduce the foreskin (pull it back over the glans). Treatment includes lubricating the foreskin and glans and then simultaneously compressing the glans and placing distal traction on the foreskin to try to push the phimotic ring past the coronal sulcus. Topical application of granulated sugar has been reported to aid in reduction of edema by creation of an osmotic gradient, facilitating reduction of paraphimosis. In addition, injection of hyaluronidase into the edematous skin has been reported to result in immediate reduction in swelling. In rare cases, emergency circumcision under general anesthesia is necessary.

CIRCUMCISION

In the United States, circumcision usually is performed for cultural reasons, but several health benefits have been identified that may outweigh the risks of the procedure. Specific benefits include prevention of urinary tract infections (UTIs) and penile cancer and reducing the risk and transmission of some sexually transmitted infections, including HIV.

UTIs are 10-15 times more common in uncircumcised *infant* males than in circumcised infants, with the urinary pathogens arising from bacteria that colonize the space between the prepuce and glans. The risk of febrile UTI (see Chapter 575) is highest between birth and 6 months, but there is an increased risk of UTI until at least 5 years of age, or age of completion of toilet training. Many recommend circumcision in infants who are predisposed to UTI, such as those with congenital hydronephrosis and vesicoureteral reflux. Circumcision reduces the risk of sexually transmitted infections in adults (see Chapter 163), in particular HIV (see Chapter 322). There have been only a handful of reports of adult males who were circumcised at birth and subsequently acquired penile carcinoma, but in Scandinavian countries, where few males are circumcised and hygiene is good, the incidence of penile cancer is low.

Circumcision should be performed by trained providers under sterile conditions. When performing a neonatal circumcision, local analgesia, such as a dorsal or penile ring block or application of EMLA (eutectic mixture of local anesthetics) cream (lidocaine 2.5% and prilocaine 2.5%) is recommended. Early and late complications after neonatal circumcision include bleeding, wound infection, meatal stenosis, secondary phimosis, removal of insufficient foreskin, and fibrous penile adhesions (skin bridge; Fig. 581.5); 0.2–3.0% of patients undergo a subsequent operative procedure. Males with a large hydrocele or hernia are at particular risk for secondary phimosis because the scrotal swelling tends to displace the penile shaft skin over the glans. Serious complications of newborn circumcision include sepsis, amputation of the distal part of the glans, removal of an excessive amount of foreskin, and urethrocutaneous fistula. Circumcision should not be performed in neonates with hypospadias, chordee without hypospadias, or a dorsal hood deformity (relative contraindication) or in those with a small penis (Fig. 581.6). In males with a "wandering raphe," in which the median raphe deviates to one side, there may be underlying penile torsion or hypospadias, and evaluation by a pediatric urologist is suggested before performing a circumcision.

PENILE TORSION

Penile torsion, a rotational defect of the penile shaft, usually occurs in a counterclockwise direction, usually to the left side (see Fig. 581.6D). In most cases, penile development is normal, and the condition is unrecognized until circumcision is performed or the foreskin is retractable. In many cases, the midline raphe of the penile shaft is deviated. Penile torsion also occurs in some males with hypospadias. The defect has primarily cosmetic significance, and correction is unnecessary if the rotation is <60 degrees from the midline. The severity of penile torsion may lessen during infancy.

INCONSPICUOUS PENIS

The term *inconspicuous penis* refers to a penis that appears to be small. A **webbed penis** is a condition in which the scrotal skin extends onto the ventral penile shaft. This deformity represents an abnormality of the attachment between the penis and scrotum. Although the deformity might appear mild, if a routine circumcision is performed, the penis can retract into the scrotum, resulting in secondary phimosis **(trapped penis).** The concealed **(hidden or buried)** penis is a normally developed penis that is camouflaged by the suprapubic fat pad (Fig. 581.7). This anomaly may be congenital, iatrogenic after circumcision, or a result of obesity. Surgical correction is indicated for cosmetic reasons or if there is a functional abnormality with a splayed stream.

A **trapped penis** is an acquired form of inconspicuous penis and refers to a phallus that becomes embedded in the suprapubic fat pad after circumcision (Fig. 581.8). This deformity can occur after neonatal circumcision in an infant who has significant scrotal swelling from a large hydrocele or inguinal hernia or after routine circumcision in an infant with a webbed penis. This complication can predispose to UTIs and can cause urinary retention. Initial treatment of a trapped penis should include topical corticosteroid cream, which often loosens the phimotic ring. In some cases, secondary repair is necessary at 6-9 months.

MICROPENIS

Micropenis is defined as a normally formed penis that is at least 2.5 standard deviations (SD) below the mean in size (Fig. 581.9). Typically, the ratio of the length of the penile shaft to its circumference is normal.

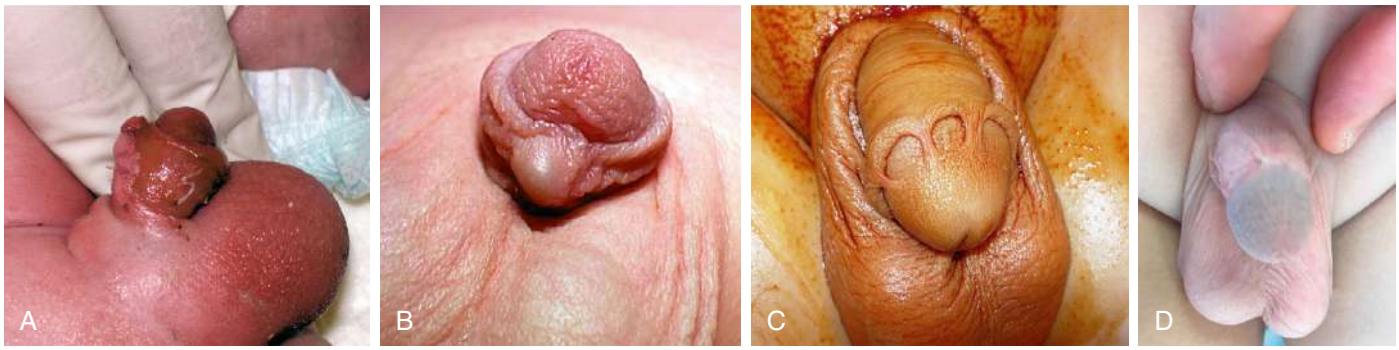

Fig. 581.5 Complications of circumcision. **A,** Denuded penile shaft. With local care, the penis healed and appeared normal. **B,** Midline epithelial inclusion cyst. **C** and **D,** Fibrous penile skin bridges.

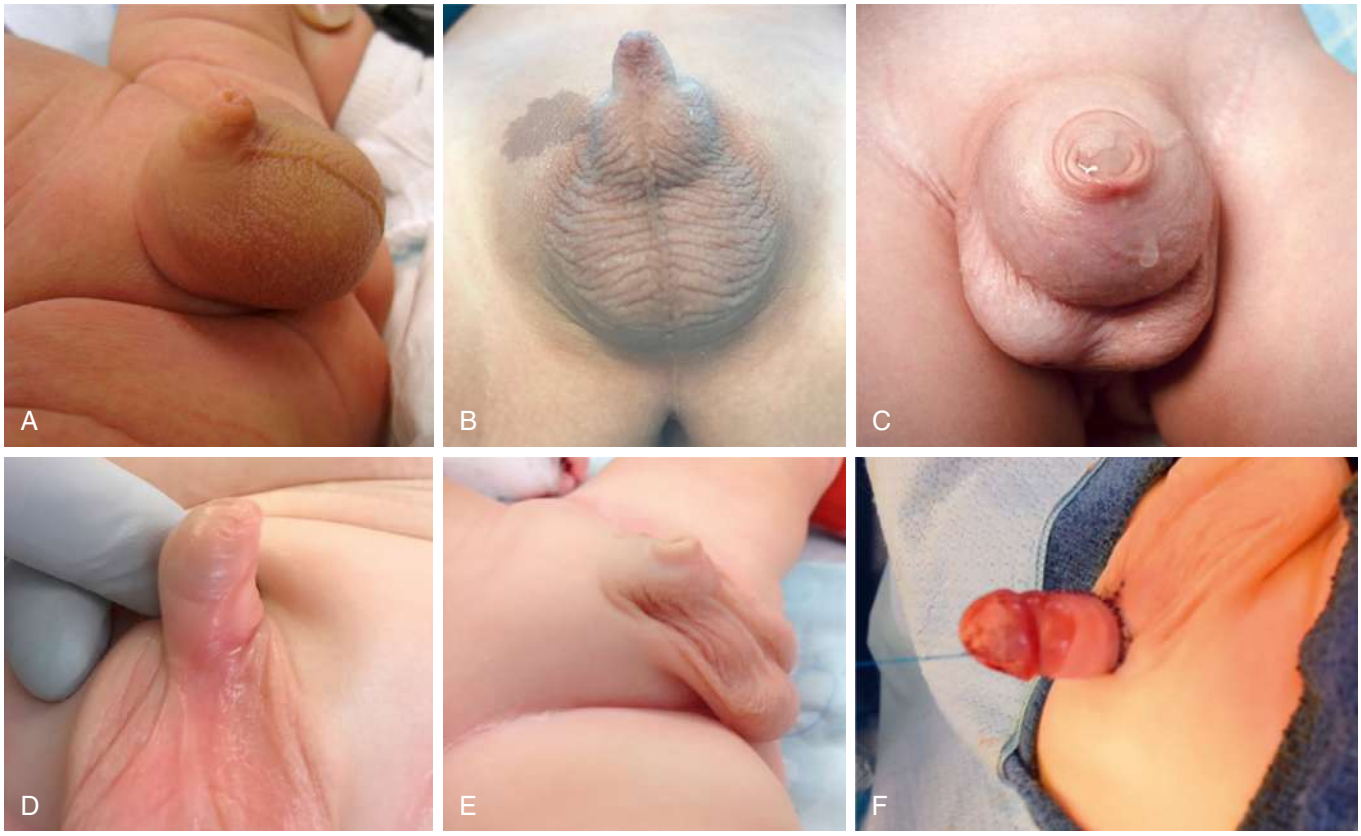

Fig. 581.6 Examples of congenital deformities in which neonatal circumcision is contraindicated. **A** and **B,** Hidden penis. **C,** Megaprepuce. **D,** Penile torsion to left side; note "wandering raphe." **E,** Webbed penis; note scrotal attachment to penile shaft. **F,** Same patient as in **E** following reconstruction at 6 mo.

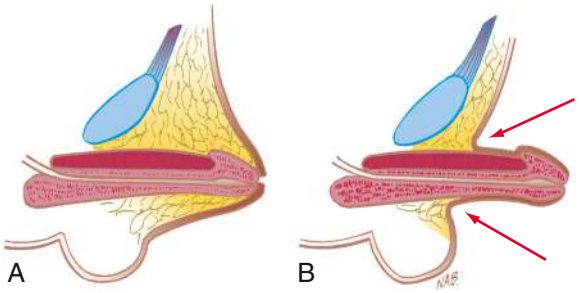

Fig. 581.7 Concealed penis **(A)**, which may be visualized by retracting skin lateral to penile shaft **(B)**. *(From Wein AJ, Kavoussi LR, Novick AC, et al., eds. Campbell-Walsh Urology, 9th ed. Philadelphia: WB Saunders; 2007: Fig. 126-4, p. 2339.)*

The pertinent measurement is the **stretched penile length**, which is measured by stretching the penis and measuring the distance from the penile base under the pubic symphysis to the tip of the glans. The mean length of the term newborn penis is 3.5 ± 0.7 cm and the diameter is 1.1 ± 0.2 cm. The diagnosis of micropenis in a male newborn is if the stretched length is <1.9 cm.

Micropenis usually results from a hormonal abnormality that occurs after the 14th week of gestation. Common causes include hypogonadotropic hypogonadism, hypergonadotropic hypogonadism (primary testicular failure), and idiopathic micropenis. If growth hormone deficiency is also present, neonatal hypoglycemia can occur. The most common cause of micropenis is failure of the hypothalamus to produce an adequate amount of gonadotropin-releasing hormone, as typically occurs in Kallmann syndrome (see Chapter 623), Prader-Willi syndrome (see Chapter 99), and Lawrence-Moon-Bardet-Biedl

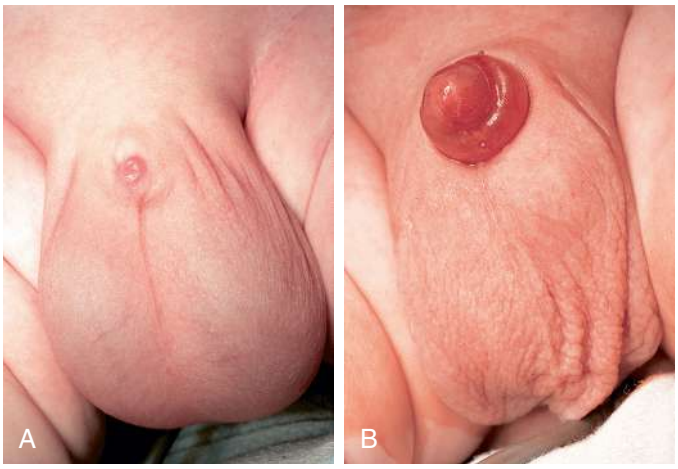

Fig. 581.8 A, Trapped (concealed) penis resulting from circumcision. B, Same patient after revision of circumcision. *(From Wein AJ, Kavoussi LR, Novick AC, et al., eds. Campbell-Walsh Urology, 9th ed. Philadelphia: WB Saunders; 2007: Fig. 126-2, p. 2340.)*

Fig. 581.9 Micropenis secondary to hypopituitarism in an 8-yr-old male. *(From Wein AJ, Kavoussi LR, Novick AC, et al., eds. Campbell-Walsh Urology, 9th ed. Philadelphia: WB Saunders; 2007: Fig. 126-5a, p. 2341.)*

syndrome. In some cases, there is growth hormone deficiency. Primary testicular failure can result from gonadal dysgenesis or rudimentary testes syndrome and also occurs in **Robinow syndrome** (characterized by hypoplastic genitals, shortening of the forearms, frontal bossing, hypertelorism, wide palpebral fissures, short broad nose, long philtrum, small chin, brachydactyly, and a normal karyotype).

A pediatric endocrinologist, geneticist, and pediatric urologist should examine all children with these syndromes, with participation by medical ethics. *Evaluation includes a karyotype, assessment of anterior pituitary function and testicular function, and MRI* to determine the anatomic integrity of the hypothalamus and the anterior pituitary gland as well as the midline structure of the brain. One of the difficult questions is whether androgen therapy is essential during childhood, because androgenic stimulation of penile growth in a prepubertal male can limit the growth potential of the penis in puberty. Studies of small groups of men with micropenis suggest that many, although not all, have satisfactory sexual function. Consequently, a decision for gender surgery in infancy is infrequently made.

PRIAPISM

Priapism is a persistent penile erection at least 4 hours in duration that continues beyond, or is unrelated to, sexual stimulation. Typically, only the corpora cavernosa is affected. There are three subtypes:

- Ischemic (venoocclusive, low-flow) priapism is characterized by little or no cavernous blood flow, and cavernous blood gases are hypoxic, hypercapnic, and acidotic. The corpora are rigid and tender to palpation. Immediate intervention is warranted.
- Nonischemic (arterial, high-flow) priapism is caused by unregulated cavernous arterial inflow. Typically, the penis is neither fully rigid nor painful. There is often a history of antecedent trauma resulting in a cavernous artery–corpora cavernosa fistula. Most cases resolve without intervention and expectant management is typical.
- Stuttering (intermittent) priapism is a recurrent form of ischemic priapism with painful erections with intervening periods of detumescence.

The most common cause of priapism in children is sickle cell disease, which is characterized by a predominance of sickle cell hemoglobin (see Chapter 511.1). As many as 29% of male patients with sickle cell disease develop priapism. The priapism is generally related to a low-flow state, secondary to sickling of red blood cells within the sinusoids of the corpora cavernosa during normal erection, resulting in venous stasis. This situation results in decreased local oxygen tension and pH, which potentiates further stasis and sickling. Priapism typically occurs during sleep, when mild hypoventilatory acidosis depresses oxygen tension and pH in the corpora. There is typically significant corporal engorgement with sparing of the glans penis. If the spongiosum is involved, voiding may be impaired. Evaluation may include a complete blood count. If the sickle cell status is unknown, hemoglobin electrophoresis should be performed. Corporal blood gas can help distinguish between a high-flow and low-flow state; ultrasound may also be used to differentiate these diagnoses. Other causes of low-flow priapism include sildenafil ingestion and leukemia.

In priapism secondary to sickle cell disease, medical therapy includes intravenous hydration, oxygen, alkalinization, and pain management with morphine. The American Urological Association guideline on priapism recommends concurrent intracavernous treatment beginning with corporal aspiration and irrigation with a sympathomimetic agent, such as phenylephrine. For patients with sickle cell disease, exchange transfusion may be considered but often takes several hours to arrange; therefore it is used when intracavernous treatment is not successful. If priapism has been present for >48 hours, ischemia and acidosis impair the intracavernous smooth muscle response to sympathomimetics. If irrigation and medical therapy are unsuccessful, a corporoglanular shunt should be considered. For stuttering priapism, administration of an oral α-adrenergic agent (pseudoephedrine) once or twice daily is first-line therapy. If this treatment is unsuccessful, an oral β-agonist (terbutaline) is recommended; a gonadotropin-releasing hormone analog plus flutamide is recommended as third-line therapy. Long-term follow-up of adults treated for sickle cell disease as children shows that satisfactory erectile function is inversely related to the patient's age at the onset of priapism and duration of priapism.

Nonischemic (high-flow) priapism most commonly follows perineal trauma, such as a straddle injury, that results in laceration of the cavernous artery. Typically, the aspirated blood is bright red, and the aspirate is similar to arterial blood. Color Doppler ultrasonography often demonstrates the fistula. The priapism spontaneously resolves in most cases. If it does not, angiographic embolization is indicated.

OTHER PENILE ANOMALIES

Aphallia (agenesis of the penis) affects approximately 1 in 10 million males. The karyotype is almost always 46, XY, and the usual appearance is that of a well-developed scrotum with descended testes and an absent penile shaft. Upper urinary tract abnormalities are common. In most cases, gender assignment surgery is recommended in the newborn period. **Diphallia** (duplication of the penis) ranges from a small accessory penis to complete duplication.

MEATAL STENOSIS

Meatal stenosis is a condition that almost always is acquired and occurs after neonatal circumcision. It most likely results from inflammation of

the denuded glans and is difficult to prevent. If the meatus is pinpoint, males void with a forceful, fine stream that goes a great distance. These males can experience dysuria, frequency, hematuria, or a combination of these conditions, typically around age 3-8 years. UTI is uncommon. Other males have dorsal deflection of the urinary stream. Although the meatus may be small, hydronephrosis or voiding difficulty is extremely rare unless there is associated balanitis xerotica obliterans (see Fig. 581.3; chronic dermatitis of unknown etiology, generally involving the glans and prepuce, occasionally extending into the urethra). Treatment is meatoplasty, in which the urethral meatus is opened surgically; this procedure can be performed either under anesthesia as an outpatient or in the office using local anesthesia (EMLA cream) with or without sedation. Routine cystoscopy is unnecessary.

OTHER MALE URETHRAL ANOMALIES

Parameatal urethral cyst manifests as an asymptomatic small cyst on one side of the urethral meatus. Treatment is excision under anesthesia. **Congenital urethral fistula** is a rare deformity in which a fistula is present from the penile urethra. It usually is an isolated abnormality. Treatment is fistula closure. **Megalourethra** is a large urethra that usually is associated with abnormal development of the corpus spongiosum. This condition is most commonly associated with prune-belly syndrome (see Chapter 577). **Urethral duplication** is a rare condition in which the two urethral channels lie in the same sagittal plane. There are many variations with complete and incomplete urethral duplication. These males often have a double stream. Most commonly, the dorsal urethra is small, and the ventral urethra is of normal caliber. Treatment involves excision of the small urethra. **Urethral hypoplasia** is a rare condition in which the entire male urethra is extremely small but patent. In some cases, a temporary cutaneous vesicostomy is necessary for satisfactory urinary drainage. Either gradual enlargement of the urethra or major urethroplasty is necessary. **Urethral atresia** refers to maldevelopment of the urethra and nearly always is fatal unless the urachus remains patent throughout gestation.

URETHRAL PROLAPSE (FEMALE)

Urethral prolapse occurs predominantly in females 1-9 years of age. The most common signs are bloody spotting on the underwear or diaper, although dysuria or perineal discomfort also can occur (Fig. 581.10). An inexperienced examiner can mistake the finding for sexual abuse. Initial therapy consists of application of estrogen cream 2-3 times daily for 3-4 weeks and sitz baths. Surgical repair is recommended for females that fail medical therapy and is curative. In some cases, this can be performed in the office under local anesthesia.

Fig. 581.10 Urethral prolapse in a 4-yr-old female who had bloody spotting on her underwear.

Fig. 581.11 Paraurethral cyst in a newborn female.

Fig. 581.12 Prolapsed ectopic ureterocele in a female infant. She had a nonfunctioning upper pole collecting system connected to the ureterocele.

OTHER FEMALE URETHRAL LESIONS

Paraurethral cyst results from retained secretions in the Skene glands secondary to ductal obstruction (Fig. 581.11). These lesions are present at birth, and most regress in size during the first 4-8 weeks, although occasionally incision and drainage is necessary. A **prolapsed ectopic ureterocele** appears as a cystic mass protruding from the urethra and is a presenting symptom in 10% of females with a ureterocele, which is a cystic swelling of the terminal ureter (Fig. 581.12). Ultrasonography should be performed to visualize the upper urinary tracts to confirm the diagnosis. Usually, either the ureterocele is incised or an upper urinary tract reconstructive procedure is necessary.

Chapter 582

Disorders and Anomalies of the Scrotal Contents

Heather N. Di Carlo and Chad B. Crigger

UNDESCENDED TESTIS (CRYPTORCHIDISM)

The absence of a palpable testis in the scrotum indicates that the testis is undescended, absent, atrophic, or retractile.

Epidemiology

An undescended **(cryptorchid)** testis is the most common congenital genitourinary tract disorder in males. At birth, approximately 4.5% of males have an **undescended testis.** Because testicular descent occurs at 7-8 months of gestation, 30% of premature male infants have an undescended testis; the incidence is 3.4% at term. As many as 50% of congenital undescended testes descend spontaneously during the first 3 months of life, and by 6 months the incidence decreases to 1.5%. Spontaneous descent occurs secondary to a temporary testosterone surge (termed a *minipuberty*) during the first 2 months, which also results in significant penile growth. If the testis has not descended by 4 months, it will remain undescended. Cryptorchidism is bilateral in 10% of cases. There is some evidence that the incidence of cryptorchidism is increasing; this is attributed to increase in utero exposure to endocrine disrupting chemicals. Although cryptorchidism usually is considered to be congenital, some older males have a scrotal testis that "ascends" to a low inguinal position and therefore requires an orchiopexy. In addition, 1–2% of neonatal and young males undergoing hernia repair develop secondary cryptorchidism from scar tissue along the spermatic cord.

Pathogenesis

The process of testicular descent is regulated by an interaction among genetic, hormonal, and mechanical factors, including testosterone, dihydrotestosterone, müllerian-inhibiting factor, the gubernaculum, intraabdominal pressure, and the genitofemoral nerve (Table 582.1). The testis develops in the abdomen at 7-8 weeks of gestation. Insulin-like factor 3 controls the transabdominal phase. At 10-11 weeks, the Leydig cells produce testosterone, which stimulates differentiation of the Wolffian (mesonephric) duct into the epididymis, vas deferens, seminal vesicle, and ejaculatory duct. At 32-36 weeks, the testis, which is anchored at the internal inguinal ring by the gubernaculum, begins its process of descent and is controlled in part by a calcium gene-related peptide produced by the genitofemoral nerve. The gubernaculum descends the inguinal canal and guides the testis into the scrotum. Following testicular descent, the patent processus vaginalis (hernia sac) normally closes.

Clinical Manifestations

Undescended testes are classified as **abdominal** (which are nonpalpable), **peeping** (abdominal but can be pushed into the upper part of the inguinal canal), **inguinal, gliding** (can be pushed into the scrotum but retracts immediately to the pubic tubercle), and **ectopic** (superficial inguinal pouch or, rarely, perineal). Most undescended testes are palpable just distal to the inguinal canal over the pubic tubercle.

A **disorder of sex development** should be suspected in a newborn phenotypic male with bilateral nonpalpable testes, as the child could be a virilized female with congenital adrenal hyperplasia (see Chapter 616). *In a male with midpenile or proximal hypospadias and a palpable undescended testis, the risk of a disorder of sexual development is 15%; the risk is 50% if the testis is nonpalpable.*

The potential **consequences of cryptorchidism** include poor testicular growth, infertility, testicular malignancy, associated hernia, torsion of the cryptorchid testis, and the possible psychologic effects of an empty scrotum.

The undescended testis is normal at birth histologically with a plethora of germ cells, but pathologic changes occur by 6-12 months of age. Delayed germ cell maturation, germ cell depletion, hyalinization of the seminiferous tubules, and reduced Leydig cell number are typical; these changes are progressive over time if the testis remains undescended. At puberty, an undescended testis has no viable sperm components. Although less severe, changes may occur in the contralateral descended testis after 4-7 years. After treatment for a unilateral undescended testis, 85% of patients are fertile, which is slightly less than the 90% rate of fertility in an unaffected population of adult males. In contrast, following bilateral orchiopexy, only 50–65% of patients are fertile.

The risk of a **germ cell malignancy** (see Chapter 552) developing in an undescended testis is four times higher than in the general population and is approximately 1 in 80 with a unilateral undescended testis and 1 in 40-50 for bilateral undescended testes. Testicular tumors are less common if orchiopexy is performed before 10 years of age, but they still occur, and adolescents should be instructed in testicular self-examination. The peak age for developing a malignant testis tumor is 15-45 years of age. The most common tumor developing in an undescended testis in an adolescent or adult is a **seminoma** (65%); after orchiopexy, nonseminomatous tumors represent 65% of testis tumors. Orchiopexy seems to reduce the risk of testicular cancer; it is uncommon for testis tumors to occur if the orchiopexy was performed before the age of 2 years. The contralateral scrotal testis may also be at a slightly increased risk for malignancy.

An indirect inguinal hernia usually accompanies a congenital undescended testis but rarely is symptomatic. Torsion and infarction of the cryptorchid testis also are uncommon but can occur because of excessive mobility of undescended testes. Consequently, inguinal pain and/or swelling in a male with an undescended testis should raise the suspicion of an inguinal hernia or torsion of the undescended testis.

An *acquired* or **ascending undescended testis** occurs when a male has a descended testis at birth, but during childhood, usually between ages 4-10 years, the testis does not remain in the scrotum. Such males often have a history of a retractile testis. With testicular ascent on physical examination, the testis can often be manipulated into the upper scrotum, but there is obvious tension on the spermatic cord. This condition is speculated to result from incomplete involution of the processus vaginalis, restricting spermatic cord growth and resulting in the testis gradually moving out of its scrotal position during a male's somatic growth.

On physical examination of the scrotum, the child should be encouraged to relax. Careful consideration of a hypoplastic ipsilateral scrotum may clue the examiner in to a diagnosis of an undescended testicle. The examiner should examine the patient's scrotum and inguinal canal using their dominant hand. The nondominant hand is positioned over the pubic tubercle and is pushed inferiorly toward the scrotum. The examiner's dominant hand is used to try to palpate the testis. If the testis is nonpalpable, the *soap test* often is useful; soap is applied to the inguinal canal and the examiner's hand, significantly reducing friction and facilitating identification of an inguinal testis. In addition, pulling on the scrotum can pull a high inguinal testis into a palpable position. One soft sign that a testis is absent is contralateral testicular hypertrophy, but this finding is not 100% diagnostic.

Retractile testes may be misdiagnosed as undescended testes. Males older than 1 year of age often have a brisk cremasteric reflex, and if the child is anxious or ticklish during scrotal examination, the testis may be difficult to manipulate into the scrotum. Males should be examined with their legs in a relaxed frog-leg position, and if the testis can be manipulated into the scrotum comfortably, it is probably retractile. It should be monitored every 6-12 months with follow-up physical examinations, because it can become an acquired undescended testis. Overall, as many as one third of males with a retractile testis develop an acquired undescended testis requiring orchiopexy, and males younger than 7 years of age at diagnosis of a retractile testis are at greatest risk. Although definitive data are not available, it is generally thought that males with a retractile testis are not at increased risk for infertility or malignancy.

Approximately 10% of undescended testes are **nonpalpable testes.** Of these, 50% are viable testes in the abdomen or high in the inguinal canal, and 50% are atrophic or absent, almost always in the scrotum,

secondary to spermatic cord torsion in utero **(vanishing testis).** If the nonpalpable testis is abdominal, it will not descend after 3 months of age. *Although sonography often is performed to try to identify whether the testis is present, it rarely changes clinical management, because the abdominal testis and atrophic testis are not identified on sonography.* Inguinal/scrotal sonography might be beneficial in obese males with a nonpalpable testis; in this clinical setting, the undescended testis often is nonpalpable, and an inguinal/scrotal sonogram can be beneficial in surgical planning. Computed tomographic imaging is relatively accurate in demonstrating the presence of the testis, but the radiation exposure is significant. MRI is even more accurate, but the disadvantage is that general anesthesia or sedation is necessary in most young children.

None of these imaging studies are 100% accurate and in general do not add significantly to clinical decision-making by the pediatric urologist or pediatric surgeon. Consequently, routine use of imaging is discouraged. A diagnostic approach is noted in Figure 582.1.

Treatment

The congenital undescended testis that does not descend by 6 months (corrected for gestational age) should be treated surgically within the next 12 months. Most testes can be brought down to the scrotum with an orchiopexy, which involves an inguinal incision, mobilization of the testis and spermatic cord, and correction of an indirect inguinal hernia. The procedure is typically performed on an outpatient basis and has a success rate of 98%. In some males with a testis that is close to the scrotum, a prescrotal orchiopexy can be performed. In this procedure, the entire operation is performed through a high scrotal incision. Often the associated inguinal hernia also can be corrected through this incision. Advantages of this approach over the inguinal approach include shorter operative time and less postoperative discomfort.

In males with a nonpalpable testis, an exam under anesthesia should be done to reassess for palpability; if testes are still nonpalpable, diagnostic laparoscopy is performed in most centers. This procedure allows safe and rapid assessment of whether the testis is intraabdominal. In most cases, orchiopexy of the intraabdominal testis located adjacent to the internal inguinal ring is successful, but orchiectomy should be considered in more difficult cases or when the testis appears to be atrophic. A two-stage orchiopexy sometimes is needed in males with a high abdominal testis. Males with abdominal testes are managed with laparoscopic techniques at many institutions. Testicular prostheses are available for older children and adolescents when the absence of the gonad in the scrotum might have an undesirable psychologic effect. The FDA has approved a saline testicular implant. Solid silicone "carving block" implants also are used (Fig. 582.2). Placement of testicular prostheses early in childhood is recommended for males with anorchia (absence of both testes).

The American Urological Association guidelines for the evaluation and treatment of males with an undescended testis are summarized in Table 582.2.

SCROTAL SWELLING

Scrotal swelling may be acute or chronic and painful or painless (Table 582.3). Abrupt onset of painful scrotal swelling necessitates prompt evaluation because some conditions, such as testicular torsion and incarcerated inguinal hernia, require emergency surgical management. Tables 582.4 and 582.5 show the differential diagnosis.

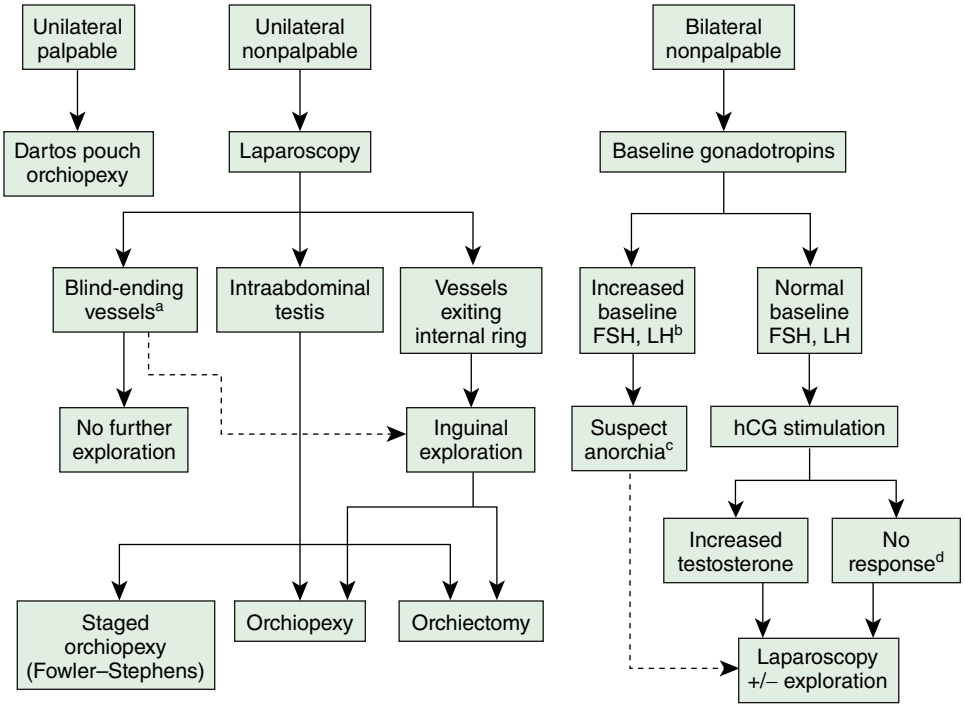

Fig. 582.1 Management algorithm for undescended testis. [a]If blind-ending vas deferens vessels are unequivocally identified, then there is no need for further exploration. [b]Baseline FSH and LH levels are elevated if values are 3 SD above the mean. *c*, Increased suspicion of anorchia with elevated baseline FSH and LH levels; however, exploration is still warranted. *d*, Testicular remnant tissue may be present despite a negative hCG stimulation test; therefore exploration for testicular remnant tissue should still be performed. *(From Bowlin PR, Lorenzo AJ. Undescended testes and testicular tumors. In: Holcomb III GW, Murphy JP, St. Peter SD, eds. Holcomb and Ashcraft's Pediatric Surgery, 7th ed. Philadelphia: Elsevier; 2020: Fig. 51-2, p. 808.)*

Table 582.2 American Urological Association Guidelines for Evaluation and Treatment of Males with an Undescended Testis

DIAGNOSIS

- Providers should obtain gestational history at initial evaluation of males with suspected cryptorchidism. *(Standard)*
- Primary care providers should palpate testes for quality and position at each recommended well-child visit. *(Standard)*
- Providers should refer infants with a history of cryptorchidism (detected at birth) who do not have spontaneous testicular descent by 6 months (corrected for gestational age) to an appropriate surgical specialist for timely evaluation. *(Standard)*
- Providers should refer males with the possibility of newly diagnosed (acquired) cryptorchidism after 6 months (corrected for gestational age) to an appropriate surgical specialist. *(Standard)*
- Providers must immediately consult an appropriate specialist for all phenotypic male newborns with bilateral, nonpalpable testes for evaluation of a possible disorder of sex development (DSD). *(Standard)*
- Providers should not perform ultrasound (US) or other imaging modalities in the evaluation of males with cryptorchidism before referral because these studies rarely assist in decision making. *(Standard)*
- Providers should assess the possibility of a disorder of sex development (DSD) when there is increasing severity of hypospadias with cryptorchidism. *(Recommendation)*
- In males with bilateral, nonpalpable testes who do not have congenital adrenal hyperplasia (CAH), providers should measure Mullerian Inhibiting Substance (MIS or Anti-Mullerian Hormone [AMH] level), and consider additional hormone testing, to evaluate for anorchia. *(Option)*
- In males with retractile testes, providers should monitor the position of the testes at least annually to monitor for secondary ascent. *(Standard)*

TREATMENT

- Providers should not use hormonal therapy to induce testicular descent because evidence shows low response rates and lack of evidence for long-term efficacy. *(Standard)*
- In the absence of spontaneous testicular descent by 6 months (corrected for gestational age), specialists should perform surgery within the next year. *(Standard)*
- In prepubertal males with palpable, cryptorchid testes, surgical specialists should perform scrotal or inguinal orchidopexy. *(Standard)*
- In prepubertal males with nonpalpable testes, surgical specialists should perform examination under anesthesia to reassess for palpability of testes. If nonpalpable, surgical exploration and, if indicated, abdominal orchidopexy should be performed. *(Standard)*
- At the time of exploration for a nonpalpable testis in boys, surgical specialists should identify the status of the testicular vessels to help determine the next course of action. *(Clinical Principle)*
- In males with a normal contralateral testis, surgical specialists may perform an orchiectomy (removal of the undescended testis) if a male has a normal contralateral testis and either very short testicular vessels and vas deferens, dysmorphic or very hypoplastic testis, or postpubertal age. *(Clinical Principle)*
- Providers should counsel males with a history of cryptorchidism and/or monorchidism and their parents regarding potential long-term risks and provide education on infertility and cancer risk. *(Clinical Principle)*

Clinical Manifestations

A detailed history is helpful in determining the cause of the swelling and includes the rapidity of onset of pain. With testicular torsion, the pain often is sudden in onset and may be associated with exercise or minor genital trauma, duration of pain, and radiation of pain. Inguinal discomfort is common with testicular torsion, inguinal hernia, or epididymitis, and associated flank pain can occur with passage of a ureteral calculus; previous episodes of similar pain, which are common in males with intermittent testicular torsion or inguinal hernia; nausea and vomiting, which

Table 582.3 Differential Diagnosis of Pediatric Adolescent Acute Scrotal Pain

- Appendage torsion
  - Appendix testis
  - Other appendage (epididymis, paradidymis, vas aberrans)
- Spermatic cord torsion
  - Intravaginal, acute or intermittent
  - Extravaginal

are associated with testicular torsion and inguinal hernia; and irritative urinary symptoms, such as dysuria, urgency, and frequency, which indicate a urinary tract infection that can cause epididymitis. Some males report a recent history of scrotal trauma. There are multiple reports of familial testicular torsion related to inheritance of bell clapper deformity (discussed later). Males with lower urinary tract pathology such as urethral stricture or neuropathic bladder may be prone to epididymitis.

Physical examination may be difficult in males with a painful scrotum. Some have advocated performing a spermatic cord block or administering intravenous analgesia to facilitate the examination, but such measures are often unnecessary. Scrotal wall erythema is common in testicular torsion, epididymitis, torsion of the appendix testis, and an incarcerated hernia. In males with a normal cremasteric reflex, testicular torsion is unlikely. Absence of a cremasteric reflex is nondiagnostic.

Laboratory Findings and Diagnosis

Pertinent laboratory studies include urinalysis and culture. A positive urinalysis suggests bacterial epididymitis (uncommon before adolescence). Serum studies are not helpful in establishing a diagnosis unless a testicular malignancy is suspected. After initial evaluation in males with testicular pain, color Doppler ultrasonography often is helpful in establishing the diagnosis because it assesses whether testicular blood flow is normal, reduced, or increased (Fig. 582.3). If a hydrocele is present and the testis is nonpalpable, or if an abnormality of the testis is found, sonography also is indicated. *Imaging studies are not 100% accurate; they should not be used to decide whether a male with testicular pain should be referred for urologic evaluation.* As such, torsion is a clinical diagnosis.

Color Doppler ultrasonography allows assessment of testicular blood flow and testicular morphologic features. Accuracy is >95% if the ultrasonographer is experienced and the patient is older than 2 years of age. The "whirlpool" sign is pathognomonic. A false-negative study (demonstrates normal testicular blood flow) can occur in a male with testicular torsion if the degree of torsion is <360 degrees and the duration of torsion is short, because there may be continued testicular perfusion. In males <1 year of age, including neonates, blood flow may be difficult to demonstrate in 15% of normal testes.

TESTICULAR (SPERMATIC CORD) TORSION

Etiology

Testicular torsion requires prompt diagnosis and treatment to salvage the testis. Torsion is the most common cause of severe testicular pain in males 12 years of age and older and is uncommon before age 10. It is caused by inadequate fixation of the testis within the scrotum, resulting from a redundant tunica vaginalis and abnormal gubernacular attachment, allowing excessive mobility of the testis. The abnormal attachment is termed a **bell clapper deformity** and may be bilateral. Following spermatic cord torsion, venous congestion occurs, and subsequently arterial flow is interrupted. The likelihood of testis survival depends on the duration and severity of torsion. After 6 hours of absent blood flow to the testis, irreversible loss of spermatogenesis can occur. Torsion is familial in 10% of males.

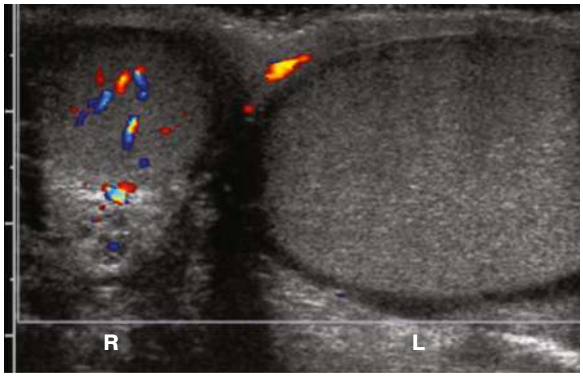

Fig. 582.3 Testicular torsion and axis change. A color Doppler ultrasound in the transverse plane shows color flow in the right testicle. The right testicle is oval to circular because it has been evaluated in the transverse plane. The left testicle is elongated as if it is in the longitudinal plane, indicating an abnormal lie within the scrotum worrisome for torsion. Lack of color Doppler flow in the left testicle confirms left testicular torsion. *(From Coley BD, ed. Caffey's Pediatric Diagnostic Imaging, 13th ed. Philadelphia: Elsevier; 2019: Fig. 125-13, p. 1195.)*

Diagnosis

Testicular torsion produces acute pain and swelling of the scrotum. On examination, the scrotum is swollen, and the testis is exquisitely tender and often difficult to examine. The cremasteric reflex is nearly always absent, though this may be absent at baseline in a proportion of males. The position (lie) of the testis is abnormal, and the testis is often located high in the scrotum. In addition, nausea and vomiting often occur. The condition can be differentiated from an incarcerated hernia because swelling in the inguinal area typically is absent with torsion. The Testicular Workup for Ischemia and Suspected Torsion (TWIST) score is a clinical tool that can be used determine the likelihood of testicular torsion. The score consists of testicular swelling (2 points), hard testis (2 points), high-riding testis (1 point), absent cremasteric reflex (1 point), and nausea/vomiting (1 point). Patients can then be stratified into low (0 points), intermediate (1-5), and high risk (6-7), which aids in determining further imaging and/or surgical consultation.

For patients who are high risk or meet the clinical diagnosis of testicular torsion, prompt surgical consultation should be obtained. If the pain duration is <4-6 hours, manual detorsion may be attempted. In 65% of cases the torsed testis rotates inward, so detorsion should be attempted in the opposite direction (e.g., the left testis is rotated clockwise). Successful manual detorsion results in dramatic pain relief. In the emergency department, patients with an intermediate risk TWIST score should undergo immediate scrotal ultrasound. In some centers, this is performed as a point of care procedure by the emergency department staff.

Some adolescents experience **intermittent testicular torsion**. These males report episodes of severe unilateral testicular pain that resolves spontaneously after 30-60 minutes. Treatment is elective bilateral scrotal orchiopexy. Close follow-up and clear return instructions are requisite in such cases until elective orchiopexy is performed.

Treatment

Treatment is prompt surgical exploration and detorsion. If the testis is explored within 6 hours of torsion, up to 90% will survive. Testicular salvage decreases rapidly with a delay of more than 6 hours. If the degree of torsion is 360 degrees or less, the testis might have sufficient arterial flow to allow the gonad to survive, even after 24-48 hours. Following detorsion, the testis is fixed in the scrotum with nonabsorbable sutures, termed **scrotal orchiopexy,** to prevent torsion in the future. The contralateral testis also should be fixed in the scrotum because the predisposing anatomic condition (bell clapper deformity) often is bilateral. If the testis appears nonviable, orchiectomy is performed (Fig. 582.4A). The detorsed testis may undergo compartment syndrome,

Fig. 582.4 A, Left testicular torsion in adolescent with acute scrotum; the testis is necrotic. B, "Late-phase torsion" in an adolescent with severe testicular pain 1 month prior. Note absence of inflammation and high position of testis in scrotum.

and following detorsion, despite blood flow to the testis, high intratesticular pressure may cause ischemia and necrosis. This condition has been treated intraoperatively by incising the tunica vaginalis (similar to a blunt testicular rupture) and placing a tunica vaginalis flap over the exposed tunica. Some adolescents do not undergo prompt evaluation and treatment and present with *late phase testicular torsion,* in which there is delayed diagnosis of torsion. Often the testis is high in the scrotum and nontender (see Fig. 582.4B). While males with torsion of longer duration prior to treatment may exhibit reduced spermatogenesis, current evidence shows pregnancy rates of couples in which the male has a history of acute testicular torsion to be similar to the general population.

Spermatic cord torsion can also occur in the fetus or neonate. This condition results from incomplete attachment of the tunica vaginalis to the scrotal wall and is "extravaginal." When torsion occurs just before delivery, the baby usually is born with a large, firm, nontender testis. Usually the ipsilateral hemiscrotum is ecchymotic (Fig. 582.5). In these cases, the testis rarely is viable because torsion was a remote event. However, the contralateral testis is at increased risk for torsion until 1-2 months beyond term. The pediatric urology community is divided regarding whether immediate exploration is necessary in a male newborn who has suspected testicular torsion at birth, but if observation is recommended, the family needs to be counseled regarding the risk of contralateral spermatic cord torsion. If the initial exam is normal and the newborn subsequently develops scrotal swelling and erythema, and imaging is consistent with spermatic cord torsion, emergency scrotal exploration is indicated.

TORSION OF THE APPENDIX TESTIS/EPIDIDYMIS

Torsion of the appendix testis is the most common cause of testicular pain in males age 4-10 years but is uncommon in adolescents. The appendix testis is a stalklike structure that is a vestigial embryonic remnant of the müllerian (paramesonephric) ductal system that is attached to the upper pole of the testis. When it undergoes torsion, progressive inflammation and swelling of the testis and epididymis occurs, resulting in testicular pain and scrotal erythema. The onset of pain is typically gradual. Palpation of the testis usually reveals a 3-5 mm tender indurated mass on the upper pole (Fig. 582.6A). In some cases, the appendage that has undergone torsion may be visible through the scrotal skin, termed the **"blue dot"** sign. In some males, distinguishing torsion of the appendix from testicular torsion is difficult. In such cases, color Doppler ultrasonography is useful because testicular blood flow is normal and shows hyperemia to the upper pole of the testis. In such cases, the radiologist often recognizes epididymal enlargement and makes the diagnosis of epididymitis, reflecting the inflammatory reaction (see Fig. 582.6B).

The natural history of torsion of the appendix testis is for the inflammation to resolve in 3-10 days. Nonoperative treatment is recommended, including bed rest for 24 hours and analgesia with nonsteroidal antiinflammatory medication for several days. If the diagnosis is uncertain, scrotal exploration is recommended.

Fig. 582.5 A and B, Right testicular torsion in a newborn. The right hemiscrotum is darker, and the testis was indurated and enlarged.

EPIDIDYMITIS

Acute bacterial inflammation of the epididymis is an ascending retrograde infection from the urethra, through the vas deferens into the epididymis. This condition causes acute scrotal pain, erythema, and swelling. It is rare before puberty and should raise the question of a congenital abnormality of the Wolffian duct, such as an ectopic ureter entering the vas. In younger males, the responsible organism is often *Escherichia coli* (see Chapter 246). After puberty, bacterial epididymitis becomes progressively more common and can cause acute painful scrotal swelling in young sexually active males. Urinalysis usually reveals pyuria. Epididymitis can be bacterial (usually gonococcus or *Chlamydia*; see Chapters 238 and 272) or viral (mumps, enterovirus, or adenovirus; see Chapters 295, 297, and 309), but often the organism remains undetermined. Familial Mediterranean fever is another cause. Treatment consists of bed rest and antibiotics as indicated. Differentiation from torsion is straightforward with scrotal ultrasonography.

IgA vasculitis, previously known as Henoch-Schönlein purpura, (see Chapter 210.1) is a systemic vasculitis that involves multiple organ systems and that can involve the kidney and spermatic cord. When the spermatic cord is involved, typically there is bilateral painful scrotal swelling with purpuric lesions involving the scrotum. Scrotal sonography should show normal testicular blood flow. Treatment is directed toward systemic treatment of the IgA vasculitis. Isolated testicular vasculitis is less common in IgA vasculitis and, in such cases, polyarteritis nodosa should be suspected.

VARICOCELE

A **varicocele** is a congenital condition in which there is abnormal dilation of the pampiniform plexus in the scrotum, often described as a "bag of worms" (Fig. 582.7). Dilation of the pampiniform venous plexus results from valvular incompetence of the internal spermatic vein. Approximately 15% of adult males have a varicocele; of these, approximately 10–15% are subfertile. Varicocele is the most common (and virtually the only) surgically correctable cause of infertility in males. A varicocele is found in 10–15% of adolescent males, but it rarely is diagnosed in males younger than 10 years old, because the varicocele becomes distended only after the increased blood flow associated with

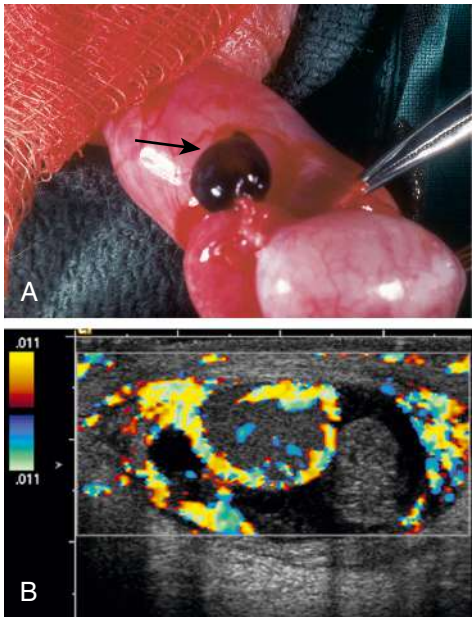

Fig. 582.6 A, Torsion of the appendix testis; the appendix testis is necrotic *(arrow)*. B, Color Doppler scrotal sonogram showing hyperemia to the testis and absent flow to the appendix testis *(right side)*. Symptoms resolved with medical therapy.

puberty occurs. Varicoceles occur predominantly on the left side, are bilateral in 2% of cases, and rarely involve the right side only. A varicocele in a male younger than 10 years or on the right side might indicate an abdominal or retroperitoneal mass; an abdominal ultrasound or CT scan should be performed in such cases.

A varicocele typically is a painless paratesticular mass. Occasionally patients describe a dull ache in the affected testis. Usually the varicocele is not apparent when the patient is supine because it is decompressed; in contrast, the varicocele becomes prominent when the patient is standing and enlarges with a Valsalva maneuver. Many pediatricians do not routinely screen adolescents for a varicocele. Varicoceles typically are graded from 1-3 with the male standing: **grade 1** is palpable only with Valsalva (clinically insignificant); **grade 2** is palpable without Valsalva but is not visible on inspection; and **grade 3** is visible with inspection. Males with a grade 3 varicocele are at greatest risk for testicular growth arrest, particularly if the varicocele is larger than the testis. Testicular size should be documented with calipers, an orchidometer, or scrotal sonography, because if the affected left testis is significantly smaller than the right testis, spermatogenesis probably has been adversely affected. A **semen analysis** should be considered in sexually mature adolescents who are Tanner stage V.

The goal of varicocelectomy is to maximize future fertility. Surgical treatment of varicoceles is indicated in males with a significant disparity in testicular size, with pain in the affected testis, if the contralateral testis is diseased or absent, or with oligospermia on semen analysis. Following treatment, typically the involved testis enlarges and catches up with the normal testis over the following 1-2 years. Varicocelectomy should also be considered in males with a large grade 3 varicocele, even if there is no disparity in testicular size. Surgical repair is accomplished with a variety of techniques by ligation of the veins of the pampiniform plexus laparoscopically or through an inguinal or subinguinal incision (with or without an operating microscope) or by ligating the internal spermatic vein in the retroperitoneum. The operation is performed on an ambulatory basis.

SPERMATOCELE

A **spermatocele** is a cystic lesion that contains sperm and is attached to the upper pole of the sexually mature testis. Spermatoceles usually are painless and are incidental findings on physical examination. Enlargement of the spermatocele or significant pain is an indication for removal.

Fig. 582.7 Left varicocele in an adolescent male.

HYDROCELE

Etiology

A hydrocele is an accumulation of fluid in the tunica vaginalis (Fig. 582.8). Between 1% and 2% of neonates have a hydrocele. In most cases, the hydrocele is noncommunicating (the processus vaginalis was obliterated during development). In such cases, the hydrocele fluid disappears by 1 year of age. If there is a persistently patent processus vaginalis, the hydrocele persists. It is typically small in the morning and may become larger during the day due to upright positioning. A rare variant of a hydrocele is the **abdominoscrotal hydrocele,** in which there is a large, tense hydrocele that extends into the lower abdominal cavity. In some older males, a noncommunicating hydrocele can result from an inflammatory condition within the scrotum, such as testicular torsion, torsion of the appendix testis, epididymitis, or testicular tumor. The long-term risk of a communicating hydrocele is the development of an inguinal hernia. Some older males and adolescents also develop a hydrocele. In some cases, hydroceles develop acutely after an episode of scrotal trauma or epididymoorchitis, whereas others develop more insidiously.

Diagnosis

On examination, hydroceles are smooth and nontender. Transillumination of the scrotum confirms the fluid-filled nature of the mass. It is important to palpate the testis, because some young males develop a hydrocele in association with a testis tumor. If the testis is nonpalpable, a scrotal ultrasound should be performed to confirm that the testis is present and normal. If compression of the fluid-filled mass completely reduces the hydrocele, an inguinal hernia/hydrocele is the likely diagnosis.

Treatment

Most congenital hydroceles resolve by 12 months of age following reabsorption of the hydrocele fluid. If the hydrocele is large and tense, however, early surgical correction should be considered, because it is difficult to verify that the child does not have a hernia, and large hydroceles rarely disappear spontaneously. Hydroceles persisting beyond 12-18 months often are communicating and should be repaired. Surgical correction is similar to a herniorrhaphy (see Chapter 394). Through an inguinal incision, the spermatic cord is identified, the hydrocele fluid is drained, and a high ligation of the processus vaginalis is performed. If an older male has a large hydrocele, often diagnostic laparoscopy can be performed to determine whether there is a patent processus vaginalis, and if the internal ring is closed, then the hydrocele may be corrected with a scrotal incision.

Fig. 582.8 Newborn with large right hydrocele.

INGUINAL HERNIA

Inguinal hernia is discussed in Chapter 394.

TESTICULAR MICROLITHIASIS

Approximately 2–3% of pediatric scrotal ultrasound examinations demonstrate calcific depositions in the testis, termed testicular microlithiasis. Typically, it is found in males undergoing an examination for testicular pain, varicocele, or scrotal swelling. In adults, it is a common finding in males with infertility and with a germ cell tumor of the testis. In pediatric patients with microlithiasis, there are no guidelines for monitoring, but the condition should be monitored for changes in testicular size or induration, with follow-up ultrasound studies as indicated.

TESTICULAR TUMOR

Testicular and paratesticular tumors can occur at any age, even in the newborn. Approximately 35% of prepubertal testis tumors are malignant; most commonly they are yolk sac tumors, although rhabdomyosarcoma and leukemia also can occur in this age group. In adolescents, 98% of painless solid testicular masses are malignant (see Chapter 552). Most manifest as a painless, hard testicular mass that does not transilluminate. Scrotal ultrasonography should be performed to confirm the finding of a testicular mass, and it can help to delineate the type of testis tumor. Serum tumor markers, including *α-fetoprotein* and *β-human chorionic gonadotropin,* should be drawn. Definitive therapy includes surgical exploration through an inguinal incision. In most cases, a radical orchiectomy, consisting of removal of the entire testis and spermatic cord, is performed. In a prepubertal male, if the ultrasonographic study or surgical exploration suggests that the tumor is localized and benign, such as a teratoma or an epidermoid cyst, testis-sparing surgery with removal only of the mass may be appropriate.

Chapter 583

Trauma to the Genitourinary Tract

Heather N. Di Carlo and Chad B. Crigger

Most injuries to the genitourinary tract in children result from blunt trauma during falls, athletic activities, or motor vehicle crashes (see Chapter 80). *Children are at greater risk of blunt renal injury than adults, because they have less body fat and because the kidneys are not located directly behind the ribs.* Children with a preexisting renal anomaly, such as hydronephrosis secondary to a ureteropelvic junction obstruction, horseshoe kidney, or renal ectopia, also are at increased risk for renal injury. Blunt abdominal or flank trauma often causes a renal injury. Falling can cause a deceleration injury that results in an injury to the renal pedicle, interrupting blood flow to the kidney. If the bladder is full, blunt lower abdominal trauma can cause a bladder rupture. Rupture of the membranous urethra occurs in 5% of pelvic fractures. Straddle injuries usually are associated with trauma to the bulbous urethra.

Symptoms and signs of urinary tract injury include gross or microscopic hematuria, bleeding from the urethral meatus, abdominal or flank pain, a flank mass, fractured lower ribs or lumbar transverse processes, and a perineal or scrotal hematoma.

In more than 50% of cases, there also are major injuries to the brain, spinal cord, skeleton, lungs, or abdominal organs.

DIAGNOSIS

Evaluation of the patient begins after an adequate airway has been established and the patient is hemodynamically stable (see Chapters 78 and 79). With significant abdominal injury, gross hematuria or >50 red blood cells per high-power field, or suspicion of renal injury (deceleration injury, flank pain, or bruise), renal imaging is indicated (Fig. 583.1). The bladder should be catheterized unless blood is dripping from the urethral meatus, which is an indication of potential urethral injury. Passing the catheter in the presence of a urethral injury can increase the extent of the damage and convert a partial membranous urethral tear into a total disruption. In these patients, a retrograde urethrogram should be performed by injecting radiopaque contrast medium into the urethral meatus under fluoroscopy. Oblique radiographs demonstrate the extent of the injury and whether urethral continuity is preserved or has been disrupted.

A three-phase spiral CT scan should be performed to evaluate the kidneys, ureters, and bladder. The delayed images are important to detect renal extravasation of blood or urine. Prompt function of both kidneys without extravasation usually excludes significant renal injury. Renal injuries are classified according to the grading scale presented in Table 583.1. Minor renal injuries are most common; these include contusion of the renal parenchyma and shallow cortical lacerations not involving the collecting system. Major renal injuries include deep lacerations involving the collecting system, shattered kidney, and renal pedicle injuries (Fig. 583.2). Complete absence of function of one kidney without contralateral compensatory hypertrophy (indicating congenital absence) should be regarded as an indication of major injury to the renal pedicle. Renal angiography, once used for further evaluation of renal injuries, particularly if a renal pedicle injury is suspected, now is rarely used because such patients are often hemodynamically unstable, and management is not significantly affected by the findings. In some cases, a preexisting renal anomaly is demonstrated on the study. A ruptured ureteropelvic junction obstruction may be apparent if the kidney is intact, but the distal ureter is not visualized.

If there is a pelvic fracture, a urethral transection injury should be suspected, particularly in males. The risk is directly related to the number of broken pubic rami and whether there is separation of the pubic symphysis or displacement of the posterior pubic arch. Radiographic evaluation with retrograde urethrography should be performed if there is blood at the urethral or vaginal meatus, inability to void, and a perineal or penile hematoma.

TREATMENT

Minor renal injuries such as contusions are managed by bed rest and monitoring of vital signs until abdominal or flank discomfort and gross hematuria have resolved. Children with a major renal injury usually are admitted to an intensive care unit for continuous monitoring of vital signs and urine output. Intravenous antibiotics are also administered. These injuries also are managed nonoperatively, because Gerota's fascia often causes tamponade of bleeding from the kidney, and dramatic healing of the injured parenchyma can occur even with significant urinary extravasation.

Approximately 10% of children with a major renal injury undergo surgical exploration because of associated abdominal injuries, hemodynamic instability, persistent extravasation, or persistent hematuria or to correct a congenital renal deformity. It can be difficult to identify normal and devitalized parenchyma, and the likelihood of having to remove the kidney is significant. If the child is undergoing exploration for other abdominal injuries, the injured kidney is examined. If there is persistent extravasation because of intermittent ureteral obstruction from a blood clot, passage of a temporary double-J stent endoscopically between the bladder and kidney might allow resolution. If the renal pedicle is injured, nephrectomy is necessary. The kidney can be salvaged by

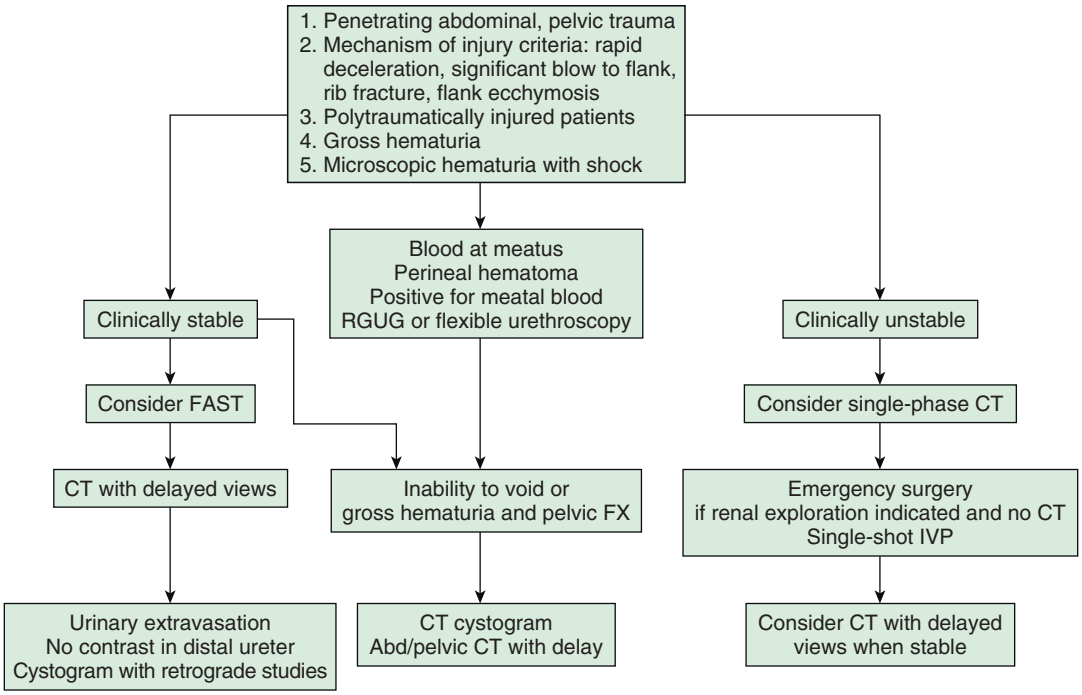

Fig. 583.1 Algorithm showing the recommended evaluation protocol for patients with a medical history or physical findings consistent with possible genitourinary injury. Abd, Abdominal; FAST, focused assessment with sonography for trauma; FX, fracture; IVP, intravenous pyelography; RGUG, retrograde urethrogram. *(From Husmann DA. Pediatric genitourinary trauma. Modified from Wein AJ, Kavoussi LR, Partin AW, Peters CA, eds. Campbell-Walsh Urology. 11th ed. Philadelphia: Elsevier; 2016: Fig. 154-6, p. 3546.)*

Table 583.1 Grading of Renal Injuries

GRADE	DESCRIPTION
1	Renal contusion or subcapsular hematoma
2	Nonexpanding perirenal hematoma, <1 cm parenchymal laceration, no urinary extravasation; all renal fragments viable; confined to renal retroperitoneum
3	Nonexpanding perirenal hematoma, >1 cm parenchymal laceration, no urinary extravasation; renal fragments may be viable or devitalized
4	Laceration extending into the collecting system with urinary extravasation; renal fragments may be vital or devitalized *or* Injury to the main renal vasculature with contained hemorrhage
5	Completely shattered kidney; by definition, multiple major lacerations >1 cm associated with multiple devitalized fragments *or* Injury to the main renal vasculature with uncontrolled hemorrhage, renal hilar avulsion

emergency renal revascularization only if the kidney is explored within 2-3 hours of the injury. Virtually all penetrating injuries of the kidneys should be explored.

In addition to loss of renal function, the main long-term complication of renal injury is renin-mediated hypertension. Children who sustain significant renal injuries should have periodic measurement of blood pressure if they have any residual renal abnormality.

Ureteral injuries usually are iatrogenic. Injuries of the ureter by blunt or penetrating trauma require immediate surgical attention.

When the bladder can be catheterized, a static cystogram is obtained, infusing a contrast solution through the catheter by gravity, ideally using fluoroscopy. Flat and oblique views are often obtained; a postvoid film also should be obtained because, in some cases, extravasation may be hidden by the full bladder. An alternative is a CT cystogram, which is highly accurate in demonstrating a bladder injury.

Bladder ruptures can be intraperitoneal or extraperitoneal. All intraperitoneal ruptures require surgical repair. Minor extraperitoneal near-ruptures might be treated by catheter drainage but generally require surgical treatment.

Treatment of a **membranous urethral injury** is controversial. Erectile dysfunction, urethral stricture, and urinary incontinence are the major late complications of rupture of the membranous urethra, and therapy is directed at minimizing the risk of these problems. A large pelvic hematoma with tamponade often is present, and an immediate attempt to repair the injury can be technically difficult and result in significant hemorrhage. Many such injuries are managed initially by temporary suprapubic cystostomy, with continuous bladder drainage for 3-6 months. Subsequently, open or endoscopic urethroplasty can be performed. Alternatively, some try to achieve urethral continuity under anesthesia and leave a urethral catheter for several months. These patients typically require subsequent open urethroplasty.

Penile injury is uncommon. Partial or complete glans amputation is a risk of newborn circumcision with a Mogen clamp. With immediate surgical repair, often the excised glans tissue can be replaced as a free graft. Some males who are in the process of toilet training sustain an injury to the glans penis if the lid of the toilet falls while they are urinating. These males often have a hematoma covering the distal half of the glans. Typically, they have no difficulty urinating and do not need extensive evaluation. Some male infants develop an inadvertent **hair tourniquet** or strangulation injury. Typically,

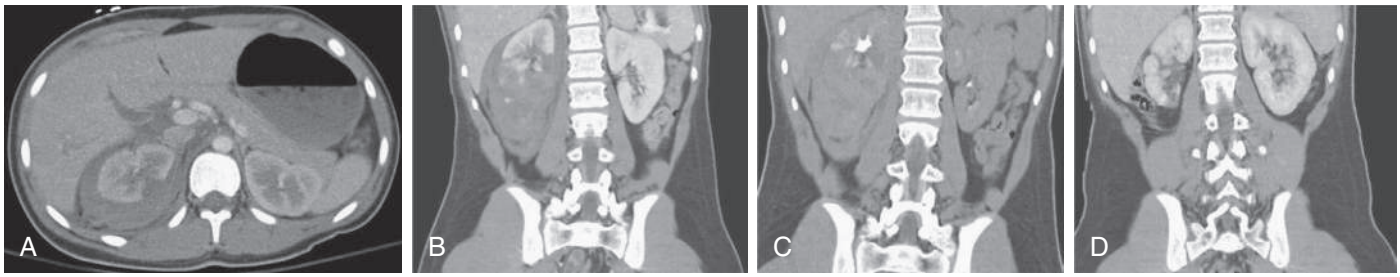

Fig. 583.2 CT images of grade 3 right renal trauma: acute, delayed, and at 3-month follow-up. **A,** Acute CT image of grade 3 renal trauma showing laceration of more than 1 cm of midrenal pole with perinephric hematoma. **B,** Acute CT image coronal reconstruction of grade 3 renal trauma, with possible devitalization of the entire lower pole of the kidney. **C,** Two-hour delayed CT image coronal reconstruction of grade 3 renal trauma, with no urinary extravasation noted and lower pole with questionable devitalization versus contusion. **D,** CT image coronal reconstruction 3 months after traumatic injury revealing parenchymal scarring at site of laceration with scarred but functional lower pole consistent with healed parenchyma following severe renal contusion. Scarring of lower pole was believed to have occurred with impoverished blood supply because of severe contusion. *(From Husmann DA. Pediatric genitourinary trauma. In: Wein AJ, Kavoussi LR, Partin AW, Peters CA, eds. Campbell-Walsh Urology. 11th ed. Philadelphia: Elsevier; 2016: Fig. 154-3, p. 3542.)*

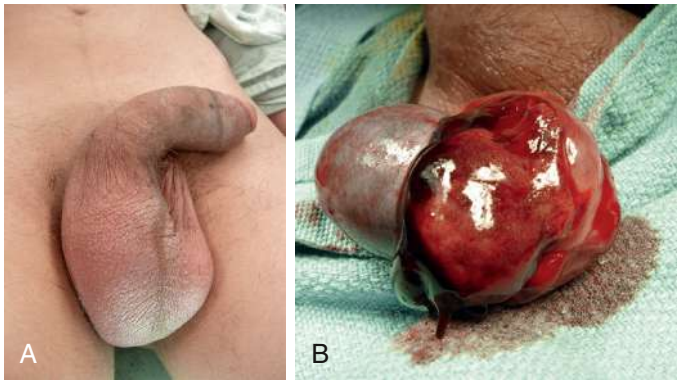

Fig. 583.3 **A,** Adolescent male with blunt right testicular injury. **B,** Tunica albuginea of testis is ruptured; the patient underwent debridement and closure of testicular capsule.

a very narrow constriction is noted with severe distal penile swelling and pain. Identification and incision of the hair allows prompt resolution of the edema. The urethra and penile vascularity should be assessed after release of the hair tourniquet. Adolescent males who indulge in extremely vigorous sexual intercourse may sustain rupture of one of the corporal bodies, resulting in penile fracture. These males have severe swelling of the penile shaft and require emergency exploration and repair. Males with penetrating injuries of the penis also require emergency debridement and repair.

Testicular injuries are relatively uncommon in children because of the small size of the testes and their mobility within the scrotum. Such injuries usually result from blunt trauma during athletic activity. Typically, these males have significant scrotal swelling, testicular pain, and tenderness (Fig. 583.3A). Ultrasonography demonstrates rupture of the tunica albuginea, which is the capsule of the testis, and surrounding hemorrhage. Prompt surgical treatment of testicular injuries increases the salvage rate (see Fig. 583.3B). An uncommon injury is the **zipper injury,** which can affect either the scrotum or foreskin. This problem generally occurs in males who do not wear underwear. The zipper can be cut with bone cutters or metal cutters. Sedation generally is unnecessary.

Chapter 584

Urinary Lithiasis

Heather N. Di Carlo and Chad B. Crigger

Urinary lithiasis in children is related to genetic, climatic, dietary, and socioeconomic factors. The incidence increased steadily over the past several decades. Adolescents are 10 times more likely to have a symptomatic calculus compared with children age 0-3 years. The increase in stone disease in the United States is attributed to obesity and changes in dietary habits, such as increased sodium and fructose intake, and decreased calcium and water intake.

Urolithiasis is less common in the United States than in other parts of the world. In the United States, 1 in 685 pediatric hospital admissions is for stone disease. Approximately 7% of urinary calculi occur in children younger than 16 years of age. In the United States, many children with stone disease have a metabolic abnormality. The exceptions are patients with a neuropathic bladder (see Chapter 579), who are prone to infection-initiated renal stones, and those who have urinary tract reconstruction with small or large intestine, which predisposes to bladder calculi. The incidence of metabolic stones is similar in males and females; they are most common in the southeastern United States. Racial and ethnic differences have been noted, with the highest prevalence among Whites. In Southeast Asia, urinary calculi are endemic and are related to dietary factors.

STONE FORMATION

Nearly 90% of urinary stones contain calcium as a major constituent, and 60% are composed of calcium oxalate. Most *spontaneous* stones are composed of calcium oxalate, or calcium phosphate crystals; others are caused by uric acid, cystine, ammonium crystals, or phosphate crystals, or a combination of these substances (Table 584.1). The risk of stone formation increases in the presence of increasing concentrations of these crystals and is reduced with increasing concentrations of urinary inhibitors. Renal calculi develop from crystals that form on the calyx and aggregate to form a calculus. Bladder calculi may be stones that formed in the kidney and traveled down the ureter, or they can form primarily in the bladder.

Table 584.1 Classification of Urolithiasis

CALCIUM STONES (CALCIUM OXALATE AND CALCIUM PHOSPHATE)*
Hypercalciuria
Absorptive: increased Ca absorption from gut; types I and II
Renal leak: decreased tubular reabsorption of Ca
Resorptive
Primary hyperparathyroidism (rare in children)
Iatrogenic
Loop diuretics
Ketogenic diet
Corticosteroids
Adrenocorticotropic hormone administration
Methylxanthines (theophylline, aminophylline)
Distal renal tubular acidosis, type 1 (calcium phosphate)
Hypocitraturia—citrate most important inhibitor of Ca crystallization
Vitamin D excess
Immobilization
Sarcoidosis
Cushing disease
Hyperuricosuria
Heterozygous cystinuria
Hyperoxaluria (calcium oxalate)
Primary hyperoxaluria, types 1 and 2
Secondary hyperoxaluria
Enteric hyperoxaluria
CYSTINE STONES
Cystinuria
STRUVITE STONES (MAGNESIUM AMMONIUM PHOSPHATE)
Urinary tract infection (urea-splitting organism)
Foreign body
Urinary stasis
URIC ACID STONES
Hyperuricosuria
Lesch-Nyhan syndrome
Myeloproliferative disorders
After chemotherapy
Inflammatory bowel disease
OTHER
Indinavir stones
Melamine
Nephrocalcinosis

*Most common.

Low urine volume, low urine pH, calcium, sodium, oxalate, and urate are known to promote stone formation. Many inorganic (e.g., citrate, magnesium) and organic (e.g., glycosaminoglycans, osteopontin) substances are known to inhibit stone formation. Organic inhibitory compounds adsorb to the surface of the crystal, thereby inhibiting crystal growth and nucleation.

Stone formation depends on four factors: matrix, precipitation-crystallization, epitaxy, and the absence of inhibitors of stone formation in the urine. **Matrix** is a mixture of protein, nonamino sugars, glucosamine, water, and organic ash that makes up 2–9% of the dry weight of urinary stones and is arranged within the stones in organized concentric laminations. **Precipitation-crystallization** refers to supersaturation of the urine with specific ions composing the crystal. Crystals aggregate by chemical and electrical forces. Increasing the saturation of urine with respect to the ions increases the rate of nucleation, crystal growth, and aggregation and increases the likelihood of stone formation and growth. **Epitaxy** refers to the aggregation of crystals of different composition but similar lattice structure, thus forming stones of a heterogeneous nature. The lattice structures of calcium oxalate and monosodium urate have similar structures, and calcium oxalate crystals can aggregate on a nucleus of monosodium urate crystals. Urine also contains **inhibitors of stone formation,** including citrate, diphosphonate, and magnesium ion.

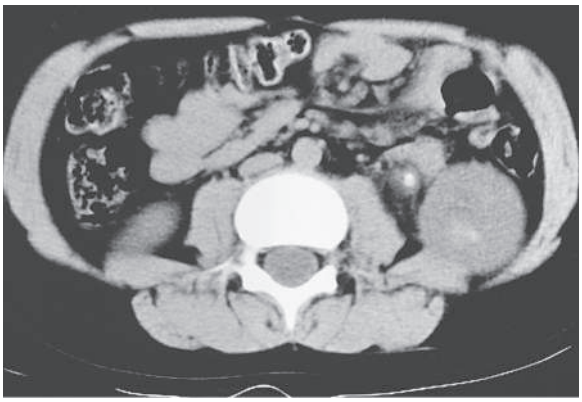

Fig. 584.1 Noncontrast CT scan of the midabdomen in a male infant with cystinuria shows a left-sided calculus at the ureteropelvic junction with proximal hydronephrosis.

CLINICAL MANIFESTATIONS

Children with urolithiasis usually have gross or microscopic hematuria. If the calculus causes ureteral or renal pelvic obstruction, then severe flank pain (renal colic) or abdominal pain occurs. The calculus typically causes obstruction at areas of narrowing of the urinary tract—the ureteropelvic junction, where the ureter crosses the iliac vessels, and the ureterovesical junction. The ureter progressively narrows distally, and its most narrow segment is the ureterovesical junction. The pain typically radiates anteriorly to the scrotum or labia. Often the pain is intermittent, corresponding to periods of obstruction of urine flow, which increases the pressure in the collecting system. If the calculus is in the distal ureter, the child can have irritative symptoms of dysuria, urgency, and frequency. If the stone passes into the bladder, the child usually becomes asymptomatic. If the stone is in the urethra, dysuria and difficulty voiding can result, particularly in males. Some children pass small amounts of gravel-like material. Stones can also be asymptomatic, although it is uncommon to pass a ureteral calculus without symptoms.

DIAGNOSIS

Approximately 90% of urinary calculi are calcified to some degree and are radiopaque on a plain abdominal film. However, many calculi are only a few millimeters in diameter and are difficult to see, particularly if they are in the ureter. Struvite (magnesium ammonium phosphate) stones are radiopaque. Cystine, xanthine, and uric acid calculi may be radiolucent but often are slightly opacified. Some children have **nephrocalcinosis,** which is calcification of the renal tissue itself. Nephrocalcinosis is seen most commonly in premature neonates receiving furosemide, which causes **hypercalciuria**, and in children with medullary sponge kidney.

In a child with suspected renal colic, there are multiple imaging options, including ultrasound, CT, and plain radiographs. The American Urological Association recommends ultrasound as the *initial* imaging modality in children as it avoids radiation. Ultrasound has high specificity (97%) but only moderate sensitivity (67%) in the diagnosis of urolithiasis; thus CT should be considered when clinical suspicion for stones is high, but ultrasound is negative. CT scan of the abdomen and pelvis is the most accurate study in diagnosis of stones with both sensitivity and specificity exceeding 96% (Fig. 584.1). This study takes only a few minutes to perform, is useful in delineating the number and location of calculi, and demonstrates whether the involved kidney is hydronephrotic. *Most pediatric imaging centers use low-dose CT to reduce radiation exposure.* A plain radiograph of the abdomen and pelvis is sometimes used to detect radiopaque stones but cannot identify obstruction and rarely visualizes renal calculi <3 mm.

In a child with a previously diagnosed calculus, renal ultrasonography can be used to follow the status of the calculus, such as whether it has grown or diminished in size or has moved. If a child has a renal pelvic calculus, a ureteropelvic junction obstruction should be suspected.

Table 584.2 Laboratory Tests Suggested for Evaluation of Urolithiasis

SERUM
Calcium
Phosphorus
Magnesium
Uric acid
Electrolytes and anion gap
Creatinine
Alkaline phosphatase
URINE
Urinalysis
Urine culture
Spot test for cystinuria
Stone analysis
If toilet-trained, 24 hour collection for:
Creatinine clearance
Calcium
Phosphate
Oxalate
Uric acid
Dibasic amino acids (if cystine spot test result is positive)
If not toilet-trained, random urine sample for:
Calcium
Creatinine
Oxalate
Citrate

In some cases, it can be difficult to determine whether hydronephrosis in such a child is secondary to an obstructing stone, ureteropelvic junction obstruction, or both.

Any material that resembles a calculus should be sent for analysis by a laboratory that specializes in identifying the components of urinary calculi.

METABOLIC EVALUATION

A metabolic evaluation for the most common predisposing factors should be undertaken in all children with urolithiasis, bearing in mind that structural, infectious and metabolic factors often coexist. This evaluation should not be undertaken in a child who is in the process of passing a stone, because the altered diet and hydration status, as well as the effect of obstruction on the kidney, can alter the results of the study. Table 584.2 lists the basic laboratory studies required, and Table 584.3 shows the normal values for 24-hour urine collections. In children with hypercalciuria, further studies of calcium excretion with dietary calcium restriction and calcium loading are necessary.

PATHOGENESIS OF SPECIFIC RENAL CALCULI

Calcium Oxalate and Calcium Phosphate Calculi

Most urinary calculi in children in the United States are composed of calcium oxalate and/or calcium phosphate. The most common metabolic abnormality in these patients is **normocalcemic hypercalciuria.** Between 30% and 60% of children with calcium stones have hypercalciuria without hypercalcemia. Other metabolic aberrations that predispose to stone disease include hyperoxaluria, hyperuricosuria, hypocitraturia, heterozygous cystinuria, hypomagnesuria, hyperparathyroidism, and **renal tubular acidosis** (RTA; see Chapter 569).

Hypercalciuria may be absorptive, renal, or resorptive. The primary disturbance in *absorptive hypercalciuria* is intestinal hyperabsorption of calcium. In some children, an increase in 1,25-dihydroxyvitamin D is associated with the increased calcium absorption, whereas in others, the process is independent of vitamin D. *Renal hypercalciuria* refers to impaired renal tubular reabsorption of calcium (see Chapter 562.4). Renal leak of calcium causes mild hypocalcemia, which triggers an increased production of parathyroid hormone, with increased intestinal absorption of calcium and increased mobilization of calcium stores. *Resorptive hypercalciuria* is uncommon and is found in patients with primary hyperparathyroidism. Excess parathyroid hormone secretion stimulates intestinal absorption of calcium and mobilization of calcium stores. Table 584.4 summarizes the metabolic evaluation of children with hypercalciuria.

Hyperoxaluria is another potentially important cause of calcium stones. Oxalate increases the solubility of calcium oxalate crystallization 7-10 times more than calcium. Consequently, hyperoxaluria significantly increases the likelihood of calcium oxalate precipitation. Oxalate is found in high concentrations in tea, coffee, spinach, and rhubarb. Primary hyperoxaluria is a rare autosomal recessive disorder that can be subclassified into glycolic aciduria and L-glyceric aciduria. Most patients with primary hyperoxaluria have glycolic aciduria; oxalic and glycolic acids are increased in the urine of affected persons. Both defects cause increased endogenous production of oxalate, with hyperoxaluria, urolithiasis, nephrocalcinosis, and injury to the kidneys. Death from renal failure occurs by age 20 in untreated patients. **Oxalosis,** defined as extrarenal deposition of calcium oxalate, occurs when renal insufficiency is present with elevated plasma oxalate. Calcium oxalate deposits appear first in blood vessels and bone marrow, and with time they appear throughout the body. Secondary hyperoxaluria is more common and can occur in patients with increased intake of oxalate and oxalate precursors such as vitamin C, in those with pyridoxine deficiency, and in children with intestinal malabsorption.

Enteric hyperoxaluria refers to disorders such as inflammatory bowel disease (see Chapter 382), pancreatic insufficiency (see Chapter 398), and biliary disease (see Chapter 404), in which there is gastrointestinal malabsorption of fatty acids, which bind intraluminal calcium and form salts that are excreted in the feces. Normally, calcium forms a complex with oxalate to reduce oxalate absorption, but if calcium is unavailable, there is increased absorption of unbound oxalate.

Hypocitraturia refers to a low excretion of citrate, which is an important inhibitor of calcium stone formation. Citrate acts as an inhibitor of calcium urolithiasis by forming complexes with calcium, increasing the solubility of calcium in the urine, and inhibiting the aggregation of calcium phosphate and calcium oxalate crystals. Disorders such as chronic diarrhea, intestinal malabsorption, and RTA can cause hypocitraturia. It may also be idiopathic.

Renal tubular acidosis (RTA) is a syndrome involving a disturbance of acid-base balance within the kidney that can be classified into three types, one of which predisposes to renal calculi that typically are calcium phosphate (see Chapter 569). In type 1 RTA, the distal nephron does not secrete hydrogen ion into the distal tubule. The urine pH is never <5.8, and hyperchloremic hypokalemic acidosis results. Patients acquire nephrolithiasis, nephrocalcinosis, muscle weakness, and osteomalacia. Type 1 RTA can be an autosomal dominant disorder, but more often it is acquired and associated with systemic diseases such as Sjögren syndrome, Wilson disease, primary biliary cirrhosis, and lymphocytic thyroiditis, or it results from amphotericin B, lithium, or toluene (an organic solvent associated with glue sniffing).

From 5–8% of patients with **cystic fibrosis** (see Chapter 454) have urolithiasis. Typically, the stones are calcium, and they often manifest in adolescence or young adulthood. Microscopic nephrocalcinosis also occurs in younger children with the disease. These patients do not have hypercalciuria, and the propensity for urolithiasis has been speculated to result from an inability to excrete a sodium chloride load or from intestinal malabsorption.

Other disorders can play a role in causing calcium stones. **Hyperuricosuria** may be related to the epitactic growth of calcium oxalate crystals around a nucleus of uric acid crystals or to the action of uric acid, which counteracts urinary mucopolysaccharides that then inhibit calcium oxalate crystallization. Heterozygous **cystinuria** is found in some patients with calcium stones. The mechanism is unknown but may be similar to that of uric acid. Sarcoidosis (see Chapter 209) causes an increased sensitivity to vitamin D_3 and thus an increased absorption of calcium from the gastrointestinal tract. In Lesch-Nyhan syndrome (see Chapter 110), there is excessive uric acid synthesis. These patients are more likely to form uric acid stones, but some of these stones may be calcified. **Immobility** can cause hypercalciuria by mobilization of calcium stores. High-dose

Table 584.3 Urine Chemistry: Normal Values

URINE CONSTITUENT	AGE	RANDOM	TIMED	COMMENTS
Calcium	0-6 mo	<0.8 mg/mg creat	<4 mg/kg/24 hours	Prandial variation

Table 584.4 Metabolic Evaluation of Children with Hypercalciuria

TYPE	SERUM CALCIUM	RESTRICTED CALCIUM (URINE)	FASTING CALCIUM (URINE)	CALCIUM LOAD (URINE)	PARATHYROID HORMONE (SERUM)
Absorptive	N or I	N or I	N	I	D or N
Renal	N	I	I	I	I
Resorptive	I	I	I	I	I

I, Increased; N, normal; D, decreased

corticosteroids can cause hypercalciuria and calcium oxalate precipitation. Furosemide, which is often administered in the neonatal intensive care unit, also can cause severe hypercalciuria, urolithiasis, and nephrocalcinosis.

In some children, calcium calculi are idiopathic. A complete metabolic evaluation must be performed before this diagnosis is made.

Cystine Calculi

Cystinuria accounts for 1% of renal calculi in children. The condition is a rare autosomal recessive disorder of the epithelial cells of the renal tubule that prevents absorption of the four dibasic amino acids (cystine, ornithine, arginine, lysine) and results in excessive urinary excretion of these products. The only known complication of this familial disease is the formation of calculi, because of the low solubility of cystine. The patients usually have acidic urine, which leads to a higher rate of precipitation. In the homozygous patient, the daily excretion of cystine usually exceeds 500 mg, and stone formation occurs at an early age. Heterozygotes excrete 100-300 mg/day and typically do not have clinical urolithiasis. The sulfur content of cystine gives these stones their faint radiopaque appearance.

Struvite Calculi

Urinary tract infections (see Chapter 575) caused by urea-splitting organisms (most often *Proteus* spp., and occasionally *Klebsiella* spp., *Escherichia coli, Pseudomonas* spp., and others) result in urinary alkalinization and excessive production of ammonia, which can lead to the precipitation of magnesium ammonium phosphate (struvite) and calcium phosphate. In the kidney, these calculi often have a staghorn configuration, filling the calyces. The calculi act as foreign bodies, causing obstruction, perpetuating infection, and causing gradual kidney damage. Patients with struvite stones also can have metabolic abnormalities that predispose to stone formation. These stones often are seen in children with neuropathic bladder, particularly those who have undergone a urinary tract reconstructive procedure (see Chapter 579). Struvite stones also can form in the reconstructed bladder of children who have undergone augmentation cystoplasty or continent urinary diversion.

Uric Acid Calculi

Calculi containing uric acid represent <5% of all cases of lithiasis in children in the United States but are more common in less-developed areas of the world. Hyperuricosuria with or without hyperuricemia is the common underlying factor in most cases. The stones are radiolucent on x-ray. The diagnosis should be suspected in a patient with persistently acidic urine and urate crystalluria.

Hyperuricosuria can result from various inborn errors of purine metabolism that lead to overproduction of uric acid, the end product of purine metabolism in humans. Children with Lesch-Nyhan syndrome and patients with glucose-6-phosphatase deficiency (see Chapter 107) form urate calculi as well. In children with short-bowel syndrome (see Chapter 385.7), and particularly those with ileostomies, chronic dehydration and acidosis sometimes are complicated by uric acid lithiasis.

One of the most common causes of uric acid lithiasis is the rapid turnover of purine with some tumors and myeloproliferative diseases. The risk of uric acid lithiasis is especially great when treatment of these diseases causes rapid breakdown of nucleoproteins. Uric acid calculi or "sludge" can fill the entire upper collecting system and cause renal failure and even anuria. Urate is also present within calcium-containing stones. In these cases, more than one predisposing factor for stone formation can exist.

Indinavir Calculi

Indinavir sulfate is a protease inhibitor approved for treating HIV infection (see Chapter 322). Up to 4% of patients acquire symptomatic nephrolithiasis. Most of the calculi are radiolucent and are composed of indinavir-based monohydrate, although calcium oxalate and/or phosphate have been present in some. After each dose, 12% of the drug is excreted unchanged in the urine. The urine in these patients often contains crystals of characteristic rectangles and fan-shaped or starburst crystals. Indinavir is soluble at a pH of <5.5. Consequently, dissolution therapy by urinary acidification with ammonium chloride or ascorbic acid should be considered.

Nephrocalcinosis

Nephrocalcinosis refers to calcium deposition within the renal tissue. Often nephrocalcinosis is associated with urolithiasis. The most common causes are furosemide (administered to premature neonates), distal RTA, hyperparathyroidism, medullary sponge kidney, hypophosphatemic rickets, sarcoidosis, cortical necrosis, hyperoxaluria, prolonged immobilization, Cushing syndrome, hyperuricosuria, monogenetic causes of hypertension, and renal candidiasis.

TREATMENT

In a child or adolescent with a renal or ureteral calculus, the decision whether to remove the stone depends on its location, size, and composition (if known) and whether obstruction and/or infection is present. Pain is managed with nonsteroidal antiinflammatory drugs or, less often, opiates. Small ureteral calculi often pass spontaneously, although the child might experience severe renal colic. The narrowest segment of the ureter is the ureterovesical junction. Calculi <5 mm will pass 80–90% of the time. An α-adrenergic blocker, such as tamsulosin, 0.4 mg at bedtime, may facilitate stone passage by decreasing ureteral pressure below the stone and decreasing the frequency of the peristaltic contractions of the obstructed ureter. This intervention is termed **medical expulsive therapy**. In many cases, passage of a ureteral stent past the stone endoscopically relieves pain and dilates the ureter sufficiently to allow the calculus to pass. In cases such as children with a uric acid calculus or an infant with a furosemide-associated calculus, dissolution alkaline therapy may be effective. Fluid management with a forced diuresis is controversial and may not improve stone passage. Nonetheless, dehydration (from anorexia or emesis) must be corrected, and intravenous fluids may offset contrast-induced renal injury if CT contrast imaging is anticipated.

If the calculus does not pass or seems unlikely to pass or if there is associated urinary tract infection, removal is necessary (Table 584.5). Lithotripsy of bladder, ureteral, and small renal pelvic calculi using the holmium laser through a flexible or rigid ureteroscope is quite effective. Extracorporeal shock wave lithotripsy has been successfully applied to children with renal and ureteral stones, with a success rate of >75%. Another alternative is percutaneous nephrostolithotomy, in which access to the renal collecting system is obtained percutaneously and the calculi are broken down by ultrasonic lithotripsy. In cases in which these modalities are unsuccessful, an alternative is laparoscopic removal; this procedure can be performed using the da Vinci robot.

STONE PREVENTION

In children with urolithiasis, the underlying metabolic disorder should be addressed (Table 584.6). Because lithiasis results from elevated concentrations of specific substances in the urine, maintaining a continuous high urine output by maintaining a high fluid intake often is an effective method of preventing further stones. The high fluid intake should be continued at night, and usually it is necessary for the child to get up at least once at night to urinate and drink more water. A daily fluid intake of 2-2.5 L in adolescent stone formers is recommended, with greater intake during summer months.

Dietary sodium intake in children has increased significantly because of increased consumption of salty, processed foods. High sodium intake increases urinary excretion of calcium and may result in hypocitraturia. In addition, increased salt intake induces metabolic acidosis. To compensate for the acid load, the kidneys conserve anions, including urinary citrate, which contributes to hypocitraturia. Reduction in dietary intake of sodium and increased potassium intake is indicated.

Although counterintuitive, low-calcium diets are less effective in the treatment of calcium stones than diets containing normal amounts of calcium and limited amounts of sodium and animal protein. Low-sodium, low-protein diets reduce urinary calcium and oxalate excretion. Children with stone disease should avoid excess calcium intake. However, children require calcium for bone development, and

recommendations for daily calcium intake vary by age. *Consequently, calcium restriction in children should be avoided.* Thiazide diuretics also reduce renal calcium excretion. The addition of potassium citrate, an inhibitor of calcium stones, with a dosage of 1-2 mEq/kg/24 hours is beneficial. An excellent source of citrate is lemonade, because 4 oz of lemon juice contains 84 mEq of citric acid. A daily mixture of 4 oz of reconstituted lemon juice in 2 L of water and sweetened to taste should significantly increase the urinary citrate level. In difficult cases, neutral orthophosphate should be given, although it is poorly tolerated.

In patients with uric acid stones, allopurinol is effective. Allopurinol is an inhibitor of xanthine oxidase and is effective in reducing the production of both uric acid and 2,8-dihydroxyadenine and can help control the recurrence of both types of stones. In addition, urinary alkalinization with sodium bicarbonate or sodium citrate is beneficial. The urine pH should be ≥6.5 and can be monitored at home by the family.

Maintaining a high urine pH can also prevent the recurrence of cystine calculi. Cystine is much more soluble when the urinary pH is >7.5, and alkalinization of urine with sodium bicarbonate or sodium citrate is effective. Another important medication is D-penicillamine, which is a chelating agent that binds to cysteine or homocysteine, increasing the solubility of the product. Although poorly tolerated by many patients, it has been reported to be effective in dissolving cystine stones and in preventing recurrences when hydration and urinary alkalinization fail. *N*-Acetylcysteine appears to have low toxicity and may be effective in controlling cystinuria, but long-term experience with it is lacking.

Treatment of type 1 RTA involves correcting the metabolic acidosis and replacing lost potassium and sodium. Sodium or potassium citrate therapy, or both, is necessary. When the metabolic acidosis is corrected, the urinary citrate excretion returns to normal.

Treatment of primary hyperoxaluria involves liver transplantation because the defective enzymes are hepatic. Ideally, this procedure is performed before renal failure occurs. In the most severe cases, kidney transplantation is also necessary. A U.S. Food and Drug Administration (FDA)-approved agent (lumasiran) greatly decreases oxalate production in children with primary hyperoxaluria type 1. It is hoped that it will prevent end-stage renal disease in this disorder.

Gynecologic Problems of Childhood

PART XXIII

Chapter 585

Gynecologic History and Physical Examination

Kathryn C. Stambough and Alla Vash-Margita

HISTORY

For the young patient, developmentally appropriate social questions directed to the patient can put them at ease and help to develop cooperation and rapport that will facilitate a subsequent examination. Specific patient, caregiver, or provider concerns about vaginal discharge or bleeding, pruritus, external genital lesions, or abnormalities should direct a problem-focused history. In a patient presenting with vaginal bleeding, questions should focus on recent growth and development, signs of pubertal progression, trauma, vaginal discharge, medication exposure, and any history of foreign objects in the vagina. For complaints of vulvovaginal irritation, pruritus, or discharge, questions should concentrate on perineal hygiene, the onset and duration of symptoms, the presence and quality of discharge, exposure to skin irritants, recent antibiotic use, travel, presence of medical comorbidities or infections in the patient and their family members, and other systemic symptoms of illness or skin conditions. Throughout the history, the patient should be encouraged to ask their own questions. Occasionally, the child is brought to the clinician because they or their parents have concerns about anatomic findings, developmental changes, or congenital anomalies. It helps to understand the family's concerns and if a specific reason, event, or family history raised the need for a gynecologic consultation.

GYNECOLOGIC EXAMINATION

The physical examination of the patient should be tailored to the child's age, complaint, and any other concerns elicited in the history. The date of onset of the last menstrual period should be included with an assessment of other vital signs as age appropriate.

Neonates

At the time of delivery, a brief examination of the external genitalia of female infants to visually confirm the patency of the vagina and assess the presence of any obvious genital anomalies should be performed. The newborn examination should note any abnormal findings, such as ambiguous genitalia, imperforate hymen, urogenital abnormalities, abdominal mass, or inguinal hernia, that might herald a gynecologic problem.

Placing the infant in the supine position with thighs flexed against the abdomen allows visualization of the neonate's external genitalia. Estrogenic effects commonly notable in neonates include prominence of the labia majora and a white vaginal discharge. The labia minora and hymen may protrude slightly from the vestibule. A small amount of neonatal vaginal bleeding from endometrial sloughing after maternal hormone withdrawal might occur. Bleeding that is excessive or persistent beyond the first month of life requires further evaluation. Breast buds may be palpable at the time of the neonatal examination but should regress in the first 3 months of life; occasionally, nipple discharge occurs.

The vaginal orifice may be difficult to see. Gentle lateral traction on the labia majora usually allows complete visualization of the hymen and vaginal orifice. The hymen should be evaluated for patency. Most hymenal variations—imperforate, microperforate, septate—do not require treatment during the neonatal period (Fig. 585.1). Variations should be noted and readdressed in subsequent visits. The hymen originates from the urogenital sinus. The uterus and upper vagina originate from the Müllerian ducts. The concomitant renal malformations seen with Müllerian anomalies are not associated with hymenal anomalies because of different embryologic origin of the two structures. Similarly, uterine anomalies are typically not observed with hymenal anomalies (see Chapter 591). Hymenal polyps seen in newborns typically regress in size as the maternal estrogen effects subside. Cervicovaginal mucus secretions can accumulate behind the blocked outflow tract of an imperforate hymen and manifest as a mucocolpos. *In this instance and if urinary obstruction occurs, correction of the imperforate hymen in the neonatal period is indicated.* In the absence of any concern for urinary obstruction, the imperforate hymen and associated mucocolpos can be observed for resolution, and the imperforate hymen is ideally repaired surgically after onset of puberty, specifically thelarche. This allows for improved healing of tissue in the presence of endogenous estrogen production.

The clitoris may appear large in proportion to the other genital structures, especially in premature infants. If the clitoris appears enlarged, the clitoral width and length should be measured; width values >6 mm or length values >6.5 mm in a newborn indicate a need for further evaluation. *If clitoromegaly and ambiguous genitalia are present, the provider should immediately obtain expert (endocrine) consultation for evaluation of the infant and to counsel the parents.* Congenital adrenal hyperplasia is the most common cause of ambiguous genitalia (accounting for >90% of cases), and the salt-wasting forms can lead to rapid dehydration with subsequent fluid and electrolyte imbalance (see Chapter 616). Delay in the diagnosis and treatment of congenital adrenal hyperplasia may be life-threatening.

In the neonate, the ovaries are <1 cm in diameter and average 1 cm^3 in volume. Antenatal or postnatal abdominopelvic ultrasound might reveal small simple ovarian cysts, which represent normal follicles. Because of the abdominal location of ovaries in the neonate, ovarian enlargement can manifest as a palpable abdominal mass. Large cysts (>4-5 cm) or those of a complex nature pose the risk of ovarian torsion, hemorrhage into the cyst, or, uncommonly, an ovarian tumor. A nonresolving or enlarging neonatal ovarian cyst warrants pediatric surgery or pediatric gynecology consultation. Percutaneous decompression has been described in cases where benign nature can be reliably ascertained. Cyst aspiration can provide temporary relief but is not recommended if cystectomy can safely be performed because the aspirated fluid may not be reliable for diagnosis and may reaccumulate. If a cystectomy is done for appropriate clinical indications, the cyst wall should be surgically excised to prevent reaccumulation of fluid and to provide a pathologic diagnosis, the remaining ovarian tissue should be left in situ, and the contralateral ovary should be inspected. Preservation of normal ovarian tissue is recommended for all benign lesions, and salpingo-oophorectomy should not be performed unless clinically indicated.

Infants and Prepubertal Girls

When the maternal estrogen effect subsides, the genitalia of the female infant change in appearance. The labia begin to flatten. The hymenal membrane loses its redundancy and becomes translucent. The hypoestrogenic prepubertal vaginal epithelium appears thin, red, and sensitive to the touch. The vaginal mucosa of young children can have longitudinal ridges running along the axis of the vagina at 3 o'clock, 6 o'clock, and 9 o'clock, which can cause small protrusions on the hymen at these locations. The cervix usually appears flat and flush with the vaginal vault. During infancy, the uterus regresses in size and does not return to its birth size until the child is 5-6 years old. The prepubertal cervix:fundus ratio is 2:1.

When puberty approaches, the child experiences increasing endocrine activity of the hypothalamus, pituitary gland, adrenal

gland, and ovaries (see Chapter 599). The labia majora begin to fill out, and the labia minora thicken and elongate as a result of increased estrogen levels. The hymen thickens and becomes more redundant. Clear or white physiologic secretions may be present. Breast buds begin to appear, either bilateral or initially unilateral with subsequent development of the contralateral breast. Pubic hair begins to appear.

Indications for Genital Examination

Genitourinary complaints or suspected genitourinary pathology warrants assessment of the external and internal genitalia of pediatric patients, specifically in cases of vaginal bleeding, vaginal discharge, vulvar trauma, presence of a foreign body, perineal or pelvic masses, vulvovaginal ulcerative or inflammatory lesions, congenital anomalies, or suspected sexual abuse.

Preparation

An examination of the external genitalia in prepubertal females requires a gentle, patient approach to maximize cooperation and minimize fear and embarrassment. A clear, simple explanation of what the examination involves can facilitate the child's comfort and cooperation. The presence of a parent or caregiver during the entire examination provides reassurance for most children. For the older prepubertal patient, the physician may discuss whether the patient wishes to have a family member present during the examination. Even in the presence of the caregiver, the examiner should speak directly to the child. Before initiating any part of the examination, the provider should explicitly verify with both the patient and their caregiver that the caregiver has given permission for the examination. This provides an opportunity to explain to the child the privacy of body parts and who may examine or touch those areas. It is useful to educate the patient and caregiver about the basic anatomy and hygiene of the external genital area. Before each step of the examination, the physician should explain what will occur. Allowing an older child the option of watching their examination with a handheld mirror may contribute to their comfort and understanding. Forcible restraint is never indicated; if optimal evaluation is not possible, the clinician must assess the acuity of the complaint and pathology and determine the potential need for multiple visits to complete the examination or an examination under anesthesia.

Positioning

A variety of techniques and positions can facilitate the genital examination in prepubertal patients. Children younger than 4 years of age can be placed on the parent or caregiver's lap with the child's legs straddling the caregiver's thighs (Fig. 585.2). If the child permits, they may be positioned on the table in the supine position with the hips fully abducted and the feet together in the frog-leg (diamond or butterfly) position. Older children may prefer to use the stirrups. The head of the examination table should be raised so that eye contact can be maintained with the patient throughout the examination. When the child is supine, grasping the labia majora along the inferior portion between the thumb and index finger and gently pulling outward and posteriorly (labial traction) allows visualization of the vaginal introitus. Alternatively, the child may be placed in the knee-chest position with elevation of the buttocks and hips (see Fig. 585.2). This position provides exposure of the inferior portion of the hymen, the lower vagina, and possibly the upper vagina and cervix but has the disadvantage of having the child face away from the examiner.

Some extremely cooperative children tolerate a vaginoscopic examination in an outpatient office setting for better intravaginal assessment. The endoscope (either a cystoscope or a hysteroscope) is placed in the vagina, and the labia are gently opposed, allowing the vagina to distend with water. This technique permits visualization of the vagina and cervix, allowing for the evaluation of an injury, lesion, and anatomic variant or for the presence of a foreign body. Application of 2% lidocaine gel at the introitus makes the insertion easier and less irritating for the patient. If a more complete examination is indicated or if the child is too young, frightened, or unable to cooperate, an examination under anesthesia is recommended.

Documentation

Clinicians should thoroughly and accurately document the genital examination findings in the medical record, reserving conclusions and diagnostic terms for the impression and plan portion of the documentation rather than in the description of exam findings. Each structure visualized should be noted (e.g., clitoris, labia majora, labia minora, urethra, vestibule, and rectum) with attention to describing normal appearance and any anatomic variations (e.g., the configuration of the hymen as annular, crescentic, and so forth). Describing any findings or lesions using a clock-face method provides a consistent reference point; a sketch or magnified photograph may also be helpful. Future examiners will rely on this documentation as a record with which they compare their findings and note any variances. Changes should be noted in any follow-up examinations.

Adolescents

Some teens prefer to initially meet and discuss the reason for their visit with the provider without their parent or guardian present, and this request should be honored (see Chapter 151). Obtaining a history from an adolescent usually begins with meeting the patient and parent or caregiver together to review their history and the reason for the visit and to explain the concepts of confidentiality and privacy. Care should be taken to ask the patient their preferred name and pronouns when addressing them. Familiarity with local laws governing limitations to confidential services should guide the protection of the adolescent and their parents' rights to information access and privacy. The Guttmacher Institute provides an up-to-date listing of state and federal laws in the United States affecting access to medical care (https://www.guttmacher.org/geography/united-states). Brief discussions of normal pubertal development and menstruation can reassure both patients and their parents or guardians and provide valuable education on appropriate menstrual flow, menstrual hygiene, and the duration and frequency of bleeding. Introducing the menstrual diary as an invaluable tool for the teen can help patients, parents, and clinicians identify abnormal bleeding patterns that might require further evaluation. Many applications are available for tracking menstrual periods on a smart phone or computer.

After the initial interview with the teen and their parent or caregiver, the confidential and sensitive portion of the history, particularly sexual history and alcohol, tobacco, and drug use, is taken with the teen alone. Such a request could be phrased as follows: "I would like to give your child an opportunity to ask any questions they might have privately, so would you mind stepping out of the room for a moment?" After obtaining the teen's assent for the confidential interview, questions regarding gender identity, sexual orientation, mental health, safety, and use of illicit substances should be asked. Any concerns regarding parent or caregiver access to personal electronic health records should be addressed. Concerns for the presence of vaginal discharge, the potential for sexually transmitted infections, pregnancy, or menstrual aberration should be explored. Teens and their parents should be informed of the proper use and accessibility of condoms, all contraceptive methods, and emergency contraception.

Resources for educating adolescents regarding their first pelvic examination and in-depth sexual history and psychosocial screening tools are available. These include the North American Society for Pediatric and Adolescent Gynecology (http://www.naspag.org), the American Academy of Pediatrics (http://www.aap.org), the Society for Adolescent Health and Medicine (http://www.adolescenthealth.org), and the American College of Obstetricians and Gynecologists (http://acog.org/Patients).

Individuals with Special Needs

Special care should be taken in the approach to individuals with both physical and cognitive disabilities (see Chapter 592). The assistance of Child Life services can be beneficial in decreasing patient anxiety.

Pelvic Examination

Table 585.1 presents the indications for the first pelvic examination in adolescents. If an adolescent does not meet one of the criteria listed in Table 585.1, the American College of Obstetricians and Gynecologists (ACOG) recommends that the first gynecologic encounter occur between the ages of 13-15 years (Table 585.2), with attention toward anticipatory guidance focusing on normal pubertal development and menstruation. All sexually active patients age

Table 585.1 Suggested Indications for Pelvic Examination in Adolescents

Age 21 yr of age for initial Papanicolaou test (Pap smear)
Unexplained menstrual irregularities, including pubertal aberrations (especially delayed puberty)
Severe dysmenorrhea
Unexplained abdominal or pelvic pain
Unexplained dysuria
Abnormal vaginal discharge
Concern for pelvic inflammatory disease
Placement of intrauterine device
Removal of foreign body
Inability to place tampons

Data from American College of Obstetricians and Gynecologists' Committee on Adolescent Health Care. The initial reproductive health visit: ACOG Committee Opinion, Number 811. *Obstet Gynecol*. 2020;136: e70–e80.

Table 585.2 Recommendations for First Gynecologic Evaluation

Occurs between 13 and 15yr of age
Focuses on patient education
Increases comfort with issues regarding adolescent sexuality
Ensures opportunity for adolescent to speak 1-on-1 with the provider
Makes the adolescent aware of limitations of confidentiality (including issues related to mandatory reporting, insurance billing, electronic health record notifications, and legal requirements)
Pelvic examination with Papanicolaou test (Pap smear) is generally not indicated until 21 yr of age, unless otherwise indicated by Table 585.1

Data from American College of Obstetricians and Gynecologists' Committee on Adolescent Health Care. The initial reproductive health visit: ACOG Committee Opinion, Number 811. *Obstet Gynecol*. 2020;136: e70–e80.

<25 years should undergo annual screening for sexually transmitted infections (STIs). This testing can also be obtained 3 months after treatment of a positive screening, with new symptoms, or with each new sexual partner. With the availability of urine and vaginal swab nucleic acid amplification testing for chlamydia, gonorrhea, and trichomoniasis, STI screening does not necessitate a speculum exam. Extragenital (rectal or pharyngeal) chlamydia and gonorrhea testing can be considered for patients based on self-reported sexual behaviors through shared clinical decision-making between the patient and the provider. Expedited partner treatment may be used according to the state law.

Before the initiation of a physical examination, all patients should be offered the choice of having a medical attendant, family member, or friend present during their examination. Presence of the chaperone is advised based on the laws of the state and the policies of the institution. At the initial gynecologic exam, the physician should explain the process in understandable terms. A thorough evaluation begins with an assessment of body mass index, blood pressure, menstruation status, thyroid, lymph nodes, breast development, abdominal exam, and skin. The external genitalia should be examined with the patient in the dorsal lithotomy position while communication is maintained between the physician and patient. Elevating the head of the examination table allows the teen and their examiner to maintain eye contact. The teen can hold a mirror to follow along with the examination, and they should be encouraged to ask questions. Inspection of the vulva is followed by inspection of the Bartholin, urethral, and Skene glands. The clitoris, normally 2-4 mm in width, is then assessed; a clitoris wider than 10 mm, especially in the presence of other signs of virilization, suggests a need for further evaluation. The hymenal anatomy should also be evaluated. Throughout the examination, the proper nomenclature for genital anatomy should be emphasized with the teen to empower them to use proper wordage with the avoidance of slang when referring to their body.

Because the initial Papanicolaou (Pap) test is deferred until 21 years of age except in certain immunocompromised patients and cultures for STIs can be obtained from urine or vaginal swabs, the need for a speculum exam is decreasing in this age group. If a speculum exam is indicated, use an appropriately sized speculum, such as the Huffman (½ in wide × 4 in long) or Pedersen (⅞ in wide × 4 in long) speculum. Shorter speculums will not allow visualization of the entire vaginal canal. The adolescent patient should be reassured that the exam may be uncomfortable but should not be painful and that their request to stop or wait will be honored. Encouraging the patient to watch with a handheld mirror facilitates patient education and can be empowering. They may be told before the insertion of the speculum that they will experience a pressure sensation. Before touching the introitus, it may be useful to touch the inner thigh with the speculum. Compression of the urethra anteriorly should be avoided. Gentle pressure with a finger for displacement of the fourchette posteriorly further facilitates proper speculum placement. After visualization of the vagina and cervix, specimens should be obtained as indicated. A bimanual examination, sometimes with a single digit, allows palpation of the vaginal walls and cervix and bimanual assessment of the uterus and adnexa. Reassurance of normal findings throughout the examination should be provided, and normal variants to anatomy should be pointed out to the teen as they are encountered (e.g., asymmetric labia minora).

After the examination, it is appropriate to review the exam findings with the teen (and parents or caregivers as appropriate) and initiate a collaborative discussion of the management plan. Encouraging the adolescent to participate in decision-making empowers them to undertake responsibility for their health, may strengthen compliance with the medical plan, and will acknowledge them as a unique individual.

Chapter 586

Vulvovaginitis

Helen M. Oquendo Del Toro and Holly R. Hoefgen

Vulvovaginitis is the most common gynecologic-based problem for prepubertal children, with a reported incidence of 17–50%. It is most typically caused by either inadequate or excessive hygiene or chemical irritants. The age of presentation peaks at 4-8 years of age. The condition is usually improved by hygiene measures and education of the caregivers and child.

ETIOLOGY

Vulvitis refers to external genital pruritus, burning, redness, or rash. **Vaginitis** denotes inflammation of the vagina, which can manifest as a discharge with or without an odor or bleeding. If these occur simultaneously, the term vulvovaginitis is used. When a child presents with vulvovaginitis, the history should include questions on hygiene (wiping from front to back) and information about possible exposure to chemical irritants (bath soaps, bubble bath, bath bombs, laundry detergents, swimming pools, or hot tubs). A detailed history of recent diarrhea, perianal itching, or nighttime itching is important. The possibility of foreign objects being placed into the vagina should also be asked, although the young child is unlikely to recall. Approximately 75% of cases of vulvovaginitis in children are nonspecific for a variety of reasons, including their lack of vaginal estrogenization and resulting atrophy and alkalinic pH, poor perianal hygiene, and the proximity of the anus to the vagina, which is without geographic barriers given the flattened labia and lack of pubic hair. Table 586.1 lists other vulvovaginal disorders commonly seen in children.

EPIDEMIOLOGY

Infectious vulvovaginitis, where a specific pathogen is isolated as the cause of symptoms, is commonly associated with fecal or respiratory pathogens, and cultures may reveal *Escherichia coli* (see Chapter 246), *Streptococcus pyogenes* (Chapter 229), *Staphylococcus aureus* (see Chapter 227), *Haemophilus influenzae* (see Chapter 240), *Enterobius vermicularis* (see Chapter 340), and, rarely, *Candida spp*. (see Chapter 280). These organisms may be transmitted by the child using improper toilet hygiene or manually from the nasopharynx to the vagina. Typical presentation includes perianal redness, introital inflammation, and often a yellow-green or mildly bloody discharge. Children may be observed to be grabbing their genital area or "digging" in their underwear, which is usually stained with yellow-brown discharge. Attempts to treat these bacterial etiologies with antifungal medication will fail, and often the antifungal product will lead to more irritation. Table 586.2 gives specific treatment recommendations based on the bacteria identified.

Neisseria gonorrhoeae or *Chlamydia trachomatis* are also causes of specific infectious vulvovaginitis (see Chapter 163). If acquired after the neonatal period, some diseases (e.g., gonorrhea, syphilis, and chlamydia) are virtually 100% indicative of sexual contact. Management of prepubertal children who have **sexually transmitted infections** requires close cooperation between clinicians and child-protection authorities. Official investigations for sexual abuse, when indicated, should be initiated promptly (see Chapter 17). For some diseases (e.g., human papillomavirus infection and herpes simplex virus), the association with sexual contact is not as clear. Presumptive treatment for prepubertal children who have been sexually assaulted or abused is not recommended, because (1) the incidence of most sexually transmitted infections in children is low after abuse/assault, (2) prepubertal females appear to be at lower risk for ascending infection than adolescent or adult women, and (3) regular follow-up of children usually can be ensured. Although *Trichomonas vaginalis* can be transmitted vertically

Table 586.1 Specific Vulvar Disorders in Children

CONDITION	PRESENTATION	DIAGNOSIS	TREATMENT
Molluscum contagiosum (Fig. 586.8)	1- to 5-mm discrete, skin-colored, dome-shaped, umbilicated lesions with a central cheesy plug	Diagnosis usually made by visual inspection	• Disease is generally self-limited and the lesions can resolve spontaneously. • Treatment choices in children may include cryosurgery, laser, application of topical anesthetic and curettage, podophyllotoxin, and topical silver nitrate. • Use of topical 5% imiquimod cream and 10% potassium hydroxide has been reported with similar effects.
Condyloma acuminata	Skin-colored papules, some with a shaggy, cauliflower-like appearance	• Diagnosis is usually made by visual inspection. • Biopsy should be reserved for when the diagnosis is in question. • Human papilloma-virus DNA testing is not helpful.	• Many lesions in children resolve spontaneously, with "wait and see" often used in children (60 days). • Topical treatment with imiquimod cream (3 times/wk at bedtime × 16 wk, wash 6-10 hr after application) and podophyllotoxin (bid × 3 days followed by 4 day break; typical treatment duration is 4 wk) is the most studied. • General anesthesia is usually required for surgical/ablative procedures (cryotherapy, laser therapy, electrocautery); reserve for symptomatic or large lesions. • Other treatments have been used in adults, including trichloroacetic acid, 5-fluorouracil, sine catechins, topical cidofovir, and cimetidine. • The efficacy and safety of these treatments in children has not been established.
Herpes simplex	Blisters that break, leaving tender ulcers	Visual inspection confirmed by culture from lesion	• *Infants*: Acyclovir 20 mg/kg body weight IV q8 hr × 21 days for disseminated and central nervous system disease or × 14 days for disease limited to the skin and mucous membranes. • *Genital/mucocutaneous disease:* • *Age 3 mo-2 yr:* 15 mg/kg/day IV divided q8h × 5-7 days. • *Age 2-12 yr (first episode):* Same as above or 40-80 mg/kg/day PO divided tid-qid × 7-10 days (max 1,000-1,200 mg/day). • *Age 2-12 yr (recurrence):* 1,000 mg/day PO in 5 divided doses × 5 days or 1,600 mg/day PO divided bid × 5 days or 2400 mg PO divided q8 × 2 days.
Labial adhesions (see Fig. 586.1)	May be asymptomatic or can cause vulvitis, urinary dribbling, urinary tract infection, or urethritis	Diagnosis made by visual inspection of the adherent labia, often with a central semitranslucent line.	• Does not require treatment if the patient is asymptomatic. • Symptomatic patients: Topical estrogen cream or betamethasone ointment applied alone or in combination daily for 6 wk directly to the line of adhesion, using a cotton swab while applying gentle labial traction. • Estrogen should be interrupted if breast budding occurs. • Mechanical or surgical separation of the adhesions is rarely indicated. • The adhesions usually resolve in 6-12 wk; unless good hygiene measures are followed, recurrence is common. • To decrease the risk of recurrence, an emollient (petroleum jelly, A and D ointment) should be applied to the inner labia for 1 mo or longer at bedtime.
Lichen sclerosus (see Fig. 586.4)	A sclerotic, atrophic, parchment-like plaque with an hourglass or keyhole appearance of vulvar, perianal, or perineal skin; subepithelial hemorrhages may be misinterpreted as sexual abuse or trauma. The patient can experience perineal itching, soreness, or dysuria.	Diagnosis usually is made by visual inspection. Biopsy should be reserved for when the diagnosis is in question.	• Ultrapotent topical corticosteroids are the first-line therapy (clobetasol propionate ointment 0.05%) once or twice a day for 4-8 wk. • Once symptoms are under control, the patient should be tapered off the drug unless therapy is required for a flare-up. • In many females, the condition resolves with puberty; however, this is not always the case and patients may require long-term follow-up. • Immunomodulators can be used: tacrolimus 1% (applied once daily) and pimecrolimus 1% (applied twice daily for 3 mo, then every other day).
Psoriasis	Children are more likely than adults to have vulvar psoriasis noted as pruritic, well-demarcated, nonscaly, brightly erythematous, symmetric plaques. The classic extragenital lesions are similar but with a silver scaly appearance.	Diagnosis may be confirmed by locating other affected areas on the scalp or in nasolabial folds or behind the ears.	Vulvar lesions may be treated with low- to medium-potency topical corticosteroids, increasing strength as necessary.
Atopic dermatitis	Chronic cases can result in crusty, weepy lesions that are accompanied by intense pruritus and erythema. Scratching often results in excoriation of the lesions and secondary bacterial or candidal infection.	May be seen in vulvar area but characteristically affects the face, neck, chest, and extremities	Children with this condition should avoid common irritants and use topical corticosteroids (such as 1% hydrocortisone) for flare-ups. If dry skin is present, lotion or bath oil can be used to seal in moisture after bathing.

Continued

Table 586.1 Specific Vulvar Disorders in Children—cont'd

CONDITION	PRESENTATION	DIAGNOSIS	TREATMENT
Contact dermatitis	Erythematous, edematous, or weepy vulvar vesicles or pustules can result, but more often the skin appears inflamed	Associated with exposure to an irritant, such as perfumed soaps, bubble bath, talcum powder, lotions, elastic bands of undergarments, or disposable diaper components	Avoidance of irritant; topical corticosteroids for flare-ups
Seborrheic dermatitis	Erythematous and greasy, yellowish scaling on vulva and labial crural folds associated with greasy dandruff-type rash of scalp, behind ears and face	Diagnosis usually made by visual inspection	Gentle cleaning, topical clotrimazole with 1% hydrocortisone added
Vitiligo (see Fig. 586.6)	Sharply demarcated hypopigmented patches, often symmetric in vaginal and anal regions; may be present in periphery at body orifices and extensor surfaces	Clinical. Test for associated illness if clinically warranted (thyroid disease, Addison disease, pernicious anemia, diabetes mellitus).	If desired, treat limited lesions with low-potency corticosteroids or tacrolimus. See dermatologist for extensive lesions.

Table 586.2 Antibiotic Recommendations for Specific Vulvovaginal Infections

ETIOLOGY	TREATMENT
Streptococcus pyogenes *Streptococcus pneumoniae*	• Penicillin V, 250 mg PO bid-tid for children < 27 kg, and 500 mg bid-tid for children > 27 kg × 10 days • Amoxicillin, 50 mg/kg/day (max: 500 mg/dose) PO divided tid × 10 days • Erythromycin ethyl succinate, 30-50 mg/kg/day (max: 400 mg/dose) PO divided qid • TMP-SMX, 6-10 mg/kg/day (TMP component) PO divided bid × 10 days • Clarithromycin, 7.5 mg/kg bid (max: 1 g/day) PO × 5-10 days • Recurrence most likely from asymptomatic pharyngeal carriage in child or family member; however, failure of penicillin regimens can occur • For penicillin resistance: Rifampin 10 mg/kg PO every 12 hr × 2 days
Staphylococcus aureus	• Topical mupirocin 2% tid to the affected skin area • If systemic therapy required: Amoxicillin-clavulanate, 45 mg/kg/day (amoxicillin) PO divided bid-tid × 7 days (first-line treatment because of high penicillin resistance) • Extensive resistance to common antibiotics noted; recommend susceptibility testing for further antibiotic use • MRSA: TMP-SMX double-strength 8-10 mg/kg/day; culture abscesses, incision and drainage
Haemophilus influenzae	• Amoxicillin, 40 mg/kg/day PO divided tid × 7 days • For cases of treatment failure or nonencapsulated *H. influenzae*, amoxicillin–clavulanate is recommended.
Yersinia	• TMP-SMX 6 mg/kg (TMP component) daily for 3 days
Shigella	• TMP-SMX 10/50 mg/kg/day (max: 160/600) PO divided bid × 5 days • Ampicillin 50-100 mg/kg/day PO divided qid (adult max: 4 g/day) × 5 days • Azithromycin 12 mg/kg (max: 500) PO × 1 day, then 6 mg/kg/day (max: 250 mg) × 4 days (in areas of high resistance to above regimens or when sensitivities are unknown) • For resistant organisms: Ceftriaxone 50-75 mg/kg/day IV or IM divided into 1 or 2 doses (max: 2 g/day) × 2-5 days

Chlamydia trachomatis	• Children weighing < 45 kg: Erythromycin base or ethylsuccinate 50 mg/kg/day PO divided qid × 14 days
	• Children weighing > 45 kg but age younger than 8 yr: Azithromycin 1 g PO in a single dose
	• Children age older than 8 yr: Azithromycin 1 g PO in a single dose or Doxycycline 100 mg PO bid × 7 days
	• Adolescents and Adults:
	  • *Preferred*: Doxycycline 100 mg PO bid × 7 days
	  • *Alternative*: Azithromycin 1 g PO in single dose or Levofloxacin 500 mg PO once daily × 7 days

Neisseria gonorrhoeae	• Children weighing < 45 kg: Ceftriaxone, 25-50 mg/kg body weight IV or IM in a single dose (max 250 mg IM) • Children weighing ≥ 45 kg: Treat with adult regimen of 500 mg IM in a single dose; add azithromycin 1 g PO in a single dose if chlamydia has not been excluded. In persons > 150 kg, provide 1 g ceftriaxone.
Trichomonas	• Metronidazole, 15-30 mg/kg/day PO bid (max: 500 mg/dose) × 7 days or Tinidazole 50 mg/kg (max 2 g) PO as a single dose for children older than 3 yr
Pinworms (*Enterobius vermicularis*)	• Mebendazole, 100 mg chewable tablet once, repeated in 2 wk or Albendazole, 200 mg PO for child younger than age 2 yr or 400 mg PO for older child once, repeated in 2 wk • Pyrantel pamoate 11 mg/kg PO once (max 1 g), repeated in 2 wk

MRSA, Methicillin-resistant *Staphylococcus aureus*; TMP-SMX, trimethoprim-sulfamethoxazole.

and can be seen in children up to 1 year of age, it is an uncommon cause of specific infectious vulvovaginitis in the unestrogenized prepubertal female.

Other causes of specific infectious vulvovaginitis include *Shigella* (see Chapter 245), which often manifests with a blood-tinged purulent discharge, and *Yersinia enterocolitica* (see Chapter 249). Candida infections (yeast) commonly cause diaper rash (diaper dermatitis), but they are unlikely to cause vaginitis in children because the alkaline pH of the prepubertal vagina does not support fungal infections. Diabetic or immunocompromised children and children taking prolonged antibiotics may be at increased risk for fungal vaginitis. Pinworms are the most common helminthic infestation in the United States, with the highest rates in school-age and preschool children. Perianal itching can lead to excoriation and, rarely, bleeding.

CLINICAL MANIFESTATIONS

Diaper Dermatitis

Diaper dermatitis is the most common dermatologic problem in infancy and occurs in half of all diaper-wearing infants and children. The moisture and contact with urine and feces irritates the skin, and colonization with *Candida spp*. increases the severity of the dermatitis. First-line treatment includes hygiene measures such as increasing the frequency of diaper changes, allowing the infant to be diaper free, frequent bathing, and application of water-repellant barriers such as zinc oxide. If diaper dermatitis persists after these conservative measures, or if the classic satellite lesions of *Candida* are present, treatment with a topical antifungal can decrease the inflammation.

Physiologic Leukorrhea

Neonates and peripubertal children can present with a white, clear, or mucus discharge, which is physiologic in nature and secondary to exposure to estrogen. Some patients may complain of the moisture and mucus. Hygiene measures, including plain warm water baths, may help decrease symptomatology, but education should also be provided to reassure the patient and their parents.

Labial Agglutination

Labial agglutination (**labial adhesions**) are described most frequently in infants and young children (Fig. 586.1). This phenomenon is thought to be secondary to an inflammatory response in the labia minora in combination with a hypoestrogenic state. Diagnosis is made on routine genital examination. Asymptomatic patients usually require no intervention. Most common symptoms include urinary frequency, vaginitis, and postvoidal dribbling; labial adhesions also increase a patient's susceptibility to urinary tract infections. First-line therapy in symptomatic patients includes topical estrogen (estradiol cream 0.01%) or a topical steroid (betamethasone dipropionate 0.05% ointment) applied twice daily to the midline raphe under gentle traction. Surgical correction is rarely necessary, but recurrence is common until the age of puberty. Liberal use of bland emollients for 6-12 months after resolution of adhesions can limit recurrences.

Genital Ulcers

Acute genital ulceration of the vulva (Fig. 586.2) is described in young adolescents who are not sexually active and can occur in association with oral aphthous ulcers. Although linked to infectious causes such as Epstein-Barr virus, cytomegalovirus, mycoplasma, mumps, and influenza A, these ulcers may also be idiopathic vulvar aphthoses. Other potential etiologies include Crohn disease, Behçet disease, pemphigoid, Stevens-Johnson syndrome, fixed drug eruption, or mouth and genital ulcers with inflamed cartilage (MAGIC) syndrome, which has combined features of relapsing polychondritis and Behçet disease.

These lesions usually appear on the mucosal surfaces of the introitus as painful red or white lesions that evolve into sharply demarcated, red-rimmed ulcers with a necrotic or eschar-like base. The time course is generally 10-14 days until remission occurs. The lesions are painful; dysuria and vulvar pain are common complaints as well. Patients with acute genital ulcers show a fairly consistent picture of flulike prodromal symptoms, including fever, nausea, and abdominal pain. One

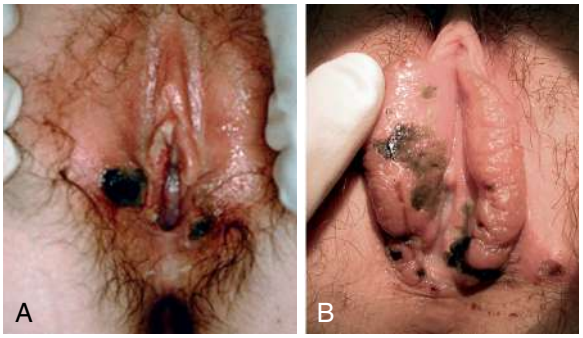

Fig. 586.2 Aphthous ulcers. *(Photo courtesy Diane F. Merritt, MD.)*

third of patients present with a history of or develop oral ulcerations. Evaluation includes culture or polymerase chain reaction (PCR) test for herpes simplex virus to exclude this etiology. Special testing for systemic disease depends on the history. Biopsies are usually nondiagnostic because they yield acute and chronic inflammatory changes. Figure 586.3 outlines the suggested evaluation and management of initial and recurrent disease. Evaluation for Behçet disease (see Chapter 202) using the International Study Group diagnostic guidelines should be considered with recurrent or severe cases (see Table 586.1 for other common etiologies). Treatment of acute genital ulcers should include topical lidocaine 2% jelly, sitz baths, good hygiene, and acetaminophen. Nonsteroidal antiinflammatory drug *avoidance* is suggested because of a possible causative link. Hospitalization may be required for pain management not controlled with oral narcotics or urinary retention requiring Foley catheterization, or for whirlpool debridement should hygiene become difficult. Antibiotic treatment is not required, unless evidence of bacterial superinfection exists or the patient is immunocompromised. Insufficient evidence exists to recommend whether oral steroid treatment is effective, but this may be helpful in the setting of recurrent outbreaks and extensive disease. Ultrapotent topical steroids (clobetasol 0.05% ointment) are beneficial in oral aphthous ulcers and may prove helpful in acute genital ulcers as well.

Dermatoses

Dermatologic conditions often affect the vulvar area in children; it is important to determine if the child presenting with vulvar irritation has a skin condition elsewhere on the body. **Lichen sclerosus** is commonly seen in the anogenital region and has a characteristic appearance of thinning and whitened skin changes associated with areas of erosion, ulceration, and petechiae. This disease can cause severe discomfort and most commonly presents with vulvar or perianal pruritus, dysuria, and constipation. Patients may also present without any symptoms, which may lead to underrecognition and undertreatment. If untreated, lichen sclerosus can lead to destruction and scarring of

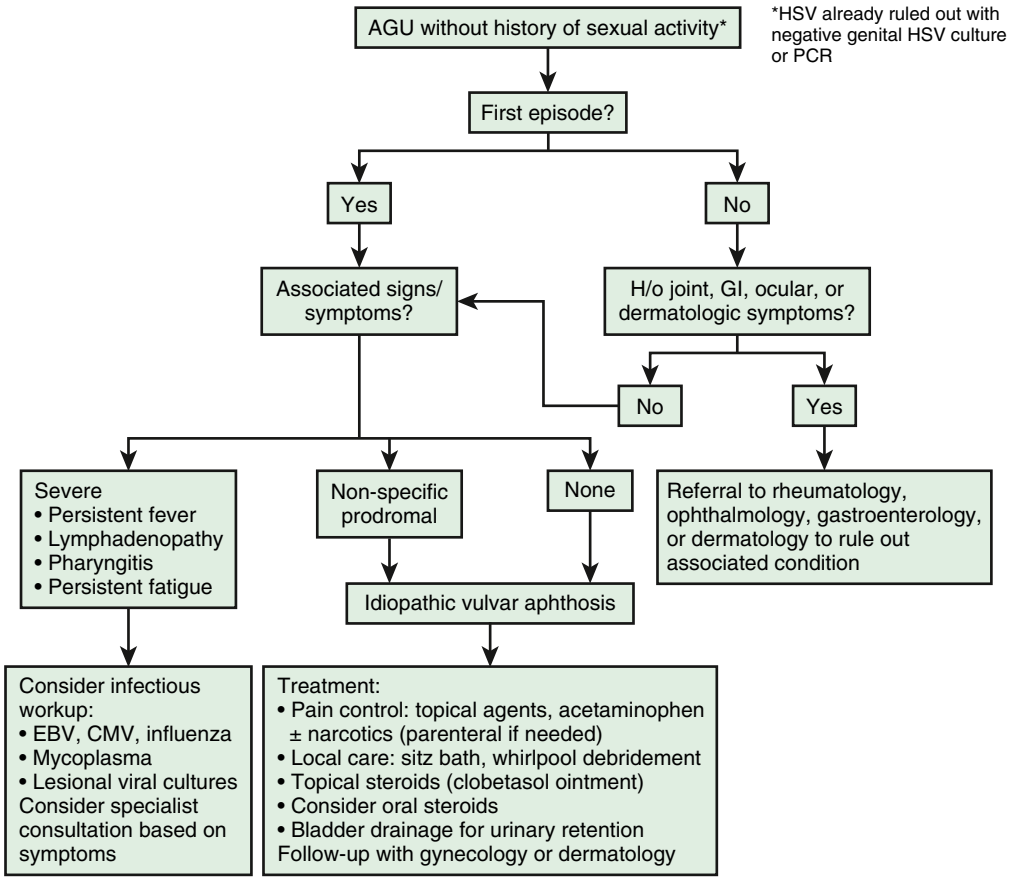

Fig. 586.3 Algorithm for evaluation and management of acute genital ulcers in non–sexually active young girls. AGU, Acute genital ulcer; CMV, cytomegalovirus; EBV, Epstein-Barr virus; GI, gastrointestinal; HSV, herpes simplex virus; PCR, polymerase chain reaction. *(From Rosman IS, Berk DR, Bayliss SJ, et al. Acute genital ulcers in nonsexually active young girls: Case series, review of the literature, and evaluation and management recommendations. Pediatr Dermatol. 2012;29[2];147-153.)*

Fig. 586.4 Lichen sclerosus. *(Photo courtesy Diane F. Merritt, MD.)*

normal genital architecture, including labial resorption, obliteration of the clitoris, narrowing of the introitus, and painful fissures that may become secondarily infected. Once thought to resolve with puberty, this theory is now controversial, and many postmenarchal adolescents still suffer from disease (Fig. 586.4). Lichen sclerosus may be treated with potent topical steroids, such as clobetasol propionate 0.05% applied once or twice daily until the symptoms resolve, and then tapered down through lower-dose topical steroids. Topical calcineurin inhibitors such as tacrolimus and pimecrolimus have been used in the treatment of lichen sclerosus. Patients should be followed every 6-12 months to evaluate for recurrence (Fig. 586.5).

Vitiligo is an acquired skin depigmentation resulting from an autoimmune process directed at epidermal melanocytes. Lesions appear as sharply demarcated patches of pigment loss, often symmetrically located around the vagina and anal area. Similar lesions of hypopigmentation can be found surrounding body orifices and extensor surfaces (Fig. 586.6). Although the diagnosis is clinical, there is an association with other autoimmune or endocrine disorders (hypothyroidism, Graves disease, Addison disease, pernicious anemia, insulin-dependent diabetes mellitus), and the workup should include evaluation for thyroid dysfunction. Mild topical corticosteroid cream or ointment may be prescribed for children. Dermatologists may offer immunomodulators (tacrolimus) and phototherapy.

Vulvar psoriasis presents as pruritic, well-demarcated, erythematous, symmetric plaques that involve the vulva, perineum, and/or gluteal folds. Lesions on the mons pubis may have the more characteristic scaly appearance. The classic signs of psoriasis may also be appreciated with pitting nailbeds, posterior auricular erythema, or a silvery scaling rash found elsewhere on the body. Many of the treatments used in adults may not be appropriate in children. Psoriasis may be treated with moisturizers, topical steroids, and light therapy. Teens may be treated with coal tar, retinoids, tacrolimus, and calcipotriene, which is a derivative of vitamin D_3.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Children with symptoms of vulvovaginitis often have had previous evaluations and treatment failures. Cultures with sensitivities to test for specific pathogens may be obtained with cotton swabs or urethral (Calgiswab) swabs moistened with nonbacteriostatic saline. Use of a swab can cause discomfort or, rarely, minimal bleeding. The

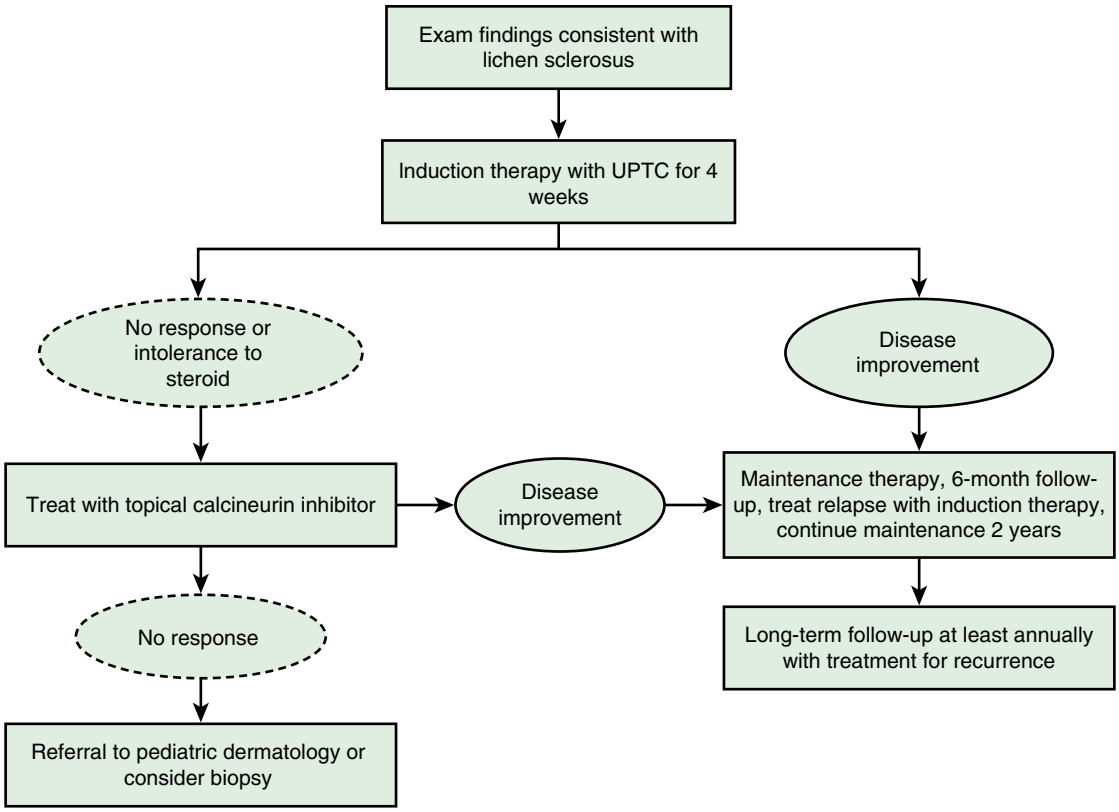

Fig. 586.5 Management algorithm for lichen sclerosus. UPTC, Ultrapotent topical corticosteroids. *(From Simms-Cendan J, Hoover K, Marathe K, Tyler K. NASPAG clinical opinion: Diagnosis and management of lichen sclerosis in pediatric and adolescent patients. J Pediatr Adolesc Gynecol. 2022;35[2]:112-120; Fig. 6.)*

Fig. 586.6 Vitiligo. *(Photo courtesy Diane F. Merritt, MD.)*

premoistened swab can be placed vertically between the labia minora to collect secretions, as it is not necessary to place the swab into the vagina. Testing for gonorrhea and chlamydia may be done by culture or by nucleic acid amplification testing, depending on institutional or state and Centers for Disease Control and Prevention guidelines. Tests for *Shigella* and *H. influenzae* might require special media and collection procedures.

If pinworms (see Chapter 340) are suspected, transparent adhesive tape or an anal swab should be applied to the anal region in the morning before defecation or bathing and then placed on a slide. Eggs seen on microscopic examination confirm the diagnosis, and sometimes the pinworms can be seen at the anal verge. Clinical history is often more indicative of disease than physical examination, and a negative tape test does not rule out this pathogen as a cause.

If the vaginal discharge is serosanguineous, if a foul odor is present, or if the discharge fails to respond to hygiene measures, presence of a vaginal foreign body (Fig. 586.7) should be considered. If inspection suggests the presence of a foreign body, the vagina can be irrigated, or an examination under anesthesia may reveal the foreign body. Vaginal irrigation may occasionally lead to expulsion of the foreign body; in cases where this does not occur, vaginoscopy is an excellent diagnostic tool and can be performed in an unsedated cooperative patient in an outpatient setting, or under general anesthesia if necessary. Using a cystoscope with saline or water irrigation to gravity, insert the endoscopic device into the vagina and gently oppose the labia; the vagina will distend, and the entire vaginal cavity and cervix may be easily assessed.

TREATMENT AND PREVENTION

The treatment of specific vulvovaginitis should be directed at the disorder or organism causing the symptoms (see Tables 586.1 and 586.2). Treatment of nonspecific vulvovaginitis includes sitz baths

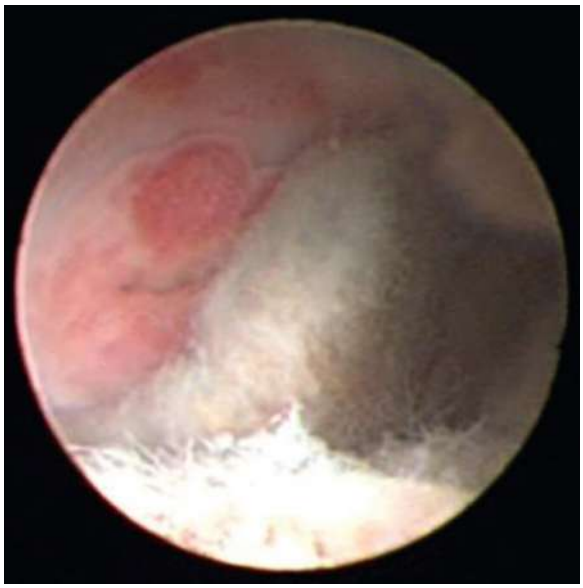

Fig. 586.7 Vaginal foreign body as seen through vaginoscope. *(Photo courtesy Diane F. Merritt, MD.)*

Fig. 586.8 Molluscum contagiosum. *(Photo courtesy Diane F. Merritt, MD.)*

and avoidance of irritating or harsh soaps and chemicals and tight clothing that abrades the perineum. External application of bland emollient barriers such as nonprescription diaper rash medications and petroleum jelly may be helpful. Proper perineal hygiene is critical for long-term improvement. Younger children need supervised perineal hygiene, and caregivers should be advised to wipe the genital area from front to back. Use of a warm moistened washcloth or diaper wipe is helpful after initially wiping with toilet tissue. Children should wear cotton underwear and limit time spent in tights, leotards, leggings, tight jeans, and wet swimsuits. Soaking in warm clean bathwater for 15-minute intervals (no shampoo or bubble bath) is soothing and helps with cleaning the area. Parents should be counseled to avoid all scented, antiseptic, and deodorant-based soaps, and to eliminate the use of fabric softeners or dryer sheets when laundering undergarments.

Chapter 587

Vaginal Bleeding in the Prepubertal Child

Kathryn C. Stambough and Christina Davis-Kankanamge

Newborn females may experience physiologic bleeding (**neonatal withdrawal bleeding**) in the first week of life secondary to diminished circulating maternal estrogen and stimulation of endometrial sloughing; this bleeding resolves in 3-4 days. Vaginal bleeding in infants lasting longer than a few days and all other vaginal bleeding in prepubescent children should be promptly evaluated because there are many pathologic etiologies that require expeditious workup. Common causes include vulvovaginitis, dermatologic conditions, vaginal foreign bodies, and urethral prolapse; less common are the effects of endogenous or exogenous estrogen; and the least common but most worrisome sources include neoplasms and trauma.

Although many cases of pediatric vaginal bleeding are idiopathic, many can be attributed to **vulvovaginitis** (see Chapter 586) stemming from transmission of respiratory, oral, fecal, or sexually communicated pathogens. Vulvovaginitis may present with serosanguineous vaginal drainage (e.g., *Streptococcus, Shigella*) or vulvar irritation. Age-appropriate anatomic and physiologic factors put prepubertal females at higher risk of developing vulvovaginitis. The protective barrier of fully developed labia is absent, leaving the vaginal introitus exposed to the external environment. The hypo-estrogenized vagina is marked by an alkaline milieu prone to infection because of lack of the protective acidic pH afforded by the lactobacilli colonization that occurs with puberty. Routine handwashing, improved perineal hygiene (e.g., wiping from front to back, use of wet wipes after bowel movements, proper cleansing of genitalia during baths), and avoidance of topical irritants, chemicals, and perfumed or deodorant soaps and bubble baths reduces nonspecific vulvovaginitis. Topical application of bland emollient barriers (e.g., over-the-counter diaper rash ointments, petroleum jelly) may be protective against and mitigate symptoms of external irritation. Antibiotics should be employed in the event of recurrent or persistent infections where a specific pathogen has been identified (see Table 586.2).

Vulvar dermatoses may initially present with bleeding. **Lichen sclerosus** (see Table 586.1 and Fig. 586.4) is characterized by chronic inflammation, intense pruritus, loss of normal architecture, and thinning and whitening of vulvar and perianal skin, often in a butterfly or keyhole distribution. Petechiae or blood blisters can complicate the classic clinical picture, leading to a mistaken assumption of sexual trauma. A tissue biopsy can provide a definitive diagnosis but is not usually necessary in prepubertal children and, if needed, is most appropriately performed under anesthesia. The first-line treatment is ultrapotent topical steroids (e.g., clobetasol propionate 0.05%). Appropriate timing and duration of application is practitioner dependent, but guidelines suggest treating children similarly to adults by starting with once or twice daily application for 4 weeks. Tapering of topical corticosteroid use can then occur with symptom control and include a decrease in the frequency of corticosteroid application, potency of the corticosteroid used, or both. Follow-up evaluations for response should start at 1 month after initiation of treatment. In the event of flare-ups, long-term maintenance therapy with a lower potency steroid may be initiated with appropriate counseling because side effects are rare.

Vaginal foreign bodies are a common finding in children presenting with blood-tinged and foul-smelling discharge. Quick identification and removal of the foreign body avoids potential complications, including recurrent urinary tract infections, dermatologic

abnormalities, vaginal perforation, or fistula formation. The most common object found in the prepubertal vagina is retained toilet paper. If physical exam in knee-chest or frog-leg position reveals the object, an attempt at removal in the office can be made using warm water flushes through a small feeding tube. If the object is not visible, irrigation is unlikely to remove it, and examination under anesthesia and vaginoscopy are often required. Direct visualization via vaginoscopy facilitates extraction of an object, as well as evaluation for potential sites of injury or unrelated sources of bleeding. In-office vaginoscopy may also be a possibility in the appropriate patient (see Chapter 585).

Several urologic conditions may have a mixed clinical picture suspicious for vaginal bleeding, including **gross hematuria** (see Chapter 558) and **urethral prolapse** (see Chapter 581) (Fig. 587.1). Prolapse involves protrusion of urethral mucosa through the external meatus, resulting in a friable hemorrhagic mass that often obscures the adjacent vaginal introitus. Predisposing factors include hypoestrogenic state, neuromuscular diseases, urethral anomalies, fascial defects, trauma, and chronic increases in intraabdominal pressure (e.g., recurrent Valsalva related to constipation or forceful coughing). Treatment of prolapse is conservative, involving twice-daily sitz baths followed by topical application of estrogen cream (e.g., Estradiol 0.01%) at the affected area for 2 weeks. If on reevaluation the prolapse remains, application should be continued until complete resolution is achieved. Surgical excision is rarely necessary and reserved primarily for management of necrotic tissue.

Vaginal bleeding may be a presenting sign of **precocious puberty** (see Chapter 600), defined as premature pubertal development occurring 2.0-2.5 standard deviations earlier than the average age in the general population. A formal evaluation should be conducted if pubic hair or breast development occurs rapidly or initiates before age 8 years in a female child. The most common source of premature development is **gonadotropin-dependent** or **central precocious puberty** (see Chapter 600.1), resulting in early enhancement of pulsatile release of hypothalamic gonadotropic-releasing hormone (GnRH) that stimulates ovarian follicular growth and subsequent estrogen production. **Gonadotropin-independent** or **peripheral precocious puberty** occurs less commonly and in the absence of hypothalamic influence, with estrogen being a product of ovarian or adrenal tumors, or McCune-Albright syndrome (see Chapter 600.6). In both instances, elevated estrogen levels lead to a thickened endometrium capable of shedding as in menses.

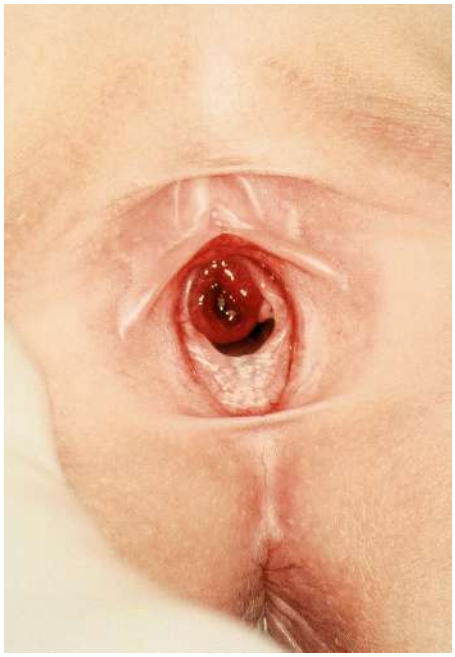

Fig. 587.1 Prepubertal urethral prolapse with high crescent-shaped hymen. *(From Lara-Torre E, Valea FA. Pediatric and adolescent gynecology: Gynecologic examination, infections, trauma, pelvic mass, precocious puberty. In Lobo RA, Gershenson DM, Lentz GM, Valea FA [eds]: Comprehensive Gynecology. Elsevier, 2022: 227; Fig. 12.6.)*

Evaluation of precocious puberty starts by examining for secondary sex characteristics and documenting the Tanner stage of breast and pubic hair development using the **Sexual Maturation Index** (see Chapter 150). Plotting height and weight on a growth chart may assist in identifying accelerated growth velocity. Supportive laboratory findings include elevated serum luteinizing hormone levels, but the gold standard remains measurement of gonadotropin levels after stimulation with GnRH or a GnRH receptor agonist. Estradiol levels greater than 100 pg/mL can indicate either the presence of premature ovarian follicles or a peripheral tumor (e.g., ovarian germ cell tumor). A pelvic ultrasound should be used to evaluate for ovarian or adrenal pathology, as well as uterine maturation in response to estrogen. However, premature ovarian follicles typically produce estrogen for a very short period, in quantities just sufficient to stimulate growth and shedding of the endometrium. Follicular involution and return of estrogen to prepubertal levels may occur before an ultrasound can be obtained. An x-ray for bone maturity is simple and noninvasive. Other supportive radiologic findings include a brain MRI demonstrating a mass in the context of central precocious puberty. If indicated, central precocious puberty can be suppressed with GnRH agonist therapy. Peripheral tumors (i.e., ovarian germ cell tumors) are treated by surgical excision with staging and chemotherapy as indicated by oncologic protocols.

Differential diagnoses of vaginal bleeding attributed to premature estrogenization must also include exposure to **exogenous estrogens,** including hormonal contraceptives, certain foods (soy), beauty products (lavender, tea tree oil), and plastics with endocrine disruptors. Ingesting large quantities of Bisphenol A (BPA), a product that may leach into the contents of plastic cups and bottles, is known to convey an estrogenic effect, although the impact remains unknown. Treatment involves elimination of any problematic sources of estrogen from the patient's daily use.

Juvenile hypothyroidism (see Chapter 603) commonly causes pubertal delay, but severe cases may present with premature breast development, vaginal bleeding, and abdominal distention secondary to ovarian enlargement and ascites. The mechanism for this condition is unclear, but it has been proposed that elevated levels of thyroid-stimulating hormone cross-react with follicle-stimulating hormone receptors, resulting in follicle maturation and estradiol production. Treatment with thyroid hormone replacement (e.g., levothyroxine) results in improvement and ultimately reversal of symptoms.

Neoplasms of the vulva and vagina (see Chapter 590) are rare causes of bleeding in the pediatric patient. **Infantile hemangiomas** are the most common benign vascular neoplasm of infancy, affecting up to 5% of all infants. Most lesions initially proliferate before resolving spontaneously and seldom require intervention. However, on identifying a perineal hemangioma, a neurologic assessment should be performed due to an association with spinal dysraphism. If a persistent lesion is superficial, application of topical β blockers (e.g., Timolol 0.5%) 2-3 times daily for 6-12 months has demonstrated good response rates. Oral β blocker use and intralesional corticosteroids may be used as well. If conservative therapies fail, laser therapy and surgical excision may be beneficial. Vaginal polyps may result in bleeding, and vaginoscopy for evaluation of any upper vaginal or cervical etiologies for bleeding with expedient excision and pathologic evaluation is recommended.

Malignant gynecologic neoplasms (see Chapter 590) are a source of pediatric genital bleeding that requires scrupulous evaluation and timely management. **Rhabdomyosarcoma** is the most common soft tissue sarcoma of childhood; 3% arise from the uterus or vagina. The embryonal variant is responsible for uterine sarcomas, whereas the embryonal subvariant sarcoma botryoides is found in the vagina. Primary **endodermal sinus** (i.e., yolk sac) **tumors** of the vagina are exceedingly rare, but early diagnosis is imperative given the malignancy's aggressive nature and poor prognosis. Both sarcomatous and endodermal sinus tumors arise primarily in the first 3 years of life, presenting on examination with a cystic or polypoid mass, bloody discharge, and occasionally urinary retention. Treatment consists of a multimodal approach, including surgery, radiation, and chemotherapy per oncologic guidelines.

Vulvovaginal trauma is an especially concerning cause of pediatric genital bleeding. Most traumatic injuries are accidental, but physical and sexual abuse must be ruled out (see Chapter 17.1). **Straddle injuries** are commonly seen after falls at home, particularly after slipping on a wet surface in the bathroom; they may result in bruising, hematomas, or lacerations (Fig. 587.2). Accidental trauma usually spares the hymen and vagina, instead affecting the external impact-absorbing tissue of the mons and labia. *However, a physical finding consistent with external injuries does not exclude the need to rule out involvement of internal genital structures. If there are no eyewitnesses to the injury, if the history does not clarify or support the clinical findings, and especially if there is a hymenal laceration, abuse must be considered in the differential diagnosis and a forensic interview of the patient and family conducted.* If after initial inspection a penetrative injury is suspected, further examination and imaging are necessary to assess for potential damage to the urethra, bladder, anus, or intraabdominal structures. An examination under anesthesia may be needed to fully assess and repair extensive injuries, while minor lacerations in a cooperative child may potentially be repaired using local anesthesia and/or conscious sedation. If the patient can void spontaneously, nonexpanding hematomas can be observed and treated with ice, pressure, and pain medications. Large expanding hematomas may require drainage, ligation of bleeding vessels, and placement of a closed suction drain if the overlying skin is showing signs of necrosis. A Foley catheter should be placed in all children who are having difficulty with voiding secondary to the injury.

Vaginal bleeding in the infant or prepubertal female is distressing to the patient and their family and can result from a wide spectrum of pathologic conditions or traumatic incidents. A detailed history and thorough physical examination must be done to identify the source of bleeding and for a management plan to be established efficiently. Presentations suspicious for trauma or abuse should involve the appropriate healthcare staff and authorities from an early stage, with findings meticulously documented. If an intervention is indicated to manage bleeding, regardless of its source, the risks and benefits of any therapy should be reviewed carefully with the family before initiation.

Chapter 588

Breast Health

Marcene R. McVay-Gillam and Amy D. DiVasta

Breast complaints in pediatric patients typically include concerns about breast appearance or development, pain, nipple discharge, or a lump/mass. Although the development of breast cancer is very rare during childhood and adolescence, this patient population should be evaluated by practitioners who have experience with the immature and developing breast to avoid overtreatment with unnecessary diagnostic or invasive procedures.

BREAST DEVELOPMENT

Prenatal breast development begins around the fifth week of gestation, when the ectoderm on the anterior body wall thickens into two **mammary ridges.** These ridges extend from the axilla to the region of the inguinal canal (Fig. 588.1). The ridge above and below the area of the pectoralis muscle recedes in utero, leaving the **mammary primordium**, which is the origin of the lactiferous ducts. The lactiferous ducts form between weeks 10 and 20 and become interspersed through the developing mesenchyme, which develops into the fibrous and fatty portions of the breast. The **breast bud**, under the stimulation of maternal estrogen, becomes palpable at week 34 of gestation. This breast bud regresses within the first month of life once estrogen stimulation is no longer present. The **areola** appears at 5 months of gestation, and the nipple is seen shortly after birth. It is initially depressed or inverted, and later becomes elevated.

Thelarche, the onset of pubertal breast development, is hormonally mediated. It occurs when the hypothalamus releases gonadotropin-releasing hormone (GnRH), which stimulates the pituitary gland to produce follicle-stimulating hormone (FSH) and luteinizing hormone (LH) (see Chapter 599). FSH and LH then stimulate the ovaries to produce estradiol, which leads to breast development. Thelarche typically occurs between ages 8 and 13 years. Age at thelarche is affected by familial predisposition and varies by ethnicity.

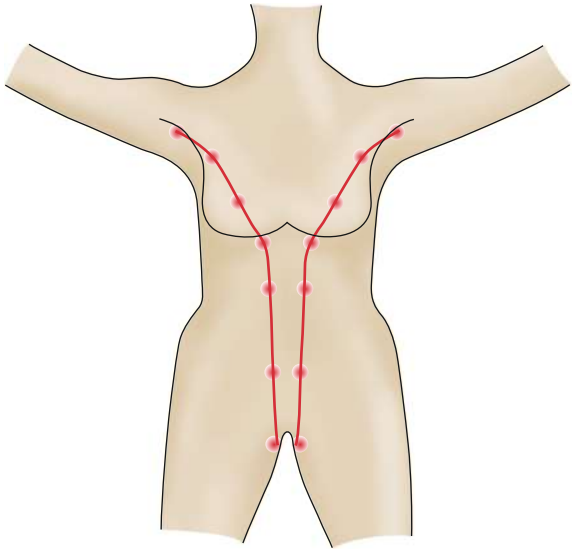

Fig. 588.1 Milk lines or mammary ridges. *(From Gao Y, Saksena MA, Brachtel EF, terMeulen DC, Rafferty EA. How to approach breast lesions in children and adolescents. Eur J Radiol. 2015;84:1350-1364; Fig. 1.)*

Breast development continues over a 2-4 year period after thelarche and is classified by the **Sexual Maturity Rating (SMR) system** (also known as **Tanner staging**) into five stages (see Chapter 150). Lack of breast development (**amastia**) by age 13 years is considered delayed and warrants evaluation. **Menarche** (onset of menses) usually occurs 2-3 years after thelarche.

BREAST EXAMINATION

Breast examination should be included in the routine healthcare maintenance examinations of all children and adolescents. Assessment of the newborn includes breast size, nipple position, presence of accessory nipples, and nipple discharge. Assessment of the prepubertal female includes inspection and palpation of the chest wall for masses, pain, nipple discharge, and signs of **premature thelarche.** Examination of the adolescent is performed with the patient in the supine position; the arm ipsilateral to the breast that is being examined should be placed next to the patient's head. The breast tissue is examined with the flat pads of the middle fingers, and the examiner should palpate all of the breast tissue in a uniform manner. The SMR should be noted and the axillary, supraclavicular, and infraclavicular nodes evaluated for lymphadenopathy. The areola should be gently compressed to assess for nipple discharge.

BREAST SELF-AWARENESS

Controversy exists as to the utility of breast self-examination in the adolescent population. Experts believe that it might be ill-advised to encourage breast self-examination in the adolescent because of a potential for unnecessary anxiety and possible unwarranted treatment in a population that is at low risk for malignant disease. The American College of Obstetricians and Gynecologists (ACOG) endorses breast self-awareness, which is defined as a female's awareness of the normal appearance and feel of their breasts. Breast self-awareness may increase an adolescent's understanding of their body, increase their comfort with exams, and provide opportunities for questions or discussion. Instruction in self-exam techniques should be considered for high-risk patients, such as those with a family history of conditions that may increase breast cancer risk or those at risk of secondary tumors. Adolescents should be educated to report any changes in their breasts or concerns to their healthcare providers.

Neonatal Breast Hypertrophy

Breast bud enlargement is a common condition in term newborns of either gender. It occurs as a result of elevated circulating maternal steroid hormones in late gestation. As maternal estrogen levels fall, prolactin levels can increase, and the breasts may produce a clear or cloudy (milk like) nipple discharge ("witch's milk") in male and female infants. Repeated manipulation of the breast can exacerbate the condition and should be discouraged.

ABNORMAL DEVELOPMENT

Premature Thelarche

Premature thelarche is defined as isolated unilateral or bilateral breast development in a female child under age 8 years without other signs of puberty; this is commonly seen in children under 3 years of age. Patient assessment includes a careful review of medications (including creams, ointments), home exposures to potential estrogens, review of growth charts, and x-ray for determination of bone age. Treatment consists of reassurance and follow-up to confirm that thelarche remains benign. Serial examinations, with particular emphasis on growth velocity, secondary sex characteristics such as pubic hair, pigmentation of the labia or areola, or vaginal bleeding, are imperative. Occasionally, patients with premature thelarche eventually develop true **central precocious puberty** (see Chapter 600.1). If puberty progresses, further workup should be performed to exclude central nervous system disorders or possible adrenal or gonadal neoplasm.

Amastia and Athelia

Complete absence of the breast, or **amastia,** is rare and is thought to occur from lack of formation of or obliteration of the mammary ridge. Amastia is usually unilateral and can be congenital or associated with systemic disorders (e.g., ectodermal dysplasia), endocrine disorders (e.g., congenital adrenal hyperplasia, gonadal dysgenesis, hypogonadotropic hypogonadism), or novel pathogenic gene variants. It can be associated with anomalies of the underlying mesoderm, such as the absence or hypoplasia of the pectoralis muscles seen in **Poland syndrome** (aplasia of the pectoralis muscles, rib deformities, webbed fingers, and radial nerve aplasia) (Fig. 588.2). Amastia or hypomastia can also be iatrogenic, resulting from injuries sustained during thoracotomy, chest tube placement, radiotherapy, severe burns, or incisional/excisional procedures on the breast bud. Surgical correction is individualized to the patient and the etiology. **Athelia**, the absence of a nipple either unilaterally or bilaterally, is rare and can be familial. It is also associated with exposure to endogenous androgens during pregnancy.

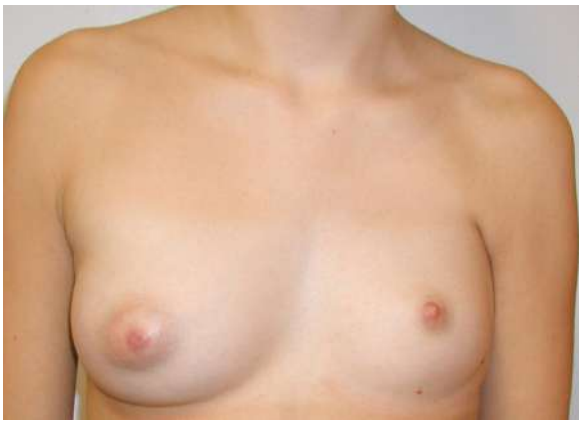

Fig. 588.2 Preoperative frontal view of a patient with left breast hypoplasia secondary to Poland syndrome. *(From Laberge LC, Bortoluzzi PA. Correction of breast asymmetry in teenagers. In: Hall-Findlay EJ, Evans GRD, eds. Aesthetic and Reconstructive Surgery of the Breast. London: Elsevier, 2010. Fig 39.14.)*

Fig. 588.3 Accessory nipple located inferior to the right breast. *(From Swartz MH. Textbook of Physical Diagnosis. Philadelphia: Elsevier, 2014; Fig 13-5.)*

Polymastia and Polythelia

Accessory breast tissue **(polymastia)** or accessory nipples **(polythelia)** occur in approximately 1–6% of the population (Fig. 588.3). The abnormally placed tissue can be seen anywhere along the mammary ridges ("milk lines") as a result of incomplete involution but is usually noted on the chest, axilla, or just inferior to the normally positioned breast. Polythelia has been reported in association with congenital malformations, particularly renal anomalies; it is therefore reasonable to perform a genitourinary ultrasound in an infant with supernumerary nipples. Surgical excision of the accessory breast or nipple is usually performed for pain (mastodynia), nipple discharge, or cosmesis.

Breast Hypoplasia and Asymmetry

Breast hypoplasia varies in degree from a near-total absence of breast tissue to well-formed breasts that are considered by the patient to be too small. Poor or absent breast development may simply be a delay in the development of normal secondary sex characteristics; the breasts develop slowly but are normal in all other respects. Family history may reveal other family members with a similar pattern. Other causes include ovarian dysfunction, hypothyroidism, eating disorders, chest wall irradiation, or surgery. Hypoplastic breast tissue can also be associated with a **tuberous breast** anomaly. Tuberous breasts are characterized by hypoplasia, a narrow breast base, and the appearance of herniation of the glandular tissue through enlarged areolae (Fig. 588.4).

More commonly, patients complain of *breast asymmetry*. Some degree of breast asymmetry is normal; it may be more pronounced during puberty while the breasts are developing. In asymmetry, the goals of evaluation are twofold. First, it is essential to exclude a neoplasm as the cause of the larger breast. Other etiologies may include a solitary large fibroadenoma, multiple fibroadenomas, or a parenchymal abscess. Alternatively, the possibility of tuberous breast development or Poland syndrome should be considered when evaluating the smaller side. Treatment depends on the underlying cause. Patients with mild asymmetry and no other associated pathology should be reassured. If a child has marked breast asymmetry, they may be initially offered cosmetic options, such as use of bra inserts or prostheses for the underdeveloped breast. Surgical correction may be pursued after breast development is complete. The American Society of Plastic Surgeons generally recommends that uncommon chest deformities or congenital breast asymmetry are the only cases in which a board-certified plastic surgeon should deem breast augmentation appropriate for a teenager. It is important that patients undergoing surgery have a realistic understanding of the potential results as well as the possible need for additional surgery. Saline-filled implants are the only type of implant approved by the U.S. Food and Drug Administration for females <22 years; saline-filled implants typically have a life span of about 10 years.

Macromastia

Adolescents may develop very large breasts **(macromastia)**, leading to both physical and psychologic symptoms. Common complaints include back pain, postural kyphosis, breast pain, intertrigo, limitation of physical activities, unwanted negative attention, diminished self-esteem, and eating disordered behaviors. Strong emotional support should be provided because macromastia can affect an adolescent's self-esteem at a vulnerable time in their psychologic development. The differential diagnosis for macromastia includes obesity, pregnancy, fibrocystic disease, end organ hormonal hypersensitivity, or lesions described in the previous paragraphs. Options for treatment of simple macromastia include surgical and nonsurgical interventions. Bras that provide maximal support can help correct symptoms. Alternatively, breast reduction mammoplasty may be desired. When adolescents are seeking breast surgery, ACOG first recommends education and reassurance regarding normal variations in anatomy, growth, and development for the patient and her family. Nonsurgical alternatives for comfort and appearance should be emphasized, and knowledge regarding indications and timing of surgical intervention and referral should be provided. Assessment of the adolescent's physical and emotional maturity level must be performed, as well as screening for **body dysmorphic disorder.**

Juvenile hypertrophy, or spontaneous massive growth of one or both breasts, is rare and should be distinguished from simple adolescent macromastia. This rapid growth of breast tissue may occur any time after thelarche but more commonly occurs abruptly over a several month period, after a preceding sustained period of normal breast development. Circulating estradiol levels are normal. Juvenile hypertrophy can cause extreme mastalgia, skin hyperemia or necrosis, and even damage to normal breast parenchyma due to compromised vascular supply. It can be unilateral or bilateral (Fig. 588.5). The etiology has not been elucidated; therefore treatment options include both pharmacologic and surgical interventions. The key to management is prompt recognition and intervention before the development of complications. Reduction mammoplasty is often the treatment of choice, with pharmacologic treatment (e.g., tamoxifen) or even mastectomy reserved for recurrence following surgery.

Infections

Mastitis is the most common infection of the breast and can occur any time from the neonatal period through adolescence and into adulthood. **Neonatal mastitis** is an infection that usually occurs in the first 2 months after delivery in term or near-term infants. Breast infections in adolescents occur most commonly with lactation. Adolescents can also develop **nonlactational mastitis** or a **breast abscess** as a result of irritation of the skin (e.g., acne lesions of the chest, shaving, or nipple stimulation), trauma, a foreign body (e.g., piercing), or ductal abnormality (such as ductal ectasia). *Staphylococcus aureus* is the cause of nearly all breast infections, but anaerobic bacilli *(Bacteroides)* may also be involved in the adolescent population. Methicillin-resistant *S. aureus* (MRSA) coverage should be considered in communities where the prevalence is high,

Fig. 588.5 Juvenile hypertrophy in a 12-year-old female. *(From Al-Saif AA, Al-Yahya GM, Al-Qattan MM. Juvenile mammary hypertrophy: is reduction mammaplasty always feasible? J Plast Reconstr Aesthet Surg. 2009;62:1470-1472; Fig. 1.)*

Fig. 588.4 Bilateral tuberous breast anomaly. *(Adapted from Pacifico MD, Kang NV. The tuberous breast revisited. J Plast Reconstr Aesthet Surg. 2007;60:455-464; Fig. 5.)*

especially for infants. Mastitis may be initially treated with warm compresses, analgesics, and oral antibiotics for 7-10 days. Antibiotic options include dicloxacillin, clindamycin, trimethoprim-sulfamethoxazole, or amoxicillin-clavulanic acid. If symptoms fail to resolve after a course of antibiotics, ultrasonography may reveal an abscess and can be used to guide needle aspiration. Incision and drainage should be reserved for failure of aspiration, and a periareolar incision is most cosmetic. Follow-up ultrasonography should be considered in adolescents to ensure that there is no remaining parenchymal lesion (e.g., cyst).

Trauma and Inflammation

Breast trauma is common in adolescent girls participating in contact sports. The trauma usually takes the form of contusion or **hematoma** and can resolve spontaneously or may be associated with late cystic changes in the breast, **fat necrosis** with calcium deposition over time, or fibrosis with retraction of the skin or the nipple over the injured area. When diagnosed with a hematoma, or when a palpable mass is present at the area of injury, serial follow-up by ultrasound is recommended until complete resolution. Persistent calcifications lasting more than 18 months after injury may require additional investigation by advanced imaging or biopsy.

Nipple Discharge

Nipple discharge must be carefully evaluated and characterized. Discharge may be milky and white **(galactorrhea)**, bloody, purulent, or serous (Table 588.1). A careful history and physical examination will help the practitioner determine the etiology. Examination of the discharge assists in diagnosis. Infection is usually associated with a purulent discharge; **ductal ectasia** (dilated subareolar ducts and periductal inflammation) may present with sticky, green or brown, or serosanguineous discharge. Discharge from the ducts of Montgomery (coming from the areola itself rather than through the nipple) may appear clear or brownish.

Galactorrhea is a specific type of nipple discharge that appears milky and is usually bilateral. Causes of galactorrhea are listed in Table 588.2. Cytologic evaluation of milky nipple discharge is not recommended. Laboratory evaluation should include a pregnancy test, prolactin, estradiol, and thyroid-stimulating hormone (TSH); these measures are obtained to rule out pregnancy, a pituitary prolactinoma, and/or the presence of a thyroid abnormality. If the prolactin level is elevated, visual field studies and a brain MRI might reveal the presence of a pituitary adenoma (see Chapter 598). Treatment is directed by results of the history, physical exam, and lab and imaging studies. Patients should be instructed to avoid nipple stimulation and stop any offending drugs, if appropriate to do so. Hypothyroidism should be treated and prolactin-releasing tumors managed with appropriate medical or surgical care. Medical treatment of galactorrhea consists primarily of dopamine agonists such as bromocriptine or cabergoline. Surgical intervention, usually transsphenoidal hypophysectomy, is rarely required.

Bloody discharge may be due to chronic nipple irritation (such as from **jogger's nipple**), ductal ectasia, phyllodes tumor, or intraductal papilloma (a rare, benign proliferative tumor). Unless the etiology of the bloody discharge is superficial (i.e., from obvious skin breakdown related to jogger's nipple), cytologic assessment of bloody discharge should be performed. Breast ultrasound may also be obtained to determine whether a mass or cyst is present.

Table 588.1 Common Causes of Nipple Discharge

DISCHARGE CHARACTERISTICS	POTENTIAL ETIOLOGY
Milky (galactorrhea)	Pregnancy or postpartum Medication use/drug use Herbal supplements Hypothyroidism Prolactinoma Chest wall trauma
Serous, serosanguineous	Ductal ectasia Intraductal papilloma
Sticky	Ductal ectasia Fibrocystic changes
Purulent	Mastitis Abscess
Bloody	Intraductal papilloma Phyllodes tumor Ductal ectasia Trauma ("jogger's nipple")
Episodic, clear to brown	Montgomery tubercles

Mastalgia

Mastalgia, or breast tenderness, is common in reproductive-age females. Mastalgia may be due to exercise, medications, early pregnancy, or benign breast changes **(fibrocystic changes)**. Physiologic swelling and tenderness can occur on a cyclic basis, most commonly during the premenstrual phase, and are secondary to hormonal stimulation and resulting proliferative changes. Hormonal imbalance can cause exaggerated responses in the breast tissue, especially in the upper and outer quadrants. Evaluation should include a pregnancy test and a breast examination. Nodularity,

poorly localized tenderness, and soreness radiating to the axilla and arm are usual accompanying findings. Treatments for mastalgia include utilization of a firm, supportive sports-type bra, heat, and analgesics (oral or topical). Low-dose combined estrogen/progestin oral contraceptives often improve the breast pain. A course of NSAIDs is also typically effective. The effect of caffeine and chocolate on mastalgia is controversial, but if pain is worsened with increased intake, they should be avoided. Evening primrose oil, vitamin E, and chamomile extract are popular but unproven treatments.

BREAST MASSES

Peripubertal Masses

Initial breast development at the onset of thelarche can be unilateral and asymmetric, with the developing breast bud being mistaken for a "mass." Such asynchronous thelarche should be recognized to avoid unnecessary biopsy and potential injury to the maturing breast. If there is any question as to the etiology of the lump, ultrasound can be used to evaluate for a mass.

Adolescent Breast Masses

The differential diagnosis for breast masses in the adolescent patient is broad (Table 588.3). The patient should be questioned about variations associated with the menstrual cycle, associated symptoms such as nipple discharge, recent trauma to the breast, family history of breast masses or cancer, and personal history of chest radiation or malignancy. Physical examination should characterize the mass location, size, and firmness and determine whether tenderness, skin changes, nipple discharge, or lymphadenopathy is present. Because breast cancer in the adolescent is extremely rare (3.2 cases per million person-years for women <25 years), masses in this population can often be expectantly managed for extended periods of time.

Fibroadenomas are the most common solid mass found in the adolescent breast. Fibroadenomas are slow-growing, hormonal dependent masses most often located in the upper, outer quadrant of the breast. The average size at diagnosis is 2-3 cm; 10–25% of patients have multiple lesions. On examination, these lesions are well circumscribed, rubbery, mobile, and not tender. Given the slow-growing nature and lack of malignant potential, conservative management is recommended for most patients. If expectant management is chosen, serial exams and/or ultrasounds every 6-12 months may be done to prove lack of progression or rapid growth. Fibroadenomas have defined sonographic characteristics; biopsy is not required to make the diagnosis. A subset of fibroadenomas behave differently and can be distinguished from their routine counterparts by rapidity of growth and excisional biopsy alone. **Juvenile fibroadenomas** (or **giant fibroadenomas**) grow rapidly over 3-6 months to >5 cm and can replace the breast tissue or cause skin necrosis. The distinction between these and **phyllodes tumor** on core needle biopsy is difficult, so excisional biopsy is the recommended intervention. The only true histologic difference between juvenile and routine fibroadenomas is hypercellularity. Surgical excision of fibroadenomas is recommended when a mass has complex ultrasonographic signs, is >5 cm or rapidly growing, or causes anxiety to the patient or their family. The presence of five or more fibroadenomas in an adolescent should prompt a genetic evaluation for *PTEN* pathogenic variant.

Breast cysts are common, often arising from ductal ectasia, glands of Montgomery, or lymphatic malformations. Ultrasound is used for diagnosis and surveillance. Simple cysts are usually self-limited. If a simple cyst persists, it may be aspirated with a needle. Aspirated fluid that is clear may be discarded. Bloody fluid and other aspirated material should be sent for cytologic examination. Cysts that resolve with aspiration should be reevaluated in 3 months by ultrasound. If they recur, biopsy or excision should be considered.

Table 588.3 Breast Masses in the Adolescent Female

Developmental	Unilateral thelarche Macromastia, simple Juvenile hypertrophy or gigantomastia Intramammary lymph node
Infectious	Mastitis Abscess
Traumatic	Fat necrosis Hematoma
Cystic	Fibrocystic change Vascular malformation (hemangioma, lymphatic malformation) Galactocele
Benign tumors	Fibroadenoma (simple or juvenile/giant) Lipoma Hamartoma Intraductal papilloma Juvenile papillomatosis
Malignant tumors	Cystosarcoma phyllodes Breast carcinoma (secretory or ductal) Metastatic disease (lymphoma, neuroblastoma, sarcoma, rhabdomyosarcoma, acute leukemia)

Malignant Masses

Phyllodes tumors are classified as sarcomas and are the most common nonepithelial tumor of the breast. They are classified as benign, borderline, or malignant based on histopathology and are characterized by asymmetric breast enlargement in association with a firm, mobile, circumscribed mass. The tumor often grows rapidly and can become quite large, mimicking a giant or juvenile fibroadenoma. The majority of these tumors have a favorable prognosis, but malignant phyllodes can recur locally or with metastases. Excision with 1 cm margins is the preferred initial therapy in adolescent patients, regardless of the histologic classification of the lesion. Survival at 10 years approaches 90% after complete excision.

Juvenile papillomatosis is a rare proliferative tumor that often presents as a discrete mass. It is a marker for increased breast cancer risk in family members, and in patients with this condition, up to 15% may have a juvenile secretory carcinoma. Treatment of juvenile papillomatosis is total resection of the lesion with preservation of the breast. Family members of these patients should be screened.

Primary breast carcinoma is extremely rare in adolescents. Surveillance Epidemiology and End Results (SEER) data from 2015–2019 established an age-specific rate for female invasive breast cancer of 0.1/100,000 for ages <20 years. Although malignancy is rare, suspicion may be raised if a lesion is enlarging, hard, immobile, and poorly circumscribed. Biopsy of lesions with suspicious imaging findings (e.g., irregular shape or microlobulated/spiculated margins) or progressive growth is imperative. Contrary to adults with primary ductal carcinoma, 10-year survival is only slightly better than 50% in adolescents.

Rather than primary breast cancer, **secondary** cancers or **metastatic** tumors are more prevalent. Adolescents with previous *therapeutic radiation* to the chest or with malignancies with the potential to metastasize to the breast should be monitored more closely for breast masses. Rhabdomyosarcoma is the most common to metastasize to the breast. Other malignancies with risk of breast metastases include neuroblastoma, melanoma, renal cell carcinoma, and Ewing sarcoma. Breast tumors also may be the first manifestation of relapse (extramedullary) in acute lymphoblastic leukemia. Those with previous radiation therapy have increased risk of developing breast cancer at a young age and require careful ongoing surveillance.

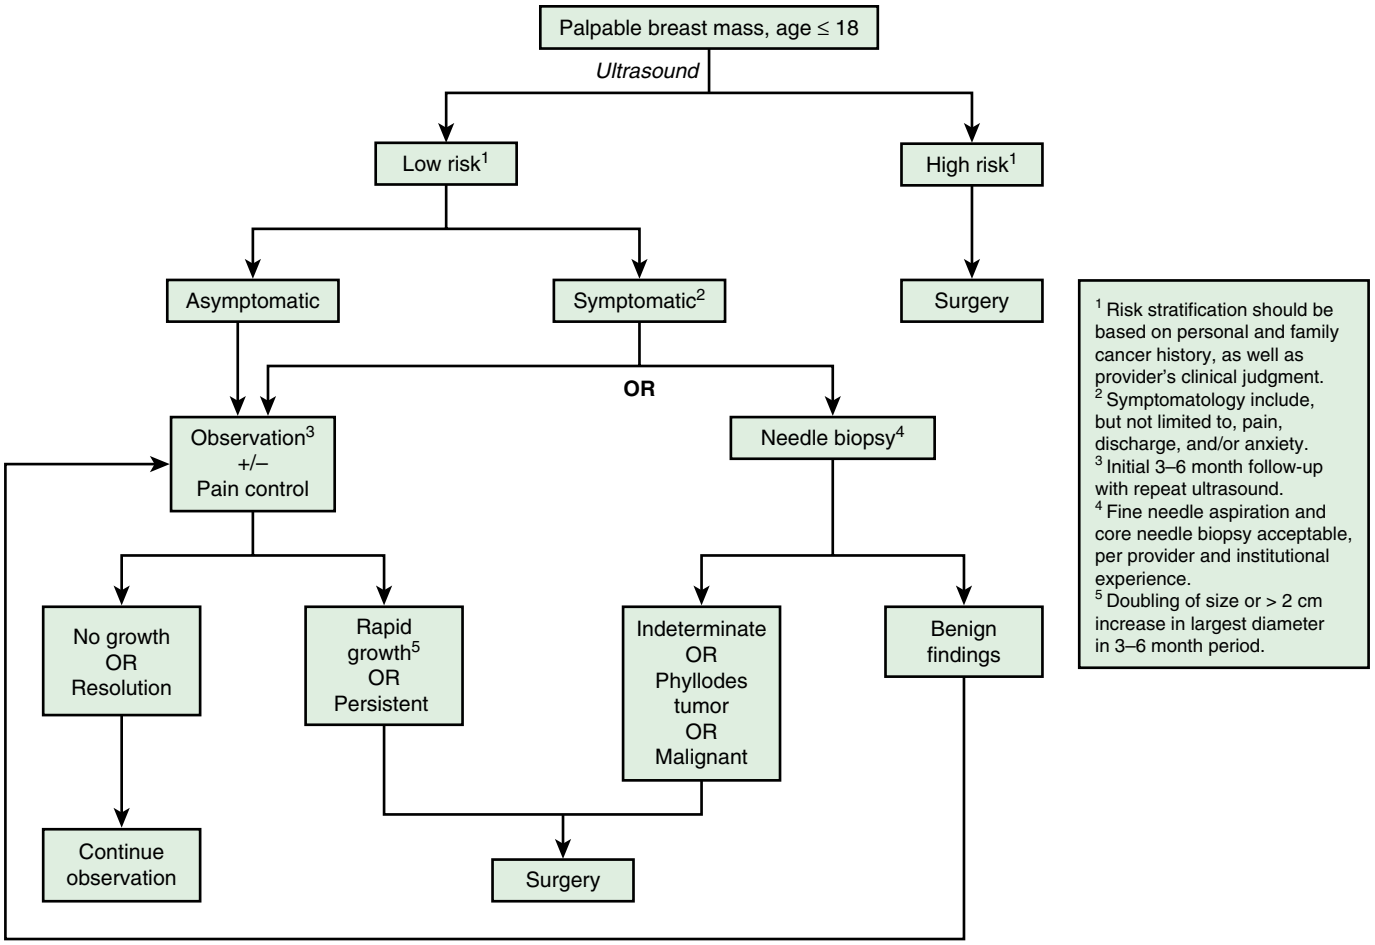

Fig. 588.6 Suggested clinical care algorithm for children presenting with a palpable breast mass. *(From McLaughlin CM, Gonzalez-Hernandez J, Bennett M, Piper HG. Pediatric breast masses: An argument for observation. J Surg Res. 2018;228:247-252; Fig 3.)*

Imaging of Breast Masses

Ultrasonography is the imaging modality of choice for palpable abnormalities in the pediatric and adolescent breast, given the diagnostic specificity and lack of ionizing radiation. MRI may be useful in select disease processes, but its use should be guided by a surgeon or oncologist. Because of the dense breast tissue in this patient population, there is no role for mammography.

MANAGEMENT OF BREAST MASSES

Figure 588.6 represents management algorithms for pediatric patients undergoing imaging for an identified breast mass. Core needle biopsy as a diagnostic tool is very sensitive but lacks specificity in distinguishing the hypercellular stroma of a juvenile fibroadenoma from a phyllodes tumor. Core needle biopsy should be recommended only for indeterminate masses, and based on co-decision-making between the patient, family, and clinician. Generally, observation and ultrasound surveillance should be the initial management for masses under 4 cm in size and excisional biopsy considered for those >4-5 cm.

Recommendations for Daughters of Women with Breast Cancer

Risk Reduction

There are a limited number of things that young people can do to lower their risk of breast cancer. The American Cancer Society recommends regular physical activity, limiting alcohol, eliminating cigarette smoking, and maintaining a healthy weight. Some studies have shown that breastfeeding for at least 1 year may slightly lower the breast cancer risk.

Screening Procedures

Screening mammography and/or ultrasound are not currently recommended in adolescents, regardless of family history. Routine testing of children and adolescents for the *BRCA1* and *BRCA2* pathogenic variants in families with a known history is also not typically recommended, because there are no guidelines for additional screening or treatment at this age, and *children* are very unlikely to develop a cancer related to an inherited *BRCA* variant.

Even in high-risk families, development of breast cancer below the age of 18 years is extremely rare. The American Cancer Society recommends a breast-screening regimen including mammography and MRI beginning at age 30 years for females with a known *BRCA* pathogenic variant or history of chest radiation between the ages of 10 and 30 years. Patients with an identified familial predisposition for malignancy should be referred for genetic evaluation to determine whether and/or when screening tests should occur. Any adolescent patient with a known primary breast malignancy should also be referred to a geneticist to be screened for pathogenic variants such as Li-Fraumeni (p53) or Cowden syndrome (*PTEN*).

Chapter 589

Polycystic Ovary Syndrome and Hirsutism

Heather G. Huddleston, Molly M. Quinn, and Mark Gibson

POLYCYSTIC OVARY SYNDROME

Etiology and Definition

Polycystic ovary syndrome (PCOS) is a common disorder of reproductive hormone function. The most widely accepted approach to the diagnosis of PCOS in adult females is the Rotterdam criteria, which require two out of three of the following features: **oligomenorrhea**, clinical or biochemical **hyperandrogenism**, and ovaries with a **polycystic morphology** on ultrasound examination (≥20 follicles in one ovary and/or ovarian volume >10 mm^3). Increased levels of antimüllarian hormone may be a marker of ovarian dysfunction and antral follicle count. Alternative criteria, such as the Androgen Excess Society and National Institutes of Health, place a greater emphasis on requiring hyperandrogenism be present (Table 589.1). The disorder, affecting 5–10% of females of reproductive age, depending on the diagnostic criteria used, typically emerges in adolescence when a normal menstrual pattern is not established and there is clinical evidence of androgen excess. Although not part of the *diagnostic* schemes, PCOS is often accompanied by cardiovascular disease risk factors, including insulin resistance, obesity, and dyslipidemia. Depression and anxiety have also been found to be more prevalent in females with PCOS.

Pathology, Pathogenesis, and Genetics

PCOS has a high concordance rate in twins, and in some studies either epigenetic or dominant inheritance patterns are observed. Nonetheless, a consistent hereditary pattern has not been identified.

Gonadotropic dysregulation with increased luteinizing hormone (LH) pulsatility and abnormally high ratios of circulating LH to follicle-stimulating hormone (FSH) are found in many patients with PCOS. Increased *ovarian* production of androgen in response to LH and impaired folliculogenesis owing to lower FSH are attributed to this gonadotropic pattern (Fig. 589.1). An increased ratio of circulating levels of LH:FSH is *not* a diagnostic criterion for PCOS.

Alterations in activities of steroidogenic enzymes that would explain *ovarian androgenic* hyperfunction are seen in PCOS subjects, but they are not consistently present in all patients, and it is unclear whether these alterations are a cause of PCOS or are a consequence of ovarian dysregulation. The size of ovarian stromal cells responsible for androgen production is increased; surgery that reduces this ovarian component (ovarian wedge resection or laparoscopic ablative procedures) reduces circulating androgen levels and often restores ovarian cyclicity. Patients with hyperandrogenic congenital or adult-onset adrenal hyperplasia exhibit PCOS-like ovarian dysfunction that can be reversed by reducing the *adrenal-derived* androgens with glucocorticoid therapy. A primary role for androgen excess in the pathophysiology of all instances of PCOS seems unlikely; many patients have minimal hyperandrogenism, and elimination of androgen excess (with gonadotropin-releasing hormone agonists) does not affect associated insulin resistance.

Measures of **insulin resistance** are greater and more prevalent among females with PCOS than controls even when accounting for body mass index (BMI). Insulin enhances ovarian androgen production directly and contributes to elevation of free testosterone levels through its suppression of hepatic production of sex steroid–binding globulin. Treatment with insulin sensitivity–enhancing agents that can reduce insulin levels is associated with modest reductions in measures of androgen excess and, in some patients, restoration of regular ovulation. The association of insulin resistance with weight might explain the appearance of features of PCOS among some females who gain weight, as well as the resolution of PCOS among affected females who lose weight.

Clinical Manifestations

PCOS, a lifelong disorder, commonly manifests as puberty progresses, but its onset can occur later, in young adulthood. Clinical hallmarks are menstrual abnormalities and manifestations of hyperandrogenism, but the severity of the disorder is variable (Table 589.2). Ovulation is typically irregular or absent, and menses are consequently irregular or absent. When menstrual bleeding does occur, it may be *anovulatory* bleeding, which is often heavy and/or protracted, resulting from an extended period of unopposed endometrial growth. Alternatively, bleeding can be relatively normal in character as a consequence of a preceding ovulation. Protracted spells of anovulation, with accompanying unopposed estrogen, are a risk factor for endometrial hyperplasia, and more severe premalignant and frankly malignant changes may eventuate. Hyperandrogenism is most commonly manifest as **hirsutism**, which is graded by the extent and locations of excessive male pattern hair growth (Fig. 589.2).

Obesity is common among individuals with PCOS. In some patients, the expression of features of PCOS is conditional on elevation of BMI and is reversible with weight loss. However, there is a subset of patients who present with a lean PCOS phenotype, and thus normal or low weight should not preclude consideration of the PCOS diagnosis. PCOS is associated with an increased prevalence of insulin resistance and type 2 diabetes independent of the tendency for many affected patients to have an elevated BMI. Additionally, PCOS confers a substantial and specific increase in risk for **metabolic syndrome** (hyperlipidemia, insulin resistance, type 2 diabetes) in adults as well as adolescent females after accounting for BMI.

Laboratory Findings, Diagnosis, and Differential Diagnosis

The diagnosis of PCOS requires exclusion of disorders that would otherwise account for hyperandrogenism and anovulation. Serum 17-hydroxyprogesterone should be measured when there is clear androgen excess to screen for adult-onset 21-hydroxylase deficiency (see Chapter 616). In the adolescent with amenorrhea but minimal hyperandrogenic findings, consideration should be given to functional hypothalamic suppression as a result of excessive exercise and/or dieting, and a careful history taken to rule out such behavioral patterns. All patients should be clinically evaluated for Cushing syndrome, and biochemical evaluation is indicated when clinical findings, including

Table 589.1 Diagnostic Criteria for Polycystic Ovary Syndrome in Adult Females*

NATIONAL INSTITUTES OF HEALTH CRITERIA	ROTTERDAM CRITERIA**	ANDROGEN EXCESS SOCIETY
Oligoovulation or anovulation *and* Clinical or biochemical hyperandrogenism	Two of three of the following: • Oligoovulation or anovulation • Polycystic ovaries on ultrasonography (20 or more follicles in a single ovary or ovarian volume of > 10 mm^3 in one ovary) • Clinical and/or biochemical hyperandrogenism	Clinical or biochemical hyperandrogenism and at least one of the following: • Polycystic ovaries *or* • Oligoovulation or anovulation

**In adolescents, diagnosis should be made when both hyperandrogenism and oligomenorrhea are present, with ultrasound criteria not required/recommended.

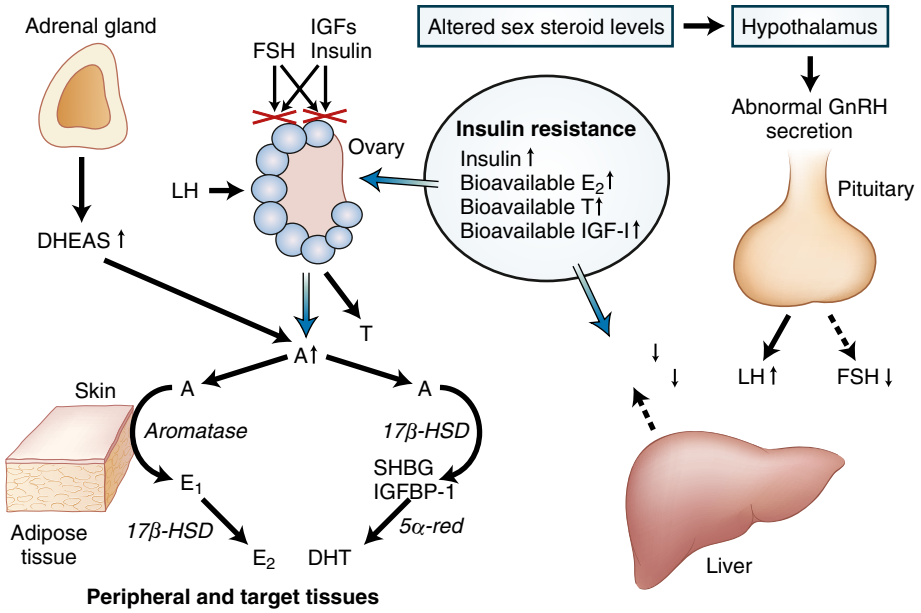

Fig. 589.1 Pathologic mechanisms in polycystic ovary syndrome (PCOS). A deficient in vivo response of the ovarian follicle to physiologic quantities of follicle-stimulating hormone (FSH), possibly because of an impaired interaction between signaling pathways associated with FSH and insulin-like growth factors (IGFs) or insulin, may be an important defect responsible for anovulation in PCOS. Insulin resistance associated with increased circulating and tissue levels of insulin and bioavailable estradiol (E_2), testosterone (T), and IGF-I gives rise to abnormal hormone production in a number of tissues. Oversecretion of luteinizing hormone (LH) and decreased output of FSH by the pituitary, decreased production of sex hormone–binding globulin (SHBG) and IGF-binding protein 1 (IGFBP-1) in the liver, increased adrenal secretion of dehydroepiandrosterone sulfate (DHEAS), and increased ovarian secretion of androstenedione (A) all contribute to the feed-forward cycle that maintains anovulation and androgen excess in PCOS. Excessive amounts of E_2 and T arise primarily from the conversion of A in peripheral and target tissues. T is converted to the potent steroids estradiol or DHT (dihydrotestosterone). Reductive 17β-hydroxysteroid dehydrogenase (17β-HSD) enzyme activity may be conferred by protein products of several genes with overlapping functions; 5α-reductase (5α-red) is encoded by at least two genes, and aromatase is encoded by a single gene. GnRH, Gonadotropin-releasing hormone. *(From Bulun SE. Physiology and pathology of the female reproductive axis. In Melmed S, Auchus RJ, Goldfine AB, eds. Williams Textbook of Endocrinology, 14th ed. Philadelphia: Elsevier, 2020. Fig 17-30.)*

hypertension and/or characteristic exam features, are suggestive (see Chapter 619). The two disorders have in common a tendency for overweight and varying degrees of insulin resistance and androgen excess, but they differ in that Cushing syndrome demonstrates muscle wasting as a result of catabolism.

Evidence for androgen excess that is *rapid in onset and/or severe,* especially if masculinizing, warrants measurement of androgens (total testosterone, dehydroepiandrosterone [DHEAS]) to exclude the possibility of an androgen-secreting adrenal or ovarian tumor. The laboratory evaluation is completed with the exclusion of hyperprolactinemia, premature ovarian failure, and thyroid disease as causes of anovulation by measurement of prolactin, FSH, and thyroid-stimulating hormone, respectively.

The diagnosis of PCOS in reproductively mature females (at 8 years post menarche) is confirmed by the constellation of oligoovulation or anovulation, androgen excess (clinically or with biochemical confirmation), and typical ovarian morphology on ultrasound. Various experts weigh these three features differently and do not, as a rule, require the presence of all (see Table 589.1). Antimüllarian hormone levels are elevated in PCOS and may be a marker for ovarian dysfunction and cyst formation. Other recommendations have clarified that ultrasound features need not be assessed in adolescents, because normative values for ovarian anatomy have not been established. Indeed, young females often exhibit the multifollicular ovaries without any evidence of hyperandrogenism or oligomenorrhea, and not all patients with PCOS by the criteria of hyperandrogenism and ovulatory disruption exhibit ovarian changes typical of PCOS. *Therefore in the adolescent, diagnosis should only be made when both oligomenorrhea and hyperandrogenism are present and other causes of these symptoms have been ruled out.* Findings of anovulatory cycles and hyperandrogenism, particularly acne, may accompany the normal pubertal transition.

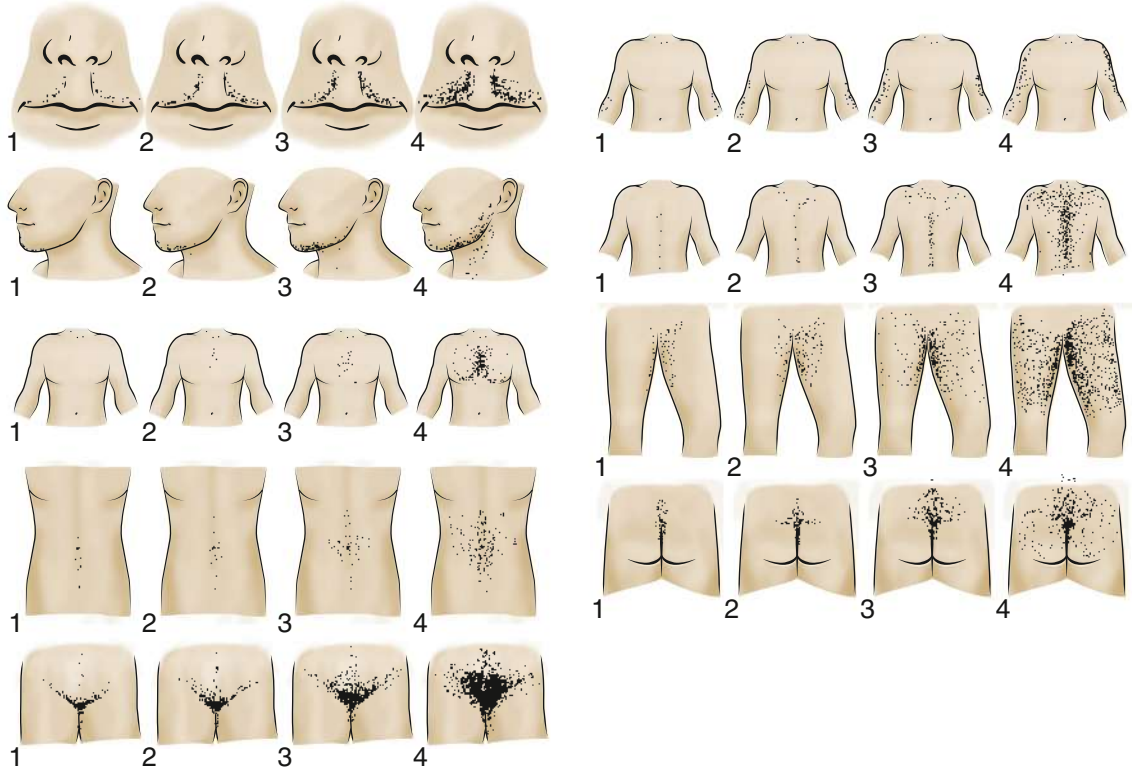

Fig. 589.2 Gender-neutral modified Ferriman-Gallwey (mFG) diagram. *(From Grimstad F, Moyer Q, Williams CR, Kremen J. A body-neutral and gender-neutral modified Ferriman-Gallwey diagram. J Pediatr Adolesc Gynecol. 2021;S1083-318800334-X. Fig 2.)*

For this reason, it is recommended that a formal PCOS diagnosis not be considered until at least 2 years post menarche. Adolescents with features of PCOS before this time can be considered "at risk" for PCOS, and a plan can be made for reevaluation in the future.

Insulin resistance is common among females with PCOS, and although not requisite for diagnosis, it should be considered when PCOS is identified. Adults, as well as adolescents, with hyperandrogenemia and anovulation should be evaluated for diabetes or impaired glucose tolerance with a 2-hour (75-g glucose load) glucose tolerance test.

Complications and Long-Term Outlook

Management of the features of hyperandrogenism, assistance with fertility, prevention of endometrial cancer, and reduction in the likelihood and severity of the common accompanying risk for the metabolic syndromes are long-term tasks for the PCOS patient and their healthcare providers (Table 589.3). Although there is a tendency for symptoms to ameliorate as menopause approaches, PCOS usually requires management throughout the reproductive years. Young patients should be counseled that modern fertility management allows most affected females to have children without great difficulty, and they should also know that the disorder does not confer reliable protection from unintended pregnancy. Endometrial cancer can develop as early as the third decade in females with PCOS who are not managed with progestins or ovulation induction; thus patients should understand the importance of long-term strategies for endometrial protection. Impaired glucose tolerance, type 2 diabetes, and metabolic syndrome are more common in females with PCOS compared to weight-matched controls. Metabolic disturbance can manifest as early as adolescence, and the prevalence increases over time. Weight control through diet and lifestyle measures, detection and management of impaired glucose tolerance and diabetes, and management of abnormal lipids are targets for long-term management.

Treatment

The management of PCOS is multifaceted and depends on the specific complaints of the patient. Primary goals include management of menstrual abnormalities, treatment of symptoms of androgen excess, and optimization of metabolic health. Weight loss through lifestyle

change, use of hormonal contraceptive agents for menstrual regulation as well as androgen suppression, antiandrogens as adjuncts for hirsutism treatment, and insulin-sensitizing agents are common components of treatment.

Lifestyle Changes

Comprehensive lifestyle programs for overweight and obese adults with PCOS aimed at fitness and weight loss can yield restoration of normal menstrual function in some patients. Lifestyle changes also lead to a reduction in the free androgen index, reduction in measures of insulin resistance, and improvement in serum lipids. Limited data show similar benefits from such interventions for obese adolescents with PCOS. Successful weight loss programs for adolescents with PCOS using both psychologic and nutritional counseling may result in improved menstrual function.

Hormonal Contraceptives

Combined (estrogen and progestin) hormonal contraceptive medications are considered first-line therapy for patients not desiring fertility (see Chapter 160). Avoidance of hyperplastic endometrial states resulting from unopposed estrogen and management of abnormal uterine bleeding in anovulatory episodes can be accomplished with the use of combined hormonal contraceptives. The progestational component inhibits endometrial proliferation, and the schedule of pill administration predictably regulates menstrual bleeding. The estrogenic component of the combined oral contraceptive elevates circulating sex hormone–binding globulin (SHBG), which reduces free and bioavailable testosterone levels. Both of the hormonal elements in oral contraceptives combine to suppress gonadotropic (particularly LH) stimulation of ovarian androgen production. DHEAS levels, often contributory to hyperandrogenemia in PCOS, are usually decreased by combined contraceptive use. Products with less androgenic progestational components (drospirenone, desogestrel) may provide better relief from androgenic symptoms.

Using hormonal contraception that is well tolerated in long-term use is more important than using a product with a particular progestational component. Products with reduced frequency and duration of pill-free intervals can provide superior androgen suppression and a welcome decrease in the frequency of bleeding episodes. Depot medroxyprogesterone acetate for contraception, endometrial protection, and androgen suppression may be a suitable alternative to combined hormonal contraceptives; it provides even more profound suppression of ovarian androgen production, but it does not elevate SHBG. Low-dose progestin-only regimens (oral minipills, implantable progestational contraceptives, and progestin-releasing intrauterine devices) also provide effective endometrial protection but would be expected to provide only partial and/or inconsistent androgen suppression and would not elevate SHBG.

Patients without the need for management of hyperandrogenic symptoms or contraception are often treated with periodic use of oral progestins to induce predictable menstrual bleeding and prevent endometrial hyperplasia and malignancy. Twelve-day courses of medroxyprogesterone acetate 10 mg daily or norethindrone acetate 5 mg daily are effective and safe for this purpose when taken every 1-2 months.

Oral contraceptives also provide the added benefit of contraception. Given the relative infrequency of ovulation, fertility in females with PCOS would be expected to be reduced relative to that of their peers, but they are still at risk for pregnancy and should be counseled accordingly.

Metformin

Metformin is a biguanide medication used to treat type 2 diabetes, which is its only FDA-approved indication. It has been used in a variety of settings and with differing objectives for patients with PCOS. Metformin exerts its principal effect by reducing hepatic production of glucose and limiting intestinal absorption of glucose. A subset of females with PCOS resume regular ovulation and menses when treated with metformin, obviating the need for progestational therapy to protect endometrial health or medications to induce ovulation. For some patients, the resulting normal reproductive function is appealing regardless of interest in fertility.

Metformin reduces insulin resistance and the levels of androgens. Its extended use can reduce the likelihood of development of impaired glucose tolerance or the progression of impaired glucose tolerance to type 2 diabetes; these effects are not yet proven for patients with PCOS. It should not be used in the presence of renal or hepatic impairment. Typical dosing is 1,500-2,000 mg/day, achieved through gradual increments because gastrointestinal intolerance is common. Long-acting preparations are helpful when gastrointestinal intolerance is a problem. The use of metformin in the treatment of PCOS depends on the patient's goals and preference. For the treatment of hyperandrogenic symptoms, metformin effects may be modest compared with other available agents. There are no empirical data supporting the theoretical benefits of long-term use of metformin in adolescents with PCOS and obesity compared with the outcomes achieved with weight loss and oral contraceptive medications. Use of metformin as a first-line agent is favored by some experts, in part for improvement in serum measures of intermediate outcomes, and in part because of evidence in other populations of reduced progression of insulin resistance. There is no evidence for a long-term benefit for clinical outcomes of adding metformin to treatment for patients managed primarily with oral contraceptives. For adolescents receiving metformin as a first-line medication, some element of progestational management (combined contraceptives or periodic progestins) will still be necessary for those not resuming ovulatory function, and oral contraceptives may still be an important adjunct for management of clinical hyperandrogenism and/or contraception. Metformin side effects include nausea, emesis, and diarrhea; more serious effects include lactic acidosis and vitamin B12 deficiency. Glucagon-like peptide receptor agonists are being studied as a possible add on therapy to metformin or as a single agent to treat PCOS.

Antiandrogens

Antiandrogenic medications may be added to other therapies or used alone for the treatment of hirsutism. These agents are usually used adjunctively with ovarian hormonal suppression, in part because of better reduction in hirsutism when antiandrogens are combined with ovarian suppression but also to reduce the risk of unintended embryonic or fetal exposure. The highly active androgen antagonist and progestin, cyproterone, is available in Europe and in Canada as a single agent for treatment of hirsutism or in combination with ethinyl estradiol as an oral contraceptive with enhanced antiandrogenic profile. In the United States, spironolactone is the most commonly used antiandrogen. Spironolactone antagonizes androgens at their receptor and also impairs androgen synthesis. Doses of 100-200 mg daily are commonly used. Other agents that have been studied are finasteride, a 5α-reductase inhibitor, and flutamide, a nonsteroidal and highly specific androgen receptor antagonist. These are rarely used because of lack of evidence of superior effectiveness, cost, and, in the case of flutamide, the potential for hepatotoxicity.

HIRSUTISM

Hirsutism is defined as abnormally increased terminal (mature, heavy, dark) hair growth in areas of the body where hair growth is normally androgen dependent (see Chapter 703). Its presence is a result of the combination of the extent of androgenic stimulation and familial regional follicle sensitivity to androgens, which varies considerably among ethnic groups. Patients' cosmetic concerns generally determine whether findings of hirsutism are a matter for clinical investigation and treatment. Hirsutism as an isolated finding is to be distinguished from **masculinization.** The latter includes alteration in muscle mass, clitoral enlargement, and voice change, generally manifesting as a rapid

evolution (over months). *Masculinization mandates a search for a neoplastic source of androgen.* Elevations of testosterone or DHEAS commonly indicate an ovarian or adrenal androgen source, respectively; specific imaging and occasionally selective catheterization studies are indicated (see Chapters 590 and 617).

Hirsutism without masculinization is common. The potential causes to consider are PCOS (when there is hyperandrogenism and anovulation), benign functional androgen excess (measurable hyperandrogenism without anovulation), idiopathic hirsutism (increased hair in androgen-dependent areas without measurable androgen excess), and adult-onset adrenal hyperplasia. Patients can be primarily distinguished by evidence of an ovulatory disorder by menstrual history, and for those with absent or irregular menses, a diagnosis of PCOS can be made. The remainder, for whom adult-onset adrenal hyperplasia and PCOS have been excluded, either have normal androgen levels with enhanced end-organ sensitivity owing to familial or ethnic predisposition or have a functional and benign overproduction of ovarian androgens. Measures of androgens (testosterone, DHEAS) may be normal or mildly elevated in the latter group. Testosterone suppresses circulating sex-steroid binding globulin, so states of testosterone overproduction might not be accompanied by elevated measures of total testosterone, although estimates of "free" or "bioavailable" testosterone reveal hyperandrogenism. Measures of unbound testosterone distinguish idiopathic hirsutism from mild benign hyperandrogenic states; making this distinction contributes little to patient management and adds cost. Idiopathic hirsutism (without evidence of androgen excess) usually responds to antiandrogen or androgen suppression therapy similarly to hirsutism associated with elevated androgens and anovulation (PCOS) and benign hyperandrogenism not associated with PCOS.

If hirsutism is present, and clinical evaluation excludes neoplasm, adult-onset adrenal hyperplasia, and Cushing syndrome, then management for symptoms of hyperandrogenism (regardless of whether measures of circulating androgens are elevated or not) can proceed as for patients with PCOS (Table 589.4). Estrogen and progestin suppression of ovarian function, with or without added antiandrogen treatment, is the mainstay of therapy for these patients. Androgen suppression and/or antagonism results in gradual regression of the size and productivity of follicles in androgen-sensitive areas of the face and body, and these changes will evolve over successive and months-long generations of hair growth and shedding. Patients should therefore be advised that the effects of medical therapy accrue slowly, over many months.

Chapter 590

Gynecologic Neoplasms and Prevention Methods for Human Papillomavirus Infections in Adolescents

Joan R. Tymon-Rosario, Levent Mutlu, and Alla Vash-Margita

OVERVIEW OF GYNECOLOGIC MALIGNANCIES IN CHILDREN AND ADOLESCENTS

Cancer is the second most common cause of death in children and adolescents, surpassed only by childhood injuries. The highest death rate is in the 5- to 14-year-old age group. Although rare, gynecologic malignancies can result in long-term sequelae such as infertility, depression, and a poor self-image, which may cause significant morbidity.

In children and adolescents younger than 18 years, ovarian cancer accounts for 87.5% of gynecologic malignancies, vaginal cancer for 4.5%, cervical cancer for 3.9%, uterine cancer for 2.5%, and vulvar cancer comprises 1.6% of all gynecologic cancers.

Ovarian cancers usually manifest as an abdominal or pelvic mass with acute or chronic lower abdominal pain and/or menstrual irregularities. The diagnostic workup includes a physical exam and laboratory tests such as a urine pregnancy test, hormone levels, and tumor markers. The preferred initial method of imaging is transabdominal pelvic ultrasonography. The differential diagnosis includes gynecologic tumors, other abdominal and pelvic organ-based tumors, and functional, physiologic, inflammatory/infectious, or pregnancy-related ovarian pathology. Although the majority of ovarian neoplasms are benign, approximately 9–33% of all pediatric or adolescent ovarian neoplasms are malignant. Ovarian neoplasms constitute 1.3% of all childhood malignancies but account for 60–70% of all gynecologic malignancies in this age group. Germ cell tumors are the most common type of neoplasm. Less often, the vagina or cervix is a site of malignant lesions in children, with a few specific tumors having their greatest incidence in this population. Vulvar and endometrial malignancies in children and adolescents are exceedingly rare.

IMPACT OF CANCER THERAPY ON FERTILITY

The treatment of gynecologic cancer, depending on the type and extent of disease, may include fertility-sparing cytoreductive surgery with adjuvant chemotherapy, definitive surgery including bilateral salpingo-oophorectomy, and comprehensive surgical staging, radiation, and/or secondary salvage surgery. Fertility-sparing surgery is defined as unilateral salpingo-oophorectomy, lymph node sampling, and omentectomy, whereas maximal cytoreduction includes hysterectomy and contralateral salpingo-oophorectomy. For malignant ovarian germ cell tumors, the most common adolescent gynecologic malignancy, the use of fertility-sparing surgery, is seen as the gold standard. This approach achieves a good prognosis, and the majority of patients achieve normal hormonal function and future pregnancies. Importantly, it does not seem to be associated with lower progression-free survival, overall survival, or mortality rates compared with radical surgery.

Platinum-based chemotherapeutic regimens are most often used for malignant ovarian tumors. The need for chemotherapy and radiation therapy is associated with acute ovarian failure, premature menopause, and infertility (Table 590.1). Risk factors include older age, abdominal or spinal radiation, and certain chemotherapeutic drugs, such as

Table 590.1 Effect of Cancer Treatment on the Development of Amenorrhea

TREATMENT	AGENT/MODALITY	IMPACT	TREATMENT FOR
Protocols containing nonalkylating agents or lower levels of alkylating agents	ABVD, CHOP, COP, multiagent therapies for leukemia	LOWER RISK <20% of women develop amenorrhea posttreatment	Non-Hodgkin lymphoma Leukemia
Protocols containing	Multiagent therapies using vincristine	VERY LOW/NO RISK No effect on menses	Leukemia Lymphomas
Protocols containing	Procarbazine MOPP and BEACOPP 3 cycles >6 cycles	HIGH RISK More than 80% develop amenorrhea posttreatment	Hodgkin lymphoma
Protocols containing	Temozolomide or BCNU + cranial radiation	HIGH RISK More than 80% develop amenorrhea posttreatment	Brain tumor
Abdominal or pelvic radiation	10-15 Gy in prepubertal females 5-10 Gy in postpubertal females	INTERMEDIATE RISK 30–70% of women develop amenorrhea posttreatment	Acute lymphoblastic leukemia Brain tumor Neuroblastoma Non-Hodgkin lymphoma Hodgkin lymphoma Spinal tumor Wilms tumor
Whole abdominal or pelvic radiation	>15 Gy in prepubertal females >10 Gy in postpubertal females >6 Gy in adult women	HIGH RISK More than 80% develop amenorrhea posttreatment	
Total cyclophosphamide	5 g/m^2 in women >30 yr 7.5 g/m^2 in women and females <20 yr	HIGH RISK More than 80% develop amenorrhea posttreatment	Non-Hodgkin lymphoma
Any alkylating agent + pelvic radiation	Busulfan, carmustine, cyclophosphamide, ifosfamide, lomustine, melphalan, procarbazine	HIGH RISK More than 80% develop amenorrhea posttreatment	Ovarian cancer Sarcoma
Any alkylating agent + total body irradiation	Busulfan, carmustine, cyclophosphamide, ifosfamide, lomustine, melphalan, procarbazine	HIGH RISK More than 80% develop amenorrhea posttreatment	Lymphomas Myelomas Choriocarcinoma Ewing sarcoma, neuroblastoma
Any cancer requiring bone marrow transplant/stem cell transplant		HIGH RISK More than 80% develop amenorrhea posttreatment	Hodgkin lymphoma Non-Hodgkin lymphoma Acute myeloid leukemia Chronic myeloid leukemia Myeloma Acute lymphoid lymphoma Chronic lymphoid lymphoma Some solid tumors (e.g., breast, ovarian, kidney, brain)

alkylating and platinum-based agents (cisplatin, cyclophosphamide, busulfan). Uterine irradiation is associated with infertility, spontaneous pregnancy loss, and intrauterine growth restriction. The vagina, bladder, ureters, urethra, and rectum can also be injured by radiation. Vaginal shortening, vaginal stenosis, urinary tract fistulas, and diarrhea are potential side effects of pelvic irradiation.

Advancements in oncologic treatments of gynecologic and systemic tumors have led to improvements in childhood cancer survival rates. Unfortunately, with these advances come an increase in short- and long-term adverse effects, which include gonadotoxicity and infertility. Approximately 15% of *all* childhood cancer survivors experience infertility, and pregnancy outcomes appear to be influenced by prior chemotherapy and radiation treatment (see Chapter 543). Cancer survivors have an increased rate of spontaneous abortion, premature delivery, and low birthweight infants compared with their healthy siblings. No data support an increased incidence of congenital malformations in offspring. Individualized risk of infertility should be discussed before gonadotoxic therapies and options for fertility preservation should be made available to all patients, with referrals to reproductive specialists and mental health professionals as appropriate. Multiple recommendations specifically address the pediatric population, stating that parents/guardians should be allowed to act for and consent in the interest of their minor children.

Mature oocyte and embryo cryopreservation are both standard of care preservation options available to postpubertal females with ample time before treatment to allow for ovarian stimulation (2-6 weeks). Ovarian tissue cryopreservation (OTC) is the only available option for prepubertal females. OTC is also an option for fertility preservation for postpubertal females with time-limiting treatment plans. The safety and feasibility of OTC and transplantation after nonsterilizing chemotherapy and in select leukemia survivors have been favorable, and there have been over 130 live births reported after orthotopic transplantation

of previously cryopreserved and thawed ovarian tissue as of 2017. Laparoscopic ovarian transposition can be used before radiation therapy where a high risk of ovarian radiation exposure in its anatomic position is expected. Hormone suppression with gonadotropin-releasing hormone (GnRH) analogs has been investigated as a means of fertility preservation, but evidence is lacking as to its efficacy.

Gonadotoxicity can also lead to primary ovarian insufficiency, which is associated with an increased risk for cardiovascular complications, osteoporosis, and difficulties with sexual function. Risks and benefits of hormone replacement therapy should be addressed as appropriate.

NEONATAL AND PEDIATRIC OVARIAN CYSTS

Normal follicles or physiologic ovarian cysts can be seen by ultrasound examination of the ovaries in healthy neonates, infants, and prepubertal females. The true incidence of neonatal cysts is unknown, but most are physiologic. Ovarian cysts are often detected during prenatal imaging and should be differentiated from masses originating from the urinary or gastrointestinal (GI) tract. Ovarian cysts that are less than 2 cm, sonolucent, and have a simple appearance on ultrasound are most likely physiologic. Simple neonatal ovarian cysts will resolve spontaneously and should be followed with observation. Larger cysts may be seen; in these cases, the interval to complete resolution is usually longer. Because of the risk of **ovarian torsion** and resultant autoamputation of the ovary, treatment modalities have been developed to prevent ovarian torsion, including ultrasound-guided aspiration, laparoscopic cystectomy, and detorsion, with the goal of ovarian preservation. Oophorectomy should be avoided. Treatment is usually reserved for the postnatal period unless the cyst is large enough to prevent embryonic development. Similarly, intervention might be necessary if the cyst is large enough to complicate delivery or if there is concern for compromise of the other organs because of the mass effect. If a conservative approach is chosen, serial ultrasonographic evaluation is reasonable until resolution in the prenatal and neonatal period. In the neonatal period, aspiration is an option for cysts that are larger than 6 cm and persistent over 4 months. Surgical exploration is generally reserved for complex, symptomatic, or enlarging cysts, with a great deal of effort exerted to preserve the surrounding normal ovary.

In **prepubertal** children, ovarian cysts are rare and, if present, usually asymptomatic and hormonally inactive. However, a careful exam is indicated because prepubertal ovarian cysts may be associated with peripheral precocious puberty. If symptomatic, cysts might present as an abdomino-pelvic mass resulting in pain, constipation, or urinary frequency. In **adolescents**, ovarian cysts are common and usually represent normal follicular development.

Cysts that are simple appearing, without septations or internal echogenicity, and less than 10 cm on transabdominal ultrasound are almost always benign, and observation is preferred (Fig. 590.1). Careful counseling and patient education should be provided for early recognition of complications related to ovarian cysts, such as cyst rupture and ovarian torsion. Unless associated with intractable symptoms or intraabdominal bleeding because of cyst rupture, cysts can be managed conservatively. Large ovarian cysts pose a risk of ovarian torsion. *Ovarian torsion* is a surgical emergency and can happen with ovarian cysts of any size, although the risk increases in adnexal masses larger than 5 cm. Rarely, torsion of the adnexa can occur without presence of an ovarian cyst, which is more common in prepubertal patients.

Functional Cysts

Over the course of several menstrual cycles, a **dominant follicle** forms and increases in size. After ovulation, the dominant follicle becomes a corpus luteum that, if it bleeds, is termed a **hemorrhagic corpus luteum**. These can become symptomatic owing to size or peritoneal irritation, and they have a characteristic complex appearance on ultrasound. Expectant and symptomatic management for a presumed functional or hemorrhagic cyst is appropriate. Physiologic cysts are usually ≤5 cm and resolve over the course of 6-8 weeks or several menstrual cycles without the need for any intervention. Monophasic oral contraceptives can be used to suppress future follicular development and prevent formation of additional cysts. When a cyst is found on ultrasound, a pregnancy test should be obtained because an adnexal mass on imaging could represent either a corpus luteum cyst that physiologically supports a normal pregnancy or an abnormal pregnancy state such as an ectopic pregnancy in the adnexa.

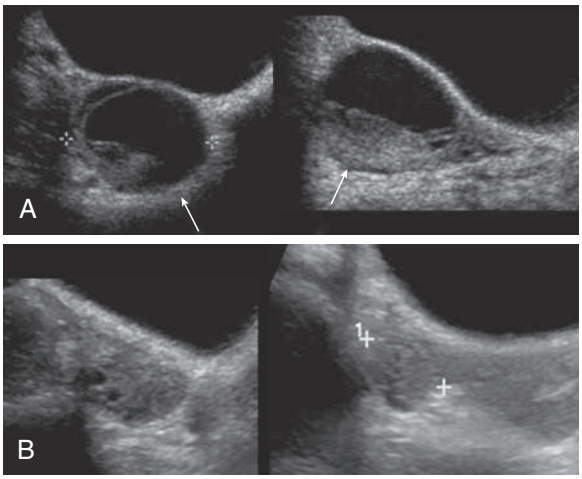

Fig. 590.1 Ovarian cyst. 14-yr-old female with pelvic pain. **A,** Transverse and sagittal images from a transabdominal pelvic ultrasound demonstrate a well-circumscribed cystic lesion in the right adnexa with a fluid–debris level *(arrows).* **B,** Follow-up imaging 6 weeks later demonstrates complete resolution of the cyst. *(From Walters MM, Robertson RL. Pediatric Radiology: The Requisites, 4th ed. Philadelphia: Elsevier, 2017:186; Fig. 6.70.)*

OVARIAN NEOPLASMS

Teratomas

Ovarian teratomas are the most common pediatric ovarian neoplasm and account for 25% of all pediatric teratomas. Aberrant migration and differentiation of primordial germ cells from the yolk sac to the gonadal ridge during embryogenesis is considered to be the embryologic origin of teratomas. Ovarian teratomas are usually asymptomatic but may become quite large and present with abdomino-pelvic pain and a palpable mass; ovarian torsion may be the initial presenting symptom. Ovarian teratomas are usually unilateral, but about 10% of cases are bilateral. **Mature cystic teratomas** (**dermoid cysts**) account for more than 95% of all teratomas. Depending on the germ layers, teratomas can be polydermal or monodermal and may contain mature tissue of ectodermal (skin, hair, sebaceous glands, neuroectodermal tissue), mesodermal (muscle, bone, cartilage, fat, teeth), and/or endodermal (thyroid, salivary, respiratory, GI) origin (Fig. 590.2). Mature teratomas are usually benign; malignant transformation is reported in less than 2% of the cases. Although any of the components of the mature teratoma can undergo malignant transformation, the most common secondary neoplasm arising from mature teratoma is squamous cell carcinoma. Teratomas have a characteristic sonographic appearance that includes findings such as fluid-fluid levels, Rokitansky nodules (a solid protuberance projecting from an ovarian cyst), echogenic sebaceous material, calcification, and hyperechoic regions. On abdominal radiograph, calcification is often a hallmark for teratomas. Ultrasound has a high sensitivity and specificity for diagnosing dermoid cysts with excellent diagnostic accuracy. Monodermal teratomas are rare and contain elements originating from a single germ cell layer. **Struma ovarii** is a monodermal teratoma that is composed of mature thyroid tissue that may result in clinically overt hyperthyroidism. **Ovarian carcinoid tumors** are another example of a monodermal teratoma. These rare tumors are generally associated with a mature teratoma but can be encountered in a pure form as a monodermal teratoma in a minority of cases. Approximately 30% of the time, clinical signs of carcinoid syndrome such as diarrhea, flushing, abdominal pain, and wheezing

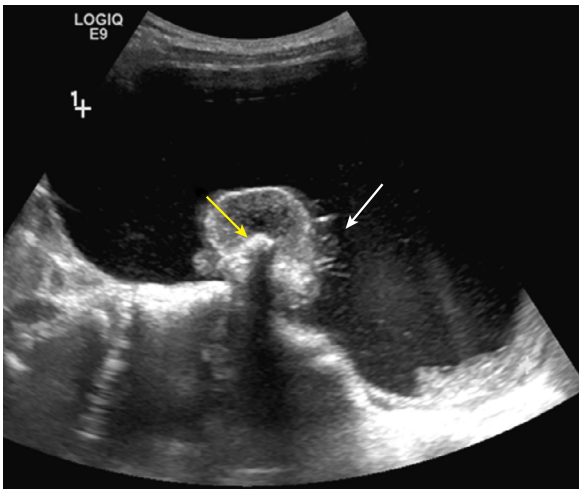

Fig. 590.2 Mature teratoma. 12-yr-old female with increasing abdominal girth. Transabdominal pelvic ultrasound image demonstrates a large pelvic mass with cystic and solid components. There is a rounded echogenic area in the center of the large, hypoechoic cystic portion. A central dense echogenic focus *(yellow arrow)* demonstrates posterior acoustic shadowing, consistent with calcification. Tiny linear echogenic foci *(white arrow)* are also associated with the central echogenic mass, representing hair. This constellation of findings is seen with a mature teratoma or dermoid cyst. *(From Walters MM, Robertson RL. Pediatric Radiology: The Requisites, 4th ed. Philadelphia: Elsevier, 2017: 187; Fig. 6.71.)*

may be present because of vasoactive amines secreted by the carcinoid tumors.

Benign teratomas can be observed if they are asymptomatic and small (<5 cm). However, when they are large or symptomatic, they should be surgically resected to prevent torsion or rupture, with preservation of the surrounding healthy ovarian parenchyma. Cystectomy is the treatment of choice, and minimally invasive techniques are increasingly used. Rupture of the cyst should be avoided as much as possible because of concerns for chemical peritonitis secondary to fatty acids of a teratoma and the rare risk of inadvertent upstaging of an occult carcinoma. During surgery, both ovaries should be evaluated for lesions. Intraoperative concern for a malignant lesion should prompt an evaluation of both the gross specimen and frozen section by pathology because malignant transformation of mature teratomas can occasionally occur.

An **immature teratoma (IT)** of the ovary is an uncommon tumor, accounting for <1% of ovarian teratomas. In contrast to the mature cystic teratoma, which is encountered most often during the reproductive years but occurs at all ages, IT has a specific age incidence, occurring most commonly in the first 2 decades of life. IT contain cells originating from three germ cell layers, but in contrast to mature teratomas, these elements have varying degrees of maturation. IT are histologically separated into three categories based on the proportion of the immature neural elements. Grade 3 IT have the highest percentage of immature neural elements, which correlates with the greatest risk of extraovarian spread. The presence of a yolk sac component also confers a higher risk of extraovarian spread. Clinically, IT present similarly to mature teratomas with pelvic pain or a mass. There is an association of dermoid tumors with neural elements and *anti–N-methyl-D-aspartase receptor (anti-NMDAR) encephalitis*. Patients may present with flu-like symptoms and progress to psychiatric and cognitive symptoms, autonomic instability, and seizure activity (see Chapter 638). The sonographic appearance of IT is nonspecific but is typically a heterogenous, partially solid mass with coarse calcifications.

Although the data are scant in the pediatric population, the stage and grade of the IT ultimately determines the treatment approach. Surgical staging for germ cell tumors in the pediatric population may differ from the adult population, and surgical staging in pediatric patients include collection of ascites and pelvic washings, examination of peritoneal surfaces with biopsy and excision of any nodules, examination of lymph nodes with sampling of any firm/enlarged lymph nodes, inspection/palpation of omentum with biopsy of any abnormal areas, and unilateral oophorectomy with preservation of the fallopian tube if uninvolved. It should be emphasized that grossly normal lymph nodes on palpation and normal appearing omentum may not need to be routinely removed. Stage I and grade 1 ITs can be managed with serial monitoring of associated tumor markers and pelvic imaging after initial fertility-sparing surgery. Grade 2-3 or stage II-IV IT are typically treated with systemic treatment in the form of the BEP chemotherapy regimen (bleomycin, etoposide, cisplatin).

Cystadenomas

Serous, mucinous, and mixed serous/endometrioid or mucinous/endometrioid cystadenomas are the second most common benign ovarian tumor in adolescents, representing 10–28% of adolescent tumors (Fig. 590.3). These tumors are usually thin walled, cystic, and may be associated with mild elevation of tumor markers such as carcinoembryonic antigen (CEA), CA-125, and CA 19-9, but high levels of these markers should raise suspicion for malignancy. These cystic lesions can become very large, yet, with care, these tumors can be resected, preserving normal ovarian tissue for future reproductive potential. Recurrence rates may be as high as 9%, and thus patients and providers may choose to continue surveillance postoperatively with pelvic ultrasound.

Endometriomas

Endometriosis is a syndrome defined by the presence of ectopic endometrial tissue usually located within the pelvis and abdomen but outside of the uterus. The principal clinical symptoms in adolescents consist of severe menstrual pain and pelvic pain but may also include abnormal uterine bleeding and GI, genitourinary, or constitutional symptoms. Diagnosis is often delayed, and a high clinical suspicion should be maintained. Although endometriosis has a variable presentation, it is associated with endometriomas in approximately 17–44% of adolescent cases; they may be unilateral or bilateral. **Endometriomas (chocolate cysts)** form when collections of old blood and hemosiderin deposit within an endometrium-lined cyst within or on the ovary. They have a typical homogeneous "ground glass" echogenic appearance on ultrasound and are more common in adults than in adolescents. Conservative management (suppressive therapy with ovulation suppression, nonsteroidal antiinflammatory drugs, combined oral contraceptives, or progestin therapy) is recommended for adolescents. An ovarian-sparing cystectomy should be performed if conservative care fails to control the symptoms or the size of the endometrioma is concerning for torsion. Recurrence of endometriosis occurs more commonly in adolescents than adults, and future fertility is associated with stage of disease. Early diagnosis and initiation of menstrual suppression with estrogen-progesterone, progesterone-only formulations, GnRH agonist, or GnRH antagonist may prevent progression of the disease.

Pelvic Inflammatory Disease and Tuboovarian Abscess

Pelvic inflammatory disease (PID) complicated by a tuboovarian abscess (TOA) should be considered in a sexually active adolescent with an adnexal mass and pain on examination (see Chapter 163). PID is a spectrum of upper genital tract inflammation and includes some combination of endometritis, salpingitis, and TOA. Rarely, TOA can occur in nonsexually active adolescents, particularly in association with obstructive Müllerian anomalies, ruptured appendicitis, obesity, and severe constipation. Patients with PID and TOA typically exhibit fever with leukocytosis, cervical motion, uterine or adnexal tenderness, vaginal discharge, nausea, peritoneal signs, and abnormal vaginal bleeding. TOAs are usually demonstrated on transvaginal ultrasound, but pelvic CT imaging may be used for uncertain cases. Treatment of PID with TOA consists of inpatient administration of intravenous (IV) antibiotics. After 48-72 hours of treatment with antibiotics

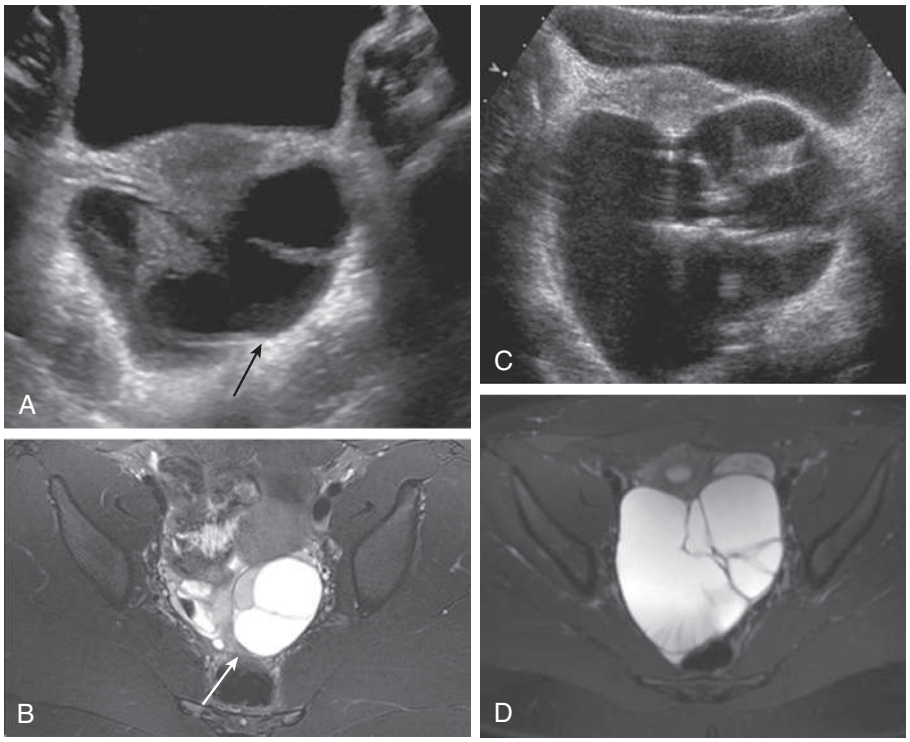

Fig. 590.3 Serous cystadenoma and mucinous cystadenoma. **A** and **B**, 20-yr-old female with pelvic pain. **A**, Transverse ultrasound and (**B**) axial T2 fat-saturated magnetic resonance images (MRIs) demonstrate a complex cystic mass with septations in the left adnexa *(arrows)*. This was removed and found to be a serous cystadenoma. **C** and **D**, 15-yr-old female with pelvic pain. **C**, Transverse ultrasound and (**D**) axial T2 fat-saturated MRIs demonstrate a cystic, septated mass posterior to the uterus. After surgical resection, pathology confirmed a mucinous cystadenoma. Note that the imaging appearances of serous and mucinous cystadenoma are similar. A specific diagnosis is difficult to discern based on imaging alone. *(From Walters MM, Robertson RL. Pediatric Radiology: The Requisites, 4th ed. Philadelphia: Elsevier, 2017; 188: Fig. 6.72.)*

alone, patients with TOAs who do not respond or who worsen should undergo imaging-guided abscess drainage. Conservative management with IV and then oral antibiotics and/or image-guided drainage is recommended as long as the patient continues to improve. TOAs that are large (>7-8 cm in the largest diameter) are associated with the need for surgical intervention and/or radiologically guided drainage. Clinical deterioration is an indication for surgical exploration, and a familiarity with bowel surgery is important with any attempt at resection of a pelvic abscess because of the challenges of encountering anatomic distortion, other organ involvement, and friable tissue planes.

Adnexal Torsion

Adnexal torsion of the ovary and/or fallopian tube is the fifth most common gynecologic emergency and occurs more often in children and adolescents than in adults. If ovarian torsion is suspected, timely surgical intervention is necessary to preserve ovarian function and future fertility. About 60% of ovarian torsions are on the right side; this is possibly because the right utero-ovarian ligament is longer than the left and/or due to the protective effect of the descending colon to the left adnexa. The most common presentation is *sudden*-onset abdominal pain, which is typically intermittent and nonradiating, with associated nausea and vomiting. Abdominal tenderness is common on physical exam and may be accompanied by peritoneal signs. Ultrasound with Doppler is the imaging modality of choice (Fig. 590.4). In adnexal torsion, ovarian venous flow is obstructed, and the fallopian tube and/or ovary become enlarged. Pelvic ultrasound findings include an edematous appearance of the ovary with subsequent hyperechogenicity, increase in size, "whirlpool" sign (twisted vascular pedicle of the ovary), and peripherally displaced follicles. Doppler studies in the evaluation of torsion are limited because of low sensitivity, and the presence of arterial flow does not rule out torsion. Therefore Doppler flow alone should not guide clinical decision-making. Prompt surgical intervention (i.e., diagnostic laparoscopy and laparoscopic ovarian detorsion) is essential to preserve ovarian function. Appearance of the ovary during surgery is not a reliable indicator for ovarian viability as even devascularized-appearing ovaries during laparoscopy have been reported to regain normal perfusion and function in several days. The goal of surgery should be to preserve the ovary regardless of the color and time from onset of symptoms to intervention. A torsed ovary should not be removed in adolescents unless it is severely necrotic and is disintegrating.

Although adnexal torsion may occur in individuals with normal ovaries, torsion occurs more commonly in adnexa enlarged by cystic changes or ovarian neoplasms. The rate of malignancy among premenarchal adolescents with ovarian torsion ranges from 0.4–5%. If an ovarian cyst is easily identified at the time of detorsion, it is reasonable to proceed with concomitant cystectomy; however, it should be noted that the concomitant cystectomy could be challenging because of the friable edematous ovary, which can result in ovarian damage and bleeding leading to oophorectomy. Given that most cysts are benign, drainage of the cyst's fluid is reasonable, and repeat ultrasound in 6-12 weeks usually demonstrates resolution of the cyst. Another approach may include detorsion and second-stage surgery at delayed interval for cystectomy. Oophoropexy is controversial, and the two most compelling reasons are the absence of a contralateral ovary and a history of recurrent ovarian torsion. Initiation of ovarian suppression is reasonable to prevent recurrent ovarian cysts.

OVARIAN MALIGNANCIES

Ovarian cancer is very uncommon in children; only 1.3% of all ovarian cancers are diagnosed in patients < 20 years old. Surveillance, Epidemiology, and End Results (SEER) age-adjusted incidence rates for 2016–2020 are 1.35/100,000 for females 15–19 years; mortality rates for this age group are 0.05/100,000.

Germ Cell Tumors

Germ cell tumors are the most common ovarian malignancy and originate from primordial germ cells that develop into a number of heterogeneous tumor types. **Dysgerminomas** are the most common malignant germ cell tumor of the ovary and have the best prognosis (Table 590.2). They may contain syncytiotrophoblastic cells that produce alpha-fetoprotein (AFP) and lactate dehydrogenase (LDH), making these serum proteins useful tumor markers for monitoring disease activity during surveillance (Table 590.3). Because of rapid growth and expansion, dysgerminomas may present as large abdomino-pelvic masses, and hemoperitoneum may result due to capsular rupture. Dysgerminomas are the most common bilateral ovarian germ cell tumor, occurring bilaterally in 10–15% of patients. **Yolk sac tumors**, also

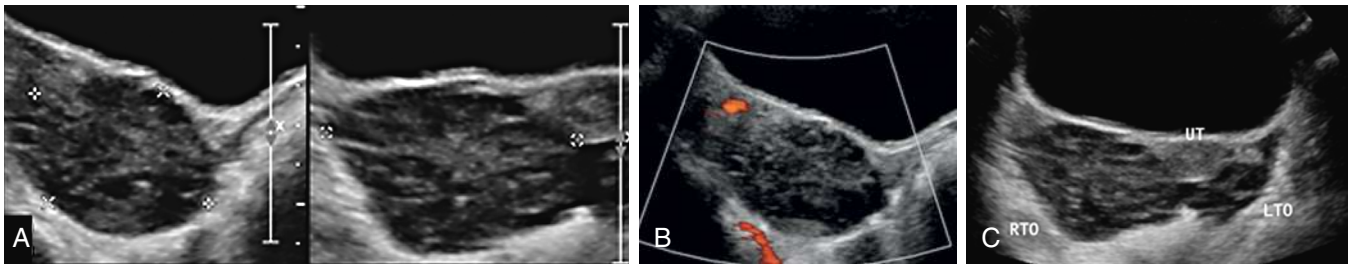

Fig. 590.4 Ovarian torsion. 15-yr-old female with acute-onset pelvic pain. **A,** Sagittal and transverse transabdominal pelvic ultrasound images demonstrate a rounded appearance of the right ovary, which is displaced medially and positioned posterior to the uterus. There is peripheralization of the ovarian follicles. **B,** Power Doppler imaging shows no demonstrable flow within the ovarian parenchyma. **C,** Transverse image of the pelvis shows marked asymmetric enlargement of the right ovary (RTO) in comparison with the normal left ovary (LTO). This patient went to surgery, and right ovarian torsion was confirmed. UT, Uterus. *(From Walters MM, Robertson RL. Pediatric Radiology: The Requisites, 4th ed. Philadelphia: Elsevier, 2017; 189: Fig. 6.74.)*

Table 590.2 Malignant Ovarian Tumors in Children and Adolescents

TUMOR	OVERALL 5-YR SURVIVAL	CLINICAL FEATURES
GERM CELL TUMORS		
Dysgerminoma	85%	10–20% bilateral Most common ovarian malignancy Gonadal dysgenesis/androgen insensitivity Sensitive to chemotherapy/radiation
Immature teratoma	97–100%	All three germ layers present
Endodermal sinus tumor	80%	Almost always large (>15cm) Schiller-Duval bodies
Choriocarcinoma	30%	Rare Can mimic ectopic pregnancy
Embryonal carcinoma	25%	Endocrinologic symptoms (precocious puberty) Highly malignant
Gonadoblastoma	100%	Primary amenorrhea Virilization 45,X or 45,X/46,XY mosaicism
SEX CORD STROMAL TUMORS		
Juvenile granulosa stroma cell tumor	92%	Produce estrogen Menstrual irregularities Isosexual precious pseudopuberty Call-Exner bodies rare
Sertoli-Leydig cell tumor	70–90%	Virilization in 40% Produce testosterone
Lipoid cell tumors	~80%	Rare heterogeneous group with lipid-filled parenchyma
Gynandroblastoma	90% or greater	Rare low-grade mixed tumors that produce either estrogen or androgen

referred to as **endodermal sinus tumors**, clinically present similarly to dysgerminomas with a rapidly enlarging pelvic mass and associated abdominal pain. Schiller Duval bodies are pathognomonic on pathology and contain a central blood vessel surrounded by cuboidal tumor cells. AFP is a useful marker for monitoring response to treatment and for surveillance. Immature teratomas and yolk sac tumors are more aggressive malignancies than dysgerminomas. Embryonal carcinomas are a relatively undifferentiated product of the primordial germ cells and are one of the most malignant germ cell tumors of the ovary. They may secrete β-hCG and AFP. **Gonadoblastomas** are almost always associated with chromosomal abnormalities; therefore chromosomal analysis is essential. Polyembryoma is a very aggressive ovarian malignancy and contains embryoid bodies. The treatment for stage Ia dysgerminomas and stage I immature teratomas is resection. For stage Ic and higher, treatment is surgical excision followed by postoperative chemotherapy. Radiotherapy may be administered for disease recurrence in dysgerminomas, but it is not included in routine treatment. For unresectable tumors or for patients who cannot undergo surgery, neoadjuvant chemotherapy is an option. Recurrences are treated with chemotherapy. Germ cell tumors may recur in up to 10% of cases, and thus yearly follow-up ultrasound is recommended.

Sex-Cord Stromal Tumors

Sex-cord stromal tumors (SCSTs) originate from the stromal component of the gonads and include benign **thecomas** and **fibromas,** as well as malignant **Sertoli-Leydig cell tumors** and **juvenile granulosa cell tumors**. Individuals with Peutz-Jeghers syndrome are at increased risk for developing SCSTs. SCSTs clinically present as an abdomino-pelvic mass, pain, and symptoms of excess sex steroid hormone production, such as hirsutism, virilization, and heterosexual or isosexual precocious puberty. When an SCST is suspected, serum levels of inhibin B, AFP, estradiol and testosterone should be obtained. SCSTs usually present as a unilateral solid mass on imaging, but some degree of necrosis could lead to a heterogenous appearance (Figs 590.5 and 590.6).

Most **juvenile granulosa** cell tumors have an intact capsule and therefore are associated with a good prognosis; however, in the case of capsular rupture or invasion, they potentially have an aggressive course. Juvenile granulosa cell tumors are usually associated with excess estrogen and precocious puberty in prepubertal females. Approximately 20% of the SCSTs in the pediatric population are **Sertoli-Leydig cell tumors,** which may be associated with clinical signs and symptoms of androgen excess. The *DICER1* pathogenic variant is associated with Sertoli-Leydig cell tumors, and the presence of the variant increases the risk of metachronous tumor in the contralateral ovary. Karyotype and referral to genetics is recommended for patients with SCSTs.

Epithelial Ovarian Cancers

Epithelial ovarian cancers are less common than germ cell tumors in the pediatric and adolescent population, comprising only 12.4% of ovarian malignancies in this group. Borderline ovarian tumors are similarly exceedingly rare in adolescents. Individuals with *BRCA1* and *BRCA2* pathogenic variants are at higher risk of developing epithelial ovarian cancer at younger ages compared with females without *BRCA* variants. Similarly, low-grade epithelial ovarian carcinomas tend to occur at younger ages compared with high-grade ovarian carcinomas. Common presenting symptoms include dysmenorrhea, abdominal pain, abdominal distention, nausea and vomiting, and vaginal

Table 590.3 Serum Tumor Markers

TUMOR	CA-125	AFP	β-HCG	LDH	E2	T	INHIBIN	MIS	VEGF	DHEA
Epithelial tumor	+									
Immature teratoma	+	+			+					+
Dysgerminoma			+	+	+					
Endodermal sinus tumor		+								
Embryonal carcinoma		+	+		+					
Choriocarcinoma			+							
Mixed germ cell		+	+	+

Sertoli-Leydig						+	+			
Gonadoblastoma					+	+	+			+
Theca-fibroma									+	

AFP, α-Fetoprotein; CA-125, cancer antigen 125; DHEA, dehydroepiandrostenedione; E2, estradiol; β-hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; T, testosterone; MIS, Müllerian-inhibiting substance; VEGF, vascular endothelial growth factor.

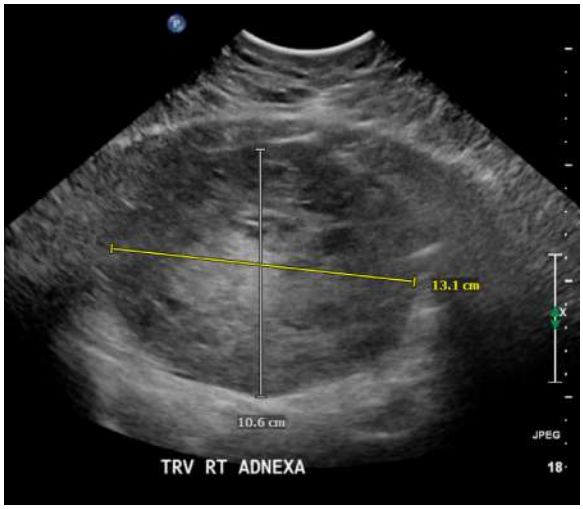

Fig. 590.5 Complex 13.1 × 8.1 × 10.6 cm solid mass with smaller cystic foci, arising from the right ovary. Final pathology demonstrated juvenile granulosa cell tumor. *(Image courtesy Alla Vash-Margita, MD.)*

discharge; CA-125 is almost always elevated. Treatment involves surgical salpingo-oophorectomy, pelvic washings, and biopsies of suspicious omental, peritoneal, and lymph node lesions, with adjuvant chemotherapy for patients with Federation of Gynecology and Obstetrics (FIGO) stage II-IV disease. Given the young age of this population, although this is not the standard of care for adult patients, fertility-sparing surgery is recommended for stage I cancer to conserve the contralateral ovary and uterus if they appear normal. Data suggest that in patients with early-stage disease, such an approach with appropriate surgical staging results in optimal outcomes but is not recommended for stage II-IV disease due to the high rate of recurrence. The number of term pregnancies and use of oral combined hormonal contraceptive pills decrease the risk of invasive epithelial ovarian cancer. Young females with a family history of ovarian cancer should consider the use of long-term oral combined hormonal contraceptive pills for the preventive benefits when pregnancy is not being sought.

UTERINE MALIGNANCIES

Uterine malignancies account for 2.5% of all gynecologic malignancies of children and adolescents less than 18 years of age. The most common types are sarcomas (34%), followed by adenocarcinomas (34%) and squamous cell carcinomas (10%). **Rhabdomyosarcomas** are the most common type of soft tissue sarcoma occurring in patients <20 years of age (see Chapter 549). They can develop in any organ or tissue in the body except bone, and roughly 3% originate from the uterus or vagina. Of the various histologic subtypes, embryonal rhabdomyosarcomas in the female patient most often occur in the genital tract of infants or young children. They are rapidly growing entities that can cause the tumor to be expelled through the cervix, with subsequent complications such as uterine inversion or large cervical polyps. Irregular vaginal bleeding may be another presenting clinical symptom. They are defined histologically by the presence of mesenchymal cells of skeletal muscle in various stages of differentiation intermixed with myxoid stroma. A genetic link has been found between Li-Fraumeni cancer susceptibility syndrome, Beckwith-Wiedemann syndrome, pleuropulmonary blastoma, Costello syndrome, Noonan syndrome, and neurofibromatosis type I. Treatment recommendations are based on protocols coordinated by the Intergroup Rhabdomyosarcoma Study Group and consist of a multimodal approach including radiation therapy and chemotherapy. Vincristine, Adriamycin-D, and cyclophosphamide (VAC) with or without radiation therapy make up the first line of treatment. Intensity-modulated radiation therapy and proton beam radiotherapy are used to reduce the therapy burden and long-term toxicity. Resection rates are very low because of the risk of losing the form and function of local tissue; chemotherapy with restrictive surgery and adjunctive irradiation has enabled many patients to retain the uterus while achieving excellent long-term survival rates.

Leiomyosarcomas and **leiomyomas** are extremely rare, occurring in <2 in 10 million individuals in the pediatric and adolescent age-groups, although their numbers are increasing among pediatric patients with AIDS. They usually involve the spleen, lung, or GI tract, but they could also originate from uterine smooth muscle. Epstein-Barr virus pathogenesis has been shown in AIDS and solid-organ transplant patient populations (see Chapter 301). Despite treatment that demands complete surgical resection (and chemotherapy for the sarcomas), they tend to recur frequently.

Endometrial stromal sarcoma and **endometrial adenocarcinoma** of the uterine corpus are extremely rare in children and adolescents. A comprehensive review described 19 cases of endometrial cancer (EC) among adolescent females younger than 21 years in which five subjects (26.3%) had a genetic condition (Cowden syndrome and Turner syndrome). This emphasizes the consideration of genetic evaluation in very young patients with EC. In most cases, patients presented with abnormal uterine bleeding and had associated comorbidities such as obesity and polycystic ovary syndrome. Standard of care for treatment of EC consists of hysterectomy, removal of both ovaries and fallopian tubes and surgical staging, followed by adjunctive radiotherapy and/

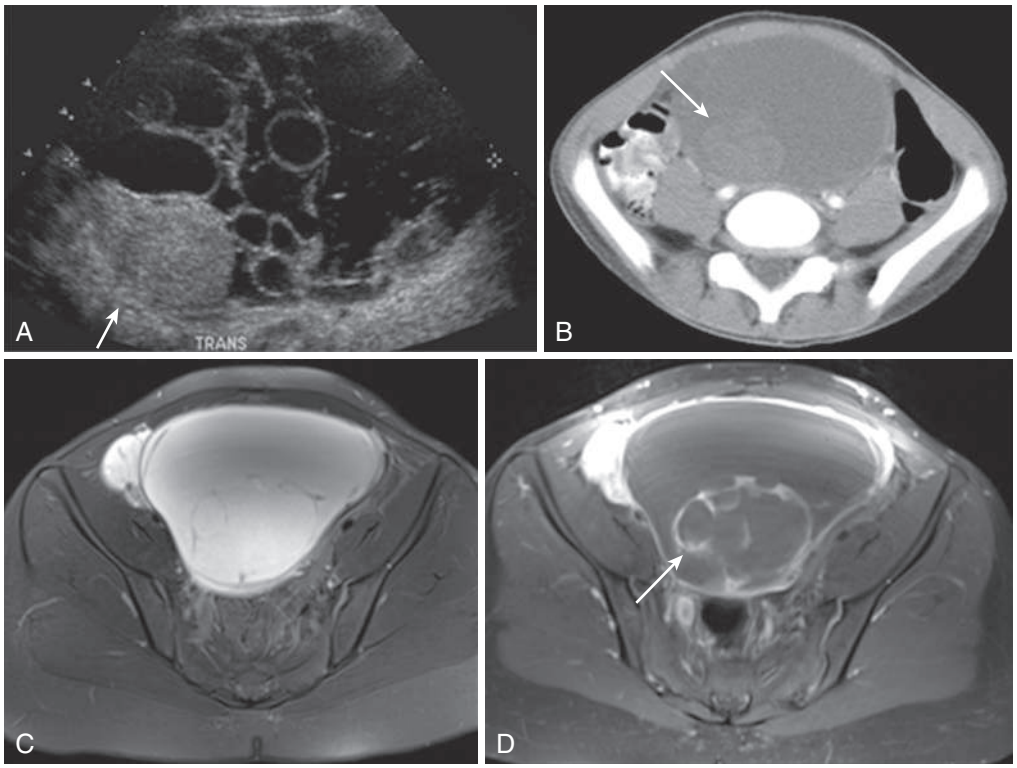

Fig. 590.6 Sertoli-Leydig cell tumor. 2-yr-old female with a palpable pelvic mass and secondary sex characteristics. **A**, Transabdominal pelvic ultrasound demonstrates a complex cystic, septated mass, with a solid component posteriorly *(arrow)*. **B**, Contrast-enhanced computed tomography shows a predominantly cystic mass, with an enhancing mural nodule along the posterior margin *(arrow)*. **C**, T2-weighted and **D**, contrast-enhanced magnetic resonance images in a different patient demonstrate a T2 hyperintense lesion in the pelvis, with enhancing internal solid components noted after contrast administration *(arrow)*. *(From Walters MM, Robertson RL. Pediatric Radiology: The Requisites, 4th ed. Philadelphia: Elsevier, 2017; 188: Fig. 6.73.)*

or chemotherapy as indicated by final pathology and stage. In young patients who desire childbearing, fertility-sparing approaches with preservation of the uterus have been increasingly utilized. Per National Comprehensive Cancer Network (NCCN) guidelines, candidates for this approach are patients with grade 1 endometrioid adenocarcinoma on dilation and curettage, patients with disease confined to endometrium by MRI (preferred imaging modality) or ultrasound, absence of metastatic disease on imaging, and no contraindications to medical therapy or pregnancy. Patients should undergo counseling that fertility-sparing options are not standard of care for the treatment of endometrial carcinoma. Existing data on hormonal therapy come from observational studies and have variable rates of outcomes. Although there is no standard follow-up protocol, patients with EC treated with hormonal therapies should be reexamined with endometrial sampling every 3-6 months.

VAGINAL MALIGNANCIES

Vaginal tumors are rare with a variable clinical presentation that may include abdomino-pelvic pain, an abdominal mass, bloody vaginal discharge, genital ulceration, or tissue protruding from the vagina. **Embryonal rhabdomyosarcoma (RMS)** is the most common vaginal malignancy followed by germ cell tumor (GCT) and clear cell adenocarcinoma (CCA). The management of pediatric vaginal tumors consists of neoadjuvant chemotherapy followed by local control with surgery or radiotherapy.

Embryonal rhabdomyosarcoma (RMS) or **sarcoma botryoides** typically arises in the anterior wall of the vagina or within the wall of the bladder and presents as an edematous grapelike mass protruding from the vagina. Overall, RMS arising in the female genital tract accounts for less than 4% of all pediatric RMS. Approximately 90% of these sarcomas present before age 5 years. Embryonal RMS of the vagina is managed with multimodality treatment. A series of Intergroup Rhabdomyosarcoma Study Group (IRSG) reports demonstrated survival rates in excess of 85% employing the use of combination chemotherapy treatment with vincristine, actinomycin-D, and cyclophosphamide (VAC) and wide excision with or without adjuvant radiation treatment. This approach spares most patients from exenterative surgery. Because of the high rates of local recurrences in patients who did not receive radiation, the Soft Tissue Sarcoma committee of the Children's Oncology Group recommends local radiation treatment unless potential toxicity is considered unacceptable.

Endodermal sinus tumors or **yolk sac tumors** are the most common subtype of pediatric germ cell tumor of the vagina but are still quite rare. These tumors present almost exclusively in children under the age of 3 years with vaginal bleeding. Typically, patients have a markedly elevated serum AFP, which can be used to monitor treatment effect and disease recurrence. Management involves combination of surgery and chemotherapy (either carboplatin/etoposide/bleomycin, BEP regimen, or VAC regimen). Unfortunately, survival rates are low despite treatment.

There is an increased incidence of **clear cell adenocarcinoma** (CCA) of the vagina in young females related to in utero exposure to diethylstilbestrol (DES) during the first 16 weeks of pregnancy. The suggested mechanism of carcinogenesis involves the retention of nests of abnormal cells of Müllerian duct origin that, after stimulation by endogenous hormones during puberty, are promoted into adenocarcinomas. Most cases involve the anterior upper third of the vaginal wall. Treatment of CCA of the vagina includes a surgery and/or radiation treatment depending on the extent of disease. Fortunately, the incidence of CCA of the vagina has decreased since the practice of prescribing DES during pregnancy has been eliminated.

VULVAR MALIGNANCIES

Pediatric vulvar malignancies are rare. Patients typically present with an ulcerated or raised lesion and/or a mass. It is imperative that any concerning vulvar lesion be biopsied and submitted for pathologic evaluation. Vulvar malignancies that have been described in the literature include invasive squamous cell carcinomas, yolk sac tumors, Ewing sarcoma/primitive neuroectodermal tumors (ES/PNET), and melanomas. Each of these entities make up approximately 10% of reported cases. Cases of pediatric vulvar squamous cell carcinoma include those lesions that are **human papillomavirus (HPV)**-mediated and HPV-independent. Possible risk factors include HPV infection, immunosuppression, Fanconi anemia, and lichen sclerosis. Extragonadal germ cell tumors involving the vulva are very uncommon, and the leading hypothesis behind their pathogenesis is possible aberrant germ cell migration along the gubernaculum. These are aggressive tumors, and treatment options include various combinations of excisional

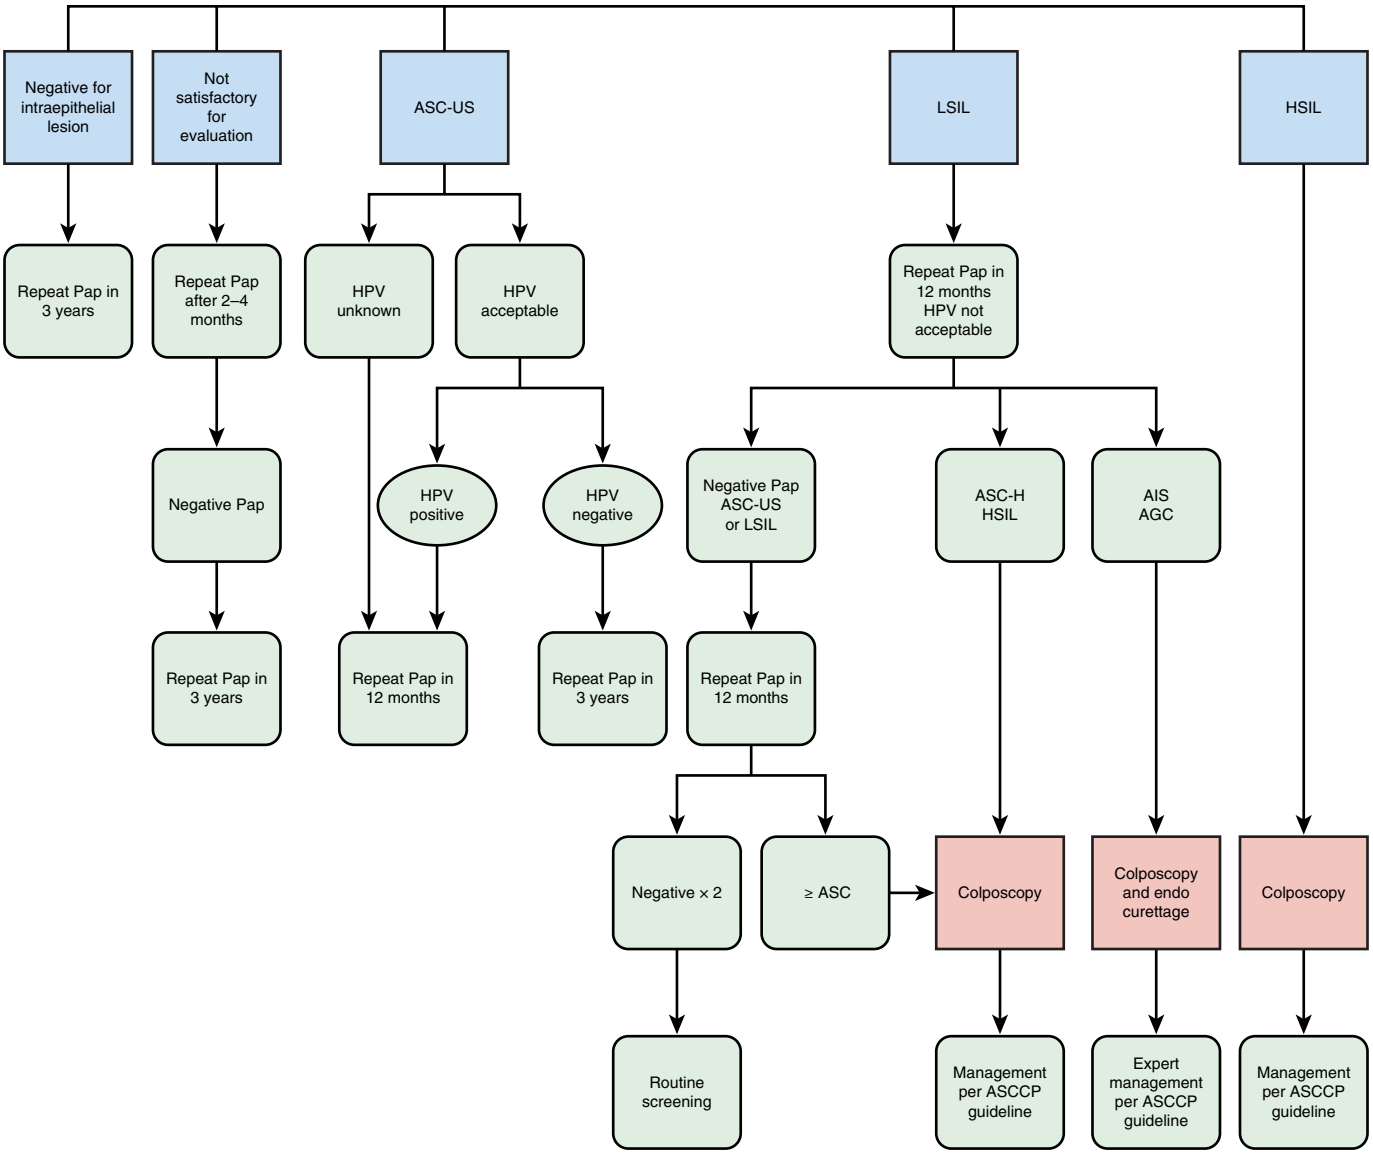

Fig. 590.7 Algorithm for the management of Pap smear results in women between age 21-24. AIS, adenocarcinoma in situ; AGC, atypical glandular cells; ASC, atypical squamous cells; ASCCP, American Society for Colposcopy and Cervical Pathology; ASC-H, atypical squamous cells that cannot exclude HSIL; ASC-US, atypical squamous cells of undetermined significance; LSIL, low-grade squamous intraepithelial lesion; HPV, human papilloma virus; HSIL, high-grade squamous intraepithelial lesion *(From Trotman GE, Vash-Margita A, Kahn JA, et al. Human papillomavirus infection and cervical cancer screening and prevention in adolescents. In: Emans SJ, Laufer MR, Di Vasta DP, eds. Pediatric and Adolescent Gynecology. Philadelphia: Lippincott Williams & Wilkins, 2020; 330–348: Fig 20.9.)*

procedures and neoadjuvant or adjuvant chemotherapy. **Malignant melanoma** of the vulva represents 2.4–10% of all vulvar malignancies, second to invasive squamous cell carcinomas in frequency. Early-stage melanoma treatment involves surgical excision followed by possible radiation treatment. Treatment of advanced stage melanoma involves systemic chemotherapy and/or targeted treatment agents such as checkpoint inhibitor immunotherapy. **Rhabdomyosarcomas** are the most common vulvar sarcomas reported in pediatric patients. The second most common sarcoma of the vulva in pediatric patients is ES/PNET. Management of both vulvar sarcomas includes surgical excision, multi-agent chemotherapy, and radiation treatment. ES/PNET cases often present in the advanced stage and have a poor prognosis.

Condyloma acuminata are common, raised, verrucous lesions of the vulva that result from squamous cell proliferation associated with HPV infection (most common genotypes HPV 6 and 11). Prevention of HPV infection and subsequent formation of condyloma acuminata has been achieved through HPV vaccination. *In young children with condyloma acuminata, sexual abuse must be ruled out.* These lesions are benign and can spontaneously regress. If lesions are bothersome, treatment modalities consist of topical podophyllin resin, imiquimod, trichloroacetic acid, local cryotherapy, electrocautery, excision, and laser ablation. Imiquimod is approved by the U.S. Food and Drug Administration (FDA) for individuals 12 years of age and above.

CERVICAL MALIGNANCIES AND THEIR PREVENTION

In 2020, cervical cancer accounted for an estimated 604,000 new cancer cases and 342,000 deaths worldwide, making it the fourth most common cancer in females of all ages. From 2016 to 2020, the United States age-adjusted incidence of cervical cancer in females under age 20 was <0.1 per 100,000. The adolescent population is at greatest risk of HPV infection, which predisposes them to development of cervical cancer because about half of HPV infections occur before the age of 24. Thus prevention of initial infection in the adolescent population is critical to decreasing cervical cancer rates.

Primary prevention of HPV infection includes vaccination before the onset of sexual activity with the HPV vaccine. The HPV vaccine is approved for males and females ages 9-26. The Centers for Disease Control and Prevention (CDC) recommends two doses of the HPV 9-valent vaccine for patients before age 15 years (typically between ages 11-12) given 6-12 months apart (see Chapter 215). For those initiating the vaccine series at 15 years of age or older, three doses of the HPV vaccine should be given at 0, 1-2, and 6 months. Three doses are also recommended for patients who are immunocompromised (i.e., solid organ transplant recipient, HIV infection). Children with a history of sexual abuse should start immunization at age 9. In 2018, the FDA approved the use of the HPV 9-valent vaccine to include adults age 27-45 years; while the vaccine is not routinely recommended in this group, it may be given after shared clinical decision-making between a patient and their healthcare provider. The HPV vaccine can be administered despite prior infection with HPV. Cervical cancer screening via Papanicolaou (Pap) testing and HPV co-testing are important secondary prevention strategies. ACOG recommends cervical cancer screening for females starting at age 21 years in immunocompetent females regardless of onset of penetrative vaginal intercourse or primary prevention with HPV vaccination. Separate guidelines describe cervical cancer screening recommendations for immunocompromised individuals. Briefly, sexually active immunocompromised adolescents (such as solid organ or hematopoietic stem cell transplant recipients, patients with inflammatory bowel disease on immunosuppressive therapy, and patients with systemic lupus erythematosus) should start screening 1 year after of onset of sexual activity and thereafter annually for 3 years. If consecutive screening is negative, patients may follow the guidelines for immunocompetent females. HIV positive patients should start screening at age 21 regardless of sexual activity. Additionally, condom use, limiting the number of sexual partners, and smoking cessation are recommended to lower the risk for cervical cancer.

Because of the high prevalence of HPV infection in the adolescent population and because HPV-associated lesions typically regress, HPV screening should be not done before age 21 years in immunocompetent patients. If an inadvertent HPV test is done in adolescents, the results should not be acted on. Guidelines on management of the abnormal results of cervical cancer screening (Pap smear) for females age 21-24 are shown in Figure 590.7. Overall, data shows that prevention strategies such as widespread implementation of HPV vaccine translates into reduced incidence of cervical cancer in the future. Pediatric providers should educate patients and caregivers about benefits of the HPV vaccine and offer it at the recommended age.

Chapter 591

Vulvovaginal and Müllerian Anomalies

Laura L. Hollenbach, Emanuele Pelosi, Miranda Margetts, and Alla Vash-Margita

EMBRYOLOGY

The formation of a normal reproductive system occurs in the developing embryo and early fetus and is regulated by several processes, including cellular differentiation, duct elongation, fusion, resorption, canalization, and programmed cell death. Numerous Müllerian and/or vulvovaginal anomalies can result from interruption of the intricate sequence or functions of any one of these processes during formation of the reproductive system (Table 591.1). Genetic, epigenetic, and environmental factors all have been described as playing some role in these processes (Table 591.2).

Table 591.1 Congenital Müllerian Anomalies

MÜLLERIAN ANOMALY	DESCRIPTION
Agenesis	Absence of uterus, cervix, and upper portion of vagina
Hypoplasia	Incomplete development of uterus, cervix, and upper portion of vagina
Unicornuate uterus	One cervix and one uterine horn, the result of failure of one Müllerian duct to descend
Septate uterus	Septum dividing the uterus, partially or completely
Didelphic uterus	Two cervices, each associated with one uterine horn
Bicornuate uterus	One cervix associated with two uterine horns
OHVIRA (obstructed hemivagina and ipsilateral renal anomaly)	Double uterus with unilateral obstructed hemivagina and ipsilateral renal agenesis
CONDITIONS ASSOCIATED WITH MÜLLERIAN ANOMALIES	**DESCRIPTION**
Hydrocolpos	Accumulation of mucus or nonsanguineous fluid in the vagina
Hematocolpos	Accumulation of blood in the vagina
Hematometra	Accumulation of blood in the uterus
Hydrosalpinx	Accumulation of serious fluid in the fallopian tube, often a result of pyosalpinx

Table 591.2 Genetic Conditions Associated with Müllerian Anomalies

MODE OF INHERITANCE	SYNDROME	ASSOCIATED MÜLLERIAN DEFECT
Autosomal dominant	Camptobrachydactyly	Longitudinal vaginal septum
	Hand-foot-genital	Incomplete Müllerian fusion
	Denys-Drash	Persistent Müllerian duct derivatives
Autosomal recessive	McKusick-Kaufman	Vaginal atresia, transverse vaginal septum
	Johanson-Blizzard	Longitudinal vaginal septum
	Renal-genital-middle ear anomalies	Vaginal atresia
	Fraser	Incomplete Müllerian fusion
	Persistent Müllerian duct	Persistent Müllerian duct derivatives
	Urioste syndrome	Persistent Müllerian duct derivatives
Polygenic/ multifactorial	Mayer-Rokitansky-Küster-Hauser	Müllerian aplasia
X-linked	Persistent Müllerian duct	Persistent Müllerian duct derivatives

Phenotypic sexual differentiation, especially during formation of the vulvovaginal and Müllerian systems, is determined from genetic, gonadal, and hormonal influences (see Chapter 622). Gonadal development determines the hormonal production regulating progression or regression of the genital ducts and subsequently the external genitalia.

In 46,XY embryos, the *SRY* (sex-determining region of Y-chromosome) gene is one of the first regulators driving the formation of a testis from a primitive gonad and triggering the expression of a cascade of additional factors responsible for testis development as well as spermatogenesis. The testis begins to develop between 6-7 weeks of gestation, first with Sertoli cells, which produce anti-Müllerian hormone (AMH), followed by Leydig cells, which produce testosterone starting at approximately 8 weeks of gestation. The genital tract in both male and female embryos initially includes both the Wolffian and the Müllerian (or paramesonephric) ducts and begins to differentiate later than the gonads. The differentiation of the Wolffian ducts, the primordia of the male reproductive tract, is regulated by testosterone, and the local action of testosterone activates development of the epididymis, vas deferens, and seminal vesicle. Concomitantly, the anti-Müllerian hormone (or Müllerian-inhibiting substance) will cause regression of the Müllerian ducts. Further male genital duct and external genital structures depend on the conversion of testosterone to dihydrotestosterone. Failure of Müllerian duct regression results in retention of Müllerian derivatives in males. One example is **persistent Müllerian duct syndrome (PMDS)**, which is characterized by the presence of Müllerian structures usually associated with undescended testes. The majority of PMDS cases are due to pathogenic variants in the *AMH* gene or its receptor *AMHR2*. Other conditions featuring the presence of Müllerian derivatives in males are **Denys-Drash syndrome** (characterized by gonadal dysgenesis), nephropathy, and Wilms tumor, each caused by pathogenic variants in the *WT1* gene, and Müllerian derivatives-lymphangiectasia-polydactyly syndrome **(Urioste syndrome)**, a condition of unknown etiology.

In a 46,XX embryo, female sexual differentiation occurs about 2 weeks later than gonadal differentiation in the male. The regression of the Wolffian ducts results from the lack of local gonadal testosterone production, and the persistence of the Müllerian ducts results from the absence of anti-Müllerian hormone production. The Müllerian ducts continue to differentiate into the fallopian tubes, uterus, and upper one-third of the vagina without interference from anti-Müllerian hormone. Because the ovaries develop separately from the Müllerian ducts, females with Müllerian ductal anomalies usually have normal ovaries and steroid hormone production. There are complex interactions among the Wolffian, Müllerian, and metanephric ducts (the latter giving rise to the urinary tract) early in embryonic development, and normal development of the Müllerian system depends on such interaction. If this process is interrupted, coexisting Müllerian and renal anomalies are often discovered in the female patient at the time of evaluation. Although most Müllerian defects seem sporadic, familial recurrence or clustering has been observed, which strongly supports the influence of genetic factors. The molecular processes underlying the developmental program of the female reproductive tract are extremely intricate and are regulated by numerous gene products, including *WNT4*, *WNT5*, *WNT7A*, *WNT9B*, *LIM1*, *HNF1B*, *EMX2*, *PAX8*, and *HOX*. The WNT family plays crucial roles in both the formation and differentiation of the Müllerian ducts, providing inductive signals for the correct patterning of the developing tract. Homeobox genes *LIM1* and *HNF1B* are expressed in duct epithelial cells and are necessary for the development of the entire urogenital tract. Similarly, *EMX2* and *PAX8* play fundamental roles in the initial steps of urogenital development by regulating the formation of the Wolffian and Müllerian ducts. The family of *HOXA* genes is one of the most well described and comprises regulatory molecules that encode highly conserved transcription factors regulating the developmental axis of the female reproductive tract. These genes display a characteristic expression pattern along the developing reproductive tract (Fig. 591.1). A role for environmental factors in Müllerian anomalies has also been proposed. During gestation, the Müllerian ducts develop in an estrogen-free environment because of the presence of α-fetoprotein

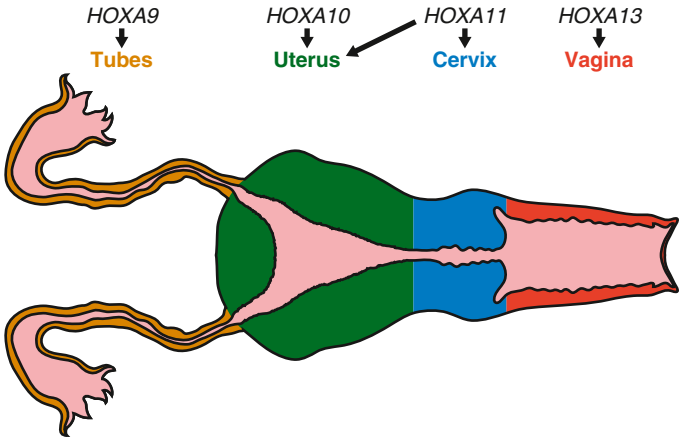

Fig. 591.1 Expression of *HOXA* genes in the developing Müllerian system. *(Adapted from Taylor HS. The role of HOX genes in the development and function of the female reproductive tract. Semin Reprod Med. 2000;18:81-89.)*

peptides that sequester estrogen molecules. Therefore attention has been turned to **endocrine-disrupting chemicals (EDCs)**, especially compounds with estrogenic activity, for their potential teratogenic role in Müllerian anomalies. A striking example is provided by diethylstilbestrol (DES), an estrogen agonist once given to pregnant patients to prevent pregnancy-related complications, including miscarriage. However, DES was found to induce epigenetic modifications and cause reproductive malformations, including a T-shaped uterus ultimately associated with higher spontaneous abortion rates.

By 10 weeks of gestation, the caudal portions of the Müllerian ducts fuse together in the midline to form the uterus, cervix, and upper vagina, in a Y-shaped structure, with the open upper arms of the Y forming the primordial fallopian tubes. Initially, the Müllerian ducts are solid cords that gradually canalize as they grow along and cross the mesonephric ducts ventrally and fuse in the midline. The Müllerian ducts caudally open into the **urogenital sinus,** where proliferation of the cells at the point of contact form the Müllerian tubercle. Cells between the Müllerian tubercle and the urogenital sinus continue to proliferate, forming the vaginal plate. At the same time of the midline fusion of the Müllerian ducts, the medial walls—forming the septum—begin to degenerate, forming the central cavity of the uterovaginal canal. Uterine septal resorption is thought to occur in a caudal to rostral direction and to be complete at approximately 20 weeks of gestation. This theory has been scrutinized because some anomalies do not fit the standard classification system; it is possible that septal resorption starts at some point in the middle and proceeds in both directions. At approximately 16 weeks of gestation, the central cells of the vaginal plate desquamate, and resorption occurs, forming the vaginal lumen. The lumen of the vagina is initially separated from the urogenital sinus by a thin hymenal membrane. The hymenal membrane undergoes apoptosis and central resorption and is usually perforate before birth.

EPIDEMIOLOGY

Müllerian anomalies can include abnormalities in portions or all of the fallopian tubes, uterus, cervix, and vagina (Fig. 591.2). True estimates of prevalence are difficult because of the varied presentations and asymptomatic nature of some of the anomalies, use of different diagnostic procedures, subjectivity of the diagnostic criteria, and the inconsistent interpretation of the classification of Müllerian anomalies.

It is estimated that Müllerian anomalies are present in 6.7% of the general female population. The prevalence of Müllerian anomalies increases in females with a history of adverse pregnancy outcomes or infertility: 8% of females who are infertile, 15% of females with primary amenorrhea, 16.7% of females with recurrent pregnancy loss, and 24.5% of females with both miscarriage and infertility have Müllerian defects.

Combinations of congenital anomalies in other organ systems are prevalent in females with Müllerian anomalies. Renal and musculoskeletal abnormalities are the most common. An estimated 29% of females with a renal anomaly will have an associated Müllerian abnormality. Concomitant congenital malformations are also prevalent in approximately 54.4% of females with **Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome**.

CLINICAL MANIFESTATIONS

Vulvovaginal and Müllerian anomalies can manifest at a variety of chronological time points during a female's life: from infancy, through childhood and adolescence, and during adulthood (see Table 591.1). The majority of external genitalia malformations manifest at birth, and often even subtle deviations from normal in either a male or female newborn warrant evaluation. Structural reproductive tract abnormalities can be seen at birth or can cluster at menarche or any time during a patient's reproductive life. Some Müllerian anomalies such as arcuate uterus are asymptomatic and have no implications clinically, whereas others can cause gynecologic, obstetric, or fertility issues.

Clinical manifestations and treatments depend on the specific type of Müllerian anomaly and are varied. There may be a pelvic mass, which may or may not be associated with symptoms. A mass bulging at the introitus or within the vagina indicates complete or partial **outflow tract obstruction.** A newborn can present with no evidence of a vaginal opening. An adolescent can present with cyclic pelvic pain either in association with **primary amenorrhea** or several months after the onset of menarche. Patients also may be asymptomatic until they present with miscarriage, pregnancy loss, or preterm delivery. When presentation is acutely symptomatic, emergency management may be required. Obstruction can result from a number of distinct anomalies, including an **imperforate hymen,** a **transverse vaginal septum,** a distal **vaginal agenesis,** or a **noncommunicating rudimentary horn.** As menstrual fluid accumulates proximal to the obstruction, the resulting **hematocolpos** (Fig. 591.3) and **hematometra** cause cyclic pain, pelvic mass and, occasionally, urinary dysfunction.

Prenatal or neonatal presentation of hydrometrocolpos from distal vaginal obstruction produces fluid accumulation in the vagina and uterus and presents as a lower abdominal mass with or without associated acute urinary tract obstruction. Hydrometrocolpos with polydactyly may be a result of two autosomal recessive disorders: **McKusick-Kaufman syndrome** (with associated congenital heart disease) and **Bardet-Biedl syndrome** (with associated obesity, learning disabilities, retinitis pigmentosa, and renal anomalies).

Adolescent patients can present with acute obstruction of the outflow tract because of a Müllerian anomaly, which requires emergency evaluation and surgical treatment. A small percentage of females can present with concomitant urinary retention caused by an altered urethral angle or pressure on the sacral plexus. Urinary hesitancy and incomplete emptying symptoms may be present before abdominopelvic pain increases from the obstruction in a patient of any age. Some menstruating adolescents may present with increasing cyclic abdominopelvic pain with their menses due to an obstructed hemivagina with uterine didelphys and ipsilateral renal agenesis (OHVIRA).

LABORATORY AND RADIOGRAPHIC FINDINGS

Laboratory evaluation in the setting of primary amenorrhea would include hormonal evaluation with assessment of the beta chorionic gonadotropin (beta-hCG) to rule out pregnancy, follicle-stimulating hormone (FSH), luteinizing hormone (LH), estradiol, and thyroid-stimulating hormone (TSH). Androgen evaluation may be done if virilization is seen on physical examination. The patient's karyotype may be obtained based on clinical presentation. Other hormonal testing might be indicated in specific cases. Several radiographic studies have been used, often in combination, to aid in diagnosis including ultrasound, hysterosalpingogram, sonohysterography (saline-infusion sonography), and MRI. The least invasive initial study for a young adolescent with cyclic pain, a pelvic mass, or amenorrhea is a transabdominal pelvic ultrasound; transvaginal pelvic ultrasound can be used in sexually active teens. MRI is considered the gold standard of care and best suited for complex anomalies because of its noninvasive, high-quality capabilities. MRI is the most sensitive and specific imaging technique used for evaluating Müllerian anomalies because it can image nearly all reproductive structures, blood flow, external contours, junctional zone resolution on T2-weighted images, and associated renal and other anomalies. MRI also has a high correlation with surgical findings because of its multiplanar capabilities and high spatial resolution. Three-dimensional ultrasound is another useful diagnostic tool and may be superior to traditional pelvic ultrasound and hysterosalpingogram but may not be easily accessible. Evaluation of the external contour of the uterus is important for differentiating types of uterine anomalies. This often requires a combination of radiologic modalities for the uterine cavity, external contour, and possible tubal patency. Diagnostic laparoscopy or hysteroscopy may be necessary depending on the presentation, but it is less common with advancement of MRI and other imaging modalities.

Diagnosis of Müllerian anomalies should include a complete history, including family history, with special attention to history of infertility for female relatives and renal and skeletal abnormalities. A complete physical exam including skeletal inspections for associated anomalies should be performed in addition to the radiology studies discussed above. Renal anomalies are noted in 30–40% and skeletal anomalies are associated in 10–15% of patients with Müllerian anomalies. Unilateral renal agenesis occurs in 15% of patients. The most common skeletal anomaly is scoliosis. Patients usually have a normal female karyotype (46, XX), and most malformations are sporadic, with a polygenic mechanism and multifactorial etiology (Table 591.2).

UTERINE ANOMALIES

Anomalous development of the uterus may be symmetric or asymmetric and/or obstructed or nonobstructed. Patients can present with primary amenorrhea or have either irregular or regular menstrual cycles. There may be an asymptomatic pelvic mass or dysmenorrhea. In adolescents and adults, pregnancy loss can cause the first suspicion of a uterine anomaly. Treatment is tailored to the specific anomaly.

Septate Uterus

Uterine septum (also known as a septate uterus) is the most common Müllerian anomaly, accounting for just over half of all abnormalities, and it is the most common structural uterine anomaly. After the two Müllerian ducts fuse in the midline, resorption must occur to unify the endometrial cavities; failure of this process results in some degree of uterine septum. It can vary in length from just below the fundus to beyond the cervix, depending on the amount of caudal resorption, but is generally defined as >1 cm. A septate uterus has a normal external uterine contour, which is what distinguishes it from a bicornuate or

didelphic uterus. An MRI can help delineate between a predominantly fibrous septum and a muscular or myometrial septum. There is insufficient evidence between an association of the uterine septum and infertility. Controversy still exists regarding whether a female should have such surgical removal of the septum as part of infertility treatment. A previous recommendation for surgical septum resection has been challenged by recent research, which demonstrated that septum resection did not improve live birth rates compared with expectant management. Limited data exist on the influence of the thickness and the length of the septum on the choice of treatment and reproductive outcomes. Differentiating precisely between bicornuate and septate uteri is extremely important to determine effective and safe treatment plans.

Bicornuate Uterus

Both Müllerian ducts develop and elongate in this anomaly, but they do not completely fuse in the midline. The vagina and external cervix are normal, but the extent of division of the two endometrial cavities can vary, depending on the extent of failed fusion between the cervix and the fundus. Bicornuate uteri are also associated with increased preterm labor and delivery, malpresentation, and miscarriage. This anomaly accounts for approximately 10–20% of Müllerian anomalies. Presently there is no pregnancy outcome data to provide evidence to support unification of a uterine duplication, and expectant management should be encouraged.

Unicornuate Uterus and Rudimentary Horns

A unicornuate uterus results from the normal creation of a fallopian tube, functional uterus, cervix, and vagina from one Müllerian duct. The other side fails to develop, resulting in either absence of the contralateral Müllerian duct or a rudimentary horn. There is a 30–40% association of renal anomalies. If a rudimentary horn is identified, it is important to determine whether functional endometrium is present (usually with T2-weighted MRI images). About two-thirds of rudimentary horns are noncommunicating, some with a fibrous band connecting the two structures. Rudimentary horns can also communicate with the contralateral uterus. A fertilized ovum can implant and develop within a rudimentary horn. Pregnancies within a rudimentary horn are incompatible with expectant management, and rupture of the horn could be life-threatening. Rupture tends to occur at a later gestation than with an ectopic pregnancy, and hemorrhage is severe. Patients with rudimentary horns with functioning endometrium can also present with pain caused by accumulating menses. Because the contralateral uterine horn has a normal outflow pathway, these patients present with cyclic pain and/or a mass, not primary amenorrhea. Pregnancies that arise in a unicornuate uterus are associated with increased preterm labor and delivery, malpresentation, and miscarriage. The patient should be counseled regarding these increased obstetric risks and be offered a preconception consult with a high-risk obstetric physician to best manage pregnancy.

Uterus Didelphys

A uterus didelphys is the result of a complete failure of fusion and represents 5% of Müllerian anomalies. There are two fallopian tubes, two separate uterine cavities, two cervices, and often two vaginal canals or two partial canals because of an associated longitudinal vaginal septum (75% of the time). At times, the longitudinal septum attaches to one sidewall and obstructs one side of the vagina (or hemivagina) (Fig. 591.4). Evaluation for renal anomalies should be pursued because they are common as well. The combination of uterine didelphys, obstructed hemivagina, and ipsilateral renal agenesis is a variant of the broad spectrum of Müllerian anomalies that is referred to as **obstructed hemivagina and ipsilateral renal anomaly (OHVIRA) syndrome** or **Herlyn-Werner-Wunderlich syndrome.** Adolescents with this disorder usually present with abdominal pain shortly after menarche. Although there still may be a risk of adverse pregnancy outcomes with a uterine didelphys (preterm labor, malpresentation), overall pregnancy outcomes are good and are associated with less risk than in other uterine anomalies, but preconception counseling and a consult with a high-risk obstetric physician should be offered.

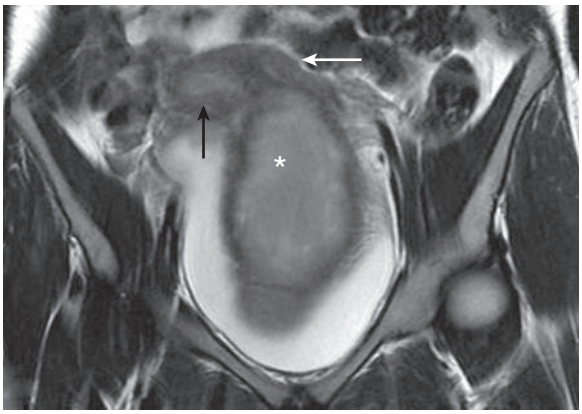

Fig. 591.4 Coronal MRI demonstrating large volume hematocolpos (*asterisk*) in a case of uterine didelphys with longitudinal vaginal septum. *Black arrow,* obstructed right uterus resulting in hematometra; white arrow, unobstructed left uterus.

Arcuate Uterus

An arcuate uterus is a uterine cavity that has a small midline septum from lack of a small amount of resorption (<1 cm), and sometimes a slight indentation of the uterine fundus. An arcuate uterus might represent a variant of normal rather than a Müllerian anomaly. Untoward pregnancy outcomes are rare, and *surgical correction is not warranted.*

Treatment

Treatment depends on the specific diagnosis and should be determined by a clinician with expertise in management of Müllerian anomalies. Most treatments focus on relief of obstruction and consider a patient's reproductive goals and history. Hysteroscopic surgical resection of the uterine septa was widely employed in the past, but a Cochrane systematic review shows no evidence to support surgical excision of the septum. Each individual case should be discussed with the patient, and a shared decision approach should be exercised based on the evidence of the benefit of such surgery.

A noncommunicating horn with functional endometrium should be resected to improve the quality of life or prevent future complications. Opinions vary as to whether resection of a communicating horn or one with no functional endometrium is warranted. Any surgical resection of a rudimentary horn requires careful surgical technique to protect the ipsilateral ovarian blood supply and the myometrium of the remaining unicornuate uterus.

Although metroplasty (also known as the Strassman unification method) had been employed with didelphic and bicornuate uteri in the past, currently most clinicians feel there is not enough evidence to support such a complicated procedure. Any obstruction to the outflow tract must be relieved; this can necessitate creation of a vaginal window or excision of the vaginal septum.

VAGINAL ANOMALIES

Abnormalities of the Hymen

An imperforate hymen is the most common obstructive anomaly, and familial occurrences have been reported (see Fig. 591.1). Its incidence is approximately 1 in 1,000. In the newborn period and early infancy, it may be diagnosed by a bulging membrane caused by a **mucocolpos** from maternal estrogen stimulation of the vaginal mucosa. This can eventually reabsorb if it is not too large or symptomatic. More often, it is diagnosed at the time of menarche when menstrual fluid accumulates **(hematocolpos)**. The clinical manifestations often are a bulging blue-black membrane, pain, and/or primary amenorrhea in a setting of normal secondary sex

characteristics. A mucocolpos or hematocolpos may obstruct urinary outflow. Depending on the circumstance, patients might have cyclic abdominal pain or a pelvic mass. Other hymenal variations can occur such as annular (most common) or crescentic configurations. In some cases, the hymenal membrane does not undergo complete resorption or perforation, resulting in a microperforate, cribriform, or septate-shaped hymen. Age of recognition varies, but hymenal variations are often discovered after menarche when it is difficult for an adolescent to place or remove a tampon.

Congenital Absence of the Vagina and Mayer-Rokitansky-Küster-Hauser Syndrome

Vaginal agenesis or atresia results when the vaginal plate fails to canalize. On physical exam, it appears as an extremely foreshortened vagina, sometimes referred to as a *vaginal dimple.* Isolated (partial) vaginal agenesis involves an area of aplasia between the distal vaginal portion and a normal upper vagina, cervix, and uterus. These patients present with cryptomenorrhea and eventually have cyclic pain caused by obstructed outflow. Each subsequent menses distends the upper vagina with menstrual blood. On initial presentation it may be confused with a low transverse septum or imperforate hymen, and therefore clear delineation of the anomaly with appropriate imaging is critical before attempting surgical repair. Surgical repair and reconstruction are complicated and best performed with consultation of specialists with expertise in managing these anomalies.

Uterine and **vaginal agenesis/aplasia** often occur together because of their close association during development, when Müllerian ductal development fails early in the process. The most common cause of uterovaginal agenesis/aplasia is **Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome,** with an incidence reported at 1 in 5,000 female births. The etiology is believed to be multigenetic and multifactorial. This condition is present at birth but often not diagnosed until mid-adolescence. Females with MRKH syndrome have normal ovarian function and undergo normal secondary sexual development at puberty but do not have a menstrual cycle (primary amenorrhea). The range and severity of MRKH syndrome can vary greatly and the disorder may be type I (isolated uterovaginal anomaly) or type II, involving additional organ systems, including the renal, skeletal, auditory, or cardiac systems. Absence of the vagina and uterus has significant anatomic, physiologic, and psychologic implications for the patient and family, and counseling is recommended. Although most patients with Müllerian agenesis have small rudimentary Müllerian bulbs, approximately 2–7% of patients can have active endometrium within these uterine structures. These patients will often present with cyclic pelvic pain. MRI may be necessary to determine if any small uterine remnant is present (often located on the pelvic sidewall or near the ovaries) and to clearly delineate the anomaly. Laparoscopy is not necessary to diagnose Müllerian agenesis but may be useful in the treatment of rudimentary uterine horns, particularly when removal of obstructed uterine structures or associated endometriosis is indicated for pelvic pain. Any diagnosis of Müllerian agenesis must be differentiated from **androgen insensitivity**; karyotype, serum testosterone levels, and pubic hair distribution help distinguish between the two because testosterone levels and adrenarche will be normal in females with MRKH syndrome.

Abnormalities involving other organ systems occur in association with MRKH type II, or Müllerian duct aplasia, renal dysplasia, and cervical somite anomalies (MURCS) association. The most common are urinary tract anomalies (15–40%) primarily involving unilateral absence of a kidney; a horseshoe or pelvic kidney; and skeletal anomalies (5–10%), which primarily involve vertebral development but can also include cardiac anomalies and hearing impairment, and these should be evaluated at the time of diagnosis.

Longitudinal Vaginal Septum

Longitudinal vaginal septa represent failure of complete canalization of the vagina. These often occur in the presence of uterine anomalies. These septa can vary in length from the cervix or cervices caudally and at times extend fully to the introitus. Patients may report menstruation that overflows their tampon because they only have a single side of the vagina occluded.

Transverse Vaginal Septum (Vertical Fusion Defects)

Vertical fusion defects can result in a transverse septum, which may be imperforate and associated with hematocolpos or hematometra in adolescents or with mucocolpos in infants. These are uncommon anomalies, reportedly found in 1 in 80,000 females. Patients commonly present with primary amenorrhea and cyclical abdominal pain around the time of menarche. However, patients who have a small opening in the transverse septa might present with prolonged vaginal drainage and mucopurulent or sanguineous discharge. Transverse vaginal septa can vary in location (15–20% occur in the lower third, but the majority are in the middle or upper third of the vagina) and thickness (but are generally ≤1 cm). High locations, thicker septa (>1 cm), and narrow vaginal orifices present challenging surgical cases.

Transverse vaginal septa may be associated with other congenital anomalies, although this occurs less often than with Müllerian agenesis. These patients have a functional normal uterus, unlike females with MRKH syndrome. In the majority of cases with outflow obstruction, there is also an increased incidence of endometriosis secondary to retrograde menstruation.

Evaluation of transverse vaginal septa includes careful pelvic examination and pelvic imaging, usually with MRI and ultrasound, to delineate the anatomic abnormalities. MRI is especially helpful to determine the thickness of the septum and verify the presence of a cervix for surgical planning. Diagnosis and treatment plans should be made as soon as possible after menarche because significant accumulation of hematometra and/or hematosalpinx could affect future reproductive success by negatively affecting uterine and/or tubal function. Alternately, menstrual suppression is another option to provide adolescent patients time to mature psychologically and participate in the treatment phase of the resection of the transverse septum.

Treatment

An imperforate hymen requires resection to prevent or relieve the outflow tract obstruction. Many approach it with a horizontal, lunate, or cruciate incision; excision of excess tissue; and approximation of the mucosal edges. Repair should be done at time of diagnosis if the patient is symptomatic, although the lesion may be repaired any time during infancy, childhood, or adolescence. Elective surgery with general anesthesia is discouraged in the very young. Elective hymenal excision in the prepubertal child may have improved healing if topical estrogen is placed at the site postoperatively. Elective excision of an imperforate hymen can be performed after onset of thelarche but ideally before menses. Variants in the hymen with microperforations or hymenal septa may interfere with tampon use, and resection of this tissue is usually electively performed using local anesthesia or sedation according to patient preference.

Treatment of congenital absence of the vagina is usually delayed until the patient is mature enough to discuss and participate in the treatment. The nonsurgical approach using vaginal dilation is the most common first-line therapy because it is safer, patient-controlled, more cost effective than surgery, and successful in 90–96% of patients. If done correctly, it is possible to achieve a functional vaginal length (6-8 cm), width, and physiologic angle for intercourse in about 6-8 months of therapy. When the ultimate size that accommodates coitus is reached, the patient must use the dilator or have coitus with a frequency that maintains adequate length.

Surgical approaches require expertise and often some postoperative vaginal dilation to ensure a functional result. Controversy exists as to when creation of a neovagina should occur. Surgery is indicated at any age if there is a medical indication such as mucocolpos that causes urinary obstruction or any other surgical emergency.

However, literature reports better outcomes with delaying creation of the neovagina to when the patient is interested in sexual activity and can participate in the decision to have surgery and in their own postoperative recovery. There is no consensus as to the best surgical option. Surgery should be reserved for the rare patient for whom primary dilator therapy was unsuccessful or for those who request surgery after a thorough informed consent. Referral to centers with expertise should be offered.

Future options for having children should be addressed, including adoption and gestational surrogacy. Assisted reproductive techniques using ovum retrieval, fertilization, and implantation of embryos into gestational carriers (surrogates) have been successful. Female offspring usually have normal reproductive tracts. Uterine transplantation has resulted in live births, but this procedure remains rare. Opportunities for family building enable patients and their families to appreciate the potential for becoming parents and help cope with the diagnosis and its implications.

Surgical resection of transverse vaginal septa should be undertaken only by surgeons with expertise. Some surgeons advocate waiting for one or more menstrual cycles or using preoperative dilators from below to increase the depth and circumference of the distal vagina and to allow menstrual blood to accumulate and dilate the upper portion of the vagina. Complete resection of the septum, with primary anastomosis of the upper and lower mucosal segments, should be attempted. A vaginal stent is sometimes placed postoperatively in the vagina to maintain patency and allow squamous epithelialization of the upper vagina and cervix. Follow-up dilation may be necessary after the stent is removed. Careful preoperative assessment is important because surgeons who begin a case believing they are operating on an imperforate hymen can find themselves in entirely different and more complex surgical planes. Regardless of the approach, vaginoplasty is often best deferred until the patient is mature and physically and psychologically prepared to participate in the healing process and postoperative dilator treatments. It can be challenging to differentiate a low transverse septum from distal vaginal agenesis. If the distal vagina cannot be palpated close to the anal sphincter by rectal examination, the patient should be allowed to continue to menstruate to distend the upper vagina to within 3 cm of the anal sphincter. This enables the surgeon to dissect up to the lower vagina and perform a pull-through procedure, anastomosing the upper vagina to the introitus. Proper timing and surgical execution yield excellent outcomes.

Longitudinal vaginal septa themselves do not lead to adverse reproductive outcomes but may be symptomatic in a patient, causing dyspareunia, traumatic bleeding with intercourse, difficulties with tampon insertion, or impedance during vaginal birth. Such complaints can warrant a resection of the vaginal septa. A carefully planned incision and resection of the oblique septum to maintain patency of the upper tract is performed in cases of OHVIRA (Herlyn-Werner-Wunderlich syndrome).

CERVICAL ANOMALIES

Congenital atresia or complete agenesis of the uterine cervix is extremely rare and often manifests at puberty with amenorrhea and pelvic pain. It is associated with significant renal anomalies in 5–10% of patients. A pelvic MRI is often warranted to completely define the abnormality. Usually, pain and obstruction are significant, and a hysterectomy is necessary. Attempts to reconnect the uterus to the vagina are rarely successful and are associated with significant morbidity and reoperation rates. The ovaries usually have normal function, and future reproduction can still occur using in vitro fertilization and a gestational carrier.

VULVAR AND OTHER ANOMALIES

Complete Vulvar Duplication

Duplication of the vulva is a rare congenital anomaly that is seen in infancy and consists of two vulvas, two vaginas, and two bladders, a didelphic uterus, a single rectum and anus, and two renal systems. Treatment is individualized and requires a multidisciplinary approach with gynecology, urology, and plastic surgery.

Labial Asymmetry and Hypertrophy

With the onset of puberty, the labia minora enlarge and grow to an adult size. A female's labia can vary in size and shape. Asymmetry of the labia, where the right and left labia are different in size and appearance, is a normal variant. Some patients are uncomfortable with what they perceive to be their asymmetric or enlarged labia minora and complain about self-consciousness and discomfort while wearing tight clothing, exercising, or having sex. The mature labia minora can protrude beyond the labia majora, and this normal variant can be functionally or psychologically bothersome. Local irritation, problems of personal hygiene with bowel movements or menses, or interference with sexual intercourse or while sitting or exercising have resulted in requests for labial reduction. Patients may find online procedures advertised to reduce uneven or enlarged labia minora. Education and reassurance are very important for adolescents who have concerns about the appearance of their labia. Surgery is not recommended unless there is significant congenital malformation or persistent symptoms directly related to the labia. Surgical alteration of the labia that is not necessary to the health of the adolescent less than age 18 is considered a violation of federal law in the United States. Complications of labial surgery include loss of sensation, keloid formation, and dyspareunia.

Clitoral Abnormalities

Agenesis of the clitoris is rare. Clitoral duplication has been reported, often associated with cloacal and bladder exstrophy. Exposure to male hormones will result in clitoral enlargement and is often a sign of a difference of sex development, a testosterone-producing tumor, or use of exogenous steroids.

Cloacal Anomalies

Cloacal anomalies are rare lesions representing a common urogenital sinus into which the gastrointestinal, urinary, and vaginal canals all exit. Usually there is an abnormality in all or some of the processes of fusion of the Müllerian ducts, development of the sinovaginal bulbs, or development of the vaginal plate. The single opening (cloaca) requires surgical correction, which is often done very early in life, preferably by a multidisciplinary pediatric surgical team.

Ductal Remnants

Even though the opposite duct regresses in both sexes, there can sometimes be a small portion of either the Müllerian or Wolffian duct that remains in either the male or female, respectively. Such remnants can form cysts, which are what make them clinically visible during surgery, examination, or imaging. Most do not cause pain, although torsion of some has been reported, and small asymptomatic ones usually do not require resection. The most commonly reported are hydatid of Morgagni cysts (remnant of a Wolffian duct arising from the fallopian tube), cysts of the broad ligament, and Gartner's duct cysts, which can form an ectopic ureter or be found along the cervix or vaginal walls.

Chapter 592

Gynecologic Care for Adolescents with Special Needs

Elisabeth H. Quint and Melina L. Dendrinos

Adolescence presents challenges for all children and their families but particularly for teens with special needs and their families. The start of menstrual periods, the mood changes associated with puberty, the concerns about sexual activity with possible unplanned pregnancies, and worries about safety and abuse present teens with disabilities and their families with additional issues.

SEXUALITY AND SEXUAL EDUCATION

Adolescents with special needs can have physical and/or developmental disabilities. These young people are often seen as asexual by their families, care providers, and society and, therefore, sexual education might not have been provided or considered necessary, even though physically disabled teens report being sexually active. The care provider needs to assess the teen's knowledge of anatomy and sexuality, gender identity, social knowledge of relationships, ability to consent to sexual and intimate activities, and sexual orientation, as well as any previous sexual activity. Education regarding HIV and other sexually transmitted infections, disease prevention, and contraception, including emergency contraception, should be offered at a developmentally appropriate level.

ABUSE

The risk for sexual abuse in teens with disabilities is difficult to estimate. Teens with disabilities may be more at risk for isolation and depression during adolescence, leading to vulnerability.

Teens with disabilities are just as sexually active or even more so than their nondisabled counterparts, but more of their activity is nonvoluntary. Patients with cognitive impairment are often taught to be cooperative, which may make them more vulnerable to coercion. Abuse prevention education can include the No! Go! Tell! model. For teens with limited verbal capacity or developmental delay, abuse may be very hard to detect; thus screening for abuse is extremely important. The care provider needs to be vigilant in looking for signs on physical exam, such as unexplained bruises or scratches, or changes in behavior, such as regression, which may be indications of sexual abuse (see Chapters 17.1 and 162).

PELVIC EXAMINATION

An internal pelvic exam is rarely indicated in teens, as Papanicolaou smears are not recommended to start until age 21. An external genital exam can be performed if there are vulvovaginal issues such as discharge, irregular bleeding, suspicion for abuse, or foreign body. The frog-leg position is usually favored over the use of stirrups. If the vagina or cervix needs to be clearly visualized for a medical indication, an exam under anesthesia by a gynecologist can be considered. Testing for sexually transmitted infections can be accomplished by urine testing or vaginal swabs (see Chapter 163).

MENSTRUATION

Irregular menstruation is common in teenagers, especially during the first 5 years after menarche, because of immaturity of the hypothalamic-pituitary-ovarian axis and subsequent anovulation (see Chapter 159). Several conditions in teens with disabilities are associated with an even higher risk of irregular cycles. Thyroid disease is more common in teens with Down syndrome. There is a higher incidence of reproductive issues, including polycystic ovarian syndrome, in teens with epilepsy or those taking certain antiepileptic drugs. Antipsychotic medication can lead to hyperprolactinemia, which can affect menstruation.

For teens with disabilities, the main issue with menstrual cycles, whether they are regular, irregular, or heavy, is the impact of menstruation on the patient's life, health, and ability to perform their normal activities. The history should focus on this aspect, and menstrual calendars may be helpful to document the cycles, behavior, and impact of treatments. Most adolescents who self-toilet can learn to use menstrual hygiene products appropriately. Menstrual underwear have been very helpful for many teens. Premenarchal anticipatory guidance is recommended, but hormonal treatment before menarche should be avoided.

The medical evaluation for abnormal bleeding is the same as for all teens (see Chapter 159.2). Areas requiring particular attention for the teen with special needs are the consideration of menstrual suppression for hygiene or cyclical behavioral issues, like crying, tantrums, or withdrawal.

Treatment of Menstruation

If the impact of cycles, whether regular, irregular, or heavy, on the patient's well-being is significant (often documented through menstrual or behavioral charting for several months), the care provider, patient, and family may decide on menstrual intervention. Menstrual regulation or suppression is not much different from that in the nondisabled teenager in general, although there are some special considerations. Goals for treatment can be to decrease the heaviness of flow, regulate cycles to predictable bleeding, relieve pain or cyclical behavior symptoms, provide contraception, and/or obtain amenorrhea. Menstrual suppression leading to complete amenorrhea is usually difficult to obtain and infrequent scheduled bleeds may be easier to manage than unpredictable spotting, a common side effect of any suppressive treatment, for certain patients. After treatment has started, providers should continue to monitor outcomes, ideally with continued menstrual or behavioral calendars to assess efficacy and need for changes.

Nonhormonal Methods

If menorrhagia or dysmenorrhea (occasionally leading to cyclical behavior changes in nonverbal teens) is the main concern, the patient can be started on scheduled nonsteroidal anti-inflammatory drugs. These can decrease the flow by up to 20% in adequate doses and can be used alone or in combination with other treatments. Use of tranexamic acid during the first 5 days of menses can also be used to decrease heavy bleeding.

Estrogen-Containing Methods

All estrogen-containing medication can be used in a cyclical fashion with scheduled medication breaks to allow for monthly menses; in a more extended fashion, where the active hormonal method is used for 3 months with a scheduled break; or a more flexible schedule, where the hormones are used until bleeding starts, and a break for withdrawal bleeding can be done at that time.

Oral Contraceptives

Cyclical oral contraceptives usually lead to regular, lighter cycles with less cramping. Continuous daily use of active oral contraceptives can suppress cycles, with amenorrhea rates improving with time. Some unpredictable spotting is usually unavoidable, and often teens with special needs prefer to have predictable cycles several times a year. Chewable oral contraceptives are available for those with swallowing issues.

Contraceptive Ring
The contraceptive ring can be used in a pattern of 3 weeks in and 1 week out, but it can also be used (off-label) in a continuous 4-week pattern, which leads to less bleeding. However, the contraceptive ring may be difficult to use for a teen with dexterity problems, and help with placement has obvious privacy issues.

Contraceptive Patch
The weekly patch can also be used in a cyclic or extended fashion. Some teens with developmental disabilities and sensory issues may remove their patch erratically, and placement out of reach (e.g., on buttocks or shoulder) is advised.

Estrogen Use, Venous Thromboembolism, and Mobility Issues
Whether immobility and wheelchair use can lead to an increased risk of venous-thromboembolic events (VTEs) in association with estrogen-containing contraceptives remains controversial. The risk of thrombosis in young females is very low overall, but the use of combined hormonal contraceptives by adolescents who are immobile or who have limited mobility has not been studied. Immobility per se is not a contraindication to estrogen-containing contraceptives; however, it may increase the risk of VTE. There are limited data to support the concern that higher-dose oral estrogen and the third- and fourth-generation progestin preparations may have a higher risk for VTE. It is important to assess for other VTE risk factors in the patient's history before initiating estrogen therapy. Careful use of lower-dose (30 or 20 μg) ethinyl estradiol preparations after appropriate counseling may be advisable, and third-generation progestin combinations should only be used if second-generation medications have failed.

Progestin-Only Methods
Intramuscular Medroxyprogesterone Acetate
Intramuscular depot medroxyprogesterone acetate (DMPA) has long been used for menstrual suppression. Two issues are particularly relevant to teens with disabilities. Studies documenting a decrease in bone density associated with longer-term use of DMPA and a black box warning by the FDA have raised concerns about use of these products in young females, although research indicates that the bone density improves after the medication is stopped. For teens with mobility issues or those with very low body weight who are already at risk for low bone density, decreased bone density is a real concern, although the risk of fractures is unclear. Adequate calcium and vitamin D is recommended. The second issue for teens with mobility issues is weight gain associated with DMPA, especially among obese teens, which can lead to transfer and mobility issues. The potential health risks associated with the effects of DMPA on bone density and weight must be balanced against the need for menstrual suppression and the likelihood of unintended pregnancy. Weight should be monitored closely. Routine bone density scanning (DEXA) is not recommended in adolescents.

Oral Progestins
Continuous oral progestins can also be very effective in obtaining amenorrhea. The contraceptive progestin-only pill (norethindrone 0.35 mg) can cause significant irregular spotting, so if full suppression is the goal, then other progestins can be used daily, such as drospirenone 4 mg, norethindrone 2.5 or 5 mg, or micronized progesterone 200 mg.

Progesterone Intrauterine Device
The 8-year levonorgestrel-intrauterine device is used for many teenagers for contraception, as well as heavy menses and dysmenorrhea (off-label use). Teens with special needs might require anesthesia for insertion if the exam is difficult because of discomfort, contractures, or a narrow vagina. Checking for strings in a clinic setting may be challenging; however, the intrauterine device location can be confirmed by sonography. There may be a significant amount of irregular bleeding and spotting in the first several months, but there is 20% rate of amenorrhea after insertion and up to 50% rate of amenorrhea after 1 year of use. The bleeding profile of the smaller and lower dose 3-5 year levonorgestrel-intrauterine devices may not be as helpful for menstrual suppression; the amenorrhea rates from the initial studies by the manufacturer are 8–12% at 1 year, but more studies are needed.

Implants
Progestin subdermal implants have relatively low amenorrhea rates and higher rates of unscheduled bleeding; therefore they are often less desirable for menstrual suppression for teens with special needs. They also require significant patient cooperation for insertion.

Hormones and Antiepileptic Drugs
Certain enzyme-inducing seizure medications can interfere with estrogen-containing contraceptives, change their contraceptive effectiveness, and/or lead to intermittent bleeding. Higher estrogen dose or shorter injection intervals for DMPA may be considered. The only antiepileptic medication that is affected by combined oral contraceptives is lamotrigine; consequently, the dose of that medication may need to be adjusted if used in conjunction with hormones, so discussion with other providers is needed.

Surgical Methods
Surgical procedures, such as endometrial ablation, a procedure where the lining of the uterus is surgically removed, and hysterectomy, are available for treatment of abnormal and heavy bleeding in adults, but they should only rarely be used in extreme situations for teenagers where all other methods have failed, and the patient's health is severely compromised by their cycles. Endometrial ablation only leads to amenorrhea approximately 30% of the time, has a higher failure rate in females younger than 40 years of age, and is not recommended in the adolescent population. Ethical considerations around these methods leading to infertility and consent issues are complicated, and state law varies on this topic.

CONTRACEPTION
See also Chapter 160.

The menstrual management methods discussed above can also be used for contraception. A request for birth control, especially coming from a caregiver and not the teen, requires an evaluation of the teen's ability to consent to sexual activity and the safety of their environment. The method chosen should be the safest method for their situation with the highest protection rate. Therefore a long-acting reversible contraceptive method may be advisable. Sexually transmitted infections and condom use should be addressed with the teen and specific guidelines on how to obtain condoms and negotiate their use may be needed. A discussion about emergency contraception is recommended, as well as ways to help the teen obtain this if indicated.

Chapter 593

Female Genital Mutilation

Deborah Hodes and Sarah M. Creighton

Female genital mutilation (FGM) is a worldwide human rights issue that constitutes violence against women and children. It is defined by the World Health Organization (WHO) as procedures that involve partial or total removal of the external female genitalia, or other injury to the female genital organs for nonmedical reasons. In September 2015 the United Nations adopted the Sustainable Development Goals (SDGs), which includes the elimination of FGM by 2030. UNICEF (United Nations International Children's Emergency Fund) estimates that at least 200 million women and young females in 30 countries have undergone FGM. There has been a decline in the prevalence of FGM, but current trends suggest that actual numbers will rise because of population growth. FGM is commonly performed in Africa, the Middle East, and Asia, with data suggesting an estimated 40 million young females in Indonesia have undergone FGM. According to the UNICEF report 2020, the COVID-19 pandemic has caused disruption to the protection of young females from FGM leading to an estimated 2 million additional cases than would otherwise have occurred.

The migration of FGM-practicing communities means that FGM is a global problem, although there are scant data on the practice in high-income countries. Despite estimates, a British pediatric surveillance unit study found low numbers presenting to pediatricians; there were very few illegal cases and only one successful prosecution in the UK by 2021. FGM is almost always carried out on children, and pediatricians must be familiar with the identification of FGM, the impact on health, and ways to protect young females from this widespread form of child abuse.

FGM has no health benefits and can cause lifelong damage to physical and psychologic health. The WHO has classified FGM into four types, depending on the extent and type of genital tissue removed (Table 593.1). The traditional practitioner performs FGM without anesthetic or sterile conditions, and in some countries, it is done as part of a wider ritual related to early child marriage. The child is restrained whilst the external genitalia are removed or damaged using a knife, scalpel, or other sharp instrument. An increasing number of procedures are performed at a younger age, and the United Nations Population Fund (UNFPA) estimates that around one in five young females subjected to FGM were cut by a trained healthcare provider. Table 593.2 lists potential risks and protective factors for FGM.

COMPLICATIONS

Immediate complications of FGM include hemorrhage and infection. Deaths have been reported, although numbers are unknown. Infections include immediate wound infection, tetanus, and gangrene. FGM has been implicated in the transmission of blood-borne infections because of the use of shared and unsterile tools. Although procedure-related blood-borne infection is probable, there are no good studies to confirm this; infections such as hepatitis B and HIV are endemic in areas where FGM is prevalent. FGM leads to obstetric, gynecologic, and psychologic consequences in adult women. Gynecologic symptoms include painful and unsightly scarring, clitoral cysts, and recurrent urinary infections. Menstrual difficulties and infertility are reported, although the underlying mechanisms of these are unclear apart from type 3 FGM, where the vagina is narrowed. FGM damages sexual function by removing sensitive sexual tissue and narrowing the vagina. Mental health problems such as anxiety and depression have been linked to FGM. FGM also has a detrimental impact on obstetric outcomes for both the mother and baby, leading to increased risks of postpartum hemorrhage, perineal trauma, and perinatal death.

Table 593.1 Summary of WHO Classification of FGM

Type 1: Clitoridectomy: Partial or total removal of the clitoris (a small sensitive and erectile part of the female genitals) and, in rare cases, only the prepuce (the fold of skin surrounding the clitoris).
Type 2: Excision: Partial or total removal of the clitoris and labia minora with or without removal of the labia majora (the labia are the "lips" that surround the vagina).
Type 3: Infibulation: Narrowing of the vaginal opening through the creation of a covering seal. The seal is formed by cutting and repositioning the labia minora or majora with or without removal of the clitoris.
Type 4: Other: All other harmful procedures to the genitalia for nonmedical reasons (e.g., pricking, piercing, incision, scraping, and cauterizing the genital area).

From the World Health Organization Female Genital Mutilation Fact Sheet. https://www.who.int/news-room/fact-sheets/detail/female-genital-mutilation

CLINICAL MANAGEMENT OF FGM

Most pediatricians will not see a child who is acutely unwell due to FGM. Management of FGM in the acute situation should include assessment for blood loss, sepsis, and urinary retention and treatment with antibiotics, analgesia, tetanus toxoid, and urinary catheterization. Pediatricians are more likely to see a child in whom FGM has been found during the investigation of other often vague symptoms as well as recurrent urinary tract infections and vulvovaginitis. FGM may also be alleged by the child or family member, or concerns may be raised by other health and social care professionals, particularly if the mother herself has undergone FGM and has little support from the husband (see Table 593.2). Pediatricians may be asked to confirm FGM on genital examination; it should be performed using a colposcope for magnification and video documentation, which can be used for peer review and in a court of law. The examination must be done in a sensitive and gentle manner by an appropriately trained clinician and in an age-appropriate setting. It is often assumed that FGM will be obvious. However, whilst type 3 FGM, in which the vagina is sealed, is usually easy to detect, other types of FGM can be more difficult to diagnose. This is particularly true for type 4 FGM, which may involve a prick or small scratch on or adjacent to the clitoris and may heal without a trace. General assessment of the child's health should include screening for blood-borne viruses.

If the child has type 3 FGM, then a deinfibulation procedure will be required at some point. Deinfibulation is a minor surgical procedure to divide any scar tissue that obscures the vaginal introitus. If the child is asymptomatic, this can be deferred until adolescence or before sexual activity. Deinfibulation procedures are usually performed under a local anesthetic in adult women, but in children a brief general anesthetic is more appropriate. The psychologic impact of FGM on a child may be severe, and flashbacks and nightmares have been reported. Input from a child psychologist or psychotherapist with experience in working with children with FGM and their families should be available. If a child is confirmed to have FGM, then other children in the family may be at risk, and local safeguarding pathways should be activated. Pediatricians must be advocates against FGM and contribute to training

Table 593.2 Factors That Influence Whether or Not a Child May Have FGM

RISK FACTORS
Mother or sister cut
Isolated mother
Grandmother influential
Little information and discussion about FGM
PROTECTIVE FACTORS
Discussing with husband or friend
Knowing the law has been implemented
TV, global debate, media
Men's attitude and knowledge
Knowing an uncut person

healthcare workers who may treat patients. In developed countries, there are concerns that the emphasis on prosecution has stigmatized and alienated communities in the diaspora who have abandoned the practice; because of this, experts emphasize the need for a more community-centric approach to current and future FGM prevention efforts.

The Endocrine System

PART XXIV

Section 1

Disorders of the Hypothalamus and Pituitary Gland

Chapter 594

Hormones of the Hypothalamus and Pituitary

Eric I. Felner and Briana C. Patterson

The pituitary and hypothalamus are the major regulators of an elaborate hormonal system. The pituitary gland receives signals from the hypothalamus and responds by sending pituitary hormones to target glands. The target glands produce hormones that provide negative feedback at the level of the hypothalamus and pituitary (Figs. 594.1 and 594.2). This feedback mechanism enables the pituitary to regulate the amount of hormone released into the bloodstream by the target glands. The pituitary's central role in this hormonal system and its ability to interpret and respond to a variety of signals have led to its designation as the *master gland*. Table 594.1 lists the hypothalamic and pituitary hormones and their functions.

ANATOMY

The pituitary gland is located at the base of the skull in a saddle-shaped cavity of the sphenoid bone called the **sella turcica**. The bony structure protects and surrounds the pituitary bilaterally and inferiorly. The dura, a dense layer of connective tissue, forms the roof of the sella turcica. An external layer of the dura continues into the sella turcica to form its lining. As a result, the pituitary is extradural and is not normally in contact with cerebrospinal fluid. The pituitary gland is connected to the hypothalamus by the pituitary stalk. The pituitary gland is composed of an anterior (adenohypophysis) and a posterior (neurohypophysis) lobe. The anterior lobe constitutes approximately 80% of the gland.

EMBRYOLOGY

The anterior pituitary gland originates from Rathke's pouch as an invagination of the oral ectoderm. It then detaches from the oral epithelium and becomes an individual structure of rapidly proliferating cells. By 6 weeks of gestation, the connection between **Rathke's pouch** and oropharynx is completely obliterated. The pouch establishes a direct connection with the downward extension of the hypothalamus, which gives rise to the pituitary stalk. Persistent remnants of the craniopharyngeal duct, the original connection between Rathke's pouch and the oral cavity, can develop into adamantinous **craniopharyngiomas** (see Chapter 546).

VASCULAR SUPPLY

The arterial blood supply of the pituitary gland originates from the internal carotid via the inferior, middle, and superior **hypophyseal arteries**. This network of vessels forms a unique portal circulation connecting the hypothalamus and pituitary. The branches of the superior hypophyseal arteries penetrate the stalk and form a network of vessels that traverse the pituitary stalk and terminate in a network of capillaries within the anterior lobe. It is through this portal venous system that hypothalamic hormones are delivered to the anterior pituitary gland. Anterior pituitary hormones, in turn, are secreted into a secondary plexus of portal veins that drain into the dural venous sinuses.

ANTERIOR PITUITARY CELL TYPES

A series of sequentially expressed transcriptional activation factors directs the differentiation and proliferation of anterior pituitary cell types. These proteins are members of a large family of DNA-binding proteins resembling homeobox genes. The consequences of pathogenic variants in several of these genes are evident in human forms of multiple pituitary hormone deficiency. Five cell types in the anterior pituitary produce six peptide hormones. **Somatotropes** produce growth

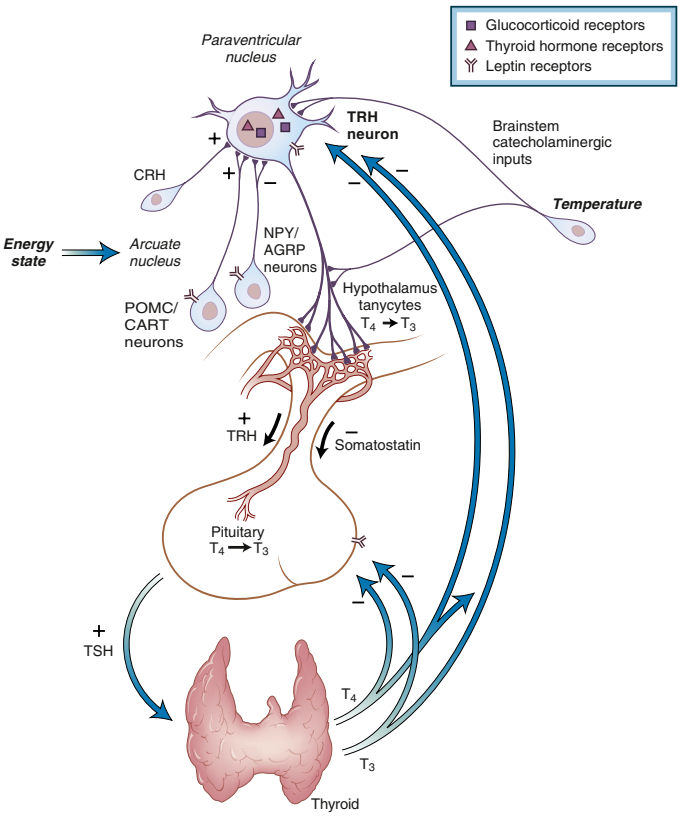

Fig. 594.1 Regulation of the hypothalamic-pituitary-thyroid axis. Neuroendocrinology. In Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, eds. Williams Textbook of Endocrinology, 13th ed. Philadelphia: Elsevier; 2016: Fig. 7.18.)*

hormone (GH), **lactotropes** produce prolactin (PRL), **thyrotropes** make thyroid-stimulating hormone (TSH), **corticotropes** express proopiomelanocortin (POMC), the precursor of adrenocorticotropic hormone (ACTH), and **gonadotropes** express luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Growth Hormone

Human GH is a 191–amino acid, single-chain polypeptide that is synthesized, stored, and secreted by somatotropes in the pituitary. Its gene *(GH1)* is the first in a cluster of five closely related genes on the long arm of chromosome 17 (q22-24). The other four genes *(CS1, CS2, GH2,* and *CSP)* have >90% sequence identity with the *GH1* gene.

GH is secreted in a pulsatile fashion under the regulation of hypothalamic hormones. The alternating secretion of GH-releasing hormone (GHRH), which stimulates GH release, and somatostatin, which inhibits GH release, accounts for the rhythmic secretion of GH. Peaks of GH occur when peaks of GHRH coincide with troughs of somatostatin. **Ghrelin**, a peptide produced in the arcuate nucleus of the hypothalamus and in much greater quantities by the stomach, also stimulates GH secretion. In addition to these three hypothalamic hormones, physiologic factors play a role in stimulating and inhibiting GH. Sleep, exercise, physical stress, trauma, acute illness, puberty, fasting, and hypoglycemia stimulate the release of GH, whereas hyperglycemia, hypothyroidism, and glucocorticoids inhibit GH release (Fig. 594.3).

GH binds to receptor molecules on the surface of target cells. The GH receptor is a 620–amino acid, single-chain molecule with an extracellular domain, a single membrane-spanning domain, and a cytoplasmic domain. Proteolytically cleaved fragments of the extracellular domain circulate in plasma and act as a GH-binding protein. Similar to other members of the cytokine receptor family, the cytoplasmic domain of the GH receptor lacks intrinsic kinase activity; instead, GH binding induces receptor dimerization and activation of a receptor-associated Janus kinase (Jak2). Phosphorylation of the kinase and other protein substrates initiates a series of events that leads to alterations in nuclear gene transcription. The signal transducer and activator of transcription 5b (STAT5b) plays a critical role in linking receptor activation to changes in gene transcription.

The biologic effects of GH include increases in linear growth, bone thickness, soft tissue growth, protein synthesis, fatty acid release from adipose tissue, insulin resistance, and blood glucose. The mitogenic actions of GH are mediated through increases in the synthesis of **insulin-like growth factor** 1 (IGF-1), formerly named *somatomedin C*, a 70–amino acid single-chain peptide coded for by a gene on the long arm of chromosome 12 with considerable homology to insulin. Circulating IGF-1 is synthesized primarily in the liver and formed locally in mesodermal and ectodermal cells, particularly in the growth plates of children, where its effect is exerted by paracrine or autocrine mechanisms. Circulating levels of IGF-1 are bound to several different binding proteins and are related to blood levels of GH and nutritional status. The major binding protein is a 150-kDa complex (IGF-BP3) that is low in GH-deficient children. Human recombinant IGF-1 has been developed as a therapeutic in conditions characterized by primary IGF-1 deficiency, end-organ resistance to GH (e.g., **Laron syndrome**), and the development of antibodies for those individuals administered GH. **Insulin-like growth factor** 2 (IGF-2) is a 67–amino acid single-chain protein that is coded for by a gene on the short arm of chromosome 11 that is also homologous to insulin and IGF-1. Less is known about its physiologic role, but it appears to be an important mitogen in bone cells, where it occurs in a concentration many times higher than that of IGF-1.

Prolactin

PRL is a 199–amino acid peptide made in pituitary lactotropes. The regulation of PRL is unique because PRL is constitutively secreted by the pituitary unless it is actively inhibited by dopamine, a peptide produced by neurons in the hypothalamus. Disruption of the hypothalamus or pituitary stalk can result in elevated PRL levels. Dopamine antagonists, states of primary hypothyroidism, administration of thyrotropin-releasing hormone (TRH), hypothalamic injury secondary to radiation therapy, and pituitary tumors result in increased serum levels of PRL. Dopamine agonists and processes causing destruction of the anterior pituitary gland can reduce levels of PRL.

The primary physiologic role for PRL is the initiation and maintenance of lactation. PRL prepares the breasts for lactation and stimulates milk production postpartum. During pregnancy, PRL stimulates the development of the milk secretory apparatus, but lactation does not occur because of the high levels of estrogen and progesterone. After delivery, the estrogen and progesterone levels drop, and physiologic stimuli such as suckling and nipple stimulation signal PRL release and initiate lactation.

Thyroid-Stimulating Hormone

TSH consists of two glycoprotein chains (α, β) linked by hydrogen bonding: the α-subunit, which is composed of 89 amino acids and is identical to other glycoproteins (FSH, LH, and human chorionic gonadotropin), and the β-subunit, composed of 112 amino acids, that is specific for TSH.

TSH is stored in secretory granules and released into circulation primarily in response to TRH, which is produced by the hypothalamus. TRH is released from the hypothalamus into the hypothalamic-pituitary portal system and ultimately stimulates TSH release from

Table 594.1 Hormones of the Hypothalamus and Pituitary Gland

HORMONES	LOCATION	S/I	FUNCTION
ACTH	Anterior pituitary	S	Production and secretion of GCs, MCs, and androgens from adrenal gland
ADH	Posterior pituitary	S	Reabsorption of water into the bloodstream via renal collecting ducts
CRH	Hypothalamus	S	Secretion of ACTH
Dopamine	Hypothalamus	I	Secretion of PRL
FSH (females)	Anterior pituitary	S	Secretion of estrogen from ovary
FSH (males)	Anterior pituitary	S	Production of sperm from testis
GH	Anterior pituitary	S	Secretion of IGF-1
GHRH	Hypothalamus	S	Secretion of GH
Ghrelin	Hypothalamus	S	Secretion of GH
GnRH	Hypothalamus	S	Secretion of FSH and LH
LH (females)	Anterior pituitary	S	Ovulation and development of the corpus luteum
LH (males)	Anterior pituitary	S	Production and secretion of testosterone
Oxytocin	Posterior pituitary	S	Contractions of uterus at birth and release of milk from breast
PRL	Anterior pituitary	S	Promotion of milk synthesis
Somatostatin	Hypothalamus	I	Secretion of GH and TSH
TRH	Hypothalamus	S	Secretion of TSH and PRL
TSH	Anterior pituitary	S	Secretion of T_4 and T_3

ACTH, Adrenocorticotropic hormone; ADH, antidiuretic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GCs, glucocorticoids; GH, growth hormone; GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; IGF-1, insulin-derived growth factor 1; LH, luteinizing hormone; MCs, mineralocorticoids; PRL, prolactin; S/I, stimulate/inhibit; T_3, triiodothyronine; T_4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone (thyrotropin).

pituitary thyrotropes. TSH stimulates release of thyroxine (T_4) and triiodothyronine (T_3) from the thyroid gland through the formation of cyclic adenosine monophosphate and the G protein second messenger system. In addition to the negative feedback inhibition by T_3, the release of TRH and TSH is inhibited by dopamine, somatostatin, and glucocorticoids.

Deficiency of TSH results in inactivity and atrophy of the thyroid gland, whereas excess TSH results in hypertrophy and hyperplasia of the thyroid gland.

Adrenocorticotropic Hormone

ACTH is a 39–amino acid single-chain peptide that is derived by proteolytic cleavage from POMC, which is a 240–amino acid precursor glycoprotein product of the pituitary gland. POMC also contains the sequences for the lipotropins, melanocyte-stimulating hormones (α, β, γ), and β-endorphin.

Secretion of ACTH is regulated by corticotropin-releasing hormone (CRH), a 41–amino acid peptide found predominantly in the median eminence but also in other areas in and outside of the brain. ACTH is secreted in a diurnal pattern. It acts on the adrenal cortex to stimulate cortisol synthesis and secretion. ACTH and cortisol levels are highest in the morning at the time of waking, are low in the late afternoon and evening, and reach their nadir within the first 2 hours after beginning sleep. Similar to TRH and TSH, CRH and ACTH function through the formation of cyclic adenosine monophosphate and the G protein second messenger system. Although CRH is the primary regulator of ACTH secretion, other hormones play a role. Arginine vasopressin, oxytocin, angiotensin II, and cholecystokinin stimulate release of CRH and ACTH, whereas atrial natriuretic peptide and opioids inhibit release of CRH and ACTH. Similar to the feedback inhibition T_3 has on TRH and TSH, cortisol also inhibits CRH and ACTH. Physiologic conditions, such as stress, fasting, and hypoglycemia, also stimulate release of CRH and ACTH.

Luteinizing Hormone and Follicle-Stimulating Hormone

Gonadotropic hormones include two glycoproteins: LH and FSH. They contain the same α subunit as TSH and human chorionic gonadotropin but distinct β subunits. Receptors for FSH on the ovarian granulosa cells and on testicular Sertoli cells mediate FSH stimulation of follicular development in the ovary and of gametogenesis in the testis. On binding to specific receptors on ovarian theca cells and testicular Leydig cells, LH promotes luteinization of the ovary and Leydig cell function of the testis (Fig. 594.4). The receptors for LH and FSH belong to a class of receptors with seven membrane-spanning protein domains. Receptor occupancy activates adenylyl cyclase through the mediation of G proteins.

LH-releasing hormone, a decapeptide, has been isolated, synthesized, and widely used in clinical studies. Because it leads to the release of LH and FSH from the same gonadotropic cells, it appears that it is the only gonadotropin-releasing hormone (GnRH).

Secretion of LH is inhibited by androgens and estrogens, and secretion of FSH is suppressed by gonadal production of inhibin, a 31-kDa glycoprotein produced by ovarian granulosa cells (females) and testicular Sertoli cells (males). Inhibin consists of α and β subunits joined by disulfide bonds. The β-β dimer activin also exists, and its actions generally oppose that of inhibin by stimulating FSH secretion. In addition to its endocrine effect, activin has paracrine effects in the testis. It facilitates LH-induced testosterone production, indicating a direct effect of Sertoli cells on Leydig cells.

POSTERIOR PITUITARY CELL TYPES

The posterior lobe of the pituitary is part of a functional unit, the neurohypophysis, that consists of the neurons of the supraoptic and paraventricular nuclei of the hypothalamus; neuronal axons, which form the pituitary stalk; and neuronal terminals in the median eminence or in the posterior lobe. Vasopressin (antidiuretic hormone

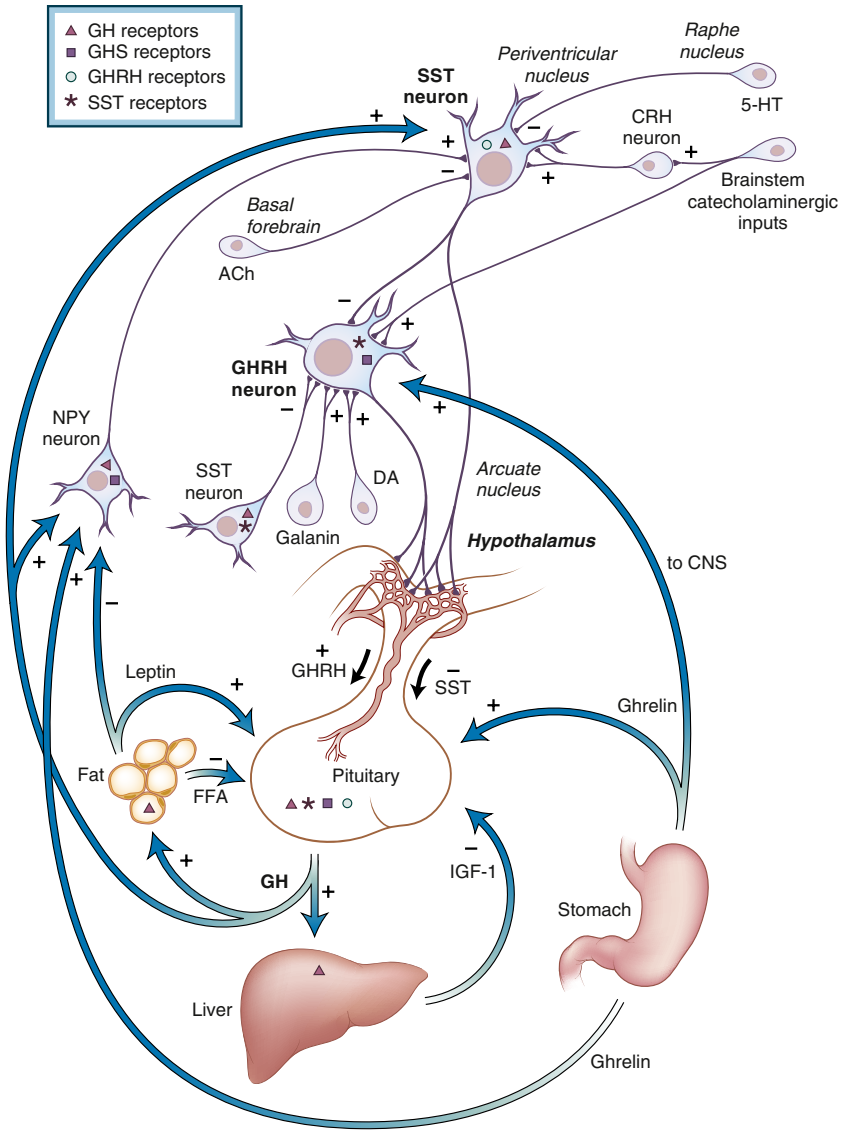

Fig. 594.3 Regulation of the hypothalamic-pituitary-growth hormone (GH) axis. GH secretion by the pituitary is stimulated by GH-releasing hormone (GHRH) and is inhibited by somatostatin (SST). Negative feedback control of GH secretion is exerted at the pituitary level by insulin-like growth factor 1 (IGF-1) and by free fatty acids (FFAs). GH itself exerts a short-loop negative feedback through activation of SST neurons in the hypothalamic periventricular nucleus. These SST neurons directly synapse on arcuate GHRH neurons and project axon collaterals to the median eminence. Neuropeptide Y (NPY) neurons in the arcuate nucleus also indirectly modulate GH secretion by integrating peripheral GH, leptin, and ghrelin signals and projecting to periventricular SST neurons. Ghrelin is secreted from the stomach and is a natural ligand for the GH secretagogue (GHS) receptor that stimulates GH secretion at both the hypothalamic and pituitary levels. On the basis of indirect pharmacologic data, it appears that release of GHRH is stimulated by galanin, γ-aminobutyric acid (GABA), and α_2-adrenergic and dopaminergic inputs and inhibited by SST. Secretion of SST is inhibited by muscarinic acetylcholine (ACh) and 5-HT-1D receptor ligands and increased by β_2-adrenergic stimuli and corticotropin-releasing hormone (CRH). CNS, Central nervous system; DA, dopamine; 5-HT, serotonin (5-hydroxytryptamine). *(From Low MJ. Neuroendocrinology. In Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, eds. Williams Textbook of Endocrinology, 13th ed. Philadelphia: Elsevier; 2016: Fig. 7.22.)*

[ADH]) and oxytocin are the two hormones produced by neurosecretion in the hypothalamic nuclei and released from the posterior pituitary. They are octapeptides and differ by only two amino acids.

Vasopressin

Vasopressin (ADH) regulates water conservation at the level of the kidney by increasing the permeability of the renal collecting duct to water. It stimulates translocation of water channels through its interaction with vasopressin 2 (V2) receptors in the collecting duct, which act through G proteins to increase adenylyl cyclase activity and increase permeability to water. These V2 receptors also mediate von Willebrand factor and tissue plasminogen activator. At higher concentrations, ADH activates vasopressin 1 (V1) receptors in smooth muscle cells and hepatocytes and exerts pressor and glycogenolytic effects through mobilization of intracellular calcium stores. Separate vasopressin 3

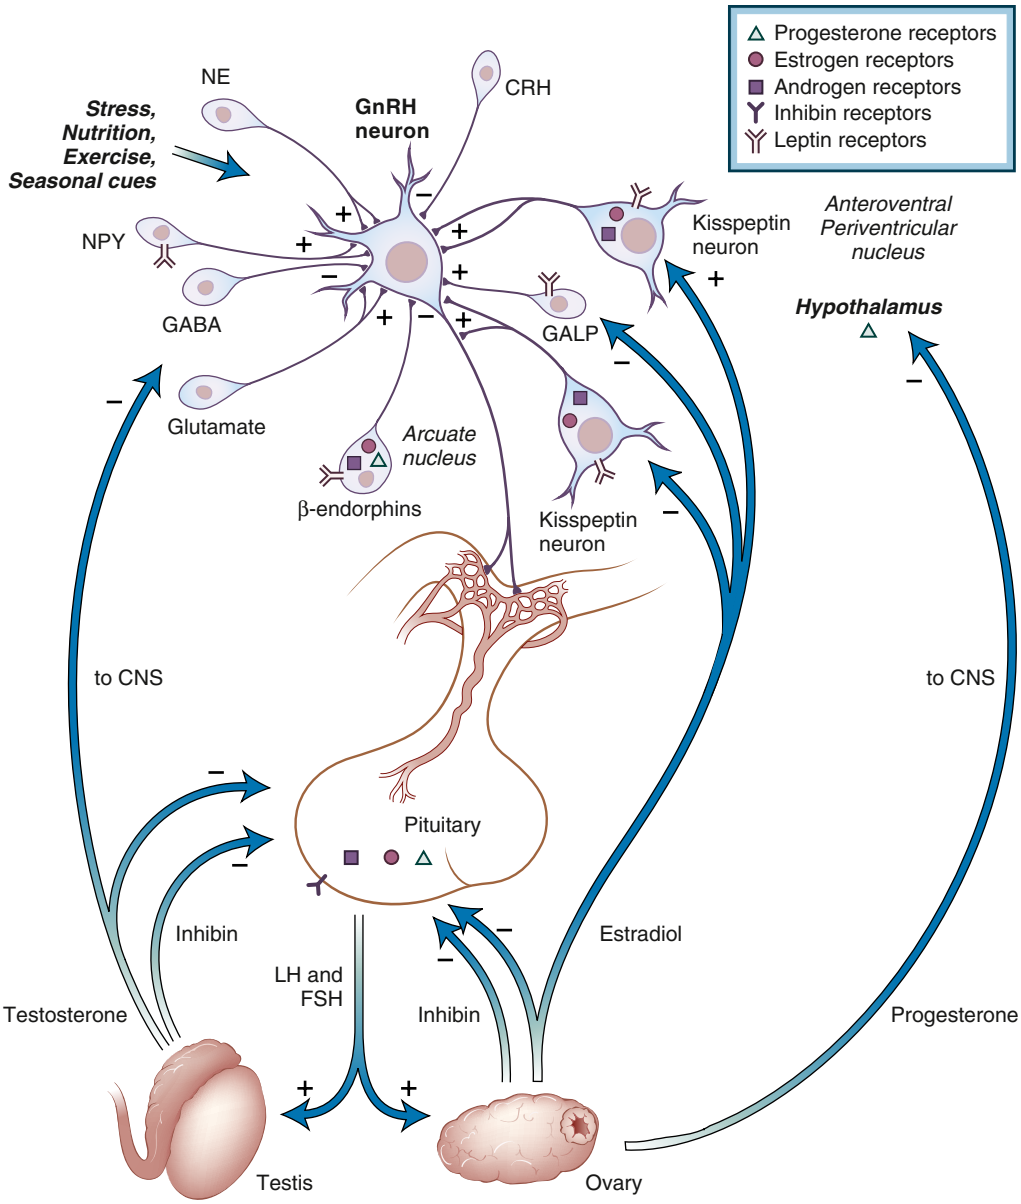

Fig. 594.4 Regulation of the hypothalamic-pituitary-gonadal axis. Schematic diagram of the hypothalamic-pituitary-gonadal axis showing neural systems that regulate gonadotropin-releasing hormone (GnRH) secretion and feedback of gonadal steroid hormones at the level of the hypothalamus and pituitary. CNS, Central nervous system; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GABA, γ-aminobutyric acid; GALP, galanin-like peptide; LH, luteinizing hormone; NE, norepinephrine; NPY, neuropeptide Y. *(From Low MJ. Neuroendocrinology. In Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, eds. Williams Textbook of Endocrinology, 13th ed. Philadelphia: Elsevier; 2016: Fig. 7.30.)*

(V3) receptors mediate stimulation of ACTH secretion. These effects involve phosphatidylinositol hydrolysis rather than cyclic adenosine monophosphate production.

Vasopressin and its accompanying protein neurophysin II are encoded by the same gene. A single preprohormone is cleaved, and both are transported to neurosecretory vesicles in equimolar amounts in the posterior pituitary.

Vasopressin has a short half-life and responds quickly to changes in hydration. The stimuli for its release are increased plasma osmolality, perceived by osmoreceptors in the hypothalamus, and decreased blood volume, perceived by baroreceptors in the carotid sinus of the aortic arch.

Oxytocin

Oxytocin stimulates uterine contractions at the time of labor and delivery in response to distention of the reproductive tract and stimulates smooth muscle contraction in the breast during suckling, which results in milk letdown. Studies suggest that oxytocin also plays a role in orgasm, social recognition, pair bonding, anxiety, trust, love, and maternal behavior. Most recently, through the interaction with its G protein–coupled receptor in pancreatic and adipose tissue, oxytocin appears to play a significant role in appetite regulation and obesity by inducing anorexia.

Chapter 595

Hypopituitarism

Briana C. Patterson and Eric I. Felner

Hypopituitarism denotes underproduction of one or more pituitary hormones. Affected children have postnatal growth impairment and other endocrine deficiencies that are specifically corrected by hormone replacement. The incidence of *congenital* hypopituitarism is thought to be between 1 in 4,000 and 1 in 10,000 live births. An epidemiologic association between hypopituitarism and breech delivery has been reported, but the causal relationship is not understood. With expanding knowledge of the genes that direct pituitary development or hormone production, an increasing proportion of cases can be attributed to specific genetic alterations. Monogenic causes can only be identified in about 10% of persons with congenital hypopituitarism. The likelihood of finding a genetic alteration is increased by consanguinity and occurrence in siblings or across generations; however, in *most* cases of *isolated* **growth hormone deficiency (GHD)** and *sporadic* **multiple pituitary hormone deficiency (MPHD)**, no specific single-gene cause can be identified. It is likely that polygenic and/or environmental factors regularly play a role in the development of congenital hypopituitarism. The genes, hormonal phenotypes, associated abnormalities, and modes of transmission of several single-gene disorders causing congenital MPHD are shown in Table 595.1. Causes of *acquired* hypopituitarism, which usually has a later onset, has different causes (Table 595.2). Single-gene alterations causing disruption of the GH axis primarily are shown in Table 595.3.

MULTIPLE PITUITARY HORMONE DEFICIENCY

Genetic Forms (see Table 595.1)

Sequentially expressed transcriptional activation factors direct the differentiation and proliferation of anterior pituitary cell types. These proteins are members of a large family of DNA-binding proteins resembling homeobox genes. Alterations in different genes may produce different manifestations of MPHD. The *PROP1* and *POU1F1* genes are expressed later in pituitary development only in cells of the anterior pituitary and result in hypopituitarism without anomalies in other organ systems. The *HESX1, LHX3, LHX4, OTX2, SOX3,* and *PITX2* genes are expressed at earlier stages and are not restricted to the pituitary. Pathogenic alterations in these genes tend to produce phenotypes that extend beyond hypopituitarism to include abnormalities in other organs, and the degree of hypopituitarism is typically variable.

PROP1

PROP1 is found in the nuclei of somatotropes, lactotropes, and thyrotropes. Its roles include turning on *POU1F1* expression and downregulating *HESX1* expression. Although no genetic alteration can be identified in most patients with MPHD, pathogenic variants of *PROP1* are the most common explanation for recessive MPHD and are 10 times as common as the combined total of alterations in other pituitary transcription factor genes. Deletions of one or two base pairs in exon 2 are most common, followed by missense, nonsense, and splice-site pathogenic mutations. Anterior pituitary hormone deficiencies may not be evident in the neonatal period. The median age at diagnosis of GHD is around 6 years. Recognition of thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), and adrenocorticotropic hormone (ACTH) deficiencies is delayed relative to recognition of GHD. Anterior pituitary size is small in most patients, but in others there is progressive enlargement of the pituitary.

POU1F1 (PIT1)

POU1F1 (formerly *PIT1*) is a nuclear protein that binds to the GH and prolactin promoters. It is necessary for the emergence and mature function of somatotropes, lactotropes, and thyrotropes. Dominant and recessive pathogenic variants in *POU1F1* are responsible for complete deficiencies of growth hormone (GH) and prolactin and variable TSH deficiency. Affected patients exhibit nearly normal fetal growth but experience severe growth failure in the first year of life. With normal production of LH and FSH, puberty develops spontaneously, although at a later-than-normal age. These patients are not at risk for development of ACTH deficiency. Anterior pituitary size is normal to small.

HESX1

The *HESX1* gene is expressed in precursors of all five cell types of the anterior pituitary early in embryologic development. Pathogenic genetic variations in *HESX1* result in heterogeneous phenotypes with differences in development of the optic nerve and pituitary. The anterior pituitary may be hypoplastic or aplastic, and the posterior pituitary may be orthotopic or ectopic. Patients may have isolated GHD or MPHDs, with or without the **optic nerve hypoplasia syndrome**, historically called *septo-optic dysplasia* (incomplete development of the septum pellucidum with optic nerve hypoplasia and pituitary insufficiency). However, the majority of patients with optic nerve hypoplasia syndrome do not have *HESX1* gene alterations.

LHX3 and *LHX4*

The phenotype produced by recessive loss-of-function alterations of the *LHX3* gene resembles that produced by *PROP1* genetic variants. There are deficiencies of GH, prolactin, TSH, LH, and FSH but not ACTH. Some affected persons show enlargement of the anterior pituitary. The first patients to be described had the unusual findings of a short neck and a rigid cervical spine. Dominantly inherited pathogenic variations in the structurally similar *LHX4* gene consistently produce GH deficiency, with the variable presence of TSH and ACTH deficiencies. Additional findings can include a very small V-shaped pituitary fossa, **Chiari I malformation**, and an ectopic posterior pituitary.

Other Congenital Forms

Pituitary hypoplasia can occur as an isolated phenomenon or in association with more extensive developmental differences such as anencephaly or holoprosencephaly. Midline facial anomalies (cleft lip, palate; see Chapter 356) or the finding of a solitary maxillary central incisor may indicate a higher likelihood of GH or other anterior or posterior hormone deficiency (Fig. 595.1). At least 12 genes have been implicated in the complex genetic etiology of **holoprosencephaly**.

Hall-Pallister syndrome is caused by dominant loss-of-function alterations in the *GLI3* gene. Absence of the pituitary gland is accompanied by hypothalamic hamartoma, polydactyly, nail dysplasia, bifid epiglottis, imperforate anus, and anomalies of the heart, lungs, and kidneys. The combination of **anophthalmia** and **hypopituitarism** has been associated with pathogenic variants in the *SIX6, SOX2,* and *OTX2* genes.

Optic nerve hypoplasia syndrome may be detected as a result of clinical observation of nystagmus and visual impairment in infancy. Neuroimaging demonstrates optic nerve and brain abnormalities and is associated with anterior and/or posterior pituitary hormone deficiencies in up to 75% of cases (Fig. 595.2). Although these patients often show the triad of a small anterior pituitary gland, an attenuated pituitary stalk, and an ectopic posterior pituitary bright spot, the primary etiology of the hypopituitarism in this condition is thought to be hypothalamic dysfunction. GH deficiency is the commonly observed hormone deficiency, and other anterior pituitary hormone deficiencies are less common. Diabetes insipidus is reported in only about 5% of cases. The etiology is likely multifactorial and may involve interaction between genetic and environmental factors. In most cases, no single-gene alteration can be identified.

Severe, early-onset MPHD, including deficiency of ACTH, is often associated with the triad of anterior pituitary hypoplasia, absence or attenuation of the pituitary stalk, and an ectopic posterior pituitary bright spot seen on MRI. Most cases are sporadic, and there is a male predominance. Some are caused by pathogenic variants of the *SOX3* gene, located on the X chromosome.

Table 595.1 Etiologic Classification of Congenital and Genetic Forms of Multiple Pituitary Hormone Deficiency

GENE OR LOCATION	PHENOTYPE	INHERITANCE
GENETIC FORMS		
POU1F1 (PIT1)	GH, PRL deficiencies, variable TSH deficiency	AR, AD
PROP1	GH, TSH, PRL, LH, FSH deficiencies, variable ACTH deficiency, variable AP	AR
LHX3	GH, TSH, PRL, LH, FSH deficiencies, variable AP, ± short neck, limited neck rotation, sensorineural deafness	AR
LHX4	GH, TSH, ACTH deficiencies, small AP, EPP, variable Arnold-Chiari, cerebellar abnormalities	AD
TPIT	ACTH deficiency, severe neonatal form	AR
HESX1	GH deficiency, variable for others, small AP, EPP, optic nerve hypoplasia; septo-optic dysplasia	AR, AD
SOX2	LH, FSH deficiencies, variable GH deficiency, anophthalmia, microphthalmia, esophageal atresia, sensorineural hearing loss	AD
SOX3	Variable deficiencies, ± MR, EPP, small AP and stalk, developmental delay	XL
PITX2	Axenfeld-Rieger syndrome: hypogonadotropic hypogonadism, pituitary hypoplasia, anterior chamber abnormalities of the eye, dental hypoplasia	AD
GLI2	Hypopituitarism, holoprosencephaly, midline defects, polydactyly	AD
GLI3	Hall-Pallister syndrome, hypopituitarism	AD
SHH (Sonic Hedgehog)	GH deficiency with single central incisor	AD
OTX2	GH or combined deficiencies, anophthalmia or microphthalmia, coloboma, developmental delay	AD
TBX19	ACTH deficiency, neonatal hypoglycemia or cholestatic jaundice	AR
PC1	Hypogonadotropic hypogonadism, ACTH deficiency	AR
GIF, SHHT, SIX3	Pituitary stalk interruption syndrome: thin or absent pituitary stalk, hypoplasia of adenohypophysis, ectopic neurohypophysis, neonatal hypoglycemia, cholestasis, micropenis	Holoprosencephaly related gene group
FGF8	Hypopituitarism, holoprosencephaly	AD
FGFR1	Hypopituitarism, pituitary hypoplasia, agenesis of the corpus callosum, ocular defects	AD
PROKR2	GH, TSH and ACTH deficiencies, micropenis and neonatal hypoglycemia	AD, AR
UNKNOWN OR POLYGENETIC ETIOLOGY		
Congenital absence of pituitary gland		
Optic nerve hypoplasia syndrome/septo-optic dysplasia	Optic nerve hypoplasia, nystagmus, absent septum pellucidum, pituitary hypoplasia	

ACTH, Adrenocorticotropic hormone; AP, anterior pituitary; AD, autosomal dominant; EPP, ectopic posterior pituitary; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; MR, mental retardation; PRL, prolactin; AR, autosomal recessive; TSH, thyroid-stimulating hormone; XL, X-linked.

Acquired Forms

Any lesion that damages the hypothalamus, pituitary stalk, or anterior pituitary can cause pituitary hormone deficiency (see Table 595.2). Because such lesions are not selective, multiple hormonal deficiencies are usually observed. Diabetes insipidus is more frequent in *acquired* than in congenital hypopituitarism. The most common structural lesion of the pituitary causing childhood-onset acquired MPHD is craniopharyngioma (see Chapter 546). Central nervous system germinoma, optic pathway or hypothalamic glioma, histiocytosis, tuberculosis, sarcoidosis, toxoplasmosis, meningitis, pituitary abscess, and aneurysms can also cause hypothalamic-hypophyseal damage and dysfunction. Additionally, children treated with radiation therapy for central nervous system or nasopharyngeal tumors are at increased risk for GHD and other pituitary hormone deficiencies to the extent that the radiation field includes the hypothalamus and/or pituitary, even if the tumor itself is anatomically remote from the pituitary and hypothalamus. The magnitude of the risk and the timing of the emergence of pituitary hormone deficiencies depend on the dose of radiation to the hypothalamic-pituitary axis and the duration of elapsed time after radiotherapy is complete. High doses of radiation (>50 Gy) are likely to produce GH deficiency sooner than 1 year after irradiation, whereas other anterior pituitary hormone deficiencies may not appear until later. GH production appears to be particularly vulnerable to the effects of irradiation, even at lower doses, whereas deficiencies of ACTH, gonadotropins, and thyrotropin-releasing hormone (TRH)/TSH occur with declining frequency and typically occur at higher doses of radiation. Irradiation alone does not typically result in diabetes insipidus. Traumatic brain injury, including abusive head trauma, motor vehicle accidents, and chronic repetitive head injury, is an increasingly recognized cause of pituitary dysfunction related to damage to the pituitary, its stalk, or the hypothalamus.

ISOLATED GROWTH HORMONE DEFICIENCY AND INSENSITIVITY

Genetic Forms of Growth Hormone Deficiency

Isolated GHD is caused by abnormalities of the GH-releasing hormone receptor, GH genes, and certain genes located on the X chromosome (see Table 595.3).

Growth Hormone–Releasing Hormone Receptor

Recessive loss-of-function alterations in the receptor for GH-releasing hormone interfere with proliferation of somatotropes during pituitary development and disrupt the most important signals for release of GH. The anterior pituitary is small, in keeping with the observation that

Modified from Kaiser U, Ho KKY. Pituitary physiology and diagnostic evaluation. In: Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, eds. *Williams Textbook of Endocrinology,* 13th ed. Philadelphia: Elsevier; 2016: Table 8.5, p. 193.

somatotropes normally account for >50% of pituitary volume. There is some compromise of fetal growth followed by severe compromise of postnatal growth.

GH1

The *GH1* gene is one of a cluster of five genes on chromosome 17q22-24. This cluster arose through successive duplications of an ancestral GH gene. Unequal crossing over at meiosis has produced a variety of gene deletions. Small deletions (<10 kb) remove only the *GH1* gene, whereas large deletions (45 kb) remove one or more of the adjacent genes (*CSL, CS1, GH2,* and *CS2*). The growth phenotype is identical with deletion of *GH1* alone or *GH1* together with one or more of the adjacent genes. Loss of the *CS1, GH2,* and *CS2* genes without loss of *GH1* causes deficiency of chorionic somatomammotropin and placental GH in the maternal circulation, but it does not result in fetal or postnatal growth retardation. Most children with *GH1* gene deletions respond very well to recombinant GH treatment, but some develop *antibodies* to GH and cease growing despite treatment.

Recessively transmitted pathogenic variants in the *GH1* gene produce a similar phenotype. Missense, nonsense, and frameshift alterations have been described. Autosomal dominant isolated GHD is also caused by variants in *GH1*. These alterations usually involve splice-site errors in intron 3 and result in a variant protein that lacks the amino acids normally encoded by exon 3. Accumulation of this protein interferes with the processing, storage, and secretion of the normal GH protein and may result in additional deficiencies of TSH and/or ACTH. There are several reports of alterations in *GH1* that lead to variant proteins with reduced biologic activity.

X-Linked Isolated Growth Hormone Deficiency

Two loci on the X chromosome have been associated with hypopituitarism. The first lies at Xq21.3-q22 in the region of the *BTK* gene. Pathogenic variants in this region produce hypogammaglobulinemia and isolated GHD. The second locus maps farther out on the long arm, at Xq24-q27.1, a region containing the *SOX2* transcription factor gene. Abnormalities in this locus have been linked to isolated GHD with intellectual disability and to MPHD with the triad of pituitary hypoplasia, missing pituitary stalk, and ectopic posterior pituitary gland.

Acquired Forms

The GH axis is more susceptible to disruption by acquired conditions than are other hypothalamic-pituitary axes. Recognized causes of acquired GHD include the use of radiotherapy for malignancy, meningitis, histiocytosis, and trauma.

Children who receive radiotherapy for central nervous system tumors, leukemia, or total body irradiation before hematopoietic stem cell transplant are at risk for developing GHD. Spinal irradiation results in disproportionately poor growth of the axial skeleton relative to the appendicular skeleton; this problem is not remediable with GH treatment. Growth typically slows during radiation therapy or chemotherapy, may improve for 1-2 years after cancer treatment, and then declines with the development of GHD. The dose and frequency of radiotherapy are important determinants of hypopituitarism. GHD is almost universal 5 years after therapy with a total dose ≥35 Gy. More subtle defects are seen with doses around 20 Gy. Deficiency of GH is the most common defect, but deficiencies of TSH and ACTH can also occur. The evaluation of GHD is more complicated when radiation-associated precocious puberty is also present. The clinician is likely to encounter children in the 8- to 10-year age range who are growing at rates that are normal for chronological age but subnormal for stage of pubertal development.

GROWTH HORMONE INSENSITIVITY

Abnormalities of the Growth Hormone Receptor

GH insensitivity is caused by disruption of pathways distal to the production of GH (Table 595.4). **Laron syndrome** involves pathogenic genetic variations in the GH receptor. Children with this condition clinically resemble those with severe isolated GHD. Birth length tends to be about 1 standard deviation (SD) below the mean, and severe short stature with lengths >4 SD below the mean is present by 1 year of age. Resting and stimulated GH levels tend to be high, and insulin-like growth factor (IGF) 1 levels are low. The GH receptor has an extracellular GH-binding domain, a transmembrane domain, and an

Table 595.3 Established Genetic Defects of the GH-IGF Axis Resulting in Isolated GH Deficiency, GH Insensitivity, or IGF-1 Deficiency

GENE	INHERITANCE	PHENOTYPE
ISOLATED GROWTH HORMONE DEFICIENCY		
GHRHR	AR	Type IB form of isolated **GHD**; low levels of GH production, but less severe than type 1A isolated **GHD**; may also be caused by pathogenic variants in GH1
GHS-R	AD	**GHD** and ISS
GH1	AR	Type IA form of isolated **GHD**, in utero growth retardation; absent GH production caused by gene deletion, antibodies to GH develop over time during treatment
GH1	AR	Type IB form of isolated **GHD**; low levels of GH production, but less severe than type 1A isolated **GHD**; may also be caused by pathogenic variants in GHRHR
GH1	AD	Type II form of isolated **GHD**; dominant negative pathogenic variants in GH1, which decrease GH secretion
BTK	XL	Type III form of isolated **GHD**; hypogammaglobulinemia
GH1	AD	Bioinactive GH molecule; rare, dominant negative pathogenic variant in GH1 that interferes with GHR signaling
GROWTH HORMONE INSENSITIVITY		
GHR	AR, AD	IGF-I deficiency; high GH level; normal, decreased or increased GHBP (depending on which domain of the receptor is affected); unresponsive to GH treatment
IGF-1 DEFICIENCY		
IGF1	AR	IGF-1 deficiency; IUGR and postnatal growth failure, sensorineural deafness, insulin resistance, microcephaly
STAT5b	AR	IGF-1 deficiency, variable immune defect, hyperprolactinemia, chronic pulmonary infections, eczema
ALS	AR	IGF-1 deficiency; variable postnatal growth failure, delayed puberty

AD, Autosomal dominant; ALS, acid-labile subunit; AR, autosomal recessive; GH, growth hormone; GHBP, GH-binding protein; GHD, growth hormone deficiency; GHRHR, GH-releasing hormone receptor; IGF, insulin-like growth factor; ISS, idiopathic short stature; IUGR, intrauterine growth retardation; XL, X-linked.

Fig. 595.1 Solitary median maxillary central incisor at age 16 mo. *(From Giannopoulou EZ, Rohrer T, Hoffmann P, et al. Solitary median maxillary central incisor. J Pediatr. 2015;167:770, Fig. 2.)*

Fig. 595.2 Septo-optic dysplasia with agenesis of the septum pellucidum. Sagittal T1 weighted MR image shows that fornices are inferiorly positioned *(long arrow)*. The optic apparatus is hypoplastic *(short arrow)*; there is no identifiable neurohypophysis. *(From Rollins N. Congenital brain malformations. In: Coley BD, ed. Caffey's Pediatric Diagnostic Imaging, 13th ed. Philadelphia: Elsevier; 2019: Fig. 31.13.)*

intracellular signaling domain. Pathogenic alterations in the extracellular domain interfere with binding of GH. Serum GH-binding protein activity, representing the circulating form of the membrane receptor for GH, is generally low. Variants in the transmembrane domain can interfere with anchoring of the receptor to the plasma membrane. In these cases, circulating GH-binding protein activity is normal or high. Alterations in the intracellular domain interfere with JAK/STAT signaling.

Post-Receptor Forms of Growth Hormone Insensitivity

Some children with severe growth failure, high GH and low IGF-1 levels, and normal GH-binding protein levels have abnormalities distal to the GH binding and activation of the GH receptor. Several have been found to have pathogenic variations in the gene-encoding signal transducer and activator of transcription 5b (STAT5b). Disruption of this key intermediate connecting receptor activation to gene transcription produces growth failure similar to that seen in Laron syndrome. These patients also suffer from *immunodeficiency* and chronic pulmonary

Table 595.4 Proposed Classification of Growth Hormone Insensitivity

PRIMARY GH INSENSITIVITY (HEREDITARY DEFECTS)
GH receptor defect (may be positive or negative for GH-binding protein)
• Extracellular alteration (e.g., Laron syndrome)
• Cytoplasmic alteration
• Intracellular alteration
GH signal transduction defects (distal to cytoplasmic domain of GH receptor)
• Stat5b pathogenic variants
Insulin-like growth factor-1 defects
• IGF-1 gene deletion
• IGF-1 transport defect (pathogenic variant in ALS)
• IGF-1 receptor defect
Bioinactive GH molecule (responds to exogenous GH)
SECONDARY GH INSENSITIVITY (ACQUIRED DEFECTS)
Circulating antibodies to GH that inhibit GH action
Antibodies to the GH receptor
GH insensitivity caused by malnutrition, liver disease, catabolic states, diabetes mellitus
Other conditions that cause GH insensitivity

ALS, Acid-labile subunit; GH, growth hormone; IGF, insulin-like growth factor.

infections, consistent with important roles for STAT5b in interleukin cytokine signaling.

IGF-1 Gene Abnormalities

Pathogenic alterations of the *IGF-1* gene produce severe prenatal and postnatal growth impairment. Microcephaly, intellectual disability, and deafness are present in patients with exon deletion and a missense variant. These patients can be expected to respond to recombinant IGF-1 treatment.

Insulin-Like Growth Factor–Binding Protein Abnormalities

Pathogenic variants in the gene encoding the acid-labile subunit of the circulating 165-kDa IGF-1, IGF-BP3, acid-labile subunit complex has been associated with short stature. Total IGF-1 levels were very low. The index case, with homozygosity for an acid-labile subunit alteration, did not show an increase in IGF-1 levels or an increase in growth rate during GH treatment.

IGF-1 Receptor Gene Abnormalities

Pathogenic variants in the gene encoding the IGF-1 receptor also compromise prenatal and postnatal growth. The phenotype does not appear to be as severe as that seen with the absence of IGF-1. Adult heights are closer to the normal range, and affected patients do not have intellectual disability or deafness.

CLINICAL MANIFESTATIONS

Congenital Hypopituitarism

The child with congenital hypopituitarism is usually of normal size and weight at birth, although those with MPHD and those with pathogenic genetic variants in the *GH1* or *GHR* gene have birth lengths that average 1 SD below the mean. Children with severe deficits in GH production or action typically fall more than 4 SD below the mean for length by 1 year of age. Those with less severe deficiencies grow at rates below the 25th percentile for age and gradually diverge from normal height percentiles. Delayed closure of the epiphyses permits growth beyond the normal age when growth should be complete. Features of GH insensitivity, including Laron syndrome, are somewhat distinct from GHD and MPHD and are noted in Table 595.5.

Infants with congenital dysfunction of the pituitary or hypothalamus may present with neonatal emergencies such as apnea, cyanosis, or severe hypoglycemia with or without seizures. Prolonged neonatal cholestatic jaundice is common. It involves elevation of conjugated and unconjugated bilirubin and may be associated with giant cell neonatal hepatitis. Nystagmus can suggest optic nerve hypoplasia syndrome (see Chapter 671). Micropenis with or without testicular maldescent in males provides an additional diagnostic clue. Deficiency of GH may be accompanied by hypoadrenalism (see Chapter 615.2) and hypothyroidism (see Chapter 603), along with gonadotropin deficiency (see Chapters 623.2 and 626.2).

Table 595.5 Clinical Features of Growth Hormone Insensitivity, Including Classic Laron Syndrome

GROWTH AND DEVELOPMENT
Near-normal birthweight
Slightly decreased birthweight
Severe postnatal growth failure
Delayed bone age (may be advanced relative to height age)
Micropenis in childhood; normal for body size in adults
Puberty may be delayed 3-7 yr
Normal sexual function and fertility
OTHER PHYSICAL CHARACTERISTICS
Sparse hair (before age 7 yr)
Frontal bossing
Normal head circumference
Small facies (resulting in craniofacial disproportion)
Hypoplastic nasal bridge
Shallow orbits
Delayed dentition
Blue sclerae
High-pitched voice
Hip dysplasia
Limited extension in elbows
LATE FINDINGS/OTHER COMPLICATIONS
Hypoglycemia in infants and children (fasting symptoms in some adults)
Delayed walking and motor milestones
Avascular necrosis of femoral head
Thin, prematurely aged skin
Osteopenia

From Sperling MA. *Pediatric Endocrinology,* 4th ed. Philadelphia: Elsevier; 2014: Box 10.5.

Toddlers and school-age children tend to present with proportionate short stature. On physical examination, the head may be round and the face short and broad. The frontal bone may be prominent, and the bridge of the nose is often depressed and saddle shaped. The nose may be small, but the nasolabial folds are well developed. The mandible and the chin may be underdeveloped, and the teeth, which erupt late, are often crowded. The neck is short, and the larynx is small. The voice is high-pitched and remains high after puberty. The extremities are well proportioned, with small hands and feet. Weight for height is often normal, but there may be an imbalance of lean mass and adipose tissue. The genitals are usually small for age in males, and sexual maturation may be delayed or absent as the child ages.

In teens with undiagnosed congenital hypopituitarism, short stature is expected. Additionally, facial, axillary, and pubic hair may be decreased, and the scalp hair is fine. Intelligence is usually normal for age, unless there are other structural brain abnormalities, and the children may seem precocious compared with younger children of a similar size.

Acquired Hypopituitarism

The child is normal initially, and manifestations similar to those seen in idiopathic pituitary growth failure gradually appear and progress. When complete or almost complete destruction of the pituitary gland occurs, signs of pituitary insufficiency are present. Atrophy of the adrenal cortex, thyroid, and gonads results in loss of weight, asthenia, sensitivity to cold, mental torpor, and absence of sweating. Sexual maturation fails to take place or regresses if already present. There may be atrophy of the gonads and genital tract with amenorrhea and loss of pubic and axillary hair. There is a tendency to hypoglycemia. Growth slows dramatically. Diabetes insipidus (see Chapter 596) may be present but can by obscured by the development of yet untreated central adrenal insufficiency.

If the lesion is an **expanding tumor**, symptoms such as headache, vomiting, visual disturbances, pathologic sleep patterns, decreased school performance, seizures, polyuria, and growth failure can occur. Documented slowing of growth can antedate neurologic signs and symptoms, especially with craniopharyngioma, yet neurologic and ophthalmologic complaints are more often the presenting problems. In other cases, evidence of pituitary insufficiency may first appear after surgical intervention. In children with craniopharyngioma, visual field defects, optic atrophy, papilledema, obesity, and cranial nerve palsy are common. Skeletal age may be delayed in acquired MPHD but may be relatively normal if the pituitary dysfunction is of very recent onset.

LABORATORY FINDINGS

MPHD and/or GHD should be suspected in infants with hypoglycemia, micropenis, congenital nystagmus, and prolonged conjugated hyperbilirubinemia and in older children with severe postnatal growth failure (Table 595.6). Criteria for short stature include height below the first percentile for age and sex or height >2 SD below sex-adjusted mid-parent height. Acquired GHD can occur at any age, and when it is of acute onset, height may be within the normal range. In both congenital and acquired GH deficiency, height velocity will be low relative to sex- and bone age–matched peers. A strong clinical suspicion is important in establishing the diagnosis because laboratory measures of GH sufficiency lack specificity. Random GH levels are not helpful in the evaluation of toddlers and older children because of the pulsatile secretion of GH, *whereas measurement of GH may be useful in the first 2 weeks of life when levels are tonically increased.* Observation of low serum levels of IGF-1 and the GH-dependent IGF-BP3 can be helpful, but IGF-1 and IGF-BP3 levels should be matched to normal values for skeletal age and sexual maturity rating, rather than chronological age. Values in the upper part of the normal range for age effectively exclude GHD. IGF-1 values in the lower part of the normal range may occur in normally growing children, children with impaired nutrition, or those with hypopituitarism. The expected range for IGF-1 in normal and GH-deficient children overlaps somewhat during infancy and early childhood. IGF-1 levels in isolation should not be used to diagnose GH deficiency.

Table 595.6 Evaluation of Suspected Growth Hormone Deficiency

History	• Birthweight and length • Obstetric complications • Breech presentation • Neonatal hypoglycemia • Prolonged neonatal jaundice/cholestasis • Review of systems for systemic illness • Diet history
Physical exam	• Linear growth failure (may be the only clinical feature present) Proportionate short stature Low height velocity • Weight for length appropriate or increased • Micropenis with or without testicular maldescent in males • Small midface • Cleft palate • High-pitched voice • Delayed dental eruption • Optic nerve hypoplasia
Imaging	• Radiologic evaluation of bone age • Central nervous system imaging to evaluate the hypothalamus/pituitary and to exclude other conditions
Laboratory evaluation	• Measurements of IGF-1 and IGF-binding protein levels • Assess thyroid function • Exclude chronic medical illness CBC, metabolic profile, inflammatory markers, celiac testing, urinalysis • Determination of peak GH levels after stimulation test
Treatment considerations	• Replacement with rhGH • Dosage adjustment IGF-1 Height velocity Pubertal status Body weight • Predictors of improved response to treatment Early initiation of treatment Higher rhGH dose • Monitor during treatment Height velocity IGF-1 levels Glucose metabolism Skeletal age Thyroid function, adrenal function

GH, Growth hormone; IGF, insulin-like growth factor; rhGH, recombinant human growth hormone.

After infancy, a definitive diagnosis of GHD traditionally requires demonstration of absent or low levels of GH in response to stimulation, but provocative testing may be omitted if the patient has the expected auxologic findings, a documented hypothalamic or pituitary defect, and at least one other pituitary hormone deficiency. A variety of provocative tests have been devised that rapidly increase the level of GH in normal children. These include administration of insulin, arginine, clonidine, levodopa, or glucagon. Macimorelin is an oral ghrelin agonist approved in the United States for growth hormone stimulation testing in adults, but not in children. *Because thyroid hormone is a prerequisite for normal GH synthesis, it must always be assessed and replaced, if needed, before provocative GH testing.* In chronic GHD, the demonstration of subnormal linear growth, a delayed skeletal age, and low peak levels of GH (<10 ng/mL) in each of two provocative tests are compatible with the diagnosis. In acute GHD, a high clinical suspicion of GHD and low peak levels of GH (<10 ng/mL) in each of two provocative tests are compatible with the diagnosis. This rather arbitrary cutoff point is higher than the criteria used for diagnosis of adult GHD. There is no consensus regarding adoption of criteria that account for age, sex, and GH assay characteristics. Some studies indicate that many GH-sufficient prepubertal children fail to achieve GH values >10 ng/mL with two pharmacologic tests; pretest, short-term sex steroid priming has been proposed to increase the diagnostic specificity of this testing.

In addition to establishing the diagnosis of GHD, it is necessary to examine other pituitary functions. Levels of TSH, free thyroxine or total thyroxine with T_3 resin uptake, ACTH, cortisol, gonadotropins, and gonadal steroids might provide evidence of other pituitary hormonal deficiencies. Antidiuretic hormone deficiency may be established by appropriate studies (see Chapter 596). Infants with clear clinical and biochemical evidence of multiple pituitary hormone deficiencies and supportive anatomic variants demonstrated on MRI of the brain may not require provocative GH testing.

RADIOLOGIC FINDINGS

Neurologic imaging should be obtained when the cause of hypopituitarism is not known. CT is appropriate for recognizing suprasellar calcification associated with craniopharyngiomas and bony changes accompanying histiocytosis. However, MRI is usually used as the initial test to anatomically characterize the pituitary and hypothalamus, as MRI provides a much more detailed view of the relevant anatomy. Many cases of severe early-onset MPHD show the triad of a small anterior pituitary gland, a missing or attenuated pituitary stalk, and an ectopic posterior pituitary bright spot at the base of the hypothalamus (Fig. 595.3). Subnormal anterior pituitary height, implying a small anterior pituitary, is common in genetic and idiopathic causes of isolated GHD. Craniopharyngiomas are rare tumors in childhood, but common causes of acquired hypopituitarism, whereas pituitary adenomas rarely cause hypopituitarism in children. Both hypoplastic and

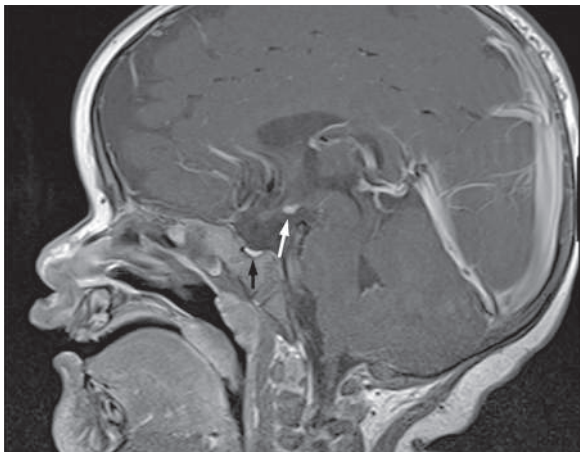

Fig. 595.3 Sagittal T1 weighted MRI shows an ectopic posterior pituitary *(white arrow)* and a small anterior pituitary *(black arrow). (From Giannopoulou EZ, Rohrer T, Hoffmann P, et al. Solitary median maxillary central incisor. J Pediatr. 2015;167:770, App Fig. 1.)*

markedly enlarged anterior pituitary glands are seen in patients with *PROP1* or *LHX3* gene alterations. Structural lesions causing isolated, acquired GHD are not common, but are important from a therapeutic perspective, such that MRI is usually recommended at the time of the diagnosis of GHD.

Skeletal maturation may be assessed with a plain film of the hand (bone age) and is delayed in patients with isolated GHD and may be even more delayed when there is combined GH and TSH deficiency. Importantly, in very recent or acute onset of hypopituitarism, initial assessment of skeletal age may not demonstrate the delay classically reported in congenital or long-standing hypopituitarism. Further, comorbid *central precocious puberty* may accelerate skeletal development when both precocious puberty and GHD are present, as may be seen in some patients with GHD after cranial irradiation. Dual-photon x-ray absorptiometry shows deficient bone mineralization, deficiencies in lean body mass, and a corresponding increase in adiposity, but it is not routinely recommended in the initial evaluation of pediatric GHD.

DIFFERENTIAL DIAGNOSIS

The causes of growth disorders are numerous. The differential diagnosis can be summarized broadly as follows: hormonal disorders, chronic illness, undernutrition, genetic conditions, nonsyndromic family trait, and constitutional delay of growth and development. Hormonal disorders include primary hypothyroidism and Cushing disease. Systemic conditions, such as inflammatory bowel disease, celiac disease, occult renal disease, and anemia, must be considered. Patients with systemic conditions often have a greater deficit of weight than length. Severe psychosocial deprivation may result in growth failure that mimics GH deficiency. Numerous **syndromic genetic** conditions include short stature as a manifestation, among other findings, whereas some specific genetic alterations may present with isolated short stature. These include Turner syndrome (see Chapter 99.4), pathogenic variants and deletions in *SHOX, ACAN, PTPN11,* and *IHH,* the skeletal dysplasias (see Chapter 735), and identifiable syndromes including Donohue *(INSR),* Kabuki *(KMT2D, KDM6A),* Noonan (RASopathy), Smith-Lemli Opitz *(DHCR7),* and Cornelia de Lange *(NIPBL, SMC1A, HDAC8, RAD21, SMC3).* Prenatal-onset short stature associated with being small for gestational age that persists during childhood may also be syndromic. Whole exome sequencing is helpful in identifying the specific syndrome.

Some otherwise normal children are short (i.e., >2.25 SD below the mean for age) and grow 5 cm/year or less but have normal levels of GH in response to provocative tests and normal spontaneous episodic secretion; this is often termed **idiopathic short stature**. Most of these children show increased rates of growth when treated with GH in doses comparable with those used to treat children with hypopituitarism. Plasma levels of IGF-1 in these patients may be normal or low. Several groups of treated children have achieved final or near-final adult heights. Different studies have found changes in adult height that range from −2.5 to +7.5 cm compared with pretreatment predictions. There are no methods that can reliably predict which of these children will become taller in adulthood as a result of GH treatment and which will have compromised adult height despite treatment.

Diagnostic strategies for distinguishing between permanent GH deficiency and other causes of impaired growth are imperfect. Children with a combination of genetic short stature and constitutional delay of growth have short stature, below-average growth rates, and delayed bone ages. Many of these children exhibit minimal GH secretory responses to provocative stimuli and may be treated with GH therapy. When children in whom idiopathic or acquired isolated GHD is diagnosed are treated with recombinant human GH and retested as adults, the majority have peak GH levels within the normal range.

Constitutional Growth Delay

Constitutional growth delay is one of the variants of normal growth commonly encountered by the pediatrician. Length and weight measurements of affected children are normal at birth, and growth is normal for the first 4-12 months of life. Height is sustained at a lower percentile during childhood. The pubertal growth spurt is delayed, so their growth rates persist at a lower prepubertal rate after their classmates have begun to accelerate. Detailed questioning often reveals other family members (often one or both parents) with histories of short stature in childhood, delayed puberty, and eventual normal stature. IGF-1 levels tend to be low for chronological age but within the normal range for bone age and sexual maturation rating. GH responses to provocative testing tend to be lower than in children with a more typical timing of puberty. The prognosis for these children to achieve normal adult height is guarded. Predictions based on height and bone age tend to overestimate eventual height to a greater extent in males than in females. Males with >2 years of pubertal delay can benefit from a short course of testosterone therapy to hasten puberty after 14 years of age. The cause of this variant of normal growth is thought to be persistence of the relative hypogonadotropic state of childhood.

TREATMENT

Although well-established treatments are available to replace the classical anterior pituitary hormone deficiencies, treatment must take into account patient age, pubertal maturation, and patient goals. Lifelong attention to correct administration of hormone replacement and monitoring for comorbidities are needed to optimize patient outcomes.

Recombinant human GH (rhGH) has been available by prescription since the 1980s. Multiple brands are marketed in the United States, which are therapeutically equivalent, with the major differences consisting of proprietary devices for subcutaneous injection and availability of solubilized liquid forms versus powders needing reconstitution before injection. Long-acting forms are under development and will need to demonstrate comparable efficacy, safety, and tolerability to the daily injections currently available.

The U.S. Food and Drug Administration (FDA) has approved eight pediatric indications for rhGH treatment to promote linear growth. They are GHD, Turner syndrome, chronic renal

failure before transplantation, idiopathic short stature, small-for-gestational-age short stature, Prader-Willi syndrome, *SHOX* gene abnormality, and Noonan syndrome. In the United States, FDA approval for a given indication does not ensure that a patient's insurance carrier will approve payment for the drug. Treatment should be started as soon as possible to narrow the gap in height between patients and their classmates during childhood and to have the greatest effect on mature height. For some infants with MPHD, initiation of rhGH treatment may be urgent to reduce the frequency and severity of episodes of hypoglycemia. The recommended initial dose of rhGH for treatment of GHD is 0.16-0.24 mg/kg/wk (22-35 μg/kg/day). Higher doses have been used during puberty and for non-GHD indications. Most currently available forms of rhGH are administered subcutaneously once daily, but a weekly preparation has been recently FDA approved for use in the United States.

Maximal response to rhGH occurs in the first year of treatment. Growth velocity during this first year is typically above the 95th percentile for age. With each successive year of treatment, the growth rate tends to decrease until it approximates a typical height velocity for skeletal age. If the growth rate drops below the 25th percentile, adherence should be evaluated before the dose is increased. IGF-1 may be measured as an objective assessment of adherence. GH therapy should be continued until near-final height is achieved. Criteria for stopping GH treatment include a decision by the adolescent that they are tall enough, a growth rate less than 1 inch per year, and a bone age greater than 14 years in females and greater than 16 years in males. Adolescents who have completed treatment for promotion of adult stature should be reevaluated for GHD based on adult criteria after treatment is complete. Some adolescents or young adults, particularly those with profound GHD and/or MPHD, may benefit from continuation of rhGH treatment as adults. The dose of rhGH is much lower in adults relative to growing teens. Children with hypopituitarism require coordinated transition to adult care and lifelong attention to their endocrine deficiencies.

Concurrent treatment with rhGH and a gonadotropin-releasing hormone agonist has been used in the hope that interruption of puberty will delay epiphyseal fusion and prolong growth. This strategy may increase adult height. Risks include increasing the discrepancy in physical maturity between GH-deficient children and their age peers, decreasing the upper to lower segment ratio, and impairing bone mineralization. There have also been attempts to forestall epiphyseal fusion in males by giving aromatase inhibitors, which inhibit the enzyme responsible for converting androgens to estrogens. These agents are not approved for this purpose in the United States, but some clinical trials have demonstrated an increase in predicted adult height with this approach.

Some patients develop either primary or central hypothyroidism while under treatment with GH. Similarly, there is a risk of developing adrenal insufficiency as an associated component of **hypopituitarism**. If unrecognized, this can be fatal. Periodic evaluation of thyroid and adrenal function is indicated for all patients diagnosed with GHD.

rhGH treatment may enhance the growth of non-GHD children as well. Intensive investigation is in progress to determine the full spectrum of short children who may benefit from treatment with GH. The FDA approval for use of GH in idiopathic short stature specifies a height below the 1.2 percentile (−2.25 SD) for age and sex, a predicted height below the 5th percentile, and open epiphyses. Studies of the effect of GH treatment on adult height suggest a median gain of 2-3 inches, depending on dose and duration of treatment.

In children with MPHD, replacement should also be directed at other hormonal deficiencies. In TSH-deficient patients, thyroid hormone replacement (levothyroxine) is given in full replacement doses. In ACTH-deficient patients, hydrocortisone should be prescribed in physiologic doses, about 8-12 mg/m^2/day. In patients deficient in both TSH and ACTH, initiation of adrenal replacement before thyroid hormone replacement is mandatory to reduce the risk of adrenal crisis. Individualized dose adjustment of hydrocortisone is needed to minimize the risk of side effects associated with excess glucocorticoid administration and prevent symptoms of adrenal insufficiency. *Increased doses of hydrocortisone are required to support vital functions and prevent adrenal crisis during illness or during and after surgical procedures (so-called "stress dosing.")*

In patients with a deficiency of gonadotropins, gonadal steroids are given at the appropriate time. Consideration of chronological age, height age, bone age, and psychosocial development may all play a role in determining the timing of initiation of low-dose sex steroid replacement in young adolescents. For infants with micropenis, one or two 3-month courses of monthly intramuscular injections of 25 mg of testosterone cypionate or testosterone enanthate can bring the penis to near-normal size without an inordinate effect on osseous maturation.

Recombinant IGF-1 (mecasermin) is approved for use in the United States for primary IGF-1 deficiency. It is given subcutaneously twice a day. Side effects are similar to rhGH, except that mecasermin can cause hypoglycemia. The risk of hypoglycemia is reduced by giving the injections concurrently with a meal or snack. In some situations, its use may be more efficacious than use of GH. These conditions include abnormalities of the GH receptor and *STAT5b* genes that alter GH signaling downstream. It may have utility for severe GHD in the rare patients who have developed clinically significant antibodies to administered rhGH. However, mecasermin is not an indicated treatment for most patients with GHD.

COMPLICATIONS AND ADVERSE EFFECTS OF GROWTH HORMONE TREATMENT

GH treatment influences glucose homeostasis. Fasting and postprandial insulin levels are characteristically low before treatment, and they normalize during GH replacement. GH treatment is associated with an increase in the risk for type 2 diabetes and no significant increase in the risk for type 1 diabetes.

Concerns have been raised about the safety of GH treatment in children who become deficient after treatment of brain tumors, leukemia, and other neoplasms. Long-term studies show no increase in risk of recurrence of craniopharyngioma, other brain tumors, or leukemia. Some studies indicate an increased risk of second neoplasms in cancer survivors treated with GH. However, other studies have found no increased risk for secondary brain tumors after adjustment for radiation therapy. Looking more broadly at young adults treated in childhood with GH for a variety of indications, the Safety and Appropriateness of Growth hormone treatments in Europe consortium (SAGhE) has reported an increase in cause-specific mortality due to circulatory and hematologic conditions, but no increase in all-cause mortality for youth treated with GH.

Other reported side effects include pseudotumor cerebri, slipped capital femoral epiphysis, gynecomastia, coarsening of features, and worsening of scoliosis. The risk of late development of Creutzfeldt-Jakob disease was limited to recipients of contaminated lots of extracted pituitary GH. No comparable risks have been seen with rhGH, which is the only pharmacologic form of hGH currently in clinical use.

Chapter 596

Diabetes Insipidus

Carmen L. Soto-Rivera, David T. Breault, and Joseph A. Majzoub

Diabetes insipidus (DI) manifests clinically with polyuria and polydipsia and can result from either vasopressin deficiency (central DI, also known as arginine vasopressin [AVP] deficiency) or vasopressin insensitivity at the level of the kidney (nephrogenic DI [NDI], also known as AVP resistance). Both central DI and NDI can arise from inherited defects of congenital or neonatal onset or can be secondary to a variety of causes (Table 596.1).

PHYSIOLOGY OF WATER BALANCE

The control of extracellular tonicity (osmolality) and volume within a narrow range is critical for normal cellular structure and function (see Chapter 73.2). Extracellular fluid tonicity is regulated almost exclusively by water intake and excretion, whereas extracellular volume is regulated by sodium intake and excretion. The control of plasma tonicity and intravascular volume involves a complex integration of endocrine, neural, behavioral, and paracrine systems (Fig. 596.1). Vasopressin, secreted from the posterior pituitary, is the principal regulator of tonicity, with its release largely stimulated by increases in plasma osmolality over 283 mOsm/kg H_2O. Volume homeostasis is largely regulated by the renin-angiotensin-aldosterone system, with contributions from both vasopressin and the natriuretic peptide family.

Vasopressin, a 9–amino acid peptide, has both antidiuretic and vascular pressor activity and is synthesized in the paraventricular and supraoptic nuclei of the hypothalamus. It is transported to the posterior pituitary via axonal projections, where it is stored awaiting release into the systemic circulation. The half-life of vasopressin in the circulation is 5-10 minutes, as it is rapidly degraded by a cysteine aminoterminal peptidase. The carboxyterminus of the vasopressin precursor, **copeptin**, is more stable than vasopressin, and blood concentrations of the two peptides are highly correlated when evaluating response to osmotic stimuli.

In addition to responding to osmotic stimuli, vasopressin is secreted in response to significant decreases in intravascular volume and pressure (minimum of 8% decrement) via afferent baroreceptor pathways arising from the aortic arch (carotid sinus) and volume receptor pathways in the cardiac atria and pulmonary veins. Osmotic and hemodynamic stimuli interact synergistically. Nausea is also a potent stimulus for vasopressin secretion.

The sensation of thirst and the release of vasopressin are regulated by cortical and hypothalamic neurons. The thirst threshold is approximately 10 mOsm/kg H_2O higher (i.e., 293 mOsm/kg H_2O) than the osmotic threshold for vasopressin release. Consequently, under conditions of hyperosmolality, vasopressin is released before thirst is initiated, allowing ingested water to be retained. Subsequently, anticipation of water ingestion by cortical and vasopressin-secreting neurons leads to a decrease in vasopressin release immediately before water ingestion, presumably to prevent subsequent hyponatremia. Chemoreceptors present in the oropharynx also downregulate vasopressin release after water ingestion. In addition, thirst drive decreases even before the ingested fluid lowers blood osmolality, presumably to prevent overdrinking leading to hyponatremia.

Vasopressin exerts its principal effect on the kidney via V2 (AVPR2) receptors located primarily in the collecting tubule, the thick ascending limb of the loop of Henle, and the periglomerular tubules. The human V2 receptor gene *(AVPR2)* is located on the long arm of the X chromosome (Xq28) at the locus associated with **congenital, X-linked, vasopressin-resistant DI**. Activation of the V2 receptor results in increases in intracellular cyclic adenosine monophosphate, which leads to the insertion of the aquaporin-2 water channel into the apical (luminal) membrane. This allows water movement along its osmotic gradient into the hypertonic inner medullary interstitium from the tubule lumen and excretion of concentrated urine. In contrast to aquaporin-2, aquaporin-3 and aquaporin-4 are expressed on the basolateral membrane of the collecting duct cells, and aquaporin-1 is expressed in the proximal tubule. These channels may also contribute to urinary concentrating ability.

Atrial natriuretic peptide, initially isolated from cardiac atrial muscle but also expressed in the brain, has several important effects on salt and water balance, including stimulation of natriuresis, inhibition of sodium resorption, inhibition of vasopressin secretion, and inhibition of vasopressin and aldosterone action in the renal tubules. Atrial natriuretic peptide is expressed in endothelial cells and vascular smooth muscle, where it appears to regulate relaxation of arterial smooth muscle. **Brain natriuretic peptide (BNP)**, synthesized and secreted by cardiac ventricular tissue, similarly induces natriuresis, whereas the physiologic role of C-type natriuretic peptide (CNP) has yet to be defined.

Table 596.1 Causes of Hypotonic Polyuria

CENTRAL (NEUROGENIC) DIABETES INSIPIDUS (DI)
Congenital (congenital malformations, autosomal dominant, arginine vasopressin [AVP] neurophysin pathogenic variants)
Drug or toxin induced (ethanol, diphenylhydantoin, snake venom)
Granulomatous (histiocytosis, sarcoidosis)
Neoplastic (craniopharyngioma, germinoma, lymphoma, leukemia, meningioma, pituitary tumor, metastases)
Infectious (meningitis, tuberculosis, encephalitis)
Inflammatory, autoimmune (lymphocytic infundibuloneurohypophysitis, immune check point inhibitors)
Trauma (neurosurgery, deceleration injury)
Vascular (cerebral hemorrhage or infarction, brain death)
Idiopathic
OSMORECEPTOR DYSFUNCTION
Granulomatous (histiocytosis, sarcoidosis)
Neoplastic (craniopharyngioma, pinealoma, meningioma, metastases)
Vascular (anterior communicating artery aneurysm or ligation, intrahypothalamic hemorrhage)
Other (hydrocephalus, ventricular or suprasellar cyst, trauma, degenerative diseases)
Idiopathic
INCREASED AVP METABOLISM
Pregnancy
NEPHROGENIC DIABETES INSIPIDUS
Congenital (X-linked recessive, AVP V2 receptor pathogenic variants, autosomal recessive or dominant, aquaporin-2 water channel pathogenic variants)
Drug induced (lithium, demeclocycline, cisplatin, methoxyflurane)
Hypercalcemia
Hypokalemia
Infiltrating lesions (sarcoidosis, amyloidosis)
Vascular (sickle cell anemia)
Mechanical (polycystic kidney disease, bilateral ureteral obstruction)
Solute diuresis (glucose, mannitol, sodium, radiocontrast dyes)
Idiopathic
PRIMARY POLYDIPSIA
Psychogenic (schizophrenia, obsessive-compulsive behaviors)
Dipsogenic (downward resetting of thirst threshold, idiopathic or similar lesions, as with central DI)

From Verbalis JG. Disorders of water balance. In Skorecki K, Chertow GM, Marsden PA, et al., eds. *Brenner & Rector's The Kidney,* 10th ed. Philadelphia: Elsevier; 2016: Table 16.2.

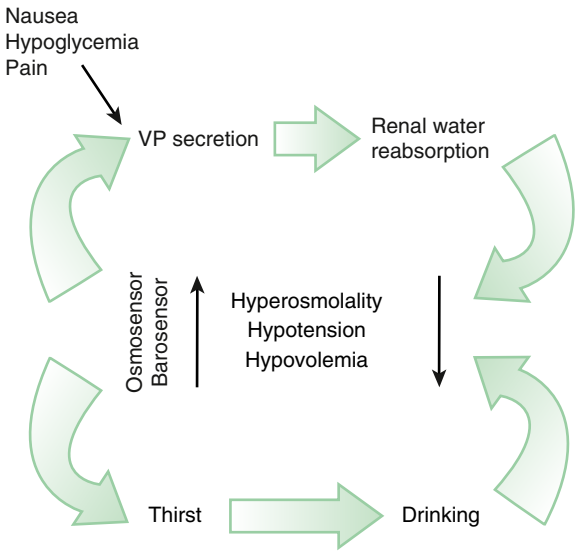

Fig. 596.1 Regulation of vasopressin secretion and serum osmolality. Hyperosmolality, hypovolemia, and hypotension are sensed by osmosensors, volume sensors, and barosensors, respectively. These stimulate both vasopressin secretion and thirst. Vasopressin, acting on the kidney, causes increased reabsorption of water (antidiuresis). Thirst causes increased water ingestion. The results of these dual negative feedback loops cause a reduction in hyperosmolality or in hypotension or hypovolemia. Additional stimuli for vasopressin secretion include nausea, hypoglycemia, and pain. *(From Srivasta A, Majzoub JA. Disorders of the posterior pituitary. In: Sperling MA, ed. Pediatric Endocrinology, 5th ed. Philadelphia: Elsevier; 2020: Fig. 12.6.)*

APPROACH TO THE PATIENT WITH POLYURIA, POLYDIPSIA, AND HYPERNATREMIA

The cause of pathologic polyuria or polydipsia (exceeding 2 L/m^2/24 hr) may be difficult to establish in children. Infants can present with irritability, failure to thrive, and intermittent fever. Patients with suspected DI should have a careful history taken, which should quantify the child's daily fluid intake and output and establish the voiding pattern, nocturia, and primary or secondary enuresis. A complete physical examination should establish the patient's hydration status, and the physician should search for evidence of visual and central nervous system dysfunction, as well as for other pituitary hormone deficiencies.

If pathologic polyuria or polydipsia is present, the following should be obtained: serum for osmolality, sodium, potassium, blood urea nitrogen, creatinine, glucose, hemoglobin A_{1c}, and calcium and urine for osmolality, specific gravity, and glucose determination. The diagnosis of DI is established if the serum osmolality is >300 mOsm/kg H_2O and the urine osmolality is <300 mOsm/kg. A baseline copeptin level above 20 pmol/L in this setting can confirm *nephrogenic* DI.

DI is unlikely if the serum osmolality is <270 mOsm/kg H_2O or the urine osmolality is >600 mOsm/kg. If the patient's serum osmolality is <300 mOsm/kg H_2O (but >270 mOsm/kg H_2O) and pathologic polyuria and polydipsia are present, a water deprivation test is indicated to establish the diagnosis of DI and to differentiate central from nephrogenic causes by assessing response to aqueous vasopressin at the end of the test.

Now that copeptin measurement is clinically available, test protocols aim to measure copeptin instead of AVP during water deprivation. Hypertonic saline infusion (3% saline) can also be given as an osmotic stimulus for copeptin secretion (instead of water deprivation tests), with a potentially higher diagnostic accuracy than water deprivation alone. In the inpatient postneurosurgical setting, central DI is likely if hyperosmolality (serum osmolality >300 mOsm/kg) is associated with urine osmolality less than serum osmolality. It is important to distinguish between polyuria resulting from postsurgical central DI and polyuria resulting from the normal diuresis of fluids received intraoperatively. Both cases may be associated with a large volume (>200 mL/m^2/hr) of dilute urine, although in patients with DI, the serum osmolality is high in comparison with patients undergoing postoperative diuresis.

CAUSES OF HYPERNATREMIA

Hypernatremia is discussed in Chapter 73.3.

Central Diabetes Insipidus

Central DI can result from multiple etiologies, including pathogenic variants in the vasopressin *(AVP)* gene; trauma (accidental or surgical) to vasopressin neurons; congenital malformations of the hypothalamus or pituitary; neoplasms; infiltrative, autoimmune, and infectious diseases affecting vasopressin neurons or fiber tracts; and increased metabolism of vasopressin. In approximately 10% of children with central DI, the etiology is idiopathic. Other pituitary hormone deficiencies may be present (see Chapter 595). *Over time, up to 35% of those with idiopathic central DI will develop other hormone deficiencies or have an underlying etiology identified.*

Autosomal dominant central DI usually occurs within the first 5 years of life and results from pathogenic variants in *AVP*. A number of these genetic variants can cause gene-processing defects in a subset of vasopressin-expressing neurons, which have been postulated to result in endoplasmic reticulum stress and cell death. **Wolfram syndrome**, which includes DI, diabetes mellitus, optic atrophy, and deafness, also results in vasopressin deficiency. Autosomal recessive pathogenic variants in the *WFS1* (most common) or *WFS2* (CISD2) genes, which give rise to endoplasmic reticulum proteins, are associated with this condition. Congenital brain abnormalities (see Chapter 631) such as **optic nerve hypoplasia syndrome** with agenesis of the corpus callosum, **Niikawa-Kuroki syndrome**, holoprosencephaly, and familial pituitary hypoplasia with absent stalk may be associated with central DI and defects in thirst perception (adipsia). Empty sella syndrome, possibly resulting from unrecognized pituitary infarction, can be associated with DI in children.

Trauma to the base of the brain and neurosurgical intervention in the region of the hypothalamus or pituitary are common causes of central DI. The **triphasic response** after surgery refers to an initial phase of transient DI, lasting 12-48 hours, followed by a second phase of syndrome of inappropriate antidiuresis (SIAD), lasting up to 10 days, which may be followed by permanent (or partial) DI. The initial phase may be the result of local edema interfering with normal vasopressin secretion; the second phase results from unregulated vasopressin release from dying neurons, whereas in the third phase, permanent DI results if more than 90% of the neurons have been destroyed.

Given the anatomic distribution of vasopressin neurons over a large area within the hypothalamus, **tumors** causing DI must either be very large and infiltrative or be strategically located near the base of the hypothalamus, where vasopressin axons converge before their entry into the posterior pituitary. Germinomas and pinealomas typically arise in this region and are among the most common primary brain tumors associated with DI. Germinomas can be very small and undetectable by MRI for several years after the onset of polyuria. Quantitative measurement of α-fetoprotein and β-human chorionic gonadotropin, often secreted by germinomas, should be performed in children with idiopathic or unexplained DI in addition to serial MRI scans. Craniopharyngiomas and optic gliomas can also cause central DI when they are very large, although this is more often a postoperative complication of the treatment for these tumors (see Chapter 546). Hematologic malignancies, such as acute myelocytic leukemia, can cause DI via infiltration of the pituitary stalk and sella.

Langerhans cell histiocytosis (see Chapter 556.2) and lymphocytic hypophysitis are common types of infiltrative disorders causing central DI, with **hypophysitis** as the cause in 50% of cases of "idiopathic" central DI. Infections involving the base of the brain (see Chapter 643), including meningitis (meningococcal, cryptococcal, listerial, toxoplasmal), congenital cytomegalovirus infection, and nonspecific

inflammatory diseases of the brain, may give rise to central DI that is often transient. Drugs associated with the inhibition of vasopressin release include ethanol, phenytoin, opiate antagonists, halothane, and α-adrenergic agents.

Nephrogenic Diabetes Insipidus

NDI can result from genetic or acquired causes. Genetic causes are less common but more severe than acquired forms of NDI. The polyuria and polydipsia associated with genetic NDI usually occur within the first several weeks of life but may become apparent only after weaning or with longer periods of nighttime sleep. Many infants initially present with fever, vomiting, and dehydration. Failure to thrive may be secondary to the ingestion of large amounts of water, resulting in caloric malnutrition. Long-standing ingestion and excretion of large volumes of water can lead to nonobstructive hydronephrosis, hydroureter, and megabladder.

Congenital X-linked NDI results from inactivating pathogenic variants of the vasopressin V2 receptor, *AVPR2*. **Congenital autosomal recessive NDI** results from defects in the aquaporin-2 gene, *AQP2*. An **autosomal dominant form of NDI** is associated with processing variants of the *AQP2* gene.

Acquired NDI can result from hypercalcemia or hypokalemia and is associated with lithium, demeclocycline, foscarnet, clozapine, amphotericin, methicillin, and rifampin. Impaired renal concentrating ability can also be seen with ureteral obstruction, chronic renal failure, polycystic kidney disease, medullary cystic disease, Sjögren syndrome, and sickle cell disease. Decreased protein or sodium intake or excessive water intake, as in primary polydipsia, can lead to diminished tonicity of the renal medullary interstitium, which impairs water reabsorption and thus the ability to concentrate the urine, leading to NDI.

TREATMENT OF CENTRAL DIABETES INSIPIDUS

Fluid Therapy

With an intact thirst mechanism and free access to oral fluids, a person with complete DI can maintain plasma osmolality and sodium in the high-normal range, although at great inconvenience. Neonates and young infants are often best treated solely with fluid therapy, given their requirement for large volumes (~3 L/m^2/24 hr) of nutritive fluid. The use of vasopressin analogs in patients with obligate high fluid intake is difficult given the risk of life-threatening hyponatremia. Although not FDA approved, the use of DDAVP (desmopressin) administered to infants with central DI, both as the diluted parenteral form given subcutaneously and as the diluted intranasal form given via the buccal mucosa, has been successful without causing severe hyponatremia. Patients with both central DI and NDI should ingest a diet without excessive solute (e.g., sodium chloride) to help decrease urine output when vasopressin action wanes.

Vasopressin Analogs

Treatment of central DI in older children is best accomplished with the use of DDAVP. DDAVP is available in an intranasal preparation (onset 5-10 minutes) and more commonly as tablets (onset 15-30 minutes). The intranasal preparation of DDAVP (10 μg/0.1 mL) can be administered by rhinal tube (allowing dose titration) or by nasal spray (10 μg/puff). Use of DDAVP oral tablets requires at least a 10-fold increase in the dosage compared with the intranasal preparation. Oral dosages of 25-300 micrograms every 8-12 hours are safe and effective in children. The appropriate dosage and route of administration are determined empirically based on the desired length of antidiuresis and patient preference. The use of oral DDAVP for the treatment of enuresis in older children should be regarded as a temporizing measure, given that it does not affect the underlying condition, and should be used with great caution given the risk of hyponatremia if water intake exceeds the capacity for renal clearance. To prevent water intoxication, patients should have at least 1 hour of urinary breakthrough between doses each day and be advised to drink only in response to thirst sensation, if present. The use of DDAVP nasal spray for childhood enuresis is no longer approved because of its risk of causing hyponatremia.

Aqueous Vasopressin

Central DI of acute onset after neurosurgery is best managed with continuous administration of synthetic aqueous vasopressin (Pitressin). Under most circumstances, total fluid intake must be limited to 1 L/m^2/24 hr during antidiuresis. A typical dosage for intravenous vasopressin therapy is 1.5 mU/kg/hr, which results in a blood vasopressin concentration of approximately 10 pg/mL. On occasion, after hypothalamic (but not transsphenoidal) surgery, higher initial concentrations of vasopressin may be required to treat acute DI, which has been attributed to the release of a vasopressin inhibitory substance. *Vasopressin concentrations >1,000 pg/mL should be avoided because they can cause cutaneous necrosis, rhabdomyolysis, cardiac rhythm disturbances, and hypertension.* Post-neurosurgical patients treated with vasopressin infusion should be switched from intravenous to oral fluids as soon as possible to allow thirst sensation, if intact, to help regulate osmolality.

Individuals with central DI caused by intracranial tumors that require chemotherapy often need hyperhydration with large amounts of intravenous fluids to prevent nephrotoxicity during treatment. Using a low-dose vasopressin continuous infusion to minimally concentrate urine above baseline can allow infusion of fluids over 1 L/m^2/day, while preventing the discomfort of full diuresis if done under careful monitoring of volume status and sodium levels.

TREATMENT OF NEPHROGENIC DIABETES INSIPIDUS

The treatment of acquired NDI focuses on eliminating, if possible, the underlying disorder, such as offending drugs, hypercalcemia, hypokalemia, or ureteral obstruction. Congenital NDI is often difficult to treat. The main goals are to ensure the intake of adequate calories for growth and to avoid severe dehydration. Foods with the highest ratio of caloric content to osmotic load (Na <1 mmol/kg/24 hr) should be ingested to maximize growth and to minimize the urine volume required to excrete the solute load. However, even with the early institution of therapy, growth failure and developmental disabilities are common.

Pharmacologic approaches to the treatment of NDI include the use of thiazide diuretics and are intended to decrease the overall urine output. Thiazides appear to induce a state of mild volume depletion by enhancing sodium excretion at the expense of water and by causing a decrease in the glomerular filtration rate, which results in proximal tubular sodium and water reabsorption. Indomethacin and amiloride may be used in combination with thiazides to further reduce polyuria. High-dose DDAVP therapy, in combination with indomethacin, has been used in some subjects with NDI. This treatment could prove useful in patients with genetic defects in the V2 receptor associated with a reduced binding affinity for vasopressin.

Chapter 597

Other Abnormalities of Arginine Vasopressin Metabolism and Action

Carmen L. Soto-Rivera, David T. Breault, and Joseph A. Majzoub

Hyponatremia (serum sodium <130 mEq/L) in children is usually associated with severe systemic disorders and is most often a result of intravascular volume depletion, excessive salt loss, or hypotonic fluid overload, especially in infants (see Chapter 73).

The initial approach to the patient with hyponatremia begins with determination of the volume status. A careful review of the patient's history, physical examination (including changes in weight), and vital signs helps to determine whether the patient is hypovolemic or hypervolemic. Supportive evidence includes laboratory data such as serum electrolytes, blood urea nitrogen, creatinine, uric acid, urine sodium, specific gravity, and osmolality (Tables 597.1 and 597.2; see Chapter 73).

CAUSES OF HYPONATREMIA

Systemic Dehydration

The initial manifestation of systemic dehydration is often hypernatremia and hyperosmolality, which subsequently lead to the activation of vasopressin secretion and a decrease in water excretion. As dehydration progresses, hypovolemia and/or hypotension become a major stimulus for vasopressin release, further decreasing free water clearance. Excessive free water intake (orally or intravenous infusion of hypotonic fluids) with ongoing salt loss can produce hyponatremia. Urinary sodium excretion is low (usually <20 mEq/L), owing to a low glomerular filtration rate and concomitant activation of the renin-angiotensin-aldosterone system unless primary renal disease or diuretic therapy is present.

Table 597.1 Differential Diagnosis of Hyponatremia

DISORDER	INTRAVASCULAR VOLUME STATUS	URINE SODIUM
Systemic dehydration	Low	Low
Decreased effective plasma volume	Low	Low
Primary salt loss (nonrenal)	Low	Low
Primary salt loss (renal)	Low	High
Adrenal insufficiency	Low	High
SIAD	High	High
Cerebral salt wasting	Low	Very high
Decreased free water clearance	Normal or high	Normal or high
Primary polydipsia	Normal or high	Normal
Runner's hyponatremia	Low	Low
NSIAD	High	High
Pseudohyponatremia	Normal	Normal
Factitious hyponatremia	Normal	Normal

NSIAD, Nephrogenic syndrome of inappropriate antidiuresis; SIAD, syndrome of inappropriate antidiuresis.

Runner's Hyponatremia

Excess hypotonic fluid ingestion during long-distance running (e.g., marathon running) can result in severe hyponatremia from hypovolemia-induced activation of arginine vasopressin secretion coupled with excessive water ingestion and is correlated with weight gain, long racing time, and extremes of body mass index.

Decreased Effective Plasma Volume

Hyponatremia can result from decreased effective plasma volume, as found in congestive heart failure, cirrhosis, nephrotic syndrome, positive pressure mechanical ventilation, severe burns, bronchopulmonary dysplasia in neonates, cystic fibrosis with obstruction, and severe asthma. The resulting decrease in cardiac output leads to reduced water and salt excretion, as with systemic dehydration, and an increase in vasopressin secretion. In patients with impaired cardiac output and elevated atrial volume (congestive heart failure, lung disease), atrial natriuretic peptide concentrations are elevated further, leading to hyponatremia by promoting natriuresis. However, owing to the marked elevation of aldosterone in these patients, their urine sodium remains low (<20 mEq/L) despite this. Unlike dehydrated patients, these patients also have excess *total body* sodium from activation of the renin-angiotensin-aldosterone system and can demonstrate peripheral edema as well.

Syndrome of Inappropriate Antidiuresis

The syndrome of inappropriate antidiuresis (SIAD) is characterized by hyponatremia, an inappropriately concentrated urine (often >800 mOsm/kg H_2O), normal or slightly elevated plasma volume, normal-to-high urine sodium, and low serum uric acid. SIAD is uncommon in children, and most cases result from excessive administration of vasopressin in the treatment of central diabetes insipidus (vasopressin deficiency). It can also occur with increased intracranial pressure, encephalitis, brain tumors, head trauma, psychiatric disease, prolonged nausea, pneumonia, tuberculous and bacterial meningitis, AIDS, and in the postictal phase after generalized seizures (Table 597.3). SIAD is the cause of the hyponatremic second phase of the triphasic response seen after hypothalamic-pituitary surgery. It is found in up to 35% of patients 1 week after surgery and can result from retrograde neuronal degeneration with cell death and vasopressin release. Common drugs that have been shown to increase vasopressin secretion or mimic vasopressin action, resulting in hyponatremia, include oxcarbazepine, carbamazepine, chlorpropamide, vinblastine, vincristine, and tricyclic antidepressants.

Nephrogenic Syndrome of Inappropriate Antidiuresis

Gain-of-function pathogenic variants in the V2 vasopressin receptor gene, *AVPR2,* on chromosome Xq28 have been described in male

Table 597.2 Clinical Parameters to Distinguish Among Syndrome of Inappropriate Antidiuresis (SIAD), Cerebral Salt Wasting, and Central Diabetes Insipidus (DI)

CLINICAL PARAMETER	SIAD	CEREBRAL SALT WASTING	CENTRAL DI
Serum sodium	Low	Low	High
Urine output	Normal or low	High	High
Urine sodium	High	Very high	Low
Intravascular volume status	Normal or high	Low	Low
Blood pressure	Normal	Decreased/ orthostatic hypotension	Decreased/ orthostatic hypotension
Vasopressin level	High	Low	Low
BUN	Low	High	High

Table 597.3 Disorders Associated with Syndrome of Inappropriate Antidiuresis

CANCER	PULMONARY DISORDERS	CENTRAL NERVOUS SYSTEM DISORDERS	OTHER DISORDERS
Thymoma	Viral pneumonia	Encephalitis (viral or bacterial)	AIDS
Lymphoma	Bacterial pneumonia	Meningitis (viral, bacterial, tuberculous, fungal)	Prolonged exercise
Ewing sarcoma	Pulmonary abscess	Head trauma	Idiopathic (in older individuals)
Oropharyngeal tumor	Tuberculosis	Brain abscess	Nephrogenic
	Aspergillosis	Guillain-Barré syndrome	Acute intermittent porphyria
	Positive pressure ventilation	Subarachnoid hemorrhage or subdural hematoma	
	Asthma	Cerebellar and cerebral atrophy	
	Pneumothorax	Cavernous sinus thrombosis	
	Cystic fibrosis	Neonatal hypoxia	
		Shy-Drager syndrome	
		Rocky Mountain spotted fever	
		Delirium tremens	
		Cerebrovascular accident (cerebral thrombosis or hemorrhage)	
		Acute psychosis	
		Peripheral neuropathy	
		Multiple sclerosis	

Modified from Verbalis JG. Disorders of water balance. In Skorecki K, Chertow GM, Marsden PA, et al., eds, *Brenner & Rector's The Kidney,* 10th ed. Philadelphia: Elsevier; 2016: Table 16.6.

neonates with an SIAD-like clinical picture with undetectable vasopressin levels. Females are most often asymptomatic carriers. It is most commonly treated by fluid restriction, but oral urea has also been used to promote osmotic diuresis and increase water clearance. Germline activating pathogenic variants in *GNAS* have also been found in infants presenting with hyponatremia. Activating variants in the aquaporin-2 gene *(AQP2)* also give rise to the same syndrome.

Cerebral Salt Wasting

Cerebral salt wasting appears to be the result of hypersecretion of natriuretic peptides and is seen primarily with central nervous system disorders, including brain tumors, head trauma, hydrocephalus, neurosurgery, cerebrovascular accidents, and brain death. Hyponatremia is accompanied by elevated urinary sodium excretion (often >150 mEq/L), excessive urine output, hypovolemia, normal or high uric acid, and elevated atrial natriuretic peptide concentrations (>20 pmol/L). Thus it is distinguished from SIAD, in which normal or decreased urine output, normal or elevated blood volume, only modestly elevated urine sodium concentration, and an elevated vasopressin level occur. The distinction between cerebral salt wasting and SIAD is important because the treatment of the two disorders differs markedly. The existence of cerebral salt wasting has been controversial; however, current data support this entity as different from SIAD.

Primary Polydipsia (Increased Water Ingestion)

In patients with normal renal function, the kidney can excrete dilute urine with an osmolality as low as 50 mOsm/kg H_2O. To excrete a daily solute load of 500 mOsm/m^2 under these circumstances, the kidney must produce 10 L/m^2 of urine per day. Therefore to avoid hyponatremia, the maximum amount of water a person with normal renal function can consume daily is 10 L/m^2, or less if solute intake is lower. However, neonates cannot dilute their urine to this degree, putting them at risk for water intoxication if water intake exceeds 4 L/m^2/day (approximately 60 mL/hr in a newborn). Infants may develop transient hyponatremic seizures after being fed pure water without electrolytes rather than breast milk or formula.

Primary Salt Loss

Hyponatremia can result from the primary loss of sodium chloride, as seen in specific disorders of the kidney (congenital polycystic kidney disease, acute interstitial nephritis, chronic renal failure), gastrointestinal tract (gastroenteritis), and sweat glands (cystic fibrosis). The hyponatremia is not solely caused by salt loss, as it is often associated with hypovolemia, leading to an increase in vasopressin. Mineralocorticoid deficiency (hypoaldosteronism), pseudohypoaldosteronism (genetic or sometimes seen in children with urinary tract obstruction or infection), and diuretics can also result in loss of sodium chloride (Table 597.4). Low aldosterone states, such as primary adrenal insufficiency (Addison disease), are associated with salt wasting, hypovolemia, hyponatremia, hyperkalemia, and failure to thrive.

Decreased Free Water Clearance

Hyponatremia as a consequence of decreased renal free water clearance, even in the absence of an increase in vasopressin secretion, can result from adrenal insufficiency or thyroid deficiency or can be related to a direct effect of drugs on the kidney. Glucocorticoids are required for normal free water clearance in a vasopressin-independent manner. In patients with unexplained hyponatremia, adrenal and thyroid insufficiency should be considered. Patients with coexisting adrenal failure and diabetes insipidus might have no symptoms of the latter until glucocorticoid therapy unmasks the need for vasopressin replacement. Certain drugs can inhibit renal water excretion through direct effects on the nephron, thus causing hyponatremia; these drugs include high-dose cyclophosphamide, vinblastine, cisplatinum, carbamazepine, and oxcarbazepine.

Pseudohyponatremia and Other Causes of Hyponatremia

Pseudohyponatremia can result from hypertriglyceridemia (see Chapter 73.3). Elevated lipid levels result in a relative decrease in serum water content. As electrolytes are dissolved in the aqueous phase of the serum, they appear low when expressed as a fraction of the total serum volume. However, as a fraction of serum water, electrolyte content is normal. Modern laboratory methods that measure sodium concentration directly, independent of sample volume, do not cause this anomaly. Factitious hyponatremia can result from obtaining a blood sample downstream to the site of intravenous hypotonic fluid infusion.

Hyponatremia is also associated with hyperglycemia, which causes the influx of water into the intravascular space. Serum sodium decreases by ~1.6 mEq/L for every 100 mg/dL increment in blood glucose >100 mg/dL. Glucose is not ordinarily an osmotically active agent and does not stimulate vasopressin release, probably because it can equilibrate freely across plasma membranes. However, in the presence of insulin deficiency and hyperglycemia, glucose acts as an osmotic agent, presumably because its normal intracellular access to osmosensor sites is prevented. Under these circumstances, an osmotic gradient exists, stimulating vasopressin release.

TREATMENT

Patients with systemic dehydration and hypovolemia should be rehydrated with salt-containing fluids such as normal saline or lactated Ringer's solution. Because of activation of the renin-angiotensin-aldosterone system, the administered sodium is avidly conserved, and water diuresis quickly

Table 597.4 Pathogenic Gene Variants Associated with Hypoaldosteronism/ Pseudohypoaldosteronism (Type IV Renal Tubular Acidosis)

GENE CHROMOSOME OMIM	PATHOPHYSIOLOGY	PATHOGENIC VARIANT–CLINICAL MANIFESTATIONS–OMIM–INHERITANCE
PRIMARY HYPOALDOSTERONISM		
CYP21A2—cytochrome P450, subfamily XXIA, polypeptide 2 6p21.3 613815	P450c21—steroid 21-hydroxylase that converts 17 α-hydroxyprogesterone to 11-deoxycortisol and progesterone to 11-deoxycorticosterone in the adrenal zona fasciculata	Loss-of-function pathogenic variants decrease synthesis of cortisol and aldosterone, the latter resulting in the salt-losing form of classic congenital adrenal hyperplasia, AR–201910
CYP11B2—cytochrome P450, subfamily XIB, polypeptide 2 8q21 124080	P450c11B2—aldosterone synthase/corticosterone methyloxidase types I and II expressed only in the zona glomerulosa; hydroxylates deoxycorticosterone at carbon-11 and corticosterone at carbon-18 and oxidizes 18-hydroxycorticosterone to aldosterone	Loss-of-function pathogenic variants associated with severe salt loss and volume depletion but not with abnormalities of genital formation or glucocorticoid synthesis AR (CMOI 203400; CMOII 610600)
PSEUDOHYPOALDOSTERONISM TYPE I (PHA1)		
NR3C2—nuclear receptor subfamily 3, group C, member 2 (MR-mineralocorticoid receptor), 4q31.1 600983	Ligand-activated nuclear transcription factor that transmits aldosterone-mediated control of gene expression by binding to the mineralocorticoid response element in the promoter region of the target gene	Loss-of-function pathogenic variants in the MR lead to mineralocorticoid resistance and salt wasting, PHA1A, AD–177735
SCNN1A—sodium channel, non–voltage-gated, α-subunit 12p13.31 600228	Inactivating pathogenic variant of α-subunit of the epithelial sodium channel	Loss-of-function pathogenic variants in the epithelial sodium channel lead to mineralocorticoid resistance and salt wasting, PHA1B, AR–264350
SCNN1B—sodium channel, non–voltage-gated, β-subunit 16p12.2 600760	Inactivating mutation of β-subunit of the epithelial sodium channel	Loss-of-function pathogenic variants in the epithelial sodium channel lead to mineralocorticoid resistance and salt wasting, PHA1B, AR–264350
SCNN1G—sodium channel, non–voltage-gated, γ-subunit 16p12.2 600761	Inactivating mutation of γ-subunit of the epithelial sodium channel	Loss-of-function pathogenic variants in the epithelial sodium channel lead to mineralocorticoid resistance and salt wasting, PHA1B AR–264350
PSEUDOHYPOALDOSTERONISM TYPE II (PHA2) (GORDON SYNDROME)		
WNK4—protein kinase, lysine-deficient 4 17q21.31 601844	Multifunctional serine-threonine protein kinase whose substrate is SLC12A3, the thiazide-sensitive sodium/chloride co-transporter (NCCT)—OMIM 600968—that also regulates lysosomal degradation of NCCT and endocytosis of the KCNJ1 potassium channel	Gain-of-function pathogenic variants lead to hyperkalemia and hypertension, PHA2B, AD–614491
WNK1—protein kinase, lysine-deficient 1 12p13.33 605232	Serine-threonine protein kinase that inactivates WNK4 by phosphorylating its kinase domain	Gain-of-function pathogenic variants lead to hyperkalemia and hypertension, PHA2C, AD–614492
KLH3—Kelch-like 3 5q31.2 605775	Adaptor protein within the ubiquitination sequence that links WNK1 and WNK4 to CUL3	Gain-of-function pathogenic variants lead to hyperkalemia and hypertension, PHA2D, AD/AR–614495
CUL3—Cullin 3 2q36.2 603136	Scaffold protein that links to RING-box E3 ligase facilitating WNK4 ubiquitination and proteasomal destruction of WNK4	Gain-of-function pathogenic variants lead to hyperkalemia and hypertension, PHA2E, AD–614496

AD, Autosomal dominant; AR, autosomal recessive; CMO, corticosterone methyloxidase; OMIM, Online Mendelian Inheritance in Man.
From Root AW. Disorders of aldosterone synthesis, secretion, and cellular function. *Curr Opin Pediatr.* 2014;26:480–486, Table 1.

ensues as volume is restored and vasopressin concentrations decrease. Under these conditions, caution must be taken to prevent a too-rapid correction of hyponatremia (with a goal increase of <0.5 mEq/L/hr), which can result in central pontine myelinolysis characterized by discrete regions of axonal demyelination and the potential for irreversible brain damage.

Hyponatremia from a decrease in effective plasma volume caused by cardiac, hepatic, renal, or pulmonary dysfunction is more difficult to reverse. The most effective therapy is treatment of the underlying systemic disorder. Patients weaned from positive pressure ventilation undergo a prompt water diuresis and resolution of hyponatremia as cardiac output is restored and vasopressin concentrations decrease. Vaptans are a class of small-molecule arginine vasopressin V2 receptor antagonists (aquaretics) useful for the treatment of hypervolemic hyponatremia associated with severe congestive heart failure and chronic liver failure. Although these agents successfully increase plasma sodium, they also lead to increased thirst and plasma vasopressin levels, which can limit their effectiveness, can increase serum sodium more rapidly than is safe, and may cause hepatoxicity.

Patients with hyponatremia from primary salt loss require supplementation with sodium chloride and fluids. Initially, intravenous replacement with isotonic fluids containing sodium chloride (150 mEq/L) may be necessary. Hypertonic fluids (450 mEq/L sodium choride) should be reserved for treatment of acute neurologic deterioration caused by severe hyponatremia. Oral salt supplementation may be required subsequently. This treatment contrasts with that of SIAD, in which water restriction without sodium supplementation is the mainstay.

Emergency Treatment of Hyponatremia

The development of acute hyponatremia (onset <12 hr) or a serum sodium concentration <120 mEq/L may be associated with lethargy,

psychosis, coma, or generalized seizures, especially in younger children. Acute hyponatremia can cause cell swelling and lead to neuronal dysfunction or to cerebral herniation. *The emergency treatment of cerebral dysfunction resulting from acute hyponatremia includes water restriction and can require rapid correction with hypertonic 3% sodium chloride*. If hypertonic saline treatment is undertaken, the serum sodium should be raised only high enough to cause an improvement in mental status and, in no case, faster than 0.5 mEq/L/hr or 12 mEq/L/24 hr.

Treatment of Syndrome of Inappropriate Antidiuresis

Chronic SIAD is best treated by oral fluid restriction. With full antidiuresis (urine osmolality of 1,000 mOsm/kg H_2O), a normal daily obligate renal solute load of 500 mOsm/m^2 would be excreted in 500 mL/m^2 water. This, plus a daily nonrenal water loss of 500 mL/m^2, would require that oral fluid intake be limited to 1,000 mL/m^2/24 hr to avoid hyponatremia. In young children, this degree of fluid restriction might not provide adequate calories for growth. In this situation, a vaptan such as tolvaptan, although not FDA approved in children and may cause initial correction of hyponatremia too rapidly, may allow sufficient fluid intake for normal growth without concomitant hyponatremia. Urea has also been safely used to induce an osmotic diuresis in infants and children.

Treatment of Cerebral Salt Wasting

Treatment of patients with cerebral salt wasting consists of restoring intravascular volume with sodium chloride and water, as for the treatment of other causes of systemic dehydration. The underlying cause of the disorder, which is usually the result of acute brain injury, should also be treated if possible. Treatment involves the ongoing replacement of urine and sodium losses volume for volume.

Chapter 598

Hyperpituitarism

Omar Ali

Hyperpituitarism is defined as the excessive secretion or production of one or more of the hormones produced by the pituitary gland. The anterior pituitary normally produces prolactin, growth hormone (GH), thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), and the gonadotropin hormones (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]); overproduction of any of these hormones is possible, though all are relatively rare. The posterior pituitary stores and releases antidiuretic hormone (ADH) and oxytocin, both produced by neurons in the hypothalamus. Although extremely rare cases of hypothalamic neurocytomas producing excess ADH have been reported (mostly in adults), these are vanishingly rare and will not be considered any further. *Hyperpituitarism refers to the overproduction of one or more of the anterior pituitary hormones.*

SECONDARY HYPERPITUITARISM

Several of the anterior pituitary hormones (all except GH and prolactin) act on other endocrine glands and regulate their secretion. They are regulated by negative feedback loops from their target glands, and their secretion increases if the end organ is not producing enough hormone. This can lead in extreme cases to severe hypertrophy of the relevant anterior pituitary cells and is a normal physiologic response to target hormone deficiencies resulting in decreased hormonal feedback, such as in hypogonadism, hypoadrenalism, or hypothyroidism. In these cases of *secondary hyperpituitarism,* chronic pituitary hypersecretion occurs in response to target hormone deficiencies that leads to pituitary hyperplasia; in extreme cases this can even enlarge and erode the sella and, on rare occasions, increase intracranial pressure. Such enlargements should not be confused with *primary* pituitary tumors; they disappear, and elevated pituitary hormone levels readily suppress to normal when the underlying hormone deficiency is treated by replacement of end-organ hormones.

Primary hypersecretion of pituitary hormones is uncommon in childhood. The most commonly diagnosed adenoma during childhood is prolactinoma, followed by corticotropinoma, and then somatotropinoma, which secrete prolactin, corticotropin, and GH, respectively. There are a handful of case reports of **thyrotropinoma** in children and adolescents. There are no pediatric reports of gonadotropinoma, but hypothalamic hamartomas that secrete excess gonadotropin-releasing hormone are one cause of precocious puberty. In very rare cases, pituitary hyperplasia can also occur in response to stimulation by ectopic production of releasing hormones such as that seen occasionally in patients with Cushing syndrome secondary to corticotropin-releasing hormone excess or in children with acromegaly secondary to growth hormone–releasing hormone (GHRH) produced by a variety of systemic tumors.

The monoclonal nature of most pituitary adenomas implies that most originate from a clonal event in a single cell. In some cases, the pituitary tumors result from stimulation with hypothalamic-releasing hormones and in other instances, as in **McCune-Albright syndrome** (MAS), the tumor is caused by activating pathogenic variants of the *GNAS1* gene that codes for the α subunit of $G_s\alpha$, a guanine nucleotide-binding protein. The clinical presentation typically depends on the pituitary hormone that is hypersecreted. In addition, disruptions of growth regulation and/or sexual maturation are common as a result of either hormone hypersecretion or local compression by the tumor. MAS also features polyostotic fibrous dysplasia of bone and café-au-lait spots in a distinct distribution.

EXCESS GROWTH HORMONE SECRETION AND PITUITARY GIGANTISM

In young persons with open epiphyses, overproduction of GH results in **gigantism**; in persons with closed epiphyses, the result is **acromegaly**. Often some acromegalic features are seen with gigantism, even in children and adolescents. After closure of the epiphyses, the acromegalic features become more prominent.

Gigantism is rare, with only several hundred reported cases worldwide to date. It must be emphasized that the vast majority of patients with tall stature will not have gigantism. The normal distribution of height predicts that 2.3% of the population will be taller than 2 standard deviations (SD) (97.7%) above the mean, and many cases of tall stature will therefore be normal-variant familial tall stature; if their growth is in line with their midparental height and no other concerning features are present, then no further investigation is needed. In cases where the tall stature is unexpected or extreme, other etiologies of rapid linear growth such as precocious puberty and hyperthyroidism should be carefully excluded. Coexisting findings (e.g., dysmorphic facial features, neurocognitive problems, hemihypertrophy) may suggest syndromic or chromosomal causes of tall stature, such as Sotos, Weaver, Klinefelter, or XYY syndrome.

The cardinal clinical feature of gigantism is longitudinal growth acceleration secondary to GH excess. The usual manifestations consist of coarse facial features and enlarging hands and feet. In young children, rapid growth of the head can precede linear growth. Some patients have behavioral and visual problems. In most recorded cases, the abnormal growth became evident at puberty, but the condition has been established as early as the newborn period. Giants have rarely been reported to grow to a height of over 8 feet. In some cases, the patient may present with local effects of the pituitary tumor (headache, visual field defects, and other pituitary hormone deficiencies) as the main complaint, and there is at least one report of a patient presenting with diabetic ketoacidosis induced by GH excess. The presentation of gigantism is usually dramatic, unlike the insidious onset of acromegaly in adults.

Pituitary adenomas secreting GH are more common in males, but females may present at an earlier age. Tumors with *AIP* pathogenic

psychosis, coma, or generalized seizures, especially in younger children. Acute hyponatremia can cause cell swelling and lead to neuronal dysfunction or to cerebral herniation. *The emergency treatment of cerebral dysfunction resulting from acute hyponatremia includes water restriction and can require rapid correction with hypertonic 3% sodium chloride*. If hypertonic saline treatment is undertaken, the serum sodium should be raised only high enough to cause an improvement in mental status and, in no case, faster than 0.5 mEq/L/hr or 12 mEq/L/24 hr.

Treatment of Syndrome of Inappropriate Antidiuresis

Chronic SIAD is best treated by oral fluid restriction. With full antidiuresis (urine osmolality of 1,000 mOsm/kg H_2O), a normal daily obligate renal solute load of 500 mOsm/m^2 would be excreted in 500 mL/m^2 water. This, plus a daily nonrenal water loss of 500 mL/m^2, would require that oral fluid intake be limited to 1,000 mL/m^2/24 hr to avoid hyponatremia. In young children, this degree of fluid restriction might not provide adequate calories for growth. In this situation, a vaptan such as tolvaptan, although not FDA approved in children and may cause initial correction of hyponatremia too rapidly, may allow sufficient fluid intake for normal growth without concomitant hyponatremia. Urea has also been safely used to induce an osmotic diuresis in infants and children.

Treatment of Cerebral Salt Wasting

Treatment of patients with cerebral salt wasting consists of restoring intravascular volume with sodium chloride and water, as for the treatment of other causes of systemic dehydration. The underlying cause of the disorder, which is usually the result of acute brain injury, should also be treated if possible. Treatment involves the ongoing replacement of urine and sodium losses volume for volume.

Chapter 598

Hyperpituitarism

Omar Ali

Hyperpituitarism is defined as the excessive secretion or production of one or more of the hormones produced by the pituitary gland. The anterior pituitary normally produces prolactin, growth hormone (GH), thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), and the gonadotropin hormones (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]); overproduction of any of these hormones is possible, though all are relatively rare. The posterior pituitary stores and releases antidiuretic hormone (ADH) and oxytocin, both produced by neurons in the hypothalamus. Although extremely rare cases of hypothalamic neurocytomas producing excess ADH have been reported (mostly in adults), these are vanishingly rare and will not be considered any further. *Hyperpituitarism refers to the overproduction of one or more of the anterior pituitary hormones.*

SECONDARY HYPERPITUITARISM

Several of the anterior pituitary hormones (all except GH and prolactin) act on other endocrine glands and regulate their secretion. They are regulated by negative feedback loops from their target glands, and their secretion increases if the end organ is not producing enough hormone. This can lead in extreme cases to severe hypertrophy of the relevant anterior pituitary cells and is a normal physiologic response to target hormone deficiencies resulting in decreased hormonal feedback, such as in hypogonadism, hypoadrenalism, or hypothyroidism. In these cases of *secondary hyperpituitarism,* chronic pituitary hypersecretion occurs in response to target hormone deficiencies that leads to pituitary hyperplasia; in extreme cases this can even enlarge and erode the sella and, on rare occasions, increase intracranial pressure. Such enlargements should not be confused with *primary* pituitary tumors; they disappear, and elevated pituitary hormone levels readily suppress to normal when the underlying hormone deficiency is treated by replacement of end-organ hormones.

Primary hypersecretion of pituitary hormones is uncommon in childhood. The most commonly diagnosed adenoma during childhood is prolactinoma, followed by corticotropinoma, and then somatotropinoma, which secrete prolactin, corticotropin, and GH, respectively. There are a handful of case reports of **thyrotropinoma** in children and adolescents. There are no pediatric reports of gonadotropinoma, but hypothalamic hamartomas that secrete excess gonadotropin-releasing hormone are one cause of precocious puberty. In very rare cases, pituitary hyperplasia can also occur in response to stimulation by ectopic production of releasing hormones such as that seen occasionally in patients with Cushing syndrome secondary to corticotropin-releasing hormone excess or in children with acromegaly secondary to growth hormone–releasing hormone (GHRH) produced by a variety of systemic tumors.

The monoclonal nature of most pituitary adenomas implies that most originate from a clonal event in a single cell. In some cases, the pituitary tumors result from stimulation with hypothalamic-releasing hormones and in other instances, as in **McCune-Albright syndrome** (MAS), the tumor is caused by activating pathogenic variants of the *GNAS1* gene that codes for the α subunit of $G_s\alpha$, a guanine nucleotide-binding protein. The clinical presentation typically depends on the pituitary hormone that is hypersecreted. In addition, disruptions of growth regulation and/or sexual maturation are common as a result of either hormone hypersecretion or local compression by the tumor. MAS also features polyostotic fibrous dysplasia of bone and café-au-lait spots in a distinct distribution.

EXCESS GROWTH HORMONE SECRETION AND PITUITARY GIGANTISM

In young persons with open epiphyses, overproduction of GH results in **gigantism**; in persons with closed epiphyses, the result is **acromegaly**. Often some acromegalic features are seen with gigantism, even in children and adolescents. After closure of the epiphyses, the acromegalic features become more prominent.

Gigantism is rare, with only several hundred reported cases worldwide to date. It must be emphasized that the vast majority of patients with tall stature will not have gigantism. The normal distribution of height predicts that 2.3% of the population will be taller than 2 standard deviations (SD) (97.7%) above the mean, and many cases of tall stature will therefore be normal-variant familial tall stature; if their growth is in line with their midparental height and no other concerning features are present, then no further investigation is needed. In cases where the tall stature is unexpected or extreme, other etiologies of rapid linear growth such as precocious puberty and hyperthyroidism should be carefully excluded. Coexisting findings (e.g., dysmorphic facial features, neurocognitive problems, hemihypertrophy) may suggest syndromic or chromosomal causes of tall stature, such as Sotos, Weaver, Klinefelter, or XYY syndrome.

The cardinal clinical feature of gigantism is longitudinal growth acceleration secondary to GH excess. The usual manifestations consist of coarse facial features and enlarging hands and feet. In young children, rapid growth of the head can precede linear growth. Some patients have behavioral and visual problems. In most recorded cases, the abnormal growth became evident at puberty, but the condition has been established as early as the newborn period. Giants have rarely been reported to grow to a height of over 8 feet. In some cases, the patient may present with local effects of the pituitary tumor (headache, visual field defects, and other pituitary hormone deficiencies) as the main complaint, and there is at least one report of a patient presenting with diabetic ketoacidosis induced by GH excess. The presentation of gigantism is usually dramatic, unlike the insidious onset of acromegaly in adults.

Pituitary adenomas secreting GH are more common in males, but females may present at an earlier age. Tumors with *AIP* pathogenic

variants **(familial isolated pituitary adenoma)** are more common in males, are larger and invasive, and secrete GH or prolactin. **X-LAG syndrome (X-linked acrogigantism)** is a recognized cause of familial pituitary adenomas, and in these patients the rapid growth begins in infancy and is more frequent in females. Patients with MAS will usually exhibit other features, including polyostotic fibrous dysplasia, café-au-lait spots, and precocious puberty.

Pituitary tumors secrete extremely high levels of GH; approximately 50% of pituitary adenomas also exhibit hyperprolactinemia because they secrete both GH and prolactin. Adenomas can compromise other anterior pituitary function through growth or cystic degeneration. Secretion of gonadotropins, thyrotropin, or corticotropin may be impaired. Delayed sexual maturation or hypogonadism can occur. When GH hypersecretion is accompanied by gonadotropin deficiency, accelerated linear growth can persist for decades. In some cases, the tumor spreads outside the sella, invading the sphenoid bone, optic nerves, and brain. GH-secreting tumors in pediatric patients are more likely to be locally invasive or aggressive than are those in adults.

Acromegalic features consist chiefly of enlargement of the distal parts of the body, but manifestations of abnormal growth involve all portions. The circumference of the skull increases, the nose becomes broad, and the tongue is often enlarged, with coarsening of the facial features. The mandible grows excessively, and the teeth become separated. Visual field defects and neurologic abnormalities are common; signs of increased intracranial pressure appear later. The fingers and toes grow chiefly in thickness. There may be dorsal kyphosis. Fatigue and lassitude are early symptoms. GH levels are elevated and occasionally exceed 100 ng/mL. There is usually no suppression of GH levels by the hyperglycemia of a glucose tolerance test, and insulin-like growth factor 1 (IGF1) and insulin-like growth factor binding protein 3 (IGFBP-3) levels are consistently elevated in acromegaly and pituitary gigantism.

Diagnosis

GH hypersecretion should be screened for by testing IGF1 and IGFBP-3 levels. An elevated IGF1 level in a patient with appropriate clinical suspicion usually indicates GH excess. Potential confusion can arise in the evaluation of normal adolescents because significantly higher IGF1 levels occur during puberty than in adulthood; the IGF1 level must be age and gender matched. Serum IGFBP-3 levels are also sensitive markers of GH elevations and will be elevated in almost all cases. If IGF1 and/or IGFBP-3 levels are elevated, then the next step is to test for GH excess by doing an oral glucose-suppression test. The gold standard for the diagnosis of GH excess in adults is the failure to suppress serum GH levels to <1 ng/dL at any time during a 2-hour oral glucose tolerance test with 1.75 g/kg oral glucose challenge (maximum: 75 g). GH levels may not be suppressed to this level in normal adolescents, and a cutoff of 5 ng/mL may be more appropriate in this age-group. If laboratory findings suggest GH excess, the presence of a pituitary adenoma should be confirmed by MRI of the brain. In rare cases, a pituitary mass is not identified. This might be from an occult pituitary microadenoma or ectopic production of GHRH or GH. CT is acceptable when MRI is unavailable.

Genetic causes: Genetic pathogenic variants are recognized as being present in ~50% of cases, though many are sporadic. In a large series, detailed genetic testing revealed pathogenic variants in *AIP* in 29% of cases, X-LAG due to microdeletions at Xq26.3 in 10% of the cases, and MAS in 5% of the cases. No genetic abnormality was identified in 54% of the cases. Although GH-secreting adenomas eventually develop in up to 60% of patients with multiple endocrine neoplasia 1 (MEN1), most of these occur in adults and therefore cause acromegaly rather than gigantism. Increased GH secretion and GH-secreting adenomas may also be seen in neurofibromatosis; tuberous sclerosis; MEN4; Carney complex; and the paraganglioma, pheochromocytoma, and pituitary adenoma association known as *3PA*.

A genetics consultation and appropriate genetic testing is therefore indicated in all cases of pituitary gigantism.

Treatment

The goals of therapy are to remove or shrink the pituitary mass, to restore GH and secretory patterns to normal, to restore IGF1 and IGFBP-3 levels to normal, to retain the normal pituitary secretion of other hormones, and to prevent recurrence of disease.

For well-circumscribed pituitary adenomas, trans-sphenoidal surgery is the treatment of choice and may be curative. The tumor should be removed completely. The likelihood of surgical cure depends greatly on the surgeon's expertise and on the size and extension of the mass. Intraoperative GH measurements can improve the results of tumor resection. Trans-sphenoidal surgery to resect the tumors is as safe in children as in adults. At times, a transcranial approach might be necessary. The primary goal of treatment is to normalize GH and IGF1 levels. GH levels (<1 ng/mL within 2 hours after a glucose load) and serum IGF1 levels (age-adjusted normal range) are the best tests to define a biochemical cure.

If GH secretion and IGF1 levels are not normalized by surgery, the options include pituitary irradiation and medical therapy. Further growth of the tumor is prevented by irradiation in >99% of patients. The main disadvantage is the delayed efficacy in decreasing GH levels. GH is reduced by approximately 50% from the initial concentration by 2 years, by 75% by 5 years, and approaches 90% by 15 years. Multiple pituitary hormone deficiency is a predictable result of pituitary radiation, occurring in 40–50% of patients 10 years after irradiation.

Surgery fails to cure a significant number of patients, and radiotherapy may not work fast enough, so medical therapy has an important role in treating patients with GH excess. Treatment is effective and well tolerated with GH antagonists, long-acting somatostatin analogs, and in some cases, by dopamine agonists.

Pegvisomant is a GH-receptor antagonist that competes with endogenous GH for binding to the GH receptor. It effectively suppresses GH and IGF1 levels in patients with acromegaly caused by pituitary tumors and ectopic GHRH hypersecretion. Normalization of IGF1 levels occurs in up to 90% of patients treated daily with this drug for 3 months or longer. The adult dosage is 10-40 mg via subcutaneous injection once daily, although twice-weekly protocols have also been reported as highly successful. IGF1 levels and hepatic enzymes must be monitored. Combined therapy with somatostatin analogs and weekly pegvisomant injections also is effective. Pediatric experience is limited, but case reports indicate that it can successfully suppress IGF1 levels when used in doses of 10-30 mg/day.

The **somatostatin analogs** are frequently effective in the treatment of patients with GH excess. Octreotide suppresses GH to <2.5 ng/mL in 65% of patients with acromegaly and normalizes IGF1 levels in 70%. The effects of octreotide are well sustained over time. Tumor shrinkage also occurs with octreotide but is generally modest. Consistent GH suppression can be obtained with a continuous subcutaneous (SC) pump infusion of octreotide or with long-acting formulations, including long-acting octreotide and lanreotide. Octreotide injection in the pediatric population has been used at doses of 1-40 μg/kg/24 hr. In adults the long-acting form is used in a dose of 10-40 mg every month, but no pediatric dose range has been established.

For patients with both GH and prolactin oversecretion, **dopamine agonists, such as bromocriptine and cabergoline**, which bind to pituitary dopamine type 2 receptors and may also suppress GH secretion, can also be considered. Prolactin levels are often adequately suppressed, but GH levels and IGF1 levels are rarely normalized with this treatment modality alone. Tumor shrinkage occurs in a minority of patients. The effectiveness of these agents may be additive to that of octreotide. Cabergoline therapy at doses of 0.25-4.0 mg/wk (given 1-2 times per week) has been used in adults with acromegaly, and because of its less frequent dosing and lower incidence of side effects as compared to bromocriptine, this is now considered the dopamine agonist of choice in both adults and children. Side effects can include nausea, vomiting, abdominal pain, arrhythmias, nasal stuffiness, orthostatic hypotension, sleep disturbances, and fatigue.

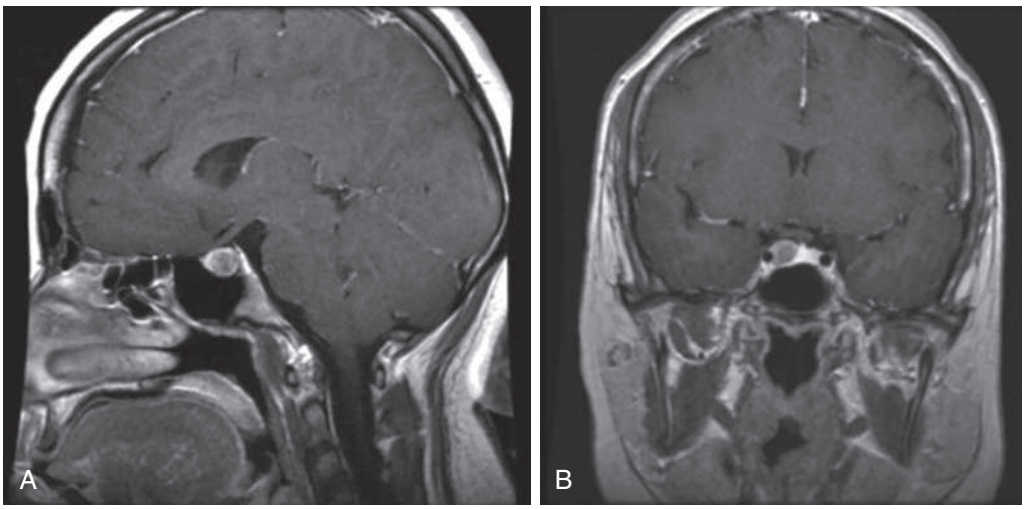

Fig. 598.1 Sagittal (A) and coronal (B) post-gadolinium T1-weighted MRI scans of a female with a microprolactinoma on the right side of the sella, who presented with amenorrhea and galactorrhea. Her serum prolactin was 89 ng/mL. *(From Wong A, Eloy JA, Couldwell WT, Liu JK. Update on prolactinomas. Part 1: clinical manifestations and diagnostic challenges. J Clin Neurosci. 2015;22:1562–1567, Fig. 1, p. 1563.)*

TREATMENT OF NORMAL-VARIANT TALL STATURE

Patients who have **familial tall stature** and no other underlying pathology usually require no treatment other than reassurance. The use of the bone age to predict adult height might provide some comfort for them, as will general supportive discussions on the social acceptability of this condition. Although treatment is possible for females and males with excessive growth, its use should be restricted to patients with predicted adult height >3-4 SD above the mean (79 inches or 200 cm in males, 73 inches or 185 cm in females) *and* evidence of significant psychosocial impairment.

Sex steroids have been used in the treatment of tall stature and are designed to accelerate puberty and to promote epiphyseal fusion; these are therefore of little benefit when given in late puberty. The lack of extensive experience with this form of therapy and the risks of estrogen or androgen treatment for tall stature should be carefully weighed and discussed with the family, and treatment should be discouraged except in the most extreme cases. Detailed discussion with the child at the child's level is also advisable, as up to 40% of those who underwent such treatments are dissatisfied as adults and feel they were not sufficiently consulted about this course of action. Therapy is initiated ideally before puberty or in early puberty (no later than bone age of 14). In the extremely rare instances where treatment is desired, testosterone enanthate is used at a dose of 250-500 mg intramuscularly every 2 weeks for 6 months in males. In females, oral estrogens in various doses have been used to reduce the predicted height, but average height reduction may be only 1.1-2.4 cm. Therapy must begin before the bone age has reached 12 years. In the rare case where treatment is advised, oral ethinyl estradiol has been used at a dose of 0.15-0.5 mg/day until cessation of growth occurs**.** Short-term side effects have included benign breast disease, cholelithiasis, hypertension, menstrual irregularities, weight gain, nausea, limb pain, galactorrhea, and thrombosis. Reduced fertility later in life may be a potential long-term complication. An alternative to sex-steroid therapy is the use of epiphysiodesis (destruction of the growth plates) around the knee to limit linear growth, but this intervention also remains controversial, and its long-term safety profile and psychologic risks and benefits remain unknown.

HYPERSECRETION OF OTHER PITUITARY HORMONES

Prolactinoma

Prolactin-secreting pituitary adenomas are the most common pituitary tumors in adolescents. With the use of MRI, more of these tumors, particularly microadenomas (<1 cm in diameter), are being detected (Fig. 598.1). The most common presenting manifestations are headache, primary or secondary amenorrhea, and galactorrhea. The disorder affects more than twice as many females as males; most patients have undergone normal puberty before becoming symptomatic. Only a few have delayed puberty. In some kindreds with **type I multiple endocrine neoplasia syndrome**, prolactinomas are the presenting feature during adolescence. Familial cases and sporadic cases with de novo pathogenic variants of the *AIP* gene and X-LAG are being recognized more often as genetic testing becomes more common.

Prolactin levels may be elevated mildly (40-50 ng/mL) or markedly (10,000-15,000 ng/mL), and there is a correlation between tumor size and prolactin levels. Most prolactinomas in children are large (macroadenomas), cause the sella to enlarge, and, in some cases, cause visual field defects. Approximately 30% of patients with macroadenomas develop other pituitary hormone deficiencies, particularly GH deficiency. Alternatively, prolactin-secreting adenomas might also stain for and secrete excess GH and/or TSH.

Prolactinomas should not be confused with the hyperprolactinemia and pituitary hyperplasia that can occur in patients with **primary hypothyroidism**, which is readily treated with thyroid hormone (see Chapter 603). Moderate elevations (<200 ng/mL) of prolactin are also associated with a variety of medications (antipsychotics, metoclopramide, phenothiazines, verapamil, opioids), with pituitary stalk dysfunction such as can occur with craniopharyngioma, with chronic renal failure, with chronic stress (rarely >40 ng/mL), and with nipple stimulation; hyperprolactinemia may also remain idiopathic in some cases (Table 598.1).

Drug-induced hyperprolactinemia is especially common, and in most cases the level is less than 100 ng/mL, though risperidone can cause elevations up to 300 ng/mL. No further investigation is needed if elevations in these ranges are seen in patients on antipsychotic medications who do not have any other suspicious features.

In extremely rare cases, prolactin may be produced by tumors outside the pituitary; in these cases there will be hyperprolactinemia with no sign of a pituitary tumor on imaging and no response to cabergoline treatment.

In some cases, extreme hyperprolactinemia is associated with a *hook effect* that leads to factitiously low values on blood tests. In cases where clinical features are compatible with hyperprolactinemia, serial dilution of the laboratory specimen should be done to rule out this kind of measurement error. On the other hand, patients may have factitiously elevated prolactin levels on immunoassay as a result of the presence of prolactin polymers and dimers **(macroprolactinemia)** that are not physiologically active. In cases where an elevated prolactin is detected in an asymptomatic patient, unnecessary diagnostic workup and treatment can be avoided by performing polyethylene glycol precipitation to exclude the presence of macroprolactinemia, which is clinically benign.

From Wong A, Eloy JA, Couldwell WT, Liu JK. Update on prolactinomas. Part 1: clinical manifestations and diagnostic challenges. *J Clin Neurosci.* 2015;22:1562–1567, Table 2.

It should be noted that there are occasional cases of galactorrhea where the prolactin level is completely normal (even after serial dilution to rule out the hook effect); the galactorrhea is usually mild in such cases and is not associated with any other clinical finding. No further treatment or investigation is indicated in these cases, and minimal galactorrhea can be left untreated. If the amount of milk discharge is bothersome, then low-dose cabergoline (0.25 mg once or twice weekly) may be effective even if elevated prolactin levels are not present.

In most patients where the hyperprolactinemia is secondary to an adenoma, it can be effectively treated with dopamine agonists. Treatment leads to lowering of prolactin levels and tumor shrinkage in the vast majority of patients and even large adenomas can usually be treated without surgical intervention. Because of its greater efficacy and lower incidence of side effects, cabergoline is considered the drug of choice for treatment of hyperprolactinemia. The usual protocol is to begin with 0.25 mg twice weekly and then increase as needed to 1 mg twice weekly. Even higher doses may be needed in some patients but should be carefully monitored; high doses of cabergoline used for long periods in older patients with parkinsonism are associated with cardiac valvular abnormalities, though this has not been reported with the doses used in pediatric hyperprolactinemia; monitoring of cardiac valves with echocardiography may be advisable if high doses are used for a prolonged period.

When dopamine agonist treatment has been unsuccessful in lowering the serum prolactin concentration or the size of the adenoma, and when symptoms or signs attributable to hyperprolactinemia or adenoma size persist during treatment, trans-sphenoidal surgery may be considered. Very rare cases of malignant prolactinomas may require chemotherapy with temozolomide, but a cure is difficult in such cases.

Corticotropinoma

Corticotropinoma is very rare in children, but unlike other types of pituitary adenomas, its incidence is higher in younger children and decreases with age. **Cushing disease** refers specifically to an ACTH-producing pituitary adenoma that stimulates excess cortisol production and secretion (see Chapter 619). It is more common than primary adrenal causes of Cushing syndrome, except in younger children (younger than 5 years of age), in whom adrenal carcinomas and adrenal activating variants of MAS are rare but dominant causes of the syndrome. Adenomas causing Cushing disease are almost always microadenomas with a diameter of <5 mm and are significantly smaller than all other types of adenomas at presentation. The most sensitive indicator of excess glucocorticoid secretion in children is growth failure, which generally precedes other manifestations. Patients develop weight gain that may be centripetal rather than generalized. Pubertal arrest, hypertension, large purplish striae, fatigue, and depression are also common. In prepubertal children, males are more frequently affected than females.

Midnight salivary cortisol measurements can be used as a screening test for cortisol excess, but confirmation requires at least one additional test (either 24-hour urinary free cortisol or an overnight dexamethasone suppression test). Location of the microadenoma is usually determined by MRI, and bilateral inferior petrosal sinus sampling may be needed in difficult cases. Trans-sphenoidal surgery is the treatment of choice for Cushing disease in children. Initial remission rates of 70–98% of patients and long-term success rates of 50–98% are reported. Residual transient hypoadrenalism is often observed after surgery, lasting as long as 30 months. Pituitary radiotherapy is used if cortisol levels remain elevated and/or ACTH levels continue to be detectable. Successful treatment may not correct the height deficit, and GH deficiency may be present after treatment and should be treated as required.

Thyrotropinomas are extremely rare, with only a few cases reported in the pediatric age-group. They present with symptoms of hyperthyroidism as well as local symptoms such as headaches and visual field defects. Laboratory testing reveals elevated thyroid hormone levels with inappropriately unsuppressed TSH levels. Treatment consists of trans-sphenoidal surgery in most cases, though radiation may be needed if surgery is unsuccessful.

598.1 Overgrowth Syndromes

Jennifer M. Kalish

OVERGROWTH IN THE FETUS AND NEONATE

Maternal diabetes is the most common cause of infants being large for gestational age. Even in the absence of clinical symptoms or a family history, the birth of a large-for-gestational-age infant should lead to evaluation for maternal (or gestational) diabetes.

Overgrowth syndromes: A group of disorders associated with excessive somatic growth and growth of specific organs has been described and is collectively referred to as *overgrowth syndromes.* These disorders are caused in many cases by excess production and availability of IGF2 encoded by the gene *IGF2.* The best described of these syndromes is **Beckwith-Wiedemann syndrome** (BWS), which is an overgrowth malformation syndrome that occurs with an incidence of 1:10,340 births, equal in males and females. It is caused by genetic or epigenetic abnormalities in the 11p15 chromosomal region, with most cases being the result of epigenetic abnormalities (loss or gain of DNA methylation) of two imprinting control regions, IC1 and IC2. Other causes include pathogenic variants, duplications, deletions, and loss of heterozygosity in this region. The imprinted genes involved in BWS and associated childhood tumors include, in addition to *IGF2,* the noncoding RNA *H19,* which is involved in *IGF2* suppression, cyclin-dependent kinase inhibitor 1C *(CDKN1C),* potassium channel voltage-gated KQT-like subfamily member 1 *(KCNQ1),* and *KCNQ1*-overlapping transcript 1 (*KCNQ1OT1*, or long QT intronic transcript 1, *LIT1*). Approximately 10% of cases are familial, whereas the rest appear to be sporadic. Cardinal clinical features of BWS include macroglossia, omphalocele, lateralized overgrowth (hemihypertrophy), bilateral Wilms tumor, hyperinsulinism, and pathologic findings (adrenal cytomegaly, pancreatic adenomatosis, and mesenchymal dysplasia). Suggestive features include macrosomia, mid-glabellar capillary malformation (nevus flammeus), earlobe creases and pits, umbilical hernia or diastasis recti, hepatomegaly, nephromegaly, transient hypoglycemia, and embryonal tumors (hepatoblastoma and unilateral Wilms tumor) (Fig. 598.2). The hyperinsulinemia is a result of pancreatic β-cell hyperplasia. These children are predisposed to embryonal tumors, including Wilms tumor, hepatoblastoma, neuroblastoma, and adrenocortical carcinoma. Management focuses on the omphalocele, airway issues (a result of macroglossia), neonatal hyperinsulinism/hypoglycemia, leg length differences, and tumor screening. Because of the cancer risk, screening is recommended until the seventh birthday. Screening includes complete abdominal ultrasound and measurement of α-fetoprotein every 3 months through the fourth birthday and renal ultrasounds every 3 months until the seventh birthday. Thereafter, renal ultrasound is recommended in cases of renal malformation such as medullary sponge kidney and nephrocalcinosis.

Pathogenic variants in *GPC3* and *GPC4,* glypican genes (which code for an IGF2–neutralizing membrane receptor), cause **Simpson-Golabi-Behmel** syndrome (Fig. 598.3). Other syndromic causes of fetal overgrowth include **Costello syndrome**, **Weaver syndrome**, **Sotos syndrome** (Fig. 598.4), and **Perlman syndrome** (Tables 598.2 and 598.3 and Fig. 598.5).

Overgrowth in Childhood or Adolescence

Normal-variant, familial, or constitutional tall stature is by far the most common cause of tall stature. Almost invariably, a family history of tall stature can be obtained, and no organic pathology is present. The child is often taller than the child's peers throughout childhood and has typical health. There are no abnormalities in the physical examination, and laboratory studies, if obtained, are negative.

Exogenous obesity is associated with rapid linear growth and relatively early onset of puberty (more so in girls). Bone age is accelerated, leading to relative tall stature in childhood but adult height is typically normal.

Klinefelter syndrome (XXY syndrome) is a relatively common (1 in 500-1,000 live male births) chromosomal abnormality associated with tall stature, learning disabilities (including requirement for speech therapy), gynecomastia, and decreased upper body:lower body segment ratio. Affected boys can have hypotonia, clinodactyly, and hypertelorism. The testes are invariably small, although androgen production by Leydig cells is often in the low-normal range. Spermatogenesis and Sertoli cell function are defective and lead to infertility. Other genital abnormalities include relatively small phallus and an increased incidence of hypospadias and cryptorchidism.

Fig. 598.2 Beckwith-Wiedemann syndrome in newborn infants. *(Courtesy Dr. Michael Cohen, Dalhousie University, Halifax, Nova Scotia. From Jones KL, Jones MC, Del Campo M. Smith's Recognizable Patterns of Human Malformation, 8th ed. Philadelphia: Elsevier; 2022, Fig. 1, p. 221.)*

Fig. 598.3 Simpson-Golabi-Behmel syndrome. Affected 16-yr-old male. Note the ocular hypertelorism, broad flat nose, 2-3 syndactyly, and nail hypoplasia. *(From Jones KL, Jones MC, Del Campo M. Smith's Recognizable Patterns of Human Malformation, 8th ed. Philadelphia: Elsevier, 2022. Fig. 1, p. 225.)*

Fig. 598.4 Cerebral gigantism (Sotos syndrome) in an 8-yr-old male. The height age was 12 yr, and the bone age was 12 yr. IQ was 60. The electroencephalogram had abnormal findings. Note the prominence of the forehead and jaw and the large hands and feet. Sexual development was consistent with chronologic age. Hormone study results were normal. The adult height was 208 cm (6 ft 10 in); his sexual development was normal. He wears size 18 shoes.

Table 598.2 Differential Diagnosis of Tall Stature and Overgrowth Syndromes

FETAL OVERGROWTH
Maternal diabetes mellitus
Sotos syndrome *(NSD1)*
Weaver syndrome *(EZH2)*
Beckwith-Wiedemann syndrome (11p15 alterations)
Marshall-Smith syndrome *(NFIX)*
POSTNATAL OVERGROWTH LEADING TO CHILDHOOD OR ADULT TALL STATURE
Nonendocrine Causes
Familial (constitutional) tall stature
Exogenous obesity
Sotos syndrome *(NSD1)*
Weaver syndrome *(EZH2)*
Perlman syndrome *(DIS3L2)*
Simpson-Golabi-Behmel syndrome *(GPC3, GPC4)*
Marfan syndrome *(FBN1)*
Homocystinuria
Beckwith-Wiedemann syndrome (11p15 alterations)
Klinefelter syndrome (XXY)
Other syndromes with extra X or Y chromosomes
Overgrowth syndromes with intellectual disability *(DNMT3A, CHD8, HIST1H1E, EED)*
Endocrine Causes
Excess GH secretion caused by adenomas (pituitary gigantism)
X-linked acrogigantism (Xq26.3 duplication)
McCune-Albright syndrome or MEN associated with excess GH secretion
Aromatase deficiency and estrogen receptor defects
Precocious puberty (initial acceleration, ultimate short stature)
Hyperthyroidism (acceleration, but not adult tall stature)

GH, Growth hormone; MEN, multiple endocrine neoplasia.

XYY syndrome is associated with tall stature, severe acne in adolescence, increased incidence of learning disabilities, and behavioral problems, particularly impulsivity. Intelligence is usually in the normal range but may be 10-15 IQ points lower than their siblings. Other rare chromosomal abnormalities in which an excess number of X or Y chromosomes are present (e.g., XXX, XXXY, XYYY) are also associated with increased height.

Marfan syndrome is an autosomal dominant connective tissue disorder consisting of tall stature, arachnodactyly, thin extremities, increased arm span, and decreased upper body:lower body segment ratio (see Chapter 743). Additional abnormalities include ocular abnormalities (e.g., lens subluxation), hypotonia, kyphoscoliosis, cardiac valvular deformities, and aortic root dilation.

Homocystinuria is an autosomal recessive inborn error of amino acid metabolism caused by a deficiency of the enzyme cystathionine synthetase. It is characterized by intellectual disability when untreated, and many of its clinical features resemble Marfan syndrome, particularly ocular manifestations (see Chapter 105).

SOTOS SYNDROME

Children with Sotos syndrome (see Fig. 598.4) are typically above the 90th percentile for both length and weight at birth and may also have an increased head size. In other cases, macrocephaly becomes more apparent postnatally. Most cases of Sotos syndrome are caused by pathogenic variants in *NSD1*, but in the Japanese population most cases are attributable to microdeletions of the 5q35 region that includes this gene. Inheritance is autosomal dominant, but 95% of cases are a result of de novo (new) mutations. Incidence is estimated to be approximately 1 in 14,000 live births. The *NSD1* gene is thought to play a role in epigenetic regulation, but the exact mechanisms by which mutations lead to the features of Sotos syndrome are not yet understood.

Although it is characterized by rapid growth, there is no evidence that Sotos syndrome is caused by endocrine dysregulation. Growth is markedly rapid; by 1 year of age, affected infants are often taller than the 97th percentile in height. Accelerated growth continues for the first 4-5 years and then returns to a normal rate. Puberty usually occurs at the expected time but may occur slightly early. Adult height is usually in the upper-normal range.

Clinically the syndrome is characterized by a large (macrocephaly) dolichocephalic head, prominent forehead and jaw, hypertelorism, downslant of the palpebral fissures, high-arched palate, and large hands and feet with thickened subcutaneous tissue. Clumsiness and awkward gait are also noted, and affected children may have difficulty in sports, in learning to ride a bicycle, and in other tasks requiring coordination. Some degree of developmental disability affects most patients; in some affected children, perceptual deficiencies may predominate. Many different types of nonfebrile seizures have been reported, and up to 25% of patients with Sotos syndrome have seizures at some point in their life. Hyperinsulinism can also occur. Affected patients may be at somewhat increased risk for neoplasms, including neuroblastoma, hepatoblastoma, and leukemia, with a lifetime risk of between 2% and 4%. Osseous maturation is usually compatible with the patient's height, although

Table 598.3 Overgrowth Syndromes

SYNDROME	CLINICAL FEATURES	GENETIC ETIOLOGY	TUMOR SURVEILLANCE
Beckwith-Wiedemann syndrome (BWS)	Hypoglycemia, macroglossia, ear pits, omphalocele or umbilical hernia, lateralized overgrowth, organomegaly, high risk of embryonal tumors until age 7	Various genetic and epigenetic abnormalities in 11p15, most commonly in the IC2 region	Tumor surveillance until at least age 7 yr
Perlman syndrome	Macrosomia, unusual facies, nephroblastosis, severe hypotonia, very high risk of Wilms tumor	*DIS3L2* (DIS3 Like 3′-5′ exoribonuclease 2) (autosomal recessive)	Routine tumor surveillance recommended
Simpson-Golabi-Behmel syndrome	Coarse facial features, macroglossia, central groove lower lip, supernumerary nipples, cardiac and skeletal defects	*GPC3* (glypican 3) (X-linked recessive)	Tumor surveillance justified (per BWS protocol)
Sotos syndrome	Excessive growth in first 4 yr, dolichocephaly, macrocrania, typical facies, long limbs, seizures, hypotonia	*NSD1* deletion or variant (autosomal dominant) Rare familial cases *NFIX* (Nuclear Factor I X) may cause related Malan syndrome	Routine tumor screening not recommended
Tatton-Brown syndrome	Round face, heavy/horizontal eyebrows, narrow palpebral fissures, intellectual disability, and increased height	*DNMT3A* (DNA Methyltransferase 3 Alpha)	Routine tumor screening not recommended
Weaver syndrome	Broad forehead, hypertelorism, small chin, long philtrum, camptodactyly, redundant nuchal skin, heart and brain defects	*EZH2* (Enhancer of zeste homolog 2) gene in some cases	Routine tumor screening not recommended
PTEN-hamartoma syndromes (including Bannayan-Ruvalcaba-Riley)	Macrocephaly, hypotonia, pigmented skin, penile macules, lipomas, seizures	*PTEN* (phosphatase and TENsin homolog)(sporadic or autosomal dominant)	Tumor surveillance recommended
PIK3CA-related overgrowth spectrum	Brain overgrowth (megalencephaly), microgyria, cutaneous vascular malformations, syndactyly, seizures, developmental delay	Pathogenic variants in various PIK3 related genes, including *PIl3R2, AKT3, CCND2, PIK3CA,* etc.	Tumor surveillance is debated
Marfan syndrome	Facial gestalt, lens dislocation, arachnodactyly, scoliosis, pectus carinatum or excavatum, aortic root dilation	*FBN1* (Fibrillin 1) (autosomal dominant)	None
Loeys-Dietz syndrome	Marfan-like habitus, aortic root dilation, aortic dissection, vasculopathy (more aggressive than Marfan syndrome)	TGF-β pathway genes including *TGFBR1, TGFBR2, SMAD3,* and *TGFB2* (autosomal dominant)	None
Homocystinuria	Marfan-like habitus, developmental delay, lens dislocation	*CBS* gene (Cystathionine β-synthase) (autosomal recessive)	None
Lujan syndrome	Marfan-like habitus, intellectual disability, no eye or cardiovascular anomalies	*MED12* (Mediator Complex Subunit 12) gene (X-linked recessive)	None

advanced bone age has been reported. Scoliosis develops in up to 30% of cases, usually starting in school-age children. GH, IGF1, and other endocrine studies are usually normal; there is no distinctive laboratory or radiologic marker for the syndrome. Abnormal electroencephalograms are common; imaging studies often reveal an enlarged ventricular system, but intracranial pressure is normal. Genetic testing for *NSD1* pathogenic variants (or fluorescence in situ hybridization for 5q35 microdeletions in Japanese patients) is available and should be routinely used. Management is symptomatic and includes paying special attention to developmental and behavioral problems (which tend to improve with age), scoliosis, and seizure disorder. No specific treatment is needed for the overgrowth itself. There is no consensus on the need for cancer surveillance at this time.

Tatton-Brown Syndrome

Tatton-Brown syndrome is characterized by distinctive facial appearance (round face, heavy/horizontal eyebrows, and narrow palpebral fissures), intellectual disability, and increased height. It is caused by pathogenic variants in *DNMT3A*, a methyltransferase. Pathogenic variants in *DNMT3A* are also seen in hematologic malignances, which like *NSD1* and *EZH2*, show dual-gene functionality in overgrowth syndromes and myeloid neoplasms.

Hyperthyroidism in adolescents is associated with rapid growth but normal final adult height. It is almost always caused by Graves disease and is much more common in girls (see Chapter 606).

Chapter 599

Physiology of Puberty

Luigi R. Garibaldi and Wassim Chemaitilly

Between early childhood and approximately 8-9 years of age (prepubertal stage), the hypothalamic-pituitary-gonadal axis is dormant, as reflected by undetectable serum concentrations of luteinizing hormone (LH) and sex hormones (estradiol in females, testosterone in males). One to 3 years before the onset of clinically evident puberty, low serum levels of LH during sleep become demonstrable. This sleep-entrained LH secretion occurs in a pulsatile fashion and reflects endogenous episodic discharge of hypothalamic gonadotropin-releasing hormone (GnRH). Nocturnal pulses of LH continue to increase in amplitude and, to a lesser extent, in frequency as clinical puberty approaches. This pulsatile secretion of gonadotropins is responsible for enlargement and maturation of the gonads and the secretion of sex hormones. The appearance of the secondary sex characteristics in early puberty is the visible culmination of the sustained, active interaction occurring among the hypothalamus, pituitary, and gonads in the peripubertal period. By mid-puberty, LH pulses become evident even during the daytime and occur at about 90- to 120-minute intervals. A second critical event occurs in middle or late adolescence in females in whom cyclicity and ovulation occur. A positive feedback mechanism develops whereby increasing levels of estrogen in midcycle cause a distinct increase of LH.

The increasing secretion of hypothalamic GnRH in a pulsatile fashion thus underlies the onset of pubertal development. The *GnRH pulse generator* is regulated by multiple neuropeptides, including glutamic acid, kisspeptin, neurokinin-B (stimulatory); γ-aminobutyric acid, preproenkephalin, and dynorphin (inhibitory). Pathogenic variants of *KISS1R* (previously known as *GPR54,* a G protein–coupled receptor gene whose ligand is kisspeptin) are a rare cause of autosomal recessive hypogonadotropic hypogonadism (loss-of-function pathogenic variants) or precocious puberty (gain-of-function pathogenic variants). The imprinted paternally expressed gene makorin RING finger protein 3 *(MKRN3)* has been described as a *brake* for the onset of puberty. Loss-of-function pathogenic variants of this gene are responsible for paternally transmitted familial precocious puberty in both sexes.

The interpretation of the hormonal changes of puberty is complex. Challenges with interpreting LH and follicle-stimulating hormone (FSH) measurements include the presence of multiple gonadotropin isoforms, immunoassay-related variability, and problems inherent to their pulsatile secretion, which mandate serial sampling in plasma. In addition, important sex differences exist in the maturation of the hypothalamus and pituitary gland because serum LH concentrations tend to increase earlier in the course of the pubertal process in males than in females. Adrenocortical androgens also have a role in sexual maturation. Serum levels of dehydroepiandrosterone (DHEA) and its sulfate (DHEAS) begin to increase at approximately 6-8 years of age, before any increase in LH or sex hormones

Physiology of Puberty

Luigi R. Garibaldi and Wassim Chemaitilly

Between early childhood and approximately 8-9 years of age (prepubertal stage), the hypothalamic-pituitary-gonadal axis is dormant, as reflected by undetectable serum concentrations of luteinizing hormone (LH) and sex hormones (estradiol in females, testosterone in males). One to 3 years before the onset of clinically evident puberty, low serum levels of LH during sleep become demonstrable. This sleep-entrained LH secretion occurs in a pulsatile fashion and reflects endogenous episodic discharge of hypothalamic gonadotropin-releasing hormone (GnRH). Nocturnal pulses of LH continue to increase in amplitude and, to a lesser extent, in frequency as clinical puberty approaches. This pulsatile secretion of gonadotropins is responsible for enlargement and maturation of the gonads and the secretion of sex hormones. The appearance of the secondary sex characteristics in early puberty is the visible culmination of the sustained, active interaction occurring among the hypothalamus, pituitary, and gonads in the peripubertal period. By mid-puberty, LH pulses become evident even during the daytime and occur at about 90- to 120-minute intervals. A second critical event occurs in middle or late adolescence in females in whom cyclicity and ovulation occur. A positive feedback mechanism develops whereby increasing levels of estrogen in midcycle cause a distinct increase of LH.

The increasing secretion of hypothalamic GnRH in a pulsatile fashion thus underlies the onset of pubertal development. The *GnRH pulse generator* is regulated by multiple neuropeptides, including glutamic acid, kisspeptin, neurokinin-B (stimulatory); γ-aminobutyric acid, preproenkephalin, and dynorphin (inhibitory). Pathogenic variants of *KISS1R* (previously known as *GPR54,* a G protein–coupled receptor gene whose ligand is kisspeptin) are a rare cause of autosomal recessive hypogonadotropic hypogonadism (loss-of-function pathogenic variants) or precocious puberty (gain-of-function pathogenic variants). The imprinted paternally expressed gene makorin RING finger protein 3 *(MKRN3)* has been described as a *brake* for the onset of puberty. Loss-of-function pathogenic variants of this gene are responsible for paternally transmitted familial precocious puberty in both sexes.

The interpretation of the hormonal changes of puberty is complex. Challenges with interpreting LH and follicle-stimulating hormone (FSH) measurements include the presence of multiple gonadotropin isoforms, immunoassay-related variability, and problems inherent to their pulsatile secretion, which mandate serial sampling in plasma. In addition, important sex differences exist in the maturation of the hypothalamus and pituitary gland because serum LH concentrations tend to increase earlier in the course of the pubertal process in males than in females. Adrenocortical androgens also have a role in sexual maturation. Serum levels of dehydroepiandrosterone (DHEA) and its sulfate (DHEAS) begin to increase at approximately 6-8 years of age, before any increase in LH or sex hormones

and before the earliest physical changes of puberty are apparent; this process has been called *adrenarche*. DHEAS is the most abundant adrenal C-19 steroid in the blood, and its serum concentration remains fairly stable over 24 hours. A single measurement of this hormone is commonly used as a marker of adrenal androgen secretion. Although adrenarche typically precedes the onset of gonadal activity (gonadarche) by a few years, the two processes do not seem to be causally related, as evidenced by adrenarche and gonadarche being dissociated in conditions such as central precocious puberty and adrenocortical failure.

The effects of gonadal steroids (testosterone in males, estradiol in females) on bone growth and osseous maturation are critical. Both aromatase deficiency and estrogen receptor defects result in delayed epiphyseal fusion and tall stature in affected males. These observations suggest that estrogens, rather than androgens, are responsible for the process of bone maturation that ultimately leads to epiphyseal fusion and cessation of growth. Estrogens also mediate the increased production of growth hormone, which along with a direct effect of sex steroids on bone growth, is responsible for the pubertal growth spurt.

The age of onset of puberty varies and is more closely correlated with osseous maturation than with chronologic age (see Chapter 150). In females, the **breast bud** (thelarche) is usually the first sign of puberty (10-11 years), followed by the appearance of **pubic hair** (pubarche) 6-12 months later. The interval to the onset of **menstrual activity** (menarche) is usually 2-2.5 years but may be as long as 6 years. In the United States, at least one sign of puberty is present in approximately 95% of females by 12 years of age and in 99% of females by 13 years of age. Peak height velocity occurs early (at breast stage II-III, typically between 11 and 12 years of age) in females and always precedes menarche. The mean age of menarche is about 12.75 years. However, there are wide variations in the sequence of changes involving growth spurt, breast bud, pubic hair, and maturation of the internal and external genitalia.

In males, **growth of the testes** (≥4 mL in volume or 2.5 cm in longest diameter) and thinning of the scrotum are the first signs of puberty (11-12 years). These are followed by pigmentation of the scrotum and growth of the penis and by **pubarche**. Appearance of **axillary hair** usually occurs in mid-puberty. In males, unlike in females, acceleration of growth begins after puberty is well underway and is maximal at genital stage IV-V (typically between 13 and 14 years of age). In males, the growth spurt occurs approximately 2 years later than in females, and growth may continue beyond 18 years of age.

Genetic and environmental factors affect the timing for the onset of puberty. Population-based studies in the United States and Europe have suggested secular trends for earlier onset of puberty over the past few decades in females and, to a lesser degree, in males. African American, and to a lesser extent Hispanic, females *appear* to be more advanced in the development of secondary sex characteristics for age than White females. However, the timing of menarche has advanced only marginally (2.5-4 months) in White females and slightly more so (up to 6 months) in African American females. The Copenhagen Puberty Study showed that the earlier onset of breast development observed in females examined in 2006–2008 than those seen in 1991–1993 (means 10.9 years vs 9.9 years) *was not* associated with different levels of gonadotropins or estradiol when females of similar chronologic ages were compared between the two groups. Hence earlier breast development may not simply reflect earlier activation or maturation of the hypothalamic-pituitary-gonadal axis but could also stem from other factors such as increased adiposity or increased exposure to certain environmental agents. Positive correlations between the degree of adiposity and earlier pubertal development in females have been reported. Conversely, female athletes in whom leanness and strenuous physical activity have coexisted from early childhood frequently exhibit a marked delay in puberty or menarche, and they frequently have oligomenorrhea or amenorrhea as adults (see Chapter 732). Pubertal delay is also prevalent in males who are physically very active. Thus energy balance is closely related to the activity of the GnRH pulse generator and the mechanisms initiating and sustaining puberty, possibly via hormonal signals such as leptin; other adipokines; or by way of the central melanocortin-4 receptor (MC4R), which controls appetite, food intake, and energy expenditure.

Chapter 600

Disorders of Pubertal Development

Luigi R. Garibaldi and Wassim Chemaitilly

INTRODUCTION

Precocious puberty is defined by the onset of secondary sexual characteristics before the age of 8 years in females and 9 years in males. The variation in the age of the onset of puberty in normal children, particularly of different ethnicities, makes this definition somewhat arbitrary. It remains in use by most clinicians.

Depending on the primary source of the hormonal production, precocious puberty may be classified as **central** (also known as **gonadotropin dependent**, or **true**) or **peripheral** (also known as **gonadotropin independent**) (Table 600.1). **Central** precocious puberty (CPP) is always isosexual and stems from hypothalamic-pituitary-gonadal activation with ensuing sex hormone secretion and progressive sexual maturation. In **peripheral** precocious puberty, some of the secondary sex characteristics appear, but there is no activation of the normal hypothalamic-pituitary-gonadal interplay. In this latter group, the sex characteristics may be isosexual or heterosexual (see Chapters 622-628).

Peripheral precocious puberty can also induce maturation of the hypothalamic-pituitary-gonadal axis and trigger the onset of central puberty at a later time. This mixed type of precocious puberty occurs in congenital adrenal hyperplasia, particularly after adrenal androgens are suppressed by treatment; McCune-Albright syndrome; and familial male-limited precocious puberty, when the bone age reaches the pubertal range (10.5-12.5 years).

600.1 Central Precocious Puberty

Luigi R. Garibaldi and Wassim Chemaitilly

CPP is defined by the onset of pubertal development due to the early activation of the hypothalamic-pituitary-gonadal axis before the ages of 8 and 9 years in females and males, respectively. It occurs 5- to 10-fold more frequently in females than in males and is usually sporadic. Although at least 90% of females have an idiopathic form, a structural central nervous system (CNS) abnormality may occur in 25–75% of males with CPP. **Genetic forms of CPP**, such as the paternally transmitted types due to pathogenic variants of *MKRN3* gene or, more rarely *DLK1,* may account for 5–10% of all cases of CPP. A high prevalence of CPP has been reported in females adopted from developing countries, particularly if adopted several months or years after birth, possibly related to undefined nutritional or environmental factors.

CLINICAL MANIFESTATIONS

In females, CPP should be suspected when breast development is noted before the age of 8 years. In males who have not been exposed to gonadotoxic agents, CPP usually manifests first via increased testicular size (volume ≥4 mL) and scrotal thinning before the age of 9 years. Sexual development in affected individuals generally follows the sequence observed in normal puberty. In females, early menstrual cycles may be more irregular than they are with normal puberty. The initial cycles are usually anovulatory, but pregnancy has been reported as early as 5.5 years of age (Fig. 600.1). In males, testicular biopsies have shown stimulation of all elements of the testes, and spermatogenesis has been observed as early as 5-6 years of age. In affected females and males, height, weight, and height velocity are accelerated. The increased rate of bone maturation results in early closure of the epiphyses and compromised adult height, particularly

Table 600.1 Classification of Sexual Precocity

TRUE PRECOCIOUS PUBERTY OR COMPLETE ISOSEXUAL PRECOCITY
(GNRH-Dependent Sexual Precocity or Premature Activation of the Hypothalamic GNRH Pulse Generator)

Idiopathic true precocious puberty
CNS tumors
Optic glioma associated with neurofibromatosis type 1
Hypothalamic astrocytoma
Other CNS disorders
Developmental abnormalities including hypothalamic hamartoma of the tuber cinereum
Encephalitis
Static encephalopathy
Brain abscess
Sarcoid or tubercular granuloma
Head trauma
Hydrocephalus
Arachnoid cyst
Myelomeningocele
Vascular lesion
Cranial irradiation
True precocious puberty after late treatment of congenital virilizing adrenal hyperplasia or other previous chronic exposure to sex steroids
True precocious puberty caused by pathogenic variants in the following genes:
KISS1R/GPR54
KISS1
MKRN3
DLK1

INCOMPLETE ISOSEXUAL PRECOCITY (HYPOTHALAMIC GNRH-INDEPENDENT)

Males
Gonadotropin-secreting tumors
hCG-secreting CNS tumors (e.g., chorioepitheliomas, germinoma, teratoma)
hCG-secreting tumors located outside the CNS (hepatoma, teratoma, choriocarcinoma)
Increased androgen secretion by adrenal or testis
Congenital adrenal hyperplasia (CYP21 and CYP11B1 deficiencies)
Virilizing adrenal neoplasm
Leydig cell adenoma
Familial male-limited precocious puberty (FMPP, "testotoxicosis") (autosomal dominant gonadotropin-independent precocious Leydig cell and germ cell maturation)
Cortisol resistance syndrome

Females
Ovarian cyst
Estrogen-secreting ovarian or adrenal neoplasm
Peutz-Jeghers syndrome with sex cord tumor with annular tubules (SCTAT)

Both Sexes
McCune-Albright syndrome
Hypothyroidism
Iatrogenic or exogenous sexual precocity (including inadvertent exposure to estrogens in food, drugs, or cosmetics)

VARIATIONS OF PUBERTAL DEVELOPMENT
Premature thelarche
Premature isolated menarche
Premature adrenarche
Adolescent gynecomastia in males
Macroorchidism

HETEROSEXUAL PRECOCITY

Feminization in Males
Adrenal neoplasm
Chorioepithelioma
Testicular neoplasm (Peutz-Jeghers syndrome)
Increased extraglandular conversion of circulating adrenal androgens to estrogen
Iatrogenic (exposure to estrogens)

Virilization in Females
Congenital adrenal hyperplasia
CYP21 deficiency
CYP11B1 deficiency
3β-HSD deficiency
Virilizing adrenal neoplasm (with or without Cushing syndrome)
Virilizing ovarian neoplasm (e.g., arrhenoblastoma)
Iatrogenic (exposure to androgens)
Cortisol resistance syndrome
Aromatase deficiency

CNS, Central nervous system; CYP11B1, 11-hydroxylase; CYP21, 21-hydroxylase; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; 3β-HSD, 3β-hydroxysteroid dehydrogenase 4,5-isomerase; KISS1R/GPR54, kisspeptin receptor/G protein–coupled receptor 54.
Modified from Styne DM, Grumbach MM. Physiology and disorders of puberty. In Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, eds. *Williams Textbook of Endocrinology,* 13th ed. Philadelphia: Elsevier; 2016: Table 25.25, p. 1163.

if puberty begins at a very early age. Historically, approximately 30% of females and an even larger percentage of males achieved a height below the fifth percentile as adults *without* treatment. Mental development is usually compatible with chronological age. Emotional behavior and mood swings are common, but serious psychologic problems are rare.

Although the clinical course is variable, three main patterns of pubertal progression can be identified. Most females (particularly those younger than 6 years of age at the onset) and a large majority of males have rapidly progressive puberty, characterized by rapid physical and osseous maturation, leading to a loss of height potential. An increasing percentage of females (older than 6 years of age at the onset with an idiopathic form) and, rarely, males have a slowly progressive variant, characterized by parallel advancement of osseous maturation and linear growth, with preserved height potential. Very rarely, central puberty may regress spontaneously (*unsustained* CPP). This variability in the natural course of sexual precocity underscores the need for longitudinal observation at the onset of sexual development before treatment is considered.

LABORATORY FINDINGS

Sex hormone concentrations are usually appropriate for the stage of puberty in both sexes (Table 600.2). Despite the availability of sensitive and specific assays for sex hormones, random serum estradiol concentrations are low or undetectable in the early phase of sexual precocity in females, as they are in normal puberty. In males, serum testosterone levels are usually detectable or elevated by the time the parents seek medical attention, provided that an early morning blood sample is obtained. With the use of highly sensitive assays, serum LH concentrations are undetectable in prepubertal children in random blood samples but become detectable in 50–75% of females and a higher percentage of males with CPP. Unfortunately, a number of hospitals use only moderately sensitive immunoenzymatic assays for LH and often insensitive assays for estradiol and testosterone, which decreases the diagnostic yield of these measurements. Measurement of LH in serial blood samples obtained during sleep has very

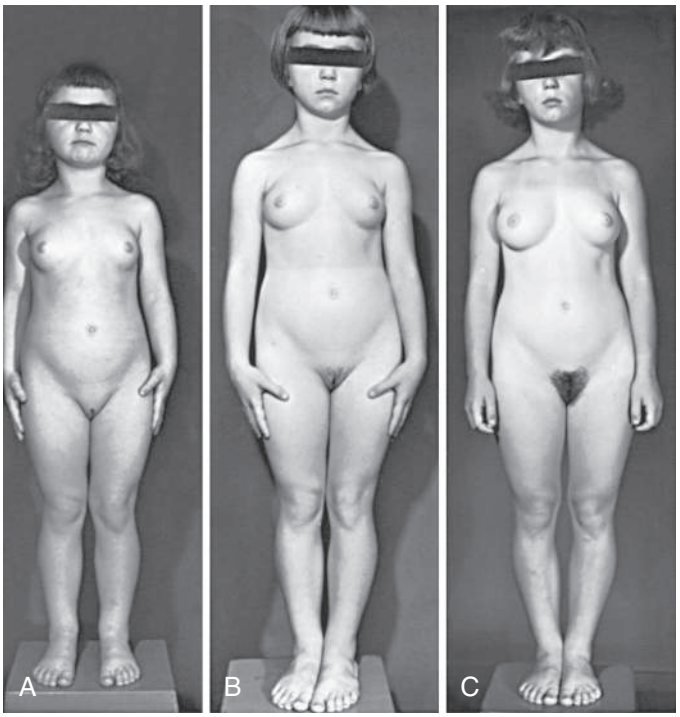

Fig. 600.1 Natural course of untreated idiopathic central precocious puberty. Patient (A) at 3 11/12, (B) at 5 8/12, and (C) at 8½ yr of age. Breast development and vaginal bleeding began at 2½ yr of age. Bone age was 7½ yr at 3 11/12 and 14 yr at 8 yr of age. Intelligence and dental age were normal for chronological age. Growth was completed at 10 yr; ultimate height was 142 cm (56 in). No effective therapy was available at the time this patient sought medical attention.

good diagnostic power and typically reveals a well-defined pulsatile secretion of LH in early puberty; it is, however, difficult to implement in a clinical setting. Dynamic tests using gonadotropin-releasing hormone (GnRH, intravenously; unavailable in the United States) or a GnRH agonist (leuprolide, subcutaneously) are helpful diagnostic tools, particularly for males, in whom a pubertal LH response (LH peak >5 IU/L) with predominance of LH over follicle-stimulating hormone (FSH) tends to occur early in the course of precocious puberty. In females with sexual precocity, however, the nocturnal LH secretion and the LH response to GnRH or GnRH agonist may be quite low at breast stages II to early III (LH peak, <5 IU/L), and the LH to FSH ratio may remain low until mid-advanced puberty. In such females with low LH response, the central nature of sexual precocity can be proven by detecting pubertal levels of estradiol (>50 pg/mL) 20-24 hours after stimulation with leuprolide.

Osseous maturation is variably advanced, often more than 2-3 standard deviations (SD). Pelvic ultrasonography in females reveals progressive enlargement of the ovaries, enlargement of the fundus, and then of the whole uterus to pubertal size. An MRI scan usually demonstrates physiologic enlargement of the pituitary gland, as seen in normal puberty; it may also reveal CNS pathology.

DIFFERENTIAL DIAGNOSIS

Organic CNS causes of central sexual precocity are more likely in males and in females who have rapid breast development, estradiol greater than 30 pg/mL, or are younger than 6 years of age. All children in these categories, and children with neurologic symptoms or signs, should undergo MRI scans of the brain and pituitary gland. Criteria for brain imaging in females older than 6 years are controversial, although some authorities recommend MRI scans for *all children* with CPP.

Gonadotropin-independent causes of isosexual precocious puberty must be considered in the differential diagnosis (see Tables 600.1 and 600.2). For females, these include tumors of the ovaries, autonomously functioning ovarian cysts, feminizing adrenal

Table 600.2 Differential Diagnosis of Sexual Precocity

DISORDER	PLASMA GONADOTROPINS	LH RESPONSE TO GNRH	SERUM SEX STEROID CONCENTRATION	GONADAL SIZE	MISCELLANEOUS
GONADOTROPIN DEPENDENT					
True (central) precocious puberty	Prominent LH pulses (premature reactivation of GnRH pulse generator), initially during sleep	Pubertal LH response	Pubertal values of testosterone or estradiol	Normal pubertal testicular enlargement or ovarian and uterine enlargement	MRI of brain to rule out CNS tumor or other abnormality
GONADOTROPIN INDEPENDENT					
Males					
Chorionic gonadotropin-secreting tumor in males	High hCG, low LH	Prepubertal LH response	Pubertal value of testosterone	Slight to moderate uniform enlargement of testes	Hepatomegaly suggests hepatoblastoma; MRI of brain if chorionic gonadotropin-secreting CNS tumor suspected
Leydig cell tumor in males	Suppressed	No LH response	High testosterone	Irregular, asymmetric enlargement of a testis	Testicular US
Familial, male-limited precocious puberty (FMPP, testotoxicosis)	Suppressed	No LH response	Pubertal values of testosterone	Testes symmetric and length >2.5 cm but smaller than expected for pubertal development; spermatogenesis occurs	Activating pathogenic variant of the LHCG receptor; autosomal dominant transmission
Virilizing congenital adrenal hyperplasia	Prepubertal	Prepubertal LH response	Elevated 17-OHP in CYP21 deficiency or elevated 11-deoxycortisol in CYP11B1 deficiency	Testes prepubertal	Autosomal recessive, variable severity/age of onset; may have salt loss in CYP21 deficiency or hypertension in CYP11B1 deficiency

Continued

Table 600.2 Differential Diagnosis of Sexual Precocity—cont'd

DISORDER	PLASMA GONADOTROPINS	LH RESPONSE TO GNRH	SERUM SEX STEROID CONCENTRATION	GONADAL SIZE	MISCELLANEOUS
Virilizing adrenal tumor	Prepubertal	Prepubertal LH response	High DHEAS, DHEA, and/or androstenedione values	Testes prepubertal	CT or MRI of abdomen
Females					
Granulosa cell tumor (follicular cysts may present similarly)	Suppressed	Prepubertal LH response	Very high estradiol	Ovarian enlargement on physical examination, CT, MRI, or US	Tumor often palpable on physical examination
Follicular cyst	Suppressed	Prepubertal LH response	Prepubertal to very high estradiol	Ovarian enlargement on physical examination, CT, MRI, or US	Single or recurrent episodes of menses and/or breast development; exclude McCune-Albright syndrome
Feminizing adrenal tumor	Suppressed	Prepubertal LH response	High estradiol, variable DHEAS increase	Ovaries prepubertal	Unilateral adrenal mass on CT or MRI
Nonclassical congenital adrenal hyperplasia	Prepubertal	Prepubertal LH response	Elevated 17-OHP in basal or in corticotropin-stimulated state	Ovaries prepubertal	Autosomal recessive
In Both Sexes					
McCune-Albright syndrome	Suppressed	Suppressed	Sex steroid pubertal; estradiol may be quite high in girls	Ovarian enlargement (asymmetrical) on US; slight (usually symmetrical) testicular enlargement	Skeletal survey/bone scan for polyostotic fibrous dysplasia and skin examination for café-au-lait macules
Primary hypothyroidism	LH prepubertal; FSH may be slightly elevated	Prepubertal; flat FSH, LH response	Estradiol often pubertal	Testicular enlargement; ovaries macrocystic	TSH very high, prolactin mildly elevated; T_4 low
INCOMPLETE PRECOCITY/VARIATIONS OF PUBERTY					
Premature thelarche	Prepubertal	Prepubertal LH	Prepubertal or early pubertal estradiol response	Ovaries prepubertal	Onset usually before 3 yr of age
Premature adrenarche (males)	Prepubertal	Prepubertal LH response	Prepubertal testosterone; DHEAS value appropriate for pubic hair stage	Testes prepubertal	Onset usually after 6 yr of age; more frequent in CNS-injured children
Premature adrenarche (females)	Prepubertal	Prepubertal LH response	Prepubertal estradiol; DHEAS value appropriate for pubic hair stage	Ovaries prepubertal	Onset usually after 6 yr of age; more frequent in brain-injured children

CNS, Central nervous system; CT, computed tomography; CYP, P450 cytochrome isoenzyme; DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; MRI, magnetic resonance imaging; 17-OHP, 17-hydroxyprogesterone; T_4, thyroxine; TSH, thyrotropin; US, ultrasonography.

Modified from Styne DM, Grumbach MM. Physiology and disorders of puberty. In: Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, eds. *Williams Textbook of Endocrinology*, 13th ed. Philadelphia: Elsevier; 2016: Table 25.41, pp. 1196–1197.

tumors, McCune-Albright syndrome, and exogenous sources of estrogens. In males, congenital adrenal hyperplasia, adrenal tumors, Leydig cell tumors, human chorionic gonadotropin (hCG)–producing tumors, exposure to exogenous androgens, and familial male precocious puberty should be considered.

TREATMENT

Virtually all males and the large subgroup of females with *rapidly progressive precocious puberty,* including CPP beginning *before age 6 years,* are candidates for treatment. Females with slowly progressive idiopathic CPP do not seem to benefit in terms of height prognosis from GnRH agonist therapy. Former small-for-gestational-age infants may be at greater risk of short stature as adults and may require more aggressive treatment of precocious puberty, possibly in conjunction with human growth hormone (hGH) therapy. Certain patients require treatment predominantly for psychologic or social reasons, including children with special needs.

The observation that the pituitary gonadotropic cells require pulsatile, rather than continuous, stimulation by GnRH to maintain the ongoing release of gonadotropins provides the rationale for using GnRH agonists for treatment of CPP. By virtue of being more potent and having a longer duration of action than native GnRH, these GnRH agonists (after a brief period of stimulation) desensitize the gonadotropic cells of the pituitary to the stimulatory effect of endogenous GnRH and effectively halt the progression of central sexual precocity.

Long-acting formulations of GnRH agonists, which maintain fairly constant serum concentration of the drug for weeks or months, constitute the preparations of choice for treatment of CPP. In the United States, the available preparations include (1) **leuprolide acetate** (Lupron Depot Ped), in a dose of 0.2-0.3 mg/kg (7.5-15 mg) intramuscularly (IM) every 28 days; (2) longer-acting preparations of depot-leuprolide, including Lupron-Depot Ped 90-day, 11.25 or 30 mg IM every 3 months, or Fensolvi 45 mg subcutaneously every 24 weeks; (3) **histrelin** (Supprelin LA), a subcutaneous 50-mg implant with effects lasting at least 12 months; and (4) **triptorelin** (Triptodur), 22.5 mg IM every 24 weeks. Other preparations

are approved for treatment of precocious puberty in other countries. Recurrent sterile fluid collections at the sites of injections are an uncommon local side effect and occur in less than 1–3% of patients treated with IM depot-leuprolide. Breakage or malfunction of the histrelin implant is rare. Other available treatment options for children who cannot tolerate the products listed previously include subcutaneous injections of aqueous leuprolide, given once or twice daily (total dose 60 mcg/kg/24 hr), or intranasal administration of the GnRH agonist **nafarelin** (Synarel), 800 mcg bid. The potential for irregular compliance with daily administration, as well as the variable absorption of the intranasal route for nafarelin, may limit the efficacy and long-term benefit of the latter preparations. GnRH antagonists, including novel oral compounds, have not been investigated sufficiently in children and are not FDA approved.

Treatment results in decrease of the growth rate, generally to age-appropriate values, and an even greater decrease of the rate of osseous maturation. Some children, particularly those with greatly advanced (pubertal) bone age, may show marked deceleration of their growth rate and an arrest in the rate of osseous maturation. Treatment results in enhancement of the predicted height, more so in younger patients at diagnosis, male patients, and those children with more rapidly progressive CPP. In females, breast size may regress in those with Tanner stage II-III development but tends to remain unchanged in females with late stage III-V development or may even increase slightly because of progressive adipose tissue deposition. The amount of glandular tissue decreases. Pubic hair usually remains stable in females or may progress slowly during treatment, reflecting the gradual increase in adrenal androgens. Menses, if present, cease. Pelvic sonography demonstrates a decrease of the ovarian and uterine size. In males, there is a decrease of testicular size, variable regression of pubic hair, and decrease in the frequency of erections. Except for a reversible decrease in bone density (of uncertain clinical significance) and a reversible increase in body mass index (BMI) percentiles in some females, no serious adverse effects of GnRH analogs have been reported in children during or after treatment for sexual precocity. If treatment is effective, the serum sex hormone concentrations decrease to prepubertal levels (testosterone <10-20 ng/dL in males; estradiol <5-10 pg/mL in females). The serum LH and FSH concentrations, as measured by sensitive immunometric assays, decrease to less than 1 IU/L in most patients, although rarely does the LH return to truly prepubertal levels (<0.1 IU/L). Moreover, the incremental FSH and LH responses to GnRH stimulation decrease to less than 2-3 IU/L. Serum LH, FSH, and sex hormone levels are suppressed more completely and evenly by the histrelin implant than by GnRH agonist injections. Therapy is typically discontinued at a pubertal chronological age, after which puberty resumes promptly. In females, menarche generally appears at an average of 18 months (range 6-24 months) after cessation of IM therapy and somewhat earlier after removal of the histrelin implant. The addition of hGH to GnRH agonists has been used on an investigational basis in children with precocious puberty, markedly advanced bone age, and prediction of short stature. The available, albeit limited, data indicate that combined therapy may increase the adult height.

600.2 Precocious Puberty Resulting from Organic Brain Lesions

Wassim Chemaitilly and Luigi R. Garibaldi

Hypothalamic hamartoma is the most common brain lesion causing CPP (Fig. 600.2). This congenital malformation consists of ectopically located neural tissue, within which glial cells can produce transforming growth factor-α (TGF-α), which has the potential to activate the GnRH pulse generator. On MRI, it appears as a small pedunculated mass attached to the tuber cinereum or the floor of the third ventricle or, less often, as a sessile mass (Fig. 600.3) that remains static in size over years.

A wide variety of other CNS lesions or insults, usually involving the hypothalamus by scarring, invasion, or pressure, have been associated with CPP (see Table 600.1). These include postencephalitic scars, tuberculous meningitis, tuberous sclerosis, severe head trauma, and hydrocephalus, either isolated or associated with myelomeningocele. Gonadotropin-dependent precocious puberty occurs in 26–29% of children with tumors developing within or near the hypothalamus or optic pathways. Low-grade gliomas, the most common types of such neoplasms, are highly prevalent (15–20%) in children with neurofibromatosis type 1 (NF-1) and constitute the main etiologic factor for the central sexual precocity encountered in a small subset (approximately 3%) of children with NF-1.

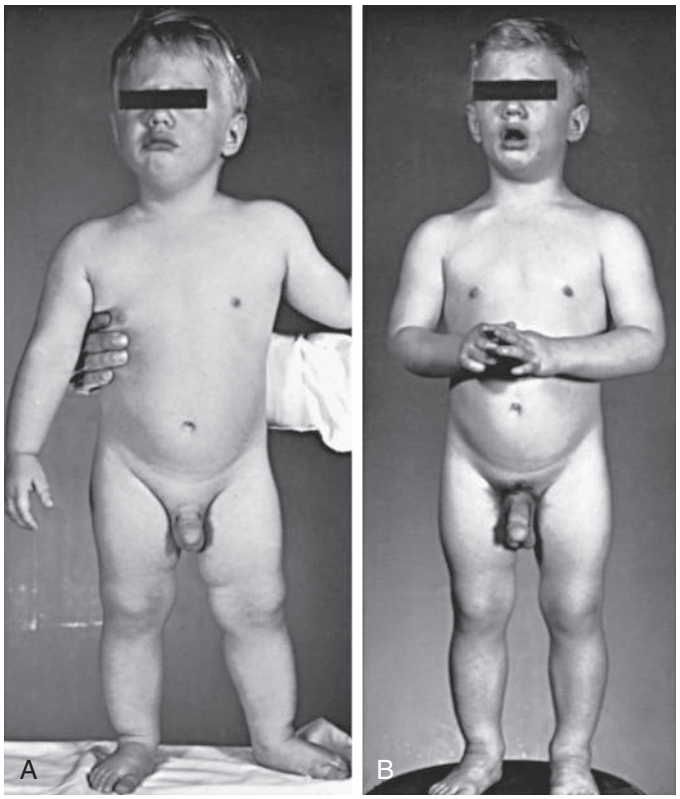

Fig. 600.2 Natural course of untreated precocious puberty with central nervous system lesion. Photographs at 1½ (A) and 2½ (B) yr of age. Accelerated growth, muscular development, osseous maturation, and testicular development were consistent with the degree of secondary sexual maturation. In early infancy, the patient began having frequent spells of rapid, purposeless motion; later in life, he had episodes of uncontrollable laughing with ocular movements. At 7 yr, he exhibited emotional lability, aggressive behavior, and destructive tendencies. Although a hypothalamic hamartoma had been suspected, it was not established until CT scanning became available when the patient was 23 yr of age. Epiphyses fused at 9 yr of age; final height was 142 cm (56 in). At 24 yr of age, he developed an embryonal cell carcinoma of the retroperitoneum.

About 50% of the tumors in the pineal region are germ cell tumors or astrocytomas; the remainder consists of a wide variety of histologically distinct tumor types. Pineal or hypothalamic germ cell tumors can cause CPP in males by secreting hCG, which stimulates the luteinizing hormone (LH) receptors in the Leydig cells of the testes (see Chapter 600.5).

CLINICAL MANIFESTATIONS

Hypothalamic hamartomas remain static in size or grow slowly and can be associated with gelastic or psychomotor seizures, but most often produce no signs other than precocious puberty. This is often rapidly progressive sexual precocity in very young children. For other lesions causing neurologic symptoms, the neuroendocrine manifestations may be present for 1-2 years before the tumor can be detected radiologically. Hypothalamic signs or symptoms such as diabetes insipidus, adipsia, hyperthermia, unnatural crying or laughing, obesity, and cachexia should suggest the possibility of an intracranial lesion. Visual signs (proptosis, decreased visual acuity, visual field defects) may be the first manifestation of an optic glioma.

The sexual precocity is always *isosexual,* and the endocrine patterns are generally those found in children without demonstrable organic

Fig. 600.3 MRI of a central nervous system lesion in a child with central precocious puberty. A 6-yr-old female was referred for stage IV breast development and growth acceleration. Serum luteinizing hormone and estradiol concentrations were in the adult range. The midsagittal T1-weighted image shows an isointense hypothalamic mass *(arrowheads)*, typical of a hamartoma. *(From Sharafuddin M, Luisiri A, Garibaldi LR, et al. MR imaging diagnosis of central precocious puberty: importance of changes in the shape and size of the pituitary gland. Am J Roentgenol. 1994;162:1167–1173.)*

lesions. In conditions other than hypothalamic hamartoma, growth hormone (GH) deficiency can occur and may be masked by the growth-promoting effect of the increased sex hormone levels. The pubertal staging of males treated with gonadotoxic modalities such as high-dose alkylating agents or testicular radiotherapy should not rely on testicular volume measurements because these are affected by treatment-induced germ cell and Sertoli depletion. Pubic hair development, scrotal thinning, and penile size may be better indicators, and providers should not hesitate to measure serum LH and testosterone levels when in doubt.

TREATMENT

GnRH agonists (depot forms or implant) are the treatment of choice of tumor-induced CPP. Neurosurgical treatment has been shown to have limited efficacy and to be associated with high complication rates in a subset of patients with hypothalamic hamartoma and associated intractable gelastic or psychomotor seizures. Stereotactic radiation therapy (gamma knife surgery) and, more recently, MRI-guided laser therapy, have been proposed as possible alternatives in these instances. For other neurologic lesions, therapy depends on the nature and location of the pathologic process. Combined GH therapy should be considered for patients with associated GH deficiency. The final height outcome will also depend on other factors such as the burden of disease from the primary tumor, side effects of cancer treatments, and associated chronic health conditions

600.3 Precocious Puberty After Irradiation of the Brain

Wassim Chemaitilly and Luigi R. Garibaldi

Children treated with cranial radiotherapy at a wide range of doses (18-50 Gy) are at an increased risk for gonadotropin-dependent precocious puberty. The prevalence of this condition in children treated with radiotherapy for tumors located outside of the hypothalamic pituitary or optic pathways region has been reported at 6.6%. Hydrocephalus, young age at exposure to radiation (<5 years), being female, and increased BMI are additional risk factors. This condition is often *associated with GH deficiency* and at times with other conditions (spinal irradiation, hypothyroidism) adversely affecting the adult height prognosis. Unless careful attention is paid to early signs of pubertal development in these children, the combination of GH deficiency and the growth-promoting effect of sex steroids often results in a normal growth rate at the expense of a rapidly advancing bone age and impaired adult height potential. The pubertal staging of males treated with gonadotoxic modalities such as high-dose alkylating agents or testicular radiotherapy should not rely on testicular volume measurements (see Chapter 600.2).

TREATMENT

GnRH analogs are effective in arresting pubertal progression, but concomitant GH (and/or thyroid hormone) deficiency should be diagnosed and treated promptly to improve the adult height prognosis.

Paradoxically, hypopituitarism with gonadotropin deficiency may subsequently develop as a late effect of high-dose CNS irradiation in patients with or without a history of precocious puberty, and it may require substitution therapy with sex steroids.

600.4 Syndrome of Precocious Puberty and Hypothyroidism

Wassim Chemaitilly and Luigi R. Garibaldi

The onset of puberty is usually delayed in children with mild forms of hypothyroidism. However, up to 50% of children with profound, untreated hypothyroidism of long duration may paradoxically develop precocious puberty (a condition known as **VanWyk-Grumbach syndrome**). **Hashimoto thyroiditis** is frequently the cause of such forms of hypothyroidism. Patients have the usual manifestations of hypothyroidism (see Chapter 603); the symptoms may be difficult to recognize in children with special needs. Children with precocious puberty caused by hypothyroidism have, contrary to other children with sexual precocity, decreased growth velocity and delayed bone age. Females may present with breast development and menstrual bleeding; the latter may occur even in females with minimal breast enlargement. Pelvic sonography may reveal large, multicystic ovaries. Males have testicular enlargement associated with modest or no penile enlargement. No pubic hair development occurs in either females or males. Enlargement of the sella, which is typical of long-standing primary hypothyroidism, may be demonstrated by skull film or MRI. Plasma levels of thyroid-stimulating hormone (TSH) are markedly elevated, often greater than 500 μU/mL, and those of prolactin and estradiol are mildly elevated. Although serum FSH is low and LH is undetectable, when measured by specific assays, the massively elevated concentrations of TSH appear to interact with the FSH receptor (specificity spillover), thus inducing FSH-like effects in the absence of LH effects on the gonads. The FSH-like effect suffices to induce estradiol secretion by the ovaries, whereas in males, testicular enlargement occurs without substantial testosterone secretion. Treatment of the hypothyroidism results in rapid return to normal of the biochemical and clinical manifestations. Possible progression to central puberty with rapid bone age advancement may occur in the months after the initiation of thyroid hormone replacement, a complication that would justify delaying puberty with GnRH analogs. Macroorchidism (testicular volume >30 mL) may persist in adult males despite adequate levothyroxine therapy. Children with a high risk of primary hypothyroidism, especially those with special needs such as patients with trisomy 21, should be screened at least annually via measurement of serum free T_4 and TSH levels.

600.5 Chorionic Gonadotropin-Secreting Tumors: Paraneoplastic Precocious Puberty

Wassim Chemaitilly and Luigi R. Garibaldi

hCG-secreting tumors are a rare cause of precocious puberty in males. Secretion of hCG activates luteinizing hormone/choriogonadotropin (LHCG) receptors in the Leydig cells causing testosterone production and virilization with minimal testicular enlargement. Testicular histology reveals interstitial cell hyperplasia with no spermatogenesis. Plasma levels of testosterone are elevated, whereas those of FSH and LH, as measured by specific assays, are low. Females with **hCG-secreting tumors** do not present with precocious puberty because the ovarian production of estradiol cannot occur in the absence of FSH stimulation.

HEPATIC TUMORS

All reported cases of hepatoblastoma causing isosexual precocious puberty have been in males, with the average age of onset of 2 years (range 4 months to 8 years). An enlarged liver or mass in the right upper quadrant should suggest the diagnosis. Plasma levels of hCG and α-fetoprotein (AFP) are usually markedly elevated and serve as useful markers for following the effects of therapy. As with other carcinomas of the liver, the prognosis for survival beyond 1-2 years from the time of diagnosis is poor.

INTRACRANIAL TUMORS

Nongerminomatous or mixed germ cell tumors, choriocarcinomas, teratomas, teratocarcinomas, and others account for <5% of intracranial tumors; are usually located in the neurohypophyseal area or the pineal area; and may cause precocious puberty in males if they secrete hCG—the mass effect can infrequently cause precocious puberty in females. Marked elevations of hCG and AFP often occur in the cerebrospinal fluid, although elevations in the blood may be modest. Treatment includes radiation, chemotherapy, and debulking surgery.

TUMORS IN OTHER LOCATIONS

Very rare locations include mediastinum, gonads, or even adrenal glands. Mediastinal germ cell tumors have been reported to cause precocious puberty in males with Klinefelter syndrome.

PERIPHERAL PRECOCIOUS PUBERTY

The adrenal causes of peripheral precocious puberty are discussed in Chapter 616, and the gonadal causes are discussed in Chapters 624 and 627.

600.6 McCune-Albright Syndrome

Luigi R. Garibaldi and Wassim Chemaitilly

McCune-Albright syndrome, or precocious puberty with *polyostotic fibrous dysplasia* and abnormal pigmentation, is a syndrome of endocrine dysfunction associated with patchy cutaneous pigmentation and fibrous dysplasia of the skeletal system. It is a rare condition with a prevalence between 1/100,000 and 1/1,000,000, characterized by autonomous hyperfunction of one or more glands (which may include pituitary, thyroid, and adrenal glands). An activating missense pathogenic variant in the *GNAS1* gene encoding the α-subunit of G_S, the G protein that stimulates cyclic adenosine monophosphate (cAMP) formation, results in activation of receptors (adrenocorticotropic hormone [ACTH], TSH, FSH, and LH receptors) that operate via a cAMP-dependent mechanism, as well as cell proliferation. Because the pathogenic variant is postzygotic rather than genomic, it is present variably in different tissues (somatic mosaicism) and hence results in variable clinical expression and limited diagnostic sensitivity of genetic testing from leukocyte DNA or unaffected tissues. The diagnostic sensitivity may improve with new techniques, however. Precocious puberty has been described predominantly in females (Fig. 600.4) and is characterized by recurrent ovarian cysts, bouts of estrogen secretion, and vaginal bleeding in the context of modest breast development. The age at onset in females is usually 3-6 years but has been reported as early as 4-6 months of age. Serum levels of LH and FSH are suppressed, with no response to GnRH stimulation. Estradiol levels fluctuate from low to markedly elevated (>300 pg/mL), are often cyclic, and may correlate with the size of the cysts. Precocious puberty is less commonly reported in males with McCune-Albright syndrome. Testicular enlargement is often symmetric and is followed by the appearance of phallic enlargement and pubic hair development, as in normal puberty. Testicular histology has shown foci or nodules (often sonographically detectable) of Leydig cell hyperplasia. In females and males, when the bone age reaches the usual pubertal age range, gonadotropin secretion begins and CPP ensues and overrides the antecedent (gonadotropin-independent) puberty. In females, menses become more regular, but often not completely so, and fertility has been documented.

Pubertal progression is variable in these patients. Functioning ovarian cysts often disappear spontaneously; aspiration or surgical excision of cysts is rarely indicated. For those females with persistent or recurrent estradiol secretion, **aromatase inhibitors** (which inhibit the final step of estrogen biosynthesis) such as **letrozole** (1.25-2.5 mg/day PO) have proven safe and effective in limiting the estrogen effects on pubertal and osseous maturation. The same compounds have also been used in males in combination with **antiandrogens**. These medications are not approved by the FDA for this indication. Associated therapy with **long-acting analogs of GnRH** is indicated only for young children whose puberty has shifted from a gonadotropin-independent to a predominantly gonadotropin-dependent mechanism. Ovarian torsion is a severe complication of large ovarian cysts.

EXTRAGONADAL MANIFESTATIONS

The hyperthyroidism that occurs in this condition is usually clinically mild or subclinical, unlike that observed in **Graves disease**. Mildly elevated triiodothyronine levels, suppressed TSH levels, and nodular abnormalities on ultrasound have been reported. Thyroidectomy is rarely necessary.

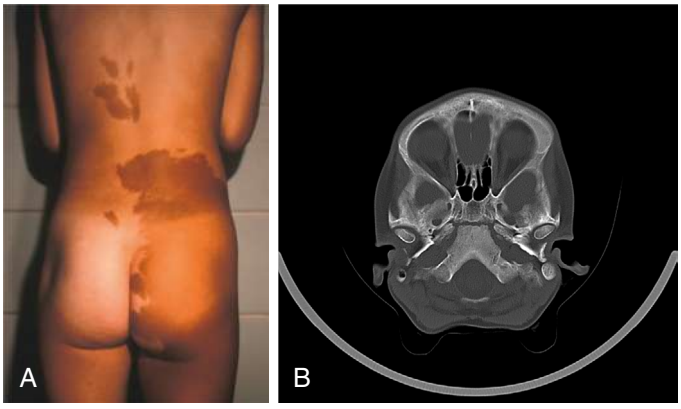

Fig. 600.4 Precocious puberty with McCune-Albright syndrome (MAS). **A,** A girl presented at 5 yr of age with early stage III breast development and vaginal bleeding. Note the extensive café-au-lait skin patches, some of which did not cross the midline. **B,** A girl presented with recurring episodes of mild breast enlargement and vaginal bleeding associated with ovarian cysts, starting at age 7 mo. She had no skin lesions and a negative skeletal survey and bone scan at age 4 yr. The diagnosis of MAS was established at 5 yr of age, when prominence of her left forehead and supraorbital ridge prompted a CT scan, which revealed unilateral thickening of the skull bones **(B)**. Skull lesions are often hyperostotic, whereas long bone lesions usually have a lytic, "ground-glass" appearance.

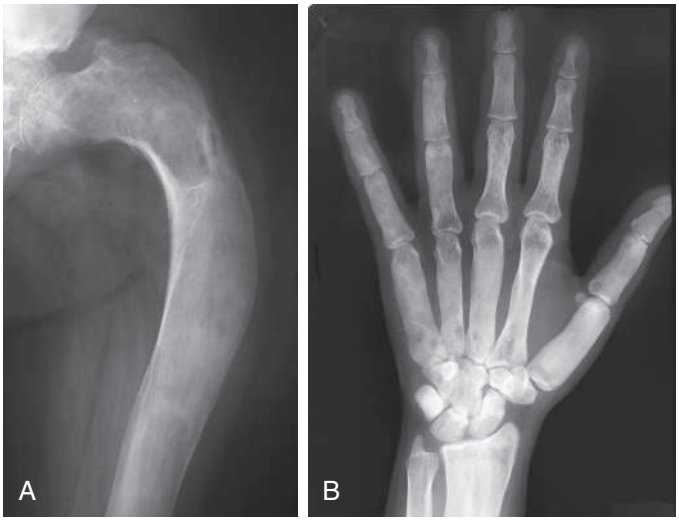

Fig. 600.5 Polyostotic fibrous dysplasia in a 22-yr-old female. A, The femur is expanded and bowed with a "shepherd's crook" deformity. The femoral trabeculae are replaced by a "ground-glass" matrix. B, Diffuse sclerosis is seen in the hand and wrist with mild expansion and indistinct transition from the cortex to medullary space. *(From Thapa MM, Kaste SC, Meyer JS. Soft tissue bone tumors. In: Coley BD, ed. Caffey's Pediatric Diagnostic Imaging, 13th ed. Philadelphia: Elsevier; 2019: Fig. 138.31.)*

Cushing syndrome caused by bilateral nodular adrenocortical hyperplasia has occurred only in neonates or young infants. ACTH levels are low, and cortisol is elevated and not suppressible by dexamethasone. The condition may resolve spontaneously; if not, treatment is bilateral adrenalectomy.

Increased secretion of GH occurs uncommonly and is manifested clinically by **gigantism** or **acromegaly**. The growth rate is increased (even in the absence of precocious puberty); serum levels of GH are elevated, increase during sleep, and are poorly suppressed by oral glucose. Serum levels of prolactin are increased in most patients. Less than 50% of the patients have a demonstrable pituitary tumor. Treatment includes octreotide or lanreotide—long-acting somatostatin analogs—to lower the elevated GH levels or pegvisomant to antagonize the effect of GH at the receptor level.

Fibrous dysplasia of (usually) multiple bones (polyostotic) represents a major cause of morbidity in this syndrome (Fig. 600.5). The base of the skull and the proximal femurs are most commonly involved, but any bone can be affected. Even in the absence of deformities, a CT scan of the cranium is recommended by several investigators. The prognosis is favorable for longevity, but deformities, repeated fractures, pain, and occasional cranial nerve compression may result from the bony lesions. Bone pain often responds to IV pamidronate or other bisphosphonates. Extensive bony lesions may be associated with phosphaturia because of oversecretion of FGF23, leading to rickets or osteomalacia. Extraglandular manifestations of this syndrome are rare, but cardiovascular and hepatic involvement (severe neonatal cholestasis) may be life threatening.

600.7 Familial Male-Limited Gonadotropin-Independent Precocious Puberty

Wassim Chemaitilly and Luigi R. Garibaldi

This rare, autosomal dominant form of peripheral precocious puberty is transmitted from affected males and unaffected female carriers of the pathogenic variant to their male offspring. Signs of puberty appear by 2-3 years of age. The testes are only slightly enlarged. Testicular biopsies show Leydig cell maturation and, sometimes, marked hyperplasia. Maturation of seminiferous tubules may be present. Testosterone levels are variably elevated, often markedly so, even above the adult male range; however, baseline levels of LH are prepubertal, pulsatile secretion of LH is absent, and LH does not respond to stimulation with GnRH or a GnRH agonist. The cause for activation of Leydig cells independently of gonadotropin stimulation is a missense pathogenic variant of *LHCGR*, which encodes the LHCG receptor leading to constitutive activation of cAMP production. Osseous maturation may be markedly advanced; when it reaches the pubertal age range, hypothalamic maturation shifts the mechanism of pubertal development to a gonadotropin-dependent one. This sequence of events is similar to that occurring in children with McCune-Albright syndrome (see Chapter 600.6) or in those with congenital adrenal hyperplasia (see Chapter 616).

Gonadotropin-independent precocious puberty has been diagnosed in a few unrelated males with **type IA pseudohypoparathyroidism** with a specific pathogenic variant of *GNAS* that encodes the $G_s\alpha$ protein. This pathogenic variant is inactivating at normal body temperature and causes pseudohypoparathyroidism, but in the cooler temperature of the testes, it is constitutionally activating, resulting in adenyl cyclase stimulation and production of testosterone. Although this pathogenic variant differs from the constitutive LH receptor pathogenic variant, which usually causes familial male gonadotropin-independent precocious puberty, the end result is the same.

TREATMENT

Young males have been treated with ketoconazole (10-15 mg/kg/day in 8-hour divided doses), an antifungal drug that inhibits C-17,20-lyase and testosterone synthesis. Complications of ketoconazole include liver toxicity and tachyphylaxis. A combination of antiandrogens (such as spironolactone 50-100 mg bid, flutamide 125-250 mg daily or bid, or bicalutamide 25-50 mg daily) and **aromatase inhibitors** (letrozole 2.5 mg/day or anastrozole 1 mg/day) has been used—the latter compounds to suppress estrogens derived from androgens, which potently stimulate bone maturation. These medications are unable to revert the serum testosterone to normal (prepubertal) concentrations or completely offset the unfavorable effects of the elevated sex hormones. They slow down, but do not halt, the progression of puberty and may not improve the height prognosis. Males whose GnRH pulse generator has matured require combined therapy with GnRH agonists.

600.8 Incomplete (Partial) Precocious Development

Wassim Chemaitilly and Luigi R. Garibaldi

Isolated development of the breasts in females and growth of sexual hair in both sexes without other signs of puberty are the two most common forms of incomplete precocity and are not unusual in a pediatric practice.

PREMATURE THELARCHE

This term applies to a sporadic, transient condition of isolated breast development that most often appears in the first 2 years of life. In some females, breast development is present at birth and persists. It may be unilateral or asymmetric and often fluctuates in degree. Growth and osseous maturation are normal or slightly advanced. The genitalia show no evidence of estrogenic stimulation. Breast development may regress after 2 years, often persists for 3-5 years, and is rarely progressive. Menarche generally occurs at a normal age, and reproduction is also normal. Basal serum levels of FSH and the FSH response to GnRH stimulation may be greater than that seen in normal controls. Plasma levels of LH and estradiol are typically undetectable. Pelvic ultrasound reveals normal-sized ovaries, but a few small (<9 mm) cysts are not uncommon.

In some females, breast development may be associated with definite evidence of systemic estrogen effects, such as growth acceleration or bone age advancement. Pelvic sonography may reveal enlarged ovaries and/or uterus. This condition, referred to as **exaggerated or atypical thelarche**, differs from CPP because it spontaneously regresses. Leuprolide or GnRH stimulation elicits a robust FSH response, a low LH response, and (after leuprolide only) a moderate estradiol increment at 24 hours (average 60-90 pg/mL). The pathogenesis of typical and exaggerated forms of thelarche is unclear. Delayed inactivation of the hypothalamic-pituitary-ovarian axis, which is active during the prenatal and early postnatal period, increased peripheral sensitivity to estrogens, and other possibilities are unproven hypotheses. In addition to a detailed history, a bone age should be obtained if there are any unusual features. Random serum concentrations of FSH, LH, and estradiol are generally low and not diagnostic. Pelvic ultrasound examination or leuprolide stimulation testing is occasionally indicated. Continued observation is important because the condition cannot be readily distinguished from true precocious puberty. Regression and recurrence suggest functioning **follicular cysts**. Occurrence of thelarche in children older than 3 years of age most often is caused by a condition other than **benign premature thelarche**.

PREMATURE PUBARCHE (ADRENARCHE)

This term has traditionally applied to the appearance of sexual hair before the age of 8 years in females or 9 years in males without other evidence of maturation. It is much more frequent in females than in males. The higher prevalence of this condition in African American and, to a smaller extent, Latino females in comparison to White females may suggest that the cutoff age for the definition of *premature* should be adjusted for different ethnic groups on epidemiologic data. Hair appears on the mons and labia majora in females and perineal and scrotal area in males; axillary hair generally appears later. Adult-type axillary odor is common. Affected children are often slightly advanced in height and osseous maturation. **Premature adrenarche** is an early maturational event of adrenal androgen production. It coincides with precocious maturation of the zona reticularis, traditionally believed to be associated with a decrease in 3β-hydroxysteroid dehydrogenase activity and an increase in C-17,20-lyase activity. These enzymatic changes result in increased basal and ACTH-stimulated serum concentrations of the Δ^5-steroids (17-hydroxypregnenolone and dehydroepiandrosterone [DHEA]) and, to a lesser extent, of the Δ^4-steroids (particularly androstenedione) compared with age-matched control subjects. One class of androgens, the 11-oxygenated steroids, have been reported to play an important role in adrenal physiology and pathology, including adrenarche. **Idiopathic premature adrenarche** is a slowly progressive condition that requires no therapy. However, a subset of patients presents with **atypical premature adrenarche** characterized by one or more features of systemic androgen effects, such as marked growth acceleration, clitoral (females) or phallic (males) enlargement, cystic acne, and advanced bone age (2 SD greater than the mean for age). In this subgroup, an ACTH stimulation test with measurement of serum 17-hydroxyprogesterone concentration is indicated to rule out **nonclassical congenital adrenal hyperplasia** due to 21-hydroxylase deficiency. The prevalence of nonclassical 21-hydroxylase deficiency is approximately 3–6% of unselected children with precocious pubarche; other enzyme defects (i.e., 3β-hydroxysteroid dehydrogenase or 11β-hydroxylase deficiencies) are extremely rare. Although idiopathic premature adrenarche has been considered a benign condition, longitudinal observations suggest that approximately 50% of females with premature adrenarche are at high risk for hyperandrogenism and **polycystic ovary syndrome**, alone or more often in combination with other components of so-called metabolic syndrome (insulin resistance possibly progressing to type 2 diabetes mellitus, dyslipidemia, hypertension, increased visceral fat) as adults. Whether the unfavorable progression to pubertal hyperandrogenism can be prevented by insulin-sensitizing agents (metformin 850-2000 mg/day) or lifestyle interventions (diet, exercise) remains to be proven in large studies. An increased risk of premature adrenarche and **metabolic syndrome** has been documented in children born small for their gestational age. This appears to be associated with insulin resistance and decreased β-cell reserve, perhaps as a consequence of fetal undernutrition.

PREMATURE MENARCHE

This is a rare entity, much less frequent than premature thelarche or premature adrenarche, and is a diagnosis of exclusion. In females with isolated vaginal bleeding in the absence of other secondary sexual characteristics, more common causes, such as vulvovaginitis, a foreign body (typically associated with malodorous discharge), or sexual abuse, and uncommon causes, such as urethral prolapse and sarcoma botryoides, must be carefully excluded. Most females with idiopathic premature menarche have only one to three episodes of bleeding; puberty occurs at the usual time, and menstrual cycles are normal. Plasma levels of gonadotropins are low, but estradiol levels may be occasionally elevated, probably owing to episodic ovarian estrogen secretion associated with ovarian follicular cysts that can be sometimes detected on ultrasound.

600.9 Medicational Precocity

Luigi R. Garibaldi and Wassim Chemaitilly

Various medicaments can induce the appearance of secondary sexual characteristics (i.e., peripheral precocious puberty). Examples include the accidental ingestion of estrogens (including contraceptive pills) and the administration of anabolic steroids. Exogenous estrogens may produce a darkening of the areola that is not usually seen in central sexual precocity. The most common cause of medicational precocity is currently related to the widespread use of **testosterone gels or creams**, which are applied to the skin for treatment of male hypogonadism. Systemic absorption from the skin area of a male relative where the gel/cream was applied may result in elevated serum testosterone levels (50-100 mg/dL or higher), with ensuing virilization of exposed children and women. Intense application of diaper rash creams or ointments has recently been reported to cause mild pubarche, with an unclear mechanism.

Less commonly, estrogens in cosmetics, hair creams, and breast augmentation creams cause breast development in females and gynecomastia in males via percutaneous absorption. Lavender and tea tree oils have been associated with prepubertal gynecomastia in several reports. Genistein, a compound from soy, has estrogenic activity in mice, but data in humans are conflicting. The physical changes disappear after cessation of exposure to the hormones. A careful history focused on exploring the possibility of accidental exposure to, or ingestion of, sex hormones is important.

600.10 Delayed or Absent Puberty

Peter M. Wolfgram

For hypofunction of testis, see Chapter 623. For hypofunction of ovaries, see Chapter 626.

Delayed puberty is the failure of development of any pubertal feature by 13 years of age in females or by 14 years of age in males. A lower cutoff may be appropriate in a child with a strong familial pattern of early puberty.

DIFFERENTIAL DIAGNOSIS

Delay or absence of puberty is caused by:

- Constitutional delay: A variant of normal.
- Hypogonadotropic hypogonadism: Low gonadotropin levels as a result of a defect of the hypothalamus and/or pituitary gland (Tables 600.3, 600.4, and 600.5).
- Hypergonadotropic hypogonadism: High gonadotropin levels as a result of a lack of negative feedback because of a gonadal problem (see Tables 600.3, 600.4, and 600.5). Females may have evidence of adrenarche with absence of normal breast development.

Table 600.3 Classification of Delayed Puberty and Sexual Infantilism

IDIOPATHIC (CONSTITUTIONAL) DELAY IN GROWTH AND PUBERTY (DELAYED ACTIVATION OF HYPOTHALAMIC GNRH PULSE GENERATOR)

HYPOGONADOTROPIC HYPOGONADISM: SEXUAL INFANTILISM RELATED TO GONADOTROPIN DEFICIENCY

CNS Disorders

Tumors
- Craniopharyngiomas
- Germinomas
- Other germ cell tumors
- Hypothalamic and optic gliomas
- Astrocytomas
- Pituitary tumors (including MEN-1, prolactinoma)

Other Causes
- Langerhans histiocytosis
- Postinfectious lesions of the CNS
- Vascular abnormalities of the CNS
- Radiation therapy
- Congenital malformations especially associated with craniofacial anomalies
- Head trauma
- Lymphocytic hypophysitis

Isolated Gonadotropin Deficiency

Kallmann syndrome (with hyposmia or anosmia; without anosmia)
GnRH receptor pathogenic variant
Congenital adrenal hypoplasia (*DAX1* pathogenic variant)
Isolated LH deficiency
Isolated FSH deficiency
Prohormone convertase 1 deficiency (PCI)

Idiopathic and Genetic Forms of Multiple Pituitary Hormone Deficiencies Including PROP1 Pathogenic Variant

Miscellaneous Disorders

See Table 600.4 for syndromic etiologies
Functional gonadotropin deficiency
- Chronic systemic disease and malnutrition
- Sickle cell disease
- Cystic fibrosis
- Acquired immunodeficiency syndrome (AIDS)
- Chronic gastroenteric disease
- Chronic renal disease
- Malnutrition

Miscellaneous Disorders (continued)
- Anorexia nervosa
- Bulimia
- Psychogenic amenorrhea
- Impaired puberty and delayed menarche in female athletes and ballet dancers (exercise amenorrhea)
- Hypothyroidism
- Diabetes mellitus
- Cushing disease
- Hyperprolactinemia
- Marijuana use
- Gaucher disease

HYPERGONADOTROPIC HYPOGONADISM

Males

The syndrome of seminiferous tubular dysgenesis and its variants (Klinefelter syndrome)
Other forms of primary testicular failure
- Chemotherapy
- Radiation therapy
- Testicular steroid biosynthetic defects
- Sertoli-only syndrome
- LH receptor mutation
- Anorchia and cryptorchidism
- Trauma/surgery

Females

The syndrome of gonadal dysgenesis (Turner syndrome) and its variants
XX and XY gonadal dysgenesis
- Familial and sporadic XX gonadal dysgenesis and its variants
- Familial and sporadic XY gonadal dysgenesis and its variants

Aromatase deficiency
Other forms of primary ovarian failure
- Premature menopause
- Radiation therapy
- Chemotherapy
- Autoimmune oophoritis
- Galactosemia
- Glycoprotein syndrome type 1
- Resistant ovary
- FSH receptor pathogenic variant
- LH/hCG resistance
- Polycystic ovarian disease
- Trauma/surgery
- Noonan or pseudo-Turner syndrome
- Ovarian steroid biosynthetic defects

Constitutional Delay of Growth and Puberty

This is the most common cause of delayed puberty and a normal variant of pubertal timing. It is predominately diagnosed in males, likely as a result of ascertainment bias from referral patterns. The cause is unknown, but approximately 50% of affected patients have a first-degree relative with delayed puberty and/or late growth. This tendency can occur in a child of the same gender as the affected parent or in a child of the opposite gender. An affected child typically presents in early adolescence, when peers are beginning to develop and having growth spurts but the patient is not. The patient's height is usually at or below the third percentile. In a classic patient, the affected child had a normal length at birth, followed by a slowdown in height velocity between 6 months and 2 years of age that resulted in a decreased height percentile, and then normal or near-normal height velocity thereafter along this decreased height percentile. The physical examination findings are unremarkable, except at the typical age of puberty the child will have delayed pubertal development and growth. The cardinal diagnostic finding is a bone age that is moderately delayed (or younger appearing) than the typical bone age for the patient's actual chronological age. There may also be a history of delayed dentition. Without intervention, final adult heights usually reach or approximate the genetic target height range. However, rarely, children with constitutional delay may have a blunted pubertal growth spurt in relation to their peers and therefore may not reach their target height range.

Hypogonadotropic Hypogonadism

A variety of CNS anomalies or injuries may disrupt production of gonadotropins. The GnRH pulse generator may be disrupted by an interfering substance, such as excess prolactin, chronic illness, malnutrition, or excessive physical activity. The hypothalamic arcuate nucleus may be damaged by trauma, radiation, infection, infiltration, increased intracranial pressure, or surgery. The most common mass lesions are craniopharyngiomas, gliomas, and cysts. Of note, congenital conditions or malformations may have allowed enough GnRH, LH, and FSH for infantile development but may not be enough later to begin and sustain puberty.

Kallmann Syndrome

This is the combination of a deficiency of gonadotropins with an impaired or absent sense of smell. Other features may include color blindness, atrial septal defects, and renal structural anomalies (unilateral renal agenesis). The X-linked form is caused by a pathogenic variant of *KAL*; there are autosomal recessive and autosomal dominant forms.

LH and FSH deficiencies may be isolated or accompanied by multiple pituitary hormone deficiencies. The deficiency may be a result of pituitary damage from trauma, radiation, infection, sickle cell disease, compression by infiltrate or tumor, or autoimmune processes. In differentiating primary pituitary deficiency from that secondary to hypothalamic deficiency, the clinician should remember that all pituitary hormones, except prolactin, are stimulated by hypothalamic-releasing hormones; however, prolactin is inhibited by hypothalamic prolactin inhibitory factor (dopamine). Therefore if all pituitary hormones, including prolactin, are deficient, the problem is in the pituitary gland. If prolactin levels are present or even elevated but the other pituitary hormones are deficient, the problem is above the pituitary gland, in the stalk or hypothalamus. In the case of isolated LH and FSH deficiencies, the primary abnormality may lie within the pituitary-hypothalamic neurons producing GnRH or farther upstream of the GnRH-secreting neurons. In particular, defects in molecules required for proper migration of GnRH neurons (including the *KAL* gene) or lack of necessary signaling to GnRH-producing neurons (defects in kisspeptin or neurokinin B and their receptors) can result in LH and FSH deficiency through inappropriate GnRH secretion.

Hypergonadotropic Hypogonadism: Males

If the testes are small, they may have been damaged by torsion, sickle cell disease, infection, autoimmune disease, chemotherapy, or radiation and may not be able to respond to LH and FSH stimulation. If the male is of pubertal age (bone age is greater than 10 years) and the hypothalamus has matured, the serum LH and FSH will be high because of lack of testicular response. Also, if there is a problem with testicular LH receptors, the LH can be high but the testosterone will not appropriately increase.

Klinefelter Syndrome

This occurs in 1:500 males and is often associated with a 47,XXY karyotype; common features include reduced intelligence, adolescent gynecomastia (often severe), and small, firm testes. The testes rarely exceed 5 mL in volume (approximately 25% of the average adult volume). Patients are often tall and thin with an eunuchoid habitus and may have delayed puberty with high FSH and LH. Virilization may be incomplete, the phallus is often smaller than average, and infertility approaches 100%.

Hypergonadotropic Hypogonadism: Females

In this condition, the ovary may be unable to synthesize estrogen (an inherited metabolic defect), the ovary may not be formed normally (dysgenesis), or the ovary may have been damaged by any of the factors listed for testicular damage and by galactosemia.

The ovary may be intact but may not be stimulated by gonadotropins—for example, FSH is present but there is an FSH receptor problem, so estradiol is not made appropriately.

Turner Syndrome

The two most common features of Turner syndrome are short stature (involving the limbs to a greater degree than the trunk) and ovarian insufficiency with high FSH. Lymphedema and a webbed neck are diagnostic features present in a neonate. Additional features include shield chest, increased carrying angle (cubitus valgus), short fourth metacarpal, hypoplastic nails, renal anomalies, and left-sided heart defects (coarctation of the aorta, bicuspid aortic valve). Approximately 50% of affected females have no stigmata except short stature and thus are typically identified later. About 20% may have spontaneous puberty with functioning ovaries for at least a short period, which is in large part dependent on the child's karyotype; the infertility rate is greater than 99%.

Females with Delayed or Absent Adrenarche

If a female has advanced breast development but no androgen signs, she may have a disorder of androgen activity as occurs in **androgen insensitivity syndrome** (testicular feminization). In females, the androgens come predominantly from the adrenal glands (adrenarche). If the bone age is less than 8 years, adrenarche may simply be delayed (delayed adrenarche). However, if the bone age is older, there may be an inherited problem in androgen synthesis from an enzyme deficiency, or the adrenal may be damaged secondary to autoimmune, infectious, or hypoxic injury. In these latter conditions of adrenal damage, other signs of adrenal insufficiency would be evident.

DIAGNOSTIC APPROACH TO DELAYED PUBERTY

A normal growth rate with delayed, but not absent, puberty and a family history of late puberty suggest the diagnosis of constitutional delay of growth and puberty, which is the most commonly encountered cause. A bone age that correlates with the patient's current pubertal status but is delayed for their chronological age confirms the clinical impression; no other testing is necessary.

Initial evaluation should include:

- Medical history: trauma, illness, medications (e.g., stimulants, chemotherapy), radiation, infection, malnutrition, autoimmune problems, sickle cell disease status, stresses, growth records, galactosemia
- Review of symptoms: vision problems, headache, vomiting, inability to detect odors (hyposmia or anosmia), age at onset of androgen signs, age at onset of estrogen signs, small genitalia at birth, signs of primary adrenal insufficiency such as hyperpigmentation, need for deodorant, need to wash hair more frequently
- Family history: timing of maternal and paternal growth and pubertal development; siblings and cousins with delayed development
- Physical examination: signs of chronic disease, temperature, blood pressure, height, weight, head circumference, dental age, hyperpigmentation, pubic and axillary hair, adult body odor, evidence of skin and hair oils, visual fields, optic discs, ability to detect odors, breast development, vaginal cornification/discharge, penis size, scrotal development, testicular volume, pubic hair stages, neurologic status, affect or mood, intellectual ability, dysmorphic features

Initial laboratory evaluation screens for chronic disease (complete blood cell count, chemistry profile, sedimentation rate), hypothyroidism (free thyroxine and TSH), and hyperprolactinemia (prolactin level) should be obtained. If growth is slow, the clinician should measure insulin-like growth factor-1 level (marker of basal GH activity) and consider GH testing. The clinician should measure testosterone levels in males and estradiol levels in females.

Measurements of random FSH and LH and results of a GnRH stimulation test may differentiate between hypogonadotropic hypogonadism and primary gonadal failure (Figs. 600.6 and 600.7). Elevated gonadotropin levels support a diagnosis of primary gonadal failure. A random LH or an LH after GnRH is not typically helpful in distinguishing between constitutional delay and hypogonadotropic hypogonadism because with both diagnoses the LH will be low. However, the child with constitutional delay eventually develops an appropriate pubertal development and LH values. If there are elevated gonadotropins, chromosomal karyotyping can be performed (Klinefelter syndrome in males and Turner syndrome in females).

If Kallmann syndrome is being considered, an MRI scan may show abnormalities in the olfactory region. If a 46,XX female has unexplained ovarian failure, antiovarian antibodies and müllerian-inhibiting substance can assess ovarian follicle reserve and potential fertility. In males, an hCG stimulation test to evaluate ability to produce testosterone and a serum level of müllerian-inhibiting substance (secreted by

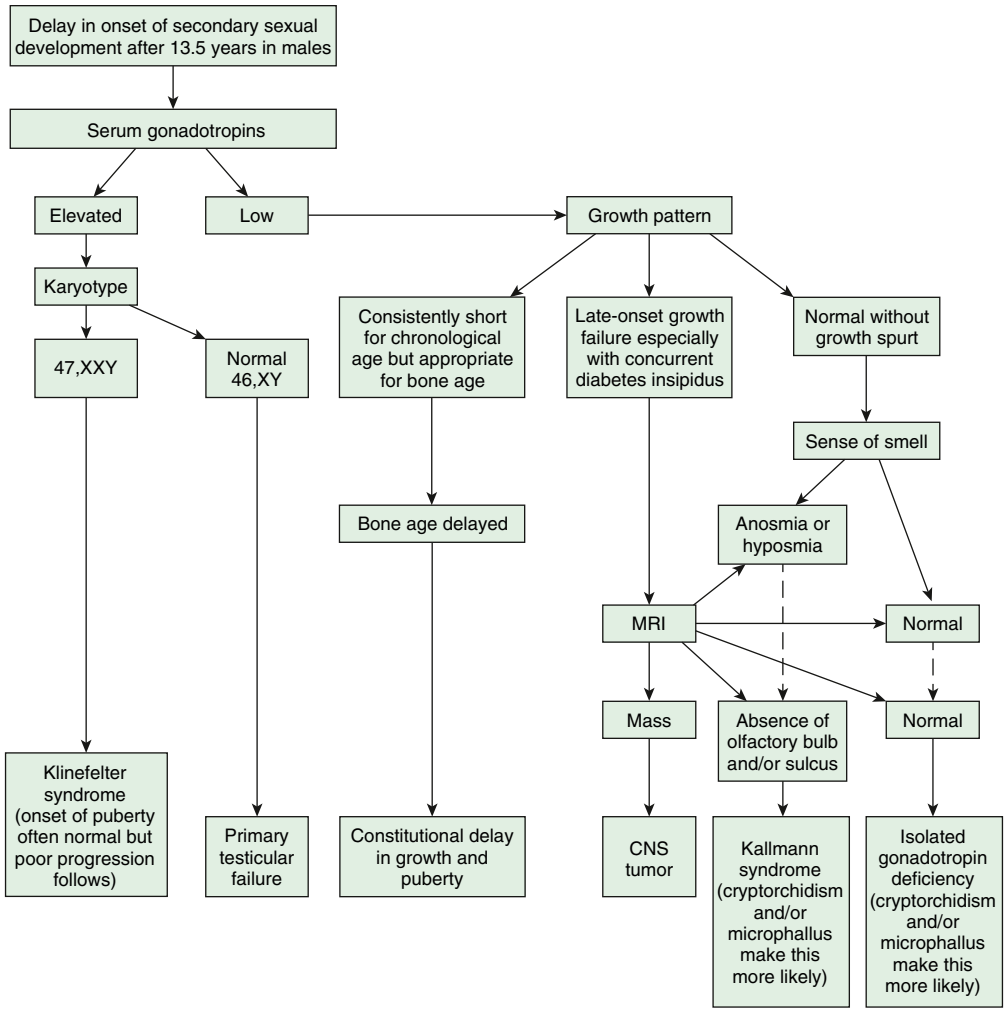

Fig. 600.6 Diagnostic algorithm for the evaluation of delayed puberty in males. CNS, Central nervous system; MRI, magnetic resonance imaging. *(From Styne DM, Grumbach MM. Physiology and disorders of puberty. In Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, eds. Williams Textbook of Endocrinology, 13th ed. Philadelphia: Elsevier; 2016: Fig. 25.48.)*

Sertoli cells) are useful for determining whether functional testicular tissue is present.

TREATMENT OF DELAYED PUBERTY

If delayed puberty is a normal physiologic variant (constitutional delay of growth and puberty), sex steroid replacement is not medically necessary. Watchful waiting is usually the appropriate course of action. However, adolescent males with constitutional delay of growth and puberty who are short, underdeveloped, and psychologically compromised may benefit from a short course of testosterone therapy. This is usually given as long-acting intramuscular testosterone, at a dosage of 50-100 mg every 4 weeks for a course ranging between 6 and 12 months. Treatment is generally begun at about 14 years of age and, if possible, when the testes have enlarged to about 6-8 mL in volume. These doses stimulate height and weight gain, allow adequate virilization (increased pubic and axillary hair growth and penile enlargement), and do not typically suppress pituitary FSH and LH secretion, thereby allowing simultaneous endogenous pubertal progression (testicular enlargement). This narrows the physical gap between the patient and peers without causing undue advancement of bone age. Acne is the principal side effect, and the adult height is not altered. It is the hope that at the conclusion of treatment, the male will continue to grow and develop rapidly, with the testosterone treatment perceived as a jump starter of endogenous puberty. Additionally, a short course of a low-dose anabolic steroid, such as oxandrolone, can also be used in prepubertal and pubertal males, and low-dose estradiol has been used in prepubertal and pubertal females with constitutional delay.

Treatment of hypogonadism aims to mimic normal physiology with stepwise replacement of testosterone in males and estrogen and progesterone in females. For males with hypogonadism, low-dose parenteral testosterone is initiated at 50 mg every 4 weeks, with increases in 50-mg increments made over a 2- to 3-year period. Most adult males receive 200 mg every 2-4 weeks, which is based on the daily adult male testosterone production rate of 6 mg. Adult men can receive testosterone by patch, which is often associated with local irritation, or by gel, but, typically in growing adolescents, intramuscular testosterone is prescribed to allow more reliable control of testosterone activity.

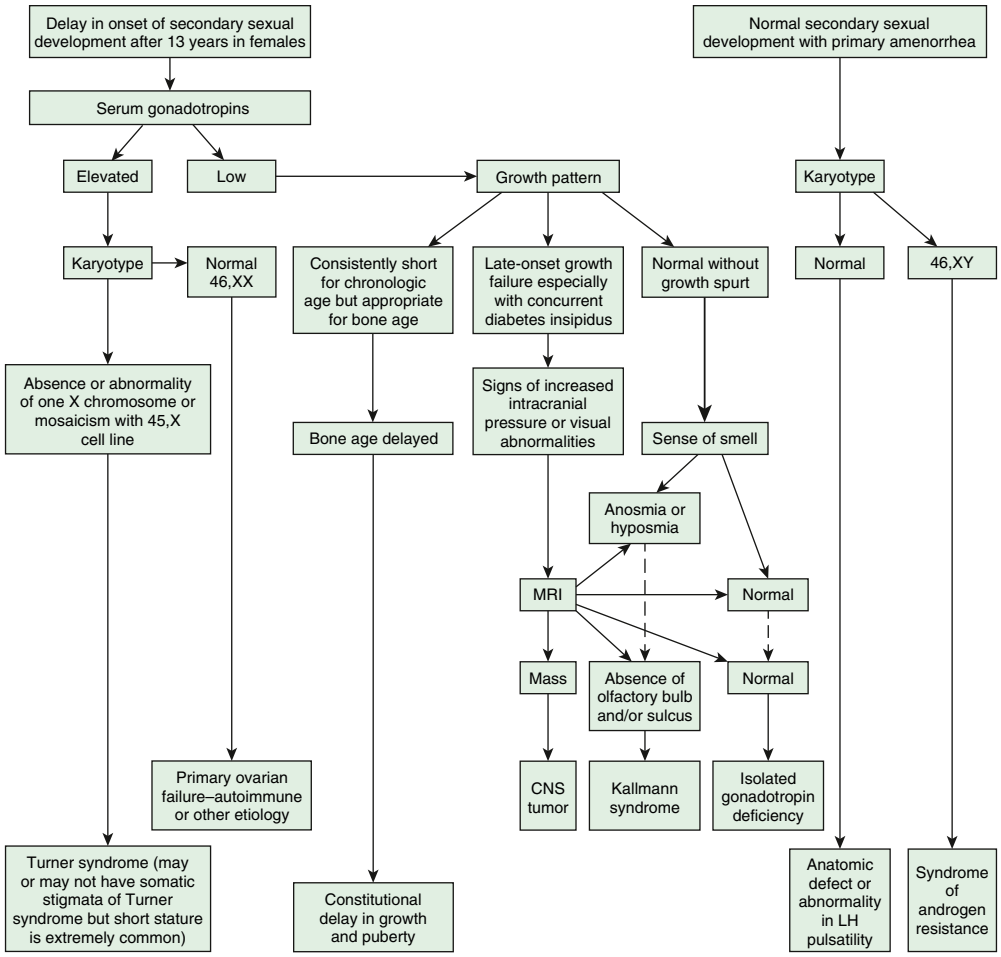

Fig. 600.7 Diagnostic algorithm for the evaluation of delayed puberty in females. CNS, Central nervous system; MRI, magnetic resonance imaging. *(From Styne DM, Grumbach MM. Physiology and disorders of puberty. In Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, eds. Williams Textbook of Endocrinology, 13th ed. Philadelphia: Elsevier; 2016: Fig. 25.49, p. 1157.)*

For females with hypogonadism, daily estrogen therapy typically is provided through a transdermal 17β-estradiol patch 25 mcg/24 hr patch, which is more physiologic than oral preparations of the estrogens (conjugated estrogens [Premarin] or ethinyl estradiol) because transdermal therapy avoids initial first-pass hepatic metabolism. The transdermal or oral dose of estrogen (Premarin starts at 0.3 mg daily) is increased over the course of about 2 years. Two years of estrogen therapy without progesterone does not place the uterus at undue risk for hyperplasia and malignancy, but after 2 years (or sooner if spotting occurs prior), progesterone should be added. Options to consider when adding progesterone include continuing the 17β-estradiol patches or estrogen-only–containing pills (conjugated estrogens or ethinyl estradiol) in conjunction with oral medroxyprogesterone acetate (Provera), a progesterone eluting intrauterine device (IUD), or switching the patient to conventional oral contraceptives. If the patient is not put on a conventional oral contraceptive or a progesterone-eluting IUD, the estrogen (pill or patch) is prescribed on days 1-23 of the calendar month with the addition of medroxyprogesterone acetate on days 10-23. With this approach, withdrawal bleeding generally occurs between day 23 and the end of the month, although there can be some variability in the timing between patients.

Patients of either sex with hypogonadotropic hypogonadism are potentially fertile, but sex-steroid therapy alone is ordinarily not sufficient to initiate gametogenesis, although there are rare cases in males in which testosterone replacement alone has stimulated spermatogenesis. The general approach to fertility induction in either sex involves the addition of either cyclical gonadotropin therapy or pump-driven GnRH therapy at the age of desired conception. *When hypogonadotropic hypogonadism is present as one component of hypopituitarism, it is critical to adequately replace all deficient hormones* (see Chapter 595). In contrast, patients with primary hypogonadism have intrinsic gonadal damage and are normally infertile.

Section 2

Disorders of the Thyroid Gland

Chapter 601

Thyroid Development and Physiology

Ari J. Wassner and Jessica R. Smith

FETAL DEVELOPMENT

The fetal thyroid arises from an outpouching of the foregut at the base of the tongue (foramen cecum) and migrates to its normal location below the cricoid cartilage by 8-10 weeks of gestation. The thyroid's bilobed shape is apparent by 7 weeks of gestation, and thyroid follicular cells capable of forming colloid are present by 10 weeks. Thyroglobulin synthesis begins at 4 weeks, iodine trapping occurs by 8-10 weeks, and synthesis and secretion of thyroxine (T_4) and, to a lesser extent, triiodothyronine (T_3) occur from 12 weeks of gestation. Several transcription factors, including NKX2.1, FOXE1, and PAX8, are important in thyroid gland morphogenesis and differentiation and possibly also in its caudal migration. Thyrotropin (TSH) secretion is evident by 10-12 weeks of gestation. Maturation of the hypothalamic-pituitary-thyroid axis occurs during the second half of gestation, but normal hormonal feedback relationships are not mature until 1-3 months of postnatal life. Other transcription factors, including PROP1 and POU1F1, are important for the differentiation and growth of pituitary thyrotrophs, along with somatotrophs and lactotrophs.

THYROID PHYSIOLOGY

The primary function of the thyroid gland is to synthesize T_4 and T_3, of which iodine is a critical component. The only known physiologic role of iodine is in the synthesis of these hormones, and iodine deficiency results in hypothyroidism. The daily recommended dietary allowance of iodine is 110-130 μg for infants, 90-120 μg for children, and 150 μg for adolescents and adults (see Chapter 605.3).

Ingested iodine reaches the thyroid gland as its ionized form, iodide [I^-]. Thyroid tissue has a unique avidity for iodide and can take up and concentrate it in the follicular lumen to synthesize thyroid hormone. Transport of iodide from the circulation into the thyroid follicular cell is facilitated by the transmembrane sodium–iodide symporter (NIS). Once taken up, iodide diffuses across the cell and is transported across the apical membrane into the colloid by pendrin (and likely another unidentified transporter).

To form thyroid hormone, trapped inorganic iodide is organified onto tyrosine residues of thyroglobulin in the follicular lumen, a reaction catalyzed by thyroperoxidase (TPO). This reaction requires the H_2O_2 produced by the enzyme DUOX2, which is expressed in conjunction with dual oxidase maturation factor 2 (DUOXA2). Thyroglobulin is a large homodimeric glycoprotein that contains 138 tyrosine residues. Iodination of specific tyrosine residues forms monoiodotyrosines (MITs) and diiodotyrosines (DITs), which are further coupled by TPO to produce T_4 or T_3. Once formed, T_4 and T_3 remain stored as part of thyroglobulin in the thyroid colloid until they are secreted through a process of follicular cell endocytosis of colloid followed by endolysosomal degradation of thyroglobulin to release T_4 and T_3.

The thyroid secretes T_4 and T_3 in a ratio of about 12 to 1. Although T_3 circulates at about one-fiftieth the concentration of T_4, T_3 is the physiologically active thyroid hormone because it binds the thyroid hormone receptor with 10- to 15-fold greater affinity than T_4. Only 20% of circulating T_3 is secreted directly by the thyroid, and the remainder is produced by conversion from T_4 in extrathyroidal tissues by iodotyrosine deiodinases (types 1 and 2).

Thyroid hormones increase oxygen consumption, stimulate protein synthesis, influence growth and differentiation, and affect carbohydrate, lipid, and vitamin metabolism. Entry of T_4 and T_3 into cells is facilitated by specific thyroid hormone transporters, of which the most important is monocarboxylate transporter 8 (MCT8). Once inside the cell, T_4 is converted to T_3 by type 1 or 2 deiodinase. Intracellular T_3 enters the nucleus and binds to thyroid hormone receptors. Thyroid hormone receptors are members of the steroid hormone receptor superfamily, and three thyroid hormone receptor isoforms (α_1, β_1, and β_2) are expressed in different tissues. Binding of T_3 to a thyroid hormone receptor causes recruitment of co-activator molecules, transcription of messenger RNA, and protein synthesis. Deiodination, transmembrane transport, and thyroid hormone receptor expression provide multiple levels of tissue-specific modulation of thyroid hormone action in the face of a given level of circulating T_4.

Approximately 70% of circulating T_4 and 50% of T_3 are bound to thyroxine-binding globulin (TBG), and most of the remainder is bound to albumin and prealbumin (also called *transthyretin*). Only 0.03% of serum T_4 and 0.3% of T_3 are unbound (free T_4 and free T_3, respectively). Because the concentration or binding of TBG is altered in many clinical circumstances, its status must be considered when interpreting total T_4 or T_3 levels.

THYROID REGULATION

The thyroid is regulated by TSH, a glycoprotein hormone secreted by the anterior pituitary thyrotrophs. Binding of TSH to its receptor in the thyroid gland activates adenylate cyclase and stimulates all steps of thyroid hormone biosynthesis (see Fig. 594.1). TSH is a heterodimer composed of α and β subunits. The α subunit is common to luteinizing hormone, follicle-stimulating hormone, and chorionic gonadotropin, and the specificity of each hormone is conferred by its unique β subunit. TSH synthesis and release are stimulated by TRH, a tripeptide synthesized in the hypothalamus and secreted into the pituitary. In states of decreased thyroid hormone, TSH and TRH are increased, and increased thyroid hormone inhibits TSH and TRH production. TSH levels can be measured in serum, whereas circulating levels of TRH are not clinically measurable.

Further control of the level of circulating thyroid hormones occurs in the periphery. In many nonthyroidal illnesses, circulating T_3 levels fall because of decreased extrathyroidal production of T_3 by type 1 deiodinase and increased inactivation of T_4 (to reverse T_3) and T_3 (to T_2) by type 3 deiodinase. These changes may be induced by factors such as fasting, chronic malnutrition, acute illness, and certain drugs. Although levels of T_3 may be significantly decreased, levels of free T_4 and TSH may remain normal. The decreased levels of T_3 may be a physiologic adaptation, resulting in decreased rates of oxygen consumption, substrate use, and other catabolic processes.

601.1 Thyroid Hormone Studies

Ari J. Wassner and Jessica R. Smith

SERUM THYROID HORMONES

Methods are available to measure many thyroid hormones in serum, including T_4, free T_4, T_3, and free T_3. The metabolically inert reverse T_3 (rT_3) is present in serum, but measuring rT_3 is rarely useful clinically. Direct assays for free T_4 are widely available and are reliable in healthy patients, but these assays may be less reliable during acute illness or with severe abnormalities of thyroid hormone binding. Therefore in such situations it may be preferable to measure total T_4 as an index of TBG binding or to measure free T_4 by the gold standard technique of equilibrium dialysis. The clinical utility of many free T_3 assays is limited by their poor standardization. Because normal thyroid function changes over time, age-specific reference ranges should be used when interpreting thyroid hormone testing in children, particularly in neonates and infants.

Measuring serum levels of TSH and free T_4 can diagnose most clinical thyroid disorders. Serum TSH is the most sensitive test for primary thyroid dysfunction, and it is elevated in primary hypothyroidism and suppressed in primary thyrotoxicosis. In central (secondary) hypothyroidism, serum TSH is low or inappropriately in the normal range despite low serum T_4 and free T_4 levels. Biotin supplements may cause a false elevation of T_4 and T_3 and a false decrease of TSH.

Thyroglobulin is a glycoprotein secreted through the apical surface of the thyroid follicular cell into the colloid. Thyroglobulin is measurable in the serum, and levels of thyroglobulin increase with TSH stimulation and in proportion to functional thyroid mass. Athyreotic infants have markedly reduced levels of thyroglobulin. In contrast, thyroglobulin levels may be increased in neonates and in patients with Graves disease and other forms of autoimmune thyroid disease, differentiated thyroid carcinoma, or endemic goiter.

FETAL AND NEWBORN THYROID

Fetal serum T_4 and free T_4 increase from midgestation to approximately 9.5 μg/dL and 1.4 ng/dL, respectively, at term. Fetal levels of T_3 are low before 20 weeks and then gradually increase to approximately 60 ng/dL at term. Reverse T_3 levels, however, are high in the fetus (300 ng/dL at 30 weeks) and decrease to 200 ng/dL at term. Serum levels of TSH gradually increase to 6 mIU/L at term. Approximately one third of fetal T_4 at term is derived from the transplacental passage of maternal T_4. Maternal T_4 plays a key role in fetal development, especially that of the brain, beginning before fetal synthesis of thyroid hormone begins. Therefore a fetus with congenital hypothyroidism may be partially protected by maternal T_4 if the mother is euthyroid but may be at risk for neurodevelopmental injury if the mother is hypothyroid.

Immediately after birth there is an acute release of TSH, with peak serum concentrations reaching 70-100 mIU/L 30 minutes after delivery in full-term infants. TSH declines rapidly over the ensuing 24 hours and more gradually over the next 5 days to <10 mIU/L. After the first 1-3 months of life, normal levels of TSH are <5 mIU/L. The postnatal surge in TSH stimulates an increase in levels of T_4 to approximately 16 μg/dL and of T_3 to approximately 300 ng/dL in about 4 hours. T_4 levels gradually decrease during the first 2 weeks of life to 10-12 μg/dL. T_3 levels decline during the first week of life to below 200 ng/dL. Reverse T_3 levels remain high for 2 weeks (200 ng/dL) and decrease by 4 weeks to around 50 ng/dL. In preterm infants, changes in thyroid function after birth are qualitatively similar to but quantitatively smaller than in full-term infants. Serum T_4 and T_3 levels are decreased in proportion to gestational age and birthweight.

SERUM THYROXINE-BINDING GLOBULIN

The thyroid hormones are transported in plasma bound primarily to TBG, a glycoprotein synthesized in the liver. TBG binds approximately 70% of T_4 and 50% of T_3. Estimating TBG binding is occasionally necessary because changes caused by various clinical conditions can affect measured levels of total (but not free) T_4 and T_3. TBG levels increase in pregnancy; in the newborn period; with hepatitis; and with the administration of estrogens (oral contraceptives), selective estrogen receptor modulators, heroin or methadone, mitotane, and 5-fluorouracil. TBG levels decrease with androgens, anabolic steroids, glucocorticoids, nicotinic acid, and L-asparaginase. These effects are the result of altered hepatic synthesis of TBG. Severe TBG deficiency may be caused by genetic variants, decreased production with hepatocellular disease, or massive protein loss in the gut (protein-losing enteropathies) or the urine (congenital nephrotic syndrome) (see Chapter 602). Some medications, including furosemide, salicylates, nonsteroidal antiinflammatory drugs, heparin, and free fatty acids, can elevate levels of free T_4 by inhibiting binding to TBG.

THYROID ULTRASONOGRAPHY

The primary clinical uses of thyroid ultrasound are to assess thyroid morphology and to evaluate the characteristics of thyroid nodules. In infants with congenital hypothyroidism, evaluation of the size and location of the thyroid may clarify the diagnosis of thyroid dysgenesis; however, the sensitivity of ultrasound is user-dependent, and it will not reliably detect ectopic thyroid glands. Ultrasound is more accurate than physical examination for estimating thyroid gland size and assessing thyroid nodules. Certain characteristics of thyroid nodules, such as irregular margins, microcalcifications, hypoechogenicity, and taller-than-wide shape, increase the likelihood that a thyroid nodule is malignant and guide decisions about the need for fine-needle aspiration. In children with autoimmune thyroiditis or Graves disease, ultrasound may reveal heterogeneous echotexture or changes in vascularity. However, ultrasound generally is not clinically useful in these conditions unless a thyroid nodule is suspected. Ultrasound may also be useful to evaluate thyroglossal duct cysts.

RADIONUCLIDE STUDIES

The availability of highly sensitive tests of thyroid function has decreased the necessity for radioiodine uptake studies except in specific clinical situations. The ability of the thyroid to take up and organify iodine can be evaluated by measuring the uptake of radioactive isotope ^{123}I (half-life: 13 hours). Technetium (^{99m}Tc) is also a useful radioisotope for children because it is trapped but not organified by the thyroid and has a half-life of only 6 hours. Thyroid scintigraphy can demonstrate the anatomic distribution of tracer uptake by thyroid tissue and may be indicated to assess for possible thyroid dysgenesis or ectopic thyroid tissue or to evaluate possible autonomous (hot) thyroid nodules. ^{131}I may be used to treat hyperthyroidism or thyroid cancer, but its use generally should be avoided for thyroid uptake and scintigraphy because of its cytotoxic effect.

Chapter 602

Disorders of Thyroxine-Binding Globulin

Ari J. Wassner and Jessica R. Smith

Approximately 70% of circulating thyroxine (T_4) and 50% of triiodothyronine (T_3) are bound to thyroxine-binding globulin (TBG), and most of the remainder is bound to albumin and prealbumin (also called *transthyretin*). Only the unbound (free) fractions of these hormones, comprising 0.03% of serum T_4 and 0.3% of T_3, can exert biologic activity. Because regulation of the hypothalamic-pituitary-thyroid axis is mediated by the concentrations of free thyroid hormones, abnormalities of thyroid hormone binding tend to alter concentrations of total, but not free, thyroid hormones. *Therefore abnormalities in levels of TBG are not associated with clinical disease and do not require treatment.* They are usually discovered as an incidental finding of abnormally low or high levels of T_4 and may be a source of confusion in the diagnosis of hypothyroidism or hyperthyroidism.

Congenital TBG deficiency is an X-linked recessive trait that occurs in 1 in 1,700 male newborns. It is most often discovered through screening programs for neonatal hypothyroidism that measure levels of T_4 as the primary screening test. Affected males have low levels of total T_4 (usually <4 μg/dL) and elevated T_3 resin uptake, but levels of free T_4 and thyrotropin (TSH) are normal. The diagnosis is confirmed by the measurement of absent or low serum levels of TBG, although rare cases may have normal concentrations of TBG with reduced affinity for T_4. No treatment is required, but testing may be indicated in potentially affected family members to avoid the incorrect diagnosis of hypothyroidism in the future. More than 40 different pathogenic variants have been reported in the TBG gene. **Acquired** causes of TBG deficiency are listed in Table 602.1.

TBG excess is a benign X-linked dominant variant that occurs in approximately 1 in 25,000 individuals. It has been recognized primarily in adults, but newborn screening programs may uncover the condition in the neonate. The level of T_4 is elevated, T_3 is variably elevated, TSH and free T_4 are normal, and T_3 resin uptake is decreased. Elevated serum levels of TBG confirm the diagnosis. Affected neonates have been found to have levels of T_4 as high as 95 μg/dL, which decrease to 20-30 μg/dL after 2-3 weeks. Affected patients are euthyroid, but family studies may be indicated to alert other affected family members. Acquired causes of TBG excess are listed in Table 602.1.

Familial dysalbuminemic hyperthyroxinemia is an autosomal dominant variant caused by an abnormal albumin with a markedly increased affinity for T_4. This leads to increased serum concentrations of T_4 (and in some cases T_3) that can be mistaken for thyrotoxicosis. However, levels of free T_4, free T_3, and TSH are normal, and affected patients are euthyroid.

Nephrotic syndrome	Heroin, methadone
Protein-losing enteropathy	Mitotane
Nicotinic acid	5-Fluorouracil
L-Asparaginase	Perphenazine

Chapter 603

Hypothyroidism

Ari J. Wassner and Jessica R. Smith

Hypothyroidism is a state of insufficient thyroid hormone action at the tissue level. Hypothyroidism most often results from deficient production of thyroid hormone caused either by a defect in the thyroid gland itself (primary hypothyroidism) or by reduced thyrotropin (TSH) stimulation (central or secondary hypothyroidism; Table 603.1). Hypothyroidism may be present from birth (congenital) or may be acquired, although some acquired cases are due to congenital defects in which the onset of hypothyroidism is delayed.

CONGENITAL HYPOTHYROIDISM

Most cases of congenital hypothyroidism are caused by abnormal formation of the thyroid gland **(thyroid dysgenesis)**, and ~30% of cases are due to inborn errors of thyroid hormone synthesis **(dyshormonogenesis)** or other causes. Most infants with congenital hypothyroidism are detected by newborn screening programs in the first week after birth, before significant clinical signs or symptoms develop. In regions without newborn screening, severely affected infants usually manifest features within the first week of life, but in infants with milder hypothyroidism, the clinical manifestations may not be evident for weeks or months.

Epidemiology

The incidence of congenital hypothyroidism was initially reported to be 1 in 4,000 infants based on the earliest established neonatal screening programs. The incidence of diagnosis has increased to about 1 in 2,000, primarily because more stringent screening algorithms have resulted in the detection of milder cases of hypothyroidism, mostly in patients with a eutopic thyroid gland.

Etiology

See Table 603.1.

Primary Hypothyroidism

Thyroid Dysgenesis. Thyroid dysgenesis is the most common cause of permanent congenital hypothyroidism, accounting for 80–85% of cases. In approximately one third of cases of dysgenesis, no thyroid tissue is present **(agenesis)**. In the other two thirds of infants, rudiments of thyroid tissue are present, either in the normal position **(hypoplasia)** or in an **ectopic** location along the embryologic path of descent of the thyroid from the base of the tongue (lingual thyroid) to the normal position. Thyroid dysgenesis occurs twice as common in females as in males.

The cause of thyroid dysgenesis is largely unknown. The condition is usually sporadic, but familial cases have been reported rarely. Thyroid developmental anomalies, such as thyroglossal duct cysts and thyroid hemiagenesis, are present in 8–10% of first-degree relatives of infants with thyroid dysgenesis. However, most thyroid dysgenesis is unlikely to be genetic given the high degree of discordance among monozygotic twins.

A small minority (2–5%) of thyroid dysgenesis is caused by genetic defects in one of several transcription factors essential for thyroid morphogenesis and differentiation, including NKX2.1 (formerly TTF1), FOXE1 (formerly TTF2), and PAX8. NKX2.1 is expressed in the thyroid, lung, and central nervous system, and recessive pathogenic variants in *NKX2-1* cause thyroid dysgenesis, respiratory distress, and neurologic problems (chorea and ataxia) **(brain-lung-thyroid syndrome)**. Recessive pathogenic variants in *FOXE1* cause thyroid dysgenesis, spiky or curly hair, cleft palate, and sometimes choanal atresia and bifid epiglottis **(Bamforth-Lazarus syndrome)**. PAX8 is expressed in the thyroid and kidney, and dominant *PAX8* variants are associated with thyroid dysgenesis and kidney and ureteral malformations.

Chapter 603

Hypothyroidism

Ari J. Wassner and Jessica R. Smith

Hypothyroidism is a state of insufficient thyroid hormone action at the tissue level. Hypothyroidism most often results from deficient production of thyroid hormone caused either by a defect in the thyroid gland itself (primary hypothyroidism) or by reduced thyrotropin (TSH) stimulation (central or secondary hypothyroidism; Table 603.1). Hypothyroidism may be present from birth (congenital) or may be acquired, although some acquired cases are due to congenital defects in which the onset of hypothyroidism is delayed.

CONGENITAL HYPOTHYROIDISM

Most cases of congenital hypothyroidism are caused by abnormal formation of the thyroid gland **(thyroid dysgenesis)**, and ~30% of cases are due to inborn errors of thyroid hormone synthesis **(dyshormonogenesis)** or other causes. Most infants with congenital hypothyroidism are detected by newborn screening programs in the first week after birth, before significant clinical signs or symptoms develop. In regions without newborn screening, severely affected infants usually manifest features within the first week of life, but in infants with milder hypothyroidism, the clinical manifestations may not be evident for weeks or months.

Epidemiology

The incidence of congenital hypothyroidism was initially reported to be 1 in 4,000 infants based on the earliest established neonatal screening programs. The incidence of diagnosis has increased to about 1 in 2,000, primarily because more stringent screening algorithms have resulted in the detection of milder cases of hypothyroidism, mostly in patients with a eutopic thyroid gland.

Etiology

See Table 603.1.

Primary Hypothyroidism

Thyroid Dysgenesis. Thyroid dysgenesis is the most common cause of permanent congenital hypothyroidism, accounting for 80–85% of cases. In approximately one third of cases of dysgenesis, no thyroid tissue is present **(agenesis)**. In the other two thirds of infants, rudiments of thyroid tissue are present, either in the normal position **(hypoplasia)** or in an **ectopic** location along the embryologic path of descent of the thyroid from the base of the tongue (lingual thyroid) to the normal position. Thyroid dysgenesis occurs twice as common in females as in males.

The cause of thyroid dysgenesis is largely unknown. The condition is usually sporadic, but familial cases have been reported rarely. Thyroid developmental anomalies, such as thyroglossal duct cysts and thyroid hemiagenesis, are present in 8–10% of first-degree relatives of infants with thyroid dysgenesis. However, most thyroid dysgenesis is unlikely to be genetic given the high degree of discordance among monozygotic twins.

A small minority (2–5%) of thyroid dysgenesis is caused by genetic defects in one of several transcription factors essential for thyroid morphogenesis and differentiation, including NKX2.1 (formerly TTF1), FOXE1 (formerly TTF2), and PAX8. NKX2.1 is expressed in the thyroid, lung, and central nervous system, and recessive pathogenic variants in *NKX2-1* cause thyroid dysgenesis, respiratory distress, and neurologic problems (chorea and ataxia) **(brain-lung-thyroid syndrome)**. Recessive pathogenic variants in *FOXE1* cause thyroid dysgenesis, spiky or curly hair, cleft palate, and sometimes choanal atresia and bifid epiglottis **(Bamforth-Lazarus syndrome)**. PAX8 is expressed in the thyroid and kidney, and dominant *PAX8* variants are associated with thyroid dysgenesis and kidney and ureteral malformations.

Table 603.1 Etiologic Classification of Congenital Hypothyroidism

PRIMARY HYPOTHYROIDISM

Defect of thyroid development (dysgenesis)
- Agenesis
- Hypoplasia
- Ectopia

Defects in thyrotropin (TSH) responsiveness
- TSH receptor–blocking antibodies
- Pathogenic variants in TSH receptor *(TSHR)*
- Defects in Gsα *(GNAS)*—pseudohypoparathyroidism

Defect in thyroid hormone synthesis (dyshormonogenesis)
- Defective iodide uptake into follicular cell: sodium–iodide symporter *(NIS)*
- Defective iodide transport from follicular cell into colloid: Pendred syndrome *(SLC26A4)*
- Iodide organification defects: thyroperoxidase *(TPO)*, dual oxidase 2 (*DUOX2*), dual oxidase maturation factor 2 *(DUOXA2)*
- Thyroglobulin synthesis defect: thyroglobulin (TG)
- Deiodination defect: iodotyrosine deiodinase (IYD)
- Thyroid hormone transport defect: monocarboxylate transporter 8 *(SLC16A2)*—X-linked

Iodine deficiency (endemic goiter)

Iodine excess

Maternal medications
- Iodides, amiodarone
- Methimazole, propylthiouracil
- Radioactive iodine (^{131}I)

CENTRAL (SECONDARY) HYPOTHYROIDISM

Isolated TSH deficiency
- Pathogenic variant in TSH β-subunit (TSHβ)—depending on variant measured TSH level may be low, normal, or elevated
- Pathogenic variant in TRH receptor *(TRHR)*
- Pathogenic variant in *IGSF1*—X-linked central hypothyroidism and macroorchidism (prolactin deficiency and variable GH deficiency)
- Pathogenic variant in other genes: *TBL1X, IRS4*

Multiple pituitary hormone deficiencies
- Pathogenic variant in *POU1F1*—deficiency of TSH, GH, and prolactin
- Pathogenic variant in *PROP1*—deficiency of TSH, GH, LH, FSH, prolactin, and variably ACTH
- Pathogenic variant in *HESX1*—variable deficiencies of TSH, GH, LH, FSH, prolactin, and ACTH
- Pathogenic variants in other genes: *OTX2, LHX3, LHX4, SOX3, FGF8, FGFR1, GLI2, LEPR*

ACTH, Adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; TRH, thyrotropin-releasing hormone.

Inactivating variants in the TSH receptor *(TSHR)* have been described in patients with congenital hypothyroidism, including thyroid dysgenesis or hypoplasia. *TSHR* variants may be homozygous or heterozygous with or without a concurrent change in another congenital hypothyroidism gene (such as *DUOX2* or *TG*). Infants with a severe TSHR defect have elevated TSH levels and are detected by newborn screening, whereas patients with a mild defect may remain euthyroid without treatment.

Congenital hypothyroidism can occur in infants with **pseudohypoparathyroidism** type 1a. These patients have somatic inactivating variants of the G-protein stimulatory α-subunit $G_s\alpha$ (GNAS), leading to impaired signaling of the TSH receptor (see Chapter 612).

Defects in Thyroid Hormone Synthesis (Dyshormonogenesis). A variety of defects in thyroid hormone biosynthesis account for 15% of cases of permanent congenital hypothyroidism detected by neonatal screening programs (1 in 30,000-50,000 live births). Because increased TSH stimulation has a trophic effect on thyroid follicular cells, a **goiter** is often present. When the synthetic defect is incomplete, the onset of hypothyroidism may be delayed for months or years.

Defective Iodide Transport. Rare defects in iodide uptake are caused by pathogenic variants in the sodium-iodide symporter (NIS) responsible for concentrating iodide in the thyroid gland. In contrast to other defects of thyroid hormone synthesis, uptake of radioiodine and pertechnetate is low, as in cases of thyroid dysgenesis. However, impaired iodide transport may be suggested by the absence of normal salivary gland iodine uptake on scintigraphy. A reduced saliva:serum ratio of ^{123}I supports the diagnosis, which can be confirmed by genetic testing of *NIS*. This condition may respond to large doses of potassium iodide, but treatment with levothyroxine is more reliable and preferable.

Pendred syndrome is a clinical syndrome consisting of sensorineural deafness and goiter. This syndrome is caused by a pathogenic variant in the chloride-iodide transport protein pendrin *(SLC26A4)* expressed in the thyroid gland and the cochlea. Pendrin allows the transport of iodide across the apical membrane of the thyroid follicular cell into the colloid, where it undergoes organification and incorporation into the tyrosine residues on thyroglobulin. Patients with a variant in *SLC26A4* have impaired iodide organification and a positive perchlorate discharge test. Pathogenic variants in pendrin are a relatively common genetic cause of sensorineural deafness, but some patients diagnosed based on their hearing disorder have no goiter or thyroid dysfunction. This finding has fueled speculation that pendrin is not the sole apical iodine transporter in the thyroid, but no other specific transporter has been confirmed to date.

Defects of Iodine Organification. Defects of iodine organification are the most common type of thyroid hormone synthetic defect. After the thyroid takes up iodide, it is rapidly oxidized and incorporated into tyrosine residues on thyroglobulin. These reactions are catalyzed by the key enzyme thyroperoxidase (TPO) and require H_2O_2 generated locally by the dual oxidase 2 system (DUOX2 and DUOXA2). Defects can occur in any of these components of organification, and there is considerable clinical and biochemical heterogeneity. In the Dutch neonatal screening program, a complete organification defect was present in 1 in 60,000 live births, but the prevalence in other areas is unknown. A characteristic finding of organification defects is a marked discharge of thyroid radioactivity when perchlorate or thiocyanate is administered 2 hours after a test dose of radioiodine (perchlorate discharge of 40–90% of radioiodine compared with <10% in normal individuals). Numerous pathogenic variants in *TPO* have been reported in children with congenital hypothyroidism.

Pathogenic variants in *DUOX2* can cause permanent or transient congenital hypothyroidism. Previously, it was thought that monoallelic *DUOX2* variants cause transient disease and biallelic variants cause permanent disease, but the reverse has been observed in some cases, and this relationship remains variable and unclear. *DUOX2* variants have been reported in 15–40% of patients with apparent dyshormonogenesis, with pathogenic variant rates as high as 50–60% in studies from China and South Korea. Dual oxidase maturation factor 2 (DUOXA2) is required to express DUOX2 enzymatic activity, and recessive variants in *DUOXA2* are a rare cause of congenital hypothyroidism.

Defects of Thyroglobulin Synthesis. Defects of thyroglobulin synthesis are characterized by congenital hypothyroidism with goiter and absent or low levels of circulating thyroglobulin. More than 40 different pathogenic variants in the thyroglobulin gene *(TG)* have been described.

Defects in Deiodination. Monoiodotyrosine and diiodotyrosine normally are released from thyroglobulin along with thyroxine (T_4) and triiodothyronine (T_3). The *IYD* gene (formerly *DEHAL1*) encodes the thyroidal enzyme iodotyrosine deiodinase, which deiodinates these intermediates so that the liberated iodide is recycled into thyroid hormone synthesis. In patients with rare variants in *IYD,* urinary excretion of monoiodotyrosine and diiodotyrosine rapidly causes severe iodine deficiency, leading to hypothyroidism and goiter that may present soon after birth or may be delayed.

Defects in Thyroid Hormone Transport. Passage of thyroid hormone into cells is facilitated by specific plasma membrane transporters. Pathogenic variants in the transporter MCT8 *(SLC16A2),* located on the X chromosome, impair the movement of T_4 and T_3 into cells. This leads to severe neurologic manifestations, including profound developmental delay, reduced muscle mass, dysarthria,

athetoid movements, and hypotonia that evolves to spastic paraplegia **(Allan-Herndon-Dudley syndrome)**. This syndrome is also characterized by low serum T_4 levels, normal or mildly elevated serum TSH levels, and elevated serum T_3 levels. Treatment with thyroid hormone analogs that do not require MCT8 for transmembrane transport can improve hypermetabolism in this disorder but has little effect on the neurologic phenotype.

Thyrotropin Receptor–Blocking Antibodies. Maternal TSHR–blocking antibodies (TRBAbs) cause about 2% of cases of congenital hypothyroidism detected by neonatal screening programs (1 in 50,000-100,000 infants). Transplacentally acquired maternal TRBAbs inhibit the binding of TSH to its receptor in the neonate. This condition should be suspected whenever there is a history of maternal autoimmune thyroid disease, including autoimmune thyroiditis or Graves disease, maternal hypothyroidism, or transient congenital hypothyroidism in previous siblings. However, TRBAbs can occur in the absence of any maternal history. When suspected, levels of TRBAb (measured as thyrotropin-binding inhibitory immunoglobulin [TBII]) should be measured in the mother during pregnancy or after birth in the neonate. Affected infants and their mothers also can have TSHR-stimulating antibodies and TPO antibodies. Ultrasonography typically demonstrates a normally positioned but small thyroid gland; however, thyroid tissue often will not be detected by scintigraphy because the blockade of TSHR function suppresses thyroidal iodine uptake. Serum thyroglobulin levels are low for the same reason. Treatment with levothyroxine is required initially, but remission of hypothyroidism occurs in approximately 3-6 months once the TRBAbs are cleared from the infant's circulation. Correct diagnosis of this cause of congenital hypothyroidism prevents unnecessarily protracted treatment and alerts the clinician to possible recurrences in future pregnancies. The prognosis is generally favorable, but developmental delay may occur in patients whose mothers had unsuspected (and untreated) hypothyroidism caused by TRBAbs during pregnancy.

Radioiodine Administration. Neonatal hypothyroidism can occur when radioiodine is administered to a mother during (a usually unrecognized) pregnancy as treatment for Graves disease or thyroid cancer. The fetal thyroid is capable of trapping iodide by 70-75 days of gestation. Therefore a pregnancy test must be performed in any individual capable of pregnancy before ^{131}I is given, regardless of menstrual history or reported history of contraception. Administration of radioactive iodine to lactating individuals is also contraindicated because it is excreted in breast milk.

Iodine Exposure. Congenital hypothyroidism can result from fetal exposure to excessive iodine. Perinatal exposure can occur from iodine-based antiseptic used to prepare the skin for cesarean section or to paint the cervix before delivery. In the neonate, especially in those of low birthweight (LBW), topical iodine-containing antiseptics used in nurseries or perioperatively can cause transient hypothyroidism, which newborn screening tests may detect. In older children, excess iodine may be present in proprietary preparations used to treat asthma or in amiodarone, an antiarrhythmic drug with high iodine content. In most of these instances, a goiter is present (see Chapter 605). Hypothyroidism has also been reported in breastfed infants born to mothers who consume large amounts of iodine daily (up to 12 mg) in nutritional supplements or large quantities of iodine-rich seaweed. Iodine-induced hypothyroidism is transient once the exposure is discontinued and therefore is important to distinguish from other forms of congenital hypothyroidism.

Iodine Deficiency (Endemic Goiter). See Chapter 605.3.

Iodine deficiency or endemic goiter is the most common cause of congenital hypothyroidism worldwide. The recommended iodine intake in adults is 150 μg daily, increasing to 220 μg daily during pregnancy to allow for fetal iodine requirements. Despite efforts at universal salt iodization, in many countries economic, political, and practical obstacles continue to prevent the realization of this goal. Although the U.S. population is generally iodine sufficient, approximately 15% of women of reproductive age are iodine deficient. Borderline iodine deficiency is more likely to cause problems in preterm infants, who depend on a maternal source of iodine for normal thyroid hormone production and often receive insufficient dietary iodine from standard preterm infant formulas or parenteral nutrition that is low in iodine.

Central (Secondary) Hypothyroidism

Thyrotropin (TSH) Deficiency. Central hypothyroidism caused by TSH deficiency can occur in any condition associated with developmental defects of the pituitary or hypothalamus (see Chapter 595). Central hypothyroidism occurs in 1 in 16,000-30,000 infants. However, neonatal screening does not detect many cases, mainly because many screening programs are designed to detect only primary hypothyroidism by measuring neonatal TSH. The majority (75%) of infants with central hypothyroidism have additional pituitary hormone deficiencies and may present with hypoglycemia, persistent jaundice, micropenis or cryptorchidism (in males), and midline defects such as midline cleft lip or palate or midface hypoplasia.

Congenital TSH deficiency may be caused by pathogenic variants in genes encoding transcription factors essential to pituitary development or thyrotroph cell differentiation. *POU1F1* variants cause deficiency of TSH, growth hormone, and prolactin. Patients with *PROP1* variants also have deficiency of TSH, growth hormone, prolactin, luteinizing hormone, follicle-stimulating hormone, and variable deficiency of adrenocorticotropic hormone. *HESX1* pathogenic variants are associated with TSH, growth hormone, prolactin, and adrenocorticotropic hormone deficiencies and are found in some patients with optic nerve hypoplasia (septo-optic dysplasia syndrome; see Chapter 631). Variants in multiple other genes involved in pituitary development can cause central hypothyroidism (Table 603.1).

Isolated congenital deficiency of TSH is rare. The most common genetic cause is a pathogenic variant in *IGSF1,* which results in an X-linked syndrome of congenital central hypothyroidism and macroorchidism. The mechanism remains unclear, but IGSF1 deficiency may impair TRH receptor signaling in pituitary thyrotrophs. Prolactin deficiency is usually present, and some patients also have growth hormone deficiency. Central hypothyroidism occurs in about 10% of female carriers of IGSF1 deficiency. Patients with pathogenic variants in the gene encoding the TSH β-subunit *(TSHB)* have central hypothyroidism with very low TSH levels, although in some cases, TSH levels are normal or even elevated. In other cases, levels of the TSH α-subunit are elevated. Variants in *TRHR,* which encodes the TRH receptor, are a rare cause of congenital central hypothyroidism. In this condition, both TSH and prolactin fail to respond to TRH stimulation.

Thyroid Function in Preterm and Low Birthweight Infants

Postnatal thyroid function in preterm and LBW infants is qualitatively similar but quantitatively reduced compared with term infants. The cord blood T_4 concentration is decreased in proportion to gestational age and birthweight. The postnatal TSH surge is reduced, and very premature or very LBW infants experience a decrease in serum T_4 in the first week of life, in contrast to term infants in whom T_4 increases during this time. Serum T_4 gradually increases to the range observed in term infants by about 6 weeks of life. However, serum free T_4 concentrations are less affected than total T_4, and free T_4 levels may be normal when measured by the gold standard technique of equilibrium dialysis. Preterm and LBW infants also have a higher incidence of delayed TSH elevation and apparent transient primary hypothyroidism. Mechanisms underlying these changes in thyroid function in preterm and LBW infants may include immaturity of the hypothalamic-pituitary-thyroid axis, loss of the maternal contribution of thyroid hormone normally present in the third trimester, severe illness and complications of prematurity, and exposure to medications that can affect thyroid function (e.g., dopamine and glucocorticoids).

Clinical Manifestations

Before neonatal screening programs, congenital hypothyroidism was rarely recognized in the newborn because most affected infants are asymptomatic at birth, even if there is complete agenesis of the thyroid gland. This is because of transplacental passage of maternal T_4, which provides fetal levels that are approximately one-third normal at

birth. Because symptoms are usually not present at birth, the clinician depends on neonatal screening tests to diagnose congenital hypothyroidism. However, some infants escape newborn screening, and laboratory errors occur, so pediatricians must be alert for symptoms and signs of hypothyroidism if they develop. Birth weight and length are normal, but head size may be slightly increased because of myxedema of the brain. The anterior and posterior fontanels are open widely, and the presence of this sign at birth may be a clue to early recognition of congenital hypothyroidism (only 3% of normal newborns have a posterior fontanel wider than 0.5 cm). Prolonged jaundice (indirect hyperbilirubinemia) may be present because of delayed maturation of hepatic glucuronide conjugation. Affected infants cry little, sleep much, have poor appetites, and are generally sluggish. Feeding difficulties, especially sluggishness, lack of interest, somnolence, and choking spells during nursing, may be present during the first month of life. Respiratory difficulties, partly caused by macroglossia, include apneic episodes, noisy respirations, and nasal obstruction. There may be constipation that does not respond to treatment. The abdomen is large, and an umbilical hernia is often present. The temperature may be subnormal (often <35°C/95°F), and the skin may be cold and mottled, particularly on the extremities. Edema of the genitals and extremities may be present. The pulse is slow, and heart murmurs, cardiomegaly, and asymptomatic pericardial effusion are common. Macrocytic anemia is often present. Because symptoms appear gradually and may be nonspecific, the clinical diagnosis of neonatal hypothyroidism is often delayed.

Approximately 10% of infants with congenital hypothyroidism have associated congenital anomalies. Cardiac anomalies are most common, but anomalies of the nervous system and eye have also been reported. Infants with congenital hypothyroidism may have associated hearing loss. Pathogenic variants in specific genes involved in thyroid gland development result in congenital hypothyroidism with other syndromic features (Table 603.2).

If congenital hypothyroidism goes undetected and untreated, the clinical manifestations progress. Delay of physical and mental development becomes more severe over time, and by 3-6 months of age, the clinical picture is fully developed (Fig. 603.1). When deficiency of thyroid hormone is only partial, the symptoms may be milder and their onset delayed. Although breast milk contains significant amounts of thyroid hormones, particularly T_3, this is inadequate to protect the breastfed infant from the effects of congenital hypothyroidism.

In the patient with untreated congenital hypothyroidism, growth is stunted, extremities are short, and head size is normal or increased. The anterior fontanel is large, and the posterior fontanel may remain open. The eyes appear far apart, and the bridge of the broad nose is depressed. The palpebral fissures are narrow, and the eyelids are swollen. The mouth is kept open, and the thick, broad tongue protrudes. Dentition is delayed. The neck is short and thick, and there may be fat deposits above the clavicles and between the neck and shoulders. The hands are broad, and the fingers are short. The skin is dry and scaly, and there is little perspiration. Myxedema occurs mainly in the skin of the eyelids, the back of the hands, and the external genitalia. The skin shows general pallor with a sallow complexion. Carotenemia can cause a yellow discoloration of the skin, but the sclerae remain white. The scalp is thickened, and the hair is coarse, brittle, and scanty. The hairline reaches far down on the forehead, which usually appears wrinkled, especially when the infant cries.

Development is usually delayed. Hypothyroid infants appear lethargic and are late in acquiring gross and fine motor skills. The voice is hoarse, and they do not learn to talk. The degree of physical and intellectual delay increases with age. Sexual maturation may be delayed or even absent. The muscles are usually hypotonic, but in rare instances, generalized muscular pseudohypertrophy occurs **(Kocher-Debré-Sémélaigne syndrome)**. Affected older children can have an athletic appearance because of pseudohypertrophy, particularly in the calf muscles. Its pathogenesis is unknown; nonspecific histochemical and ultrastructural changes seen on muscle biopsy return to normal with treatment.

Some infants with mild congenital hypothyroidism have normal thyroid function at birth and are not identified by newborn screening programs. In particular, some children with ectopic thyroid tissue produce adequate amounts of thyroid hormone for some time (even years) until the abnormal thyroid tissue fails. Affected children come to clinical attention because of a growing mass at the base of the tongue or in the midline of the neck, often at the level of the hyoid. Occasionally, thyroid ectopy is associated with **thyroglossal duct cysts**. Surgical removal of ectopic thyroid tissue from a euthyroid patient usually results in hypothyroidism because most such patients have no other thyroid tissue.

Laboratory Findings

In countries where newborn screening is performed, this is the most important method for identifying infants with congenital hypothyroidism. Blood obtained by heelprick between 1 and 5 days of life is placed on a filter paper card and sent to a central screening laboratory. Most

Table 603.2 Genes and Thyroid Development

GENE	THYROID PHENOTYPE	OTHER FEATURES
FOXE1	Athyreosis	Cleft palate, choanal atresia, kinky hair, bifid epiglottis
NKX2-1	Athyreosis to normal gland	Respiratory distress syndrome, developmental delays/hypotonia, ataxia/choreoathetosis
PAX8	Athyreosis to normal gland	Cysts within thyroid remnants, kidney and urinary tract malformations
GLIS3	Athyreosis to normal gland	Congenital glaucoma; deafness; liver/kidney and pancreatic abnormalities
TSHR	Athyreosis to normal gland	None
NKX2-5	Athyreosis, ectopy	Cardiac defects

From Kim G, Nandi-Munshi D, Diblasi CC. Disorders of the thyroid gland. In: Gleason CA, Juul SE, eds. *Avery's Diseases of the Newborn*, 10th ed. Philadelphia: Elsevier; 2018, Table 98.3, p. 1396.

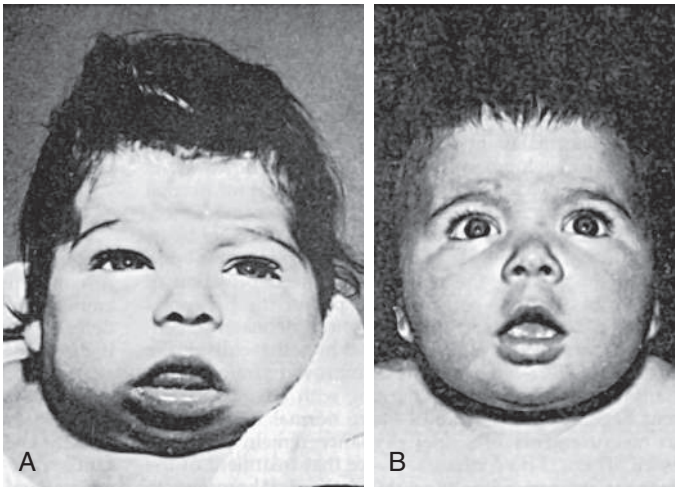

Fig. 603.1 Congenital hypothyroidism in an infant 6 mo of age. The infant ate poorly in the neonatal period and was constipated. She had persistent nasal discharge and a large tongue, was very lethargic, and had no social smile and no head control. **A,** Notice the puffy face, dull expression, and hirsute forehead. Tests revealed a negligible uptake of radioiodine. Osseous development was that of a newborn. **B,** Four months after treatment, note decreased face puffiness, decreased hirsutism of the forehead, and the alert appearance.

screening programs measure the level of TSH, which detects infants with primary hypothyroidism, including some with milder disease in whom TSH is elevated but T_4 is normal. However, this approach may not detect rarer disorders such as central hypothyroidism or primary congenital hypothyroidism with delayed TSH elevation. Some screening programs begin by measuring levels of T_4, followed by reflex measurement of TSH when the T_4 is low. This approach identifies infants with primary hypothyroidism, some with central hypothyroidism or delayed TSH elevation, and infants with thyroxine-binding globulin deficiency (a benign variant). All newborn screening results should be interpreted based on age-specific reference ranges, particularly in the first week of life (Table 603.3). Regardless of the approach used for screening, some infants escape detection because of technical or human errors, and clinicians must remain vigilant for clinical manifestations of hypothyroidism.

Several groups of patients deserve vigilance for congenital hypothyroidism. Infants with trisomy 21 or cardiac defects have an increased risk of congenital hypothyroidism. Monozygotic twins are usually *discordant* for congenital hypothyroidism. However, if twins are monochorionic, fetal hypothyroidism in the affected twin may be compensated by the normal twin through their shared fetal circulation. In such cases, the affected twin may go undetected on newborn screening in the first days of life and present later with untreated hypothyroidism. Preterm and LBW neonates have an increased incidence of congenital hypothyroidism and are more likely to have delayed TSH elevation that may be missed on initial screening. Therefore in all of these groups of infants, many newborn screening programs perform a routine second test 2-4 weeks after birth.

Patients with congenital hypothyroidism have low serum levels of T_4 and free T_4. Serum levels of T_3 are often normal and are not helpful for diagnosis. If primary hypothyroidism is present, levels of TSH are elevated, often to >100 mU/L in severe cases. Serum levels of thyroglobulin are usually low in infants with thyroid agenesis, defects of the TSH receptor (including *TSHR* pathogenic variants and TRBAb), or defects in the synthesis or secretion of thyroglobulin itself. In contrast, thyroglobulin levels are usually elevated in patients with thyroid ectopy and other defects of thyroid hormone synthesis, but there is a wide overlap of ranges.

Delay of osseous development can be shown radiographically at birth in approximately 60% of congenitally hypothyroid infants and indicates some deficiency of thyroid hormone during intrauterine life. The distal femoral and proximal tibial epiphyses, normally present at birth, are often absent (Fig. 603.2A). In untreated patients, the discrepancy between chronologic age and osseous development increases over time. The epiphyses often have multiple foci of ossification (epiphyseal dysgenesis; see Fig. 603.2B). Deformity (beaking) of the 12th thoracic or 1st or 2nd lumbar vertebra is common. X-rays of the skull show large fontanels and wide sutures, and intersutural (wormian) bones are common. The sella turcica may be enlarged and round, and in rare instances, there may be bony erosion and thinning. Formation and eruption of teeth can be delayed. Cardiac enlargement or pericardial effusion may be present.

Scintigraphy can help define the underlying cause in infants with congenital hypothyroidism, but treatment should not be delayed to obtain such imaging. ^{123}I–sodium iodide is superior to ^{99m}Tc–sodium pertechnetate for this purpose. Scintigraphy will demonstrate an ectopic thyroid gland, but the absence of uptake in disorders of the TSH receptor (including TRBAb) or NIS may be mistaken for thyroid agenesis. Ultrasound of the thyroid can document the presence or absence of an anatomically normal gland, but it can miss some ectopic glands that are detectable by scintigraphy. Demonstration of ectopic thyroid tissue or the absence of thyroid tissue in its normal location is diagnostic of thyroid dysgenesis and establishes the need for lifelong treatment. A normally located thyroid gland with normal or increased uptake indicates a defect in thyroid hormone synthesis. Although extensive evaluation can be performed to elucidate the precise nature of the synthetic defect, this rarely affects clinical management and is unnecessary in most cases. Similarly, genetic testing may reveal potentially relevant variants in 60% or more of patients with defects of thyroid hormone synthesis. However, such testing may be costly, is not always conclusive, and usually does not alter management.

Treatment

Levothyroxine (L-T_4) given orally is the treatment for congenital hypothyroidism. Although T_3 is the biologically active form of thyroid hormone, 80% of circulating T_3 is derived from deiodination of circulating T_4, and therefore treatment with L-T_4 alone restores normal serum levels of T_4 and T_3. The recommended initial dose of L-T_4 is 10-15 μg/kg/day (37.5-50 μg/day for most term infants), and within this range the starting dose can be adjusted based on the severity of hypothyroidism. Newborns with more severe hypothyroidism, as judged by a serum T_4 <5 μg/dL and/or imaging studies confirming aplasia, should be started at the higher end of the dosage range. Rapid normalization of thyroid function (ideally within 2 weeks) is essential in achieving optimal neurodevelopmental outcomes. Lower doses of L-T_4 (8-10 mcg/kg/day) may be considered for infants with mild hypothyroidism (mildly elevated TSH and normal free T_4).

L-T_4 should be prescribed in tablet form. A liquid L-T_4 preparation has been approved, but optimal dosing may differ slightly from the tablet form. Tablets should be crushed and mixed with a small volume (1-2 mL) of liquid. L-T_4 tablets should not be mixed with soy protein formulas, concentrated iron, or calcium because these can inhibit L-T_4 absorption. Although it is often recommended to administer L-T_4 on an empty stomach and avoid food for 30-60 minutes, this is not practical in an infant. As long as the method of administration is consistent, dosing can be adjusted based on serum thyroid test results to achieve the desired treatment goals. One trial has suggested that brand-name L-T_4 may be superior to generic formulations in children with severe congenital hypothyroidism.

The goals of treatment are to maintain serum TSH in the reference range for age and the serum free T_4 or total T_4 in the upper half of the reference range for age (see Table 603.3). Levels of serum T_4 or free T_4 and TSH should be monitored at recommended intervals (every 1-2 months in the first 6 months of life, and then every 2-4 months between 6 months and 3 years of age). Care should be taken to avoid undertreatment, which has been related to adverse neurodevelopmental outcomes, including decreased intelligence quotient (IQ).

About 35% of infants with congenital hypothyroidism and a normally located thyroid gland have transient disease and do not require lifelong therapy. In patients who might have transient disease, a trial of L-T_4 may be undertaken after 3 years of age for 4 weeks to assess whether the TSH rises significantly, indicating the presence of permanent hypothyroidism. Such a trial is unnecessary in infants with proven thyroid dysgenesis or in those who have previously manifested elevated levels of TSH after 6-12 months of therapy because of poor medication adherence or an inadequate dose of T_4.

Prognosis

Thyroid hormone is critical for normal neurodevelopment, particularly in the early postnatal months. Prompt diagnosis and initiation of adequate treatment of congenital hypothyroidism in the first 2 weeks of life are essential to prevent irreversible brain damage and normal growth and development. In most infants detected by newborn screening, verbal development, psychomotor development, and global IQ scores are similar to unaffected siblings. However, the most severely affected newborns—those with the lowest T_4 levels and most delayed skeletal maturation—may have reduced IQ and other neuropsychologic sequelae such as incoordination, hypotonia or hypertonia, or problems with attention or speech despite early diagnosis and adequate treatment. Psychometric testing can show problems with vocabulary and reading comprehension, arithmetic, and memory. Approximately 10% of children with congenital hypothyroidism have a neurosensory hearing deficit. Outcome studies in adults diagnosed and treated as neonates reveal delayed social development, lower self-esteem, and a lower health-related quality of life. The latter appears to be related to those individuals with lower neurocognitive outcomes and associated congenital malformations.

Delay in diagnosis or treatment, failure to rapidly correct the initial hypothyroidism, inadequate treatment, or poor adherence to treatment

Table 603.3 Thyroid Function Tests

AGE	U.S. REFERENCE VALUE	CONVERSION FACTOR	SI REFERENCE VALUE
THYROID THYROGLOBULIN, SERUM			
Cord blood	14.7-101.1 ng/mL	×1	14.7-101.1 μg/L

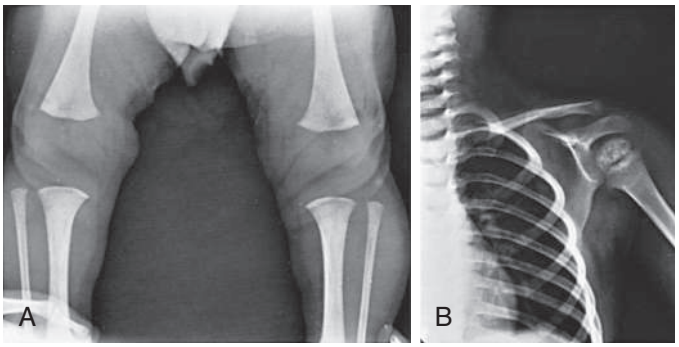

Fig. 603.2 Congenital hypothyroidism. **A,** Absence of distal femoral epiphyses in a 3-mo-old infant who was born at term. This is evidence for onset of the hypothyroid state during fetal life. **B,** Epiphyseal dysgenesis in the head of the humerus in a 9-yr-old girl who had been inadequately treated with thyroid hormone.

in the first 2-3 years of life may result in variable degrees of neurodevelopmental impairment. Without treatment, severely affected infants have profound intellectual disability and growth stunting. When hypothyroidism develops after 2 years of age, the outlook for neurodevelopment is much better even if diagnosis and treatment are delayed, which illustrates the critical dependence of brain development on thyroid hormone in the first year of life.

ACQUIRED HYPOTHYROIDISM

Epidemiology

Hypothyroidism occurs in approximately 0.3% (1 in 333) of school-age children. *Subclinical hypothyroidism* (defined as an elevated TSH with normal T_4 or free T_4) is more common, occurring in approximately 2% of adolescents. Autoimmune thyroiditis is the most common cause of acquired hypothyroidism: 6% of children age 12-19 years have evidence of autoimmune thyroiditis, and females are twice as likely to be affected as males. Although this condition typically arises in adolescence, it may present as early as the first year of life.

Etiology

The most common cause of acquired hypothyroidism (Table 603.4) is **autoimmune thyroiditis** (also called *Hashimoto* or *chronic lymphocytic thyroiditis*; see Chapter 604). Children with trisomy 21, Turner syndrome, Klinefelter syndrome, celiac disease, or type 1 diabetes mellitus are at higher risk for associated autoimmune thyroid disease (see Chapter 604), as are those with **autoimmune polyglandular syndromes** (**APSs**; see Chapter 608). APS type 1 (APS-1) is a rare autosomal recessive disorder caused by pathogenic variants in *AIRE*. It is classically characterized by the triad of mucocutaneous candidiasis, hypoparathyroidism, and primary adrenal insufficiency. Autoimmune thyroiditis is a less common feature (~10%), as are type 1 diabetes mellitus, primary hypogonadism, pernicious anemia, vitiligo, alopecia, nephritis, hepatitis, and gastrointestinal dysfunction. APS type 2 (APS-2) is far more common than APS-1, and its pathogenesis remains an obscure combination of genetic and environmental factors. APS-2 may consist of any combination of autoimmune thyroiditis (~70%), type 1 diabetes mellitus, celiac disease, or less common manifestations such as primary adrenal insufficiency, primary hypogonadism, pernicious anemia, and vitiligo. Patients with any of these other autoimmune conditions are at increased risk of developing hypothyroidism. For example, about 20% of children with **type 1 diabetes mellitus** develop thyroid autoantibodies and about 5% become hypothyroid.

In children with **trisomy 21**, thyroid autoantibodies develop in approximately 30%, and subclinical or overt hypothyroidism occurs in approximately 15–20%. In females with **Turner syndrome**, thyroid autoantibodies

Table 603.4 Etiologic Classification of Acquired Hypothyroidism

- Autoimmune
  - Autoimmune thyroiditis (Hashimoto thyroiditis)
  - Autoimmune polyglandular syndromes types 1 and 2 (APS-1, APS-2)
  - IPEX
  - Celiac disease
- Drug-induced
  - Excess iodide: amiodarone, nutritional supplements, expectorants
  - Anticonvulsants: oxcarbazepine, phenytoin, phenobarbital, valproate
  - Antithyroid drugs: methimazole, propylthiouracil
  - Miscellaneous: lithium, rifampin, tyrosine kinase inhibitors, interferon-α, stavudine, thalidomide, aminoglutethimide, dopamine, amiodarone, tetracycline, ipilimumab, nivolumab
- Iatrogenic
  - Irradiation (e.g., cancer therapy, bone marrow transplant)
  - Radioactive iodine (^{131}I)
  - Thyroidectomy
- Systemic infiltrative disease
  - Cystinosis
  - Langerhans cell histiocytosis
- Consumptive: inactivation of thyroid hormone by large liver hemangiomas (type 3 deiodinase)
- Decreased sensitivity to thyroid hormone (*MCT8, SEC16A2, THRA, THRB* pathogenic variants)
- Hypothalamic-pituitary disease (often with multiple pituitary hormone deficiencies)
  - Central nervous system tumors (e.g., craniopharyngioma)
  - Meningoencephalitis
  - Cranial irradiation
  - Head trauma
  - Langerhans cell histiocytosis

IPEX, Immunodysregulation polyendocrinopathy X-linked.

develop in approximately 40%, and subclinical or overt hypothyroidism occurs in approximately 15–30%, rising with increasing age. Additional autoimmune conditions with an increased risk of hypothyroidism include immune dysregulation–polyendocrinopathy–enteropathy–X-linked syndrome (IPEX) and IPEX-like disorders, immunoglobulin G_4–related diseases, Sjögren syndrome, and multiple sclerosis. **Williams syndrome** is associated with subclinical hypothyroidism, but this does not appear to be autoimmune, and thyroid autoantibodies are absent.

Medications can cause acquired hypothyroidism. Some medications containing iodine (e.g., expectorants or nutritional supplements) may cause hypothyroidism through the Wolff-Chaikoff effect (see Chapter 605). Amiodarone, a drug used for cardiac arrhythmias and consisting of 37% iodine by weight, causes hypothyroidism in approximately 20–30% of treated children. Children treated with amiodarone should have serial monitoring of thyroid function.

Anticonvulsants, including phenytoin, phenobarbital, and valproate, may cause thyroid dysfunction, usually in the form of subclinical hypothyroidism. In some cases, this is because of their effect of stimulating hepatic cytochrome P450 metabolism and excretion of T_4. The anticonvulsant oxcarbazepine can cause central (secondary) hypothyroidism. Hypothyroidism can be caused by overtreatment with antithyroid drugs (methimazole or propylthiouracil) for Graves disease. Additional drugs that can produce hypothyroidism include lithium, rifampin, tyrosine kinase inhibitors, interferon-α, stavudine, thalidomide, and aminoglutethimide.

Children who receive **therapeutic irradiation**, such as for Hodgkin disease or other head and neck malignancies or before bone marrow transplantation, are at risk for thyroid damage and hypothyroidism. Approximately 30% of such children acquire elevated TSH levels within a year after therapy, and another 15–20% progress to hypothyroidism within 5-7 years. **Radioactive iodine** ablative treatment or **thyroidectomy** for Graves disease or thyroid cancer results in iatrogenic hypothyroidism. Thyroid tissue in a thyroglossal duct cyst may constitute the only source of thyroid hormone, and in this case, excision of the cyst results in hypothyroidism. Ultrasonographic examination or a radionuclide scan before surgery is indicated in these patients.

Children with **nephropathic cystinosis,** a disorder characterized by intralysosomal storage of cystine in body tissues, acquire impaired thyroid function. Hypothyroidism is usually subclinical but may be overt, and periodic assessment of TSH levels is indicated. By 13 years of age, two thirds of these patients require L-T_4 replacement.

Histiocytic infiltration of the thyroid in children with **Langerhans cell histiocytosis** (see Chapter 556.1) can result in hypothyroidism. Children with chronic **hepatitis C infection** are at risk for subclinical hypothyroidism that does not appear to be autoimmune.

Consumptive hypothyroidism can occur in children with large hemangiomas of the liver. These tumors may express massive amounts of the enzyme type 3 deiodinase, which inactivates T_4 and T_3, respectively, to the inert metabolites reverse T_3 and diiodothyronine (T_2). Hypothyroidism occurs when increased thyroidal secretion of thyroid hormones is insufficient to compensate for their rapid inactivation.

Some patients with mild forms of congenital hypothyroidism (thyroid dysgenesis or genetic defects in thyroid hormone synthesis) do not develop clinical manifestations until childhood. Although these conditions are often detected by newborn screening, very mild defects can escape detection and present later with apparently acquired hypothyroidism.

Any **hypothalamic** or **pituitary** disease can cause acquired central hypothyroidism (see Chapter 595). TSH deficiency may result from a hypothalamic-pituitary tumor (craniopharyngioma is most common in children) or from treatment for a tumor. Central hypothyroidism may develop in up to 10% of children receiving craniospinal irradiation. Other causes include head trauma or infiltrative diseases affecting the pituitary gland, such as Langerhans cell histiocytosis.

Clinical Manifestations

Slowing of growth is usually the first clinical manifestation of acquired hypothyroidism, but this sign often goes unrecognized (Figs. 603.3 and 603.4). Goiter is a common presenting feature of primary hypothyroidism. In autoimmune thyroiditis, the thyroid is typically nontender

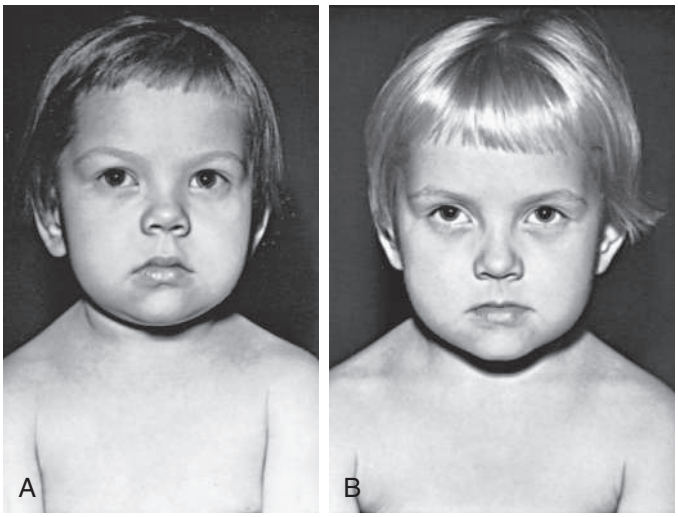

Fig. 603.3 **A,** Acquired hypothyroidism in a 6-yr-old female. She was treated with a wide variety of hematinics for refractory anemia for 3 years. She had almost complete cessation of growth, constipation, and sluggishness for 3 years. The height age was 3 years; the bone age was 4 years. She had a sallow complexion and immature facies with a poorly developed nasal bridge. Serum cholesterol, 501 mg/dL; radioiodine uptake, 7% at 24 hr; protein-bound iodine *(PBI),* 2.8 mg/dL. **B,** After therapy for 18 months, note the nasal development, increased luster and decreased pigmentation of hair, and maturation of the face. The height age was 5.5 years; the bone age was 7 years. There was a decided improvement in her general condition. Menarche occurred at 14 years. The ultimate height was 155 cm (61 in). She graduated from high school. The disorder was well controlled with daily L-thyroxine.

Fig. 603.4 **A,** This 12-yr-old male with hypothyroidism has short stature (108 cm, <3rd percentile), generalized myxedema, sleepy expression, protuberant abdomen, and coarse hair. Body proportions are immature for his age (1.25:1). **B,** Same boy 4 months after treatment. His height increased by 4 cm, and there is a marked change in body habitus owing to loss of myxedema, improved muscle tone, and bright facial expression. *(From LaFranchi SH. Hypothyroidism. Pediatr Clin North Am. 1979;26:33–51.)*

and firm, with a rubbery consistency and pebbly (bosselated) surface. Weight gain is mainly caused by fluid retention (myxedema), not true adiposity. Myxedematous changes of the skin, constipation, cold intolerance, decreased energy, and an increased need for sleep develop insidiously. School performance usually does not suffer, even in severely hypothyroid children. Additional features may include bradycardia, muscle weakness or cramps, nerve entrapment, and ataxia. Skeletal maturation is delayed, and the degree of delay reflects the duration of the hypothyroidism. Adolescents typically have delayed puberty. Older adolescent females may have menometrorrhagia, and some may develop galactorrhea because of increased TRH, which stimulates prolactin secretion. In fact, long-standing primary hypothyroidism can result in enlargement of the pituitary gland, sometimes leading to headaches and vision problems. This is believed to result from thyrotroph hyperplasia but may be mistaken for a pituitary tumor, particularly a prolactinoma if prolactin is elevated (see Chapter 595). Rarely, young children with profound hypothyroidism may develop secondary sex characteristics (pseudoprecocious puberty), including breast development or vaginal bleeding in females and testicular enlargement in males. It is hypothesized that this phenomenon results from abnormally high concentrations of TSH binding and stimulating the follicle-stimulating hormone receptor.

Laboratory abnormalities in hypothyroidism may include hyponatremia, macrocytic anemia, hypercholesterolemia, and elevated creatine phosphokinase. Table 603.5 lists complications of severe hypothyroidism, all of which normalize with adequate replacement of T_4.

Diagnostic Studies

Children with suspected hypothyroidism should undergo measurement of serum TSH and free T_4. Because the normal range for thyroid tests varies by age and is different in children than in adults, it is important to interpret results using age-specific reference ranges (see Table 603.3). Detection of autoantibodies to thyroglobulin or TPO is diagnostic of autoimmune thyroiditis. Measurement of urine iodine can confirm excess iodine exposure, if suspected. In cases of goiter resulting from autoimmune thyroiditis, ultrasonography typically shows diffuse enlargement and heterogeneous echotexture, but ultrasonography generally is not indicated unless the physical exam raises suspicion for a thyroid nodule. A bone age x-ray at diagnosis may suggest the duration and severity of hypothyroidism based on the degree of bone age delay.

Treatment and Prognosis

L-T_4 is the treatment for children with hypothyroidism. The dose on a weight basis gradually decreases with age. For children ages 1-3 years, the average daily L-T_4 dose is 4-6 μg/kg; for ages 3-10 years, 3-5 μg/kg; and for ages 10-16 years, 2-4 μg/kg. Treatment should be monitored by measuring serum TSH every 4-6 months and 4-6 weeks after any change in dosage, and TSH should be maintained in the age-specific reference range. In young children (under age 3 years), serum free T_4 should also be measured and ideally maintained in the upper half of the age-specific reference range. In older children with primary hypothyroidism, serum free T_4 need not be measured routinely but may be helpful in certain situations, such as to assess for poor medication adherence. In children with central hypothyroidism, in which TSH levels by definition do not reflect systemic thyroid status, serum free T_4 alone should be monitored and maintained in the upper half of the age-specific reference range.

During the first year of treatment, deterioration of schoolwork, poor sleeping habits, restlessness, short attention span, and behavioral problems may develop. However, these issues are transient and more easily managed if families are forewarned about them. Some practitioners feel that these symptoms may be partially ameliorated by starting at a lower dose of L-T_4 and advancing slowly. The development of persistent headaches or vision changes should prompt an evaluation for pseudotumor cerebri, a rare complication after initiation of L-T_4 treatment in older children (age 8-13 years).

In older children, after catch-up growth is complete, the growth rate provides a good index of the adequacy of therapy. In children with long-standing hypothyroidism, catch-up growth may be incomplete, and final adult height may be irremediably compromised (see Fig. 603.4).

Table 603.5 Clinical Presentation and Implications of Hypothyroidism

	PRESENTATION	SIGNS AND IMPLICATIONS
General metabolism	Weight gain, cold intolerance, fatigue	Increase in body mass index, low metabolic rate, myxedema,* hypothermia*
Cardiovascular	Fatigue on exertion, shortness of breath	Dyslipidemia, bradycardia, hypertension, endothelial dysfunction or increased intima–media thickness,* diastolic dysfunction,* pericardial effusion,* hyperhomocysteinemia,* electrocardiogram changes*
Neurosensory	Hoarseness of voice, decreased taste, vision, or hearing	Neuropathy, cochlear dysfunction, decreased olfactory and gustatory sensitivity
Neurologic and psychiatric	Impaired memory, paresthesia, mood impairment	Impaired cognitive function, delayed relaxation of tendon reflexes, depression,* dementia,* ataxia,* carpal tunnel syndrome, and other nerve entrapment syndromes,* myxedema coma*
Gastrointestinal	Constipation	Reduced esophageal motility, nonalcoholic fatty liver disease,* ascites (very rare)
Endocrinologic	Infertility and subfertility, menstrual disturbance, galactorrhea	Goiter, glucose metabolism dysregulation, infertility, sexual dysfunction, increased prolactin, pituitary hyperplasia*
Musculoskeletal	Muscle weakness, muscle cramps, arthralgia	Creatine phosphokinase elevation, Hoffman syndrome,* osteoporotic fracture* (most probably caused by overtreatment)
Hemostasis and hematologic	Bleeding, fatigue	Mild anemia, acquired von Willebrand disease,* decreased protein C and S,* increased red cell distribution width,* increased mean platelet volume*
Skin and hair	Dry skin, hair loss	Coarse skin, loss of lateral eyebrows,* yellow palms of the hand,* alopecia areata*
Electrolytes and kidney function	Deterioration of kidney function	Decreased estimated glomerular filtration rate, hyponatremia*

*Uncommon presentation.

Chapter 604

Thyroiditis

Jessica R. Smith and Ari J. Wassner

Thyroiditis refers to inflammation of the thyroid gland. Thyroiditis can be acute or chronic and can be categorized by etiology, pathology, and/or clinical features. Painful thyroiditis is typically due to infection or trauma, whereas painless thyroiditis is often autoimmune-mediated or due to drug exposure.

Depending on the etiology and phase of illness, patients with thyroiditis may be euthyroid, hypothyroid, or thyrotoxic. The classic pattern of thyroid function changes in transient forms of thyroiditis is thyrotoxicosis followed by hypothyroidism and then restoration of euthyroidism. In some cases, hypothyroidism can persist after transient thyroiditis. The thyrotoxicosis caused by thyroiditis is not due to increased thyroid hormone synthesis (in contrast to Graves disease), but rather release of preformed thyroid hormone from the damaged gland, which can last up to 60 days.

Treatment for patients with thyroiditis is directed at alleviating symptoms of pain and symptoms of thyrotoxicosis such as tachycardia, palpations, and tremors. Nonsteroidal antiinflammatory drugs (NSAIDs) usually alleviate thyroid pain effectively, but a short course of steroids (prednisone) can be considered if pain is severe. Because the thyrotoxicosis is caused by the release of preformed thyroid hormone, antithyroid drugs (which block thyroid hormone synthesis) are ineffective. Instead, treatment with β blockers (atenolol or propranolol) may be used to control cardiovascular symptoms until thyrotoxicosis resolves. Thyroid function tests should be monitored every 6-8 weeks until they normalize. If hypothyroidism is prolonged or symptomatic, replacement with levothyroxine may be initiated.

THYROIDITIS WITH PAIN

Acute infectious (suppurative) thyroiditis is uncommon in children and typically is preceded by a respiratory infection or pharyngitis. The most common pathogenic organisms are α-hemolytic streptococci and *Staphylococcus aureus,* followed by gram-negative organisms and anaerobic bacteria. Other pathogens, including mycobacteria, fungi, and pneumocystis, cause more indolent infection and occur in immunocompromised patients. Abscess formation can occur, and the left thyroid lobe is more commonly affected than the right. Recurrent episodes or detection of mixed bacterial flora suggest that the infection arises from a **piriform sinus fistula** or, less commonly, from a **thyroglossal duct** remnant. Acute infectious thyroiditis is characterized by acute onset of neck pain, thyroid tenderness, swelling, erythema, dysphagia, and decreased range of motion of the neck. Fever, chills, sore throat, and leukocytosis are common. Thyroid function is usually normal, but thyrotoxicosis can occur. A suspected abscess can be assessed by thyroid ultrasound, and fine needle aspiration can help identify the responsible microorganism. Treatment of a thyroid abscess includes incision and drainage and administration of parenteral antibiotics. After the infection subsides, a CT scan with contrast may be obtained to identify a fistulous tract that may require surgical resection.

Subacute thyroiditis (de Quervain disease, subacute granulomatous thyroiditis) is believed to have a viral or postviral etiology and is usually transient. It typically presents with low-grade fever, minimal thyroid tenderness, and laboratory evidence of thyrotoxicosis (suppressed TSH and elevated T_4 and T_3). Mild symptoms of thyrotoxicosis may be present, but radioiodine uptake is depressed in the thyrotoxic phase. The erythrocyte sedimentation rate (ESR) is increased. The course is variable but usually follows the classic pattern of thyrotoxicosis, hypothyroidism, and finally resolution to euthyroidism, usually occurring over several months. There is a strong association with HLA-B35.

Radiation thyroiditis can occur after treatment with radioactive iodine or external beam radiation. Thyroid pain and tenderness develop after 2-5 days because of radiation-induced destruction of the thyroid follicular cells and subsequent release of preformed thyroid hormone. The neck pain is responsive to antiinflammatory therapies.

Palpation- or trauma-induced thyroiditis can result from direct trauma to the thyroid gland, typically from surgery, accidental trauma, biopsy, or rarely, vigorous palpation.

THYROIDITIS WITHOUT PAIN

Autoimmune Thyroiditis (Hashimoto Thyroiditis, Chronic Lymphocytic Thyroiditis)

Autoimmune thyroiditis is the most common cause of thyroid disease in children and adolescents and accounts for many of the formerly designated *adolescent* or *simple* goiters. It is also the most common cause of acquired hypothyroidism, with or without goiter. Between 1 and 2% of school-age children and 6–8% of adolescents have positive thyroid autoantibodies as evidence of autoimmune thyroid disease.

Etiology

This typical organ-specific autoimmune disease results from a combination of inherited susceptibility in genes involved in immunoregulation and from environmental triggers, both poorly characterized. Early in the disease, there may be thyroid hyperplasia only. This is followed by infiltration of lymphocytes and plasma cells into thyroid follicles and formation of lymphoid follicles with germinal centers. Chronic inflammation eventually leads to follicular fibrosis and atrophy. Certain human leukocyte antigen (HLA) haplotypes (HLA-DR4, HLA-DR5) are associated with an increased risk of goiter and thyroiditis, and others (HLA-DR3) are associated with the atrophic variant of thyroiditis.

A variety of different autoantibodies to thyroid antigens are also present. Circulating antibodies to thyroperoxidase (TPO-Abs) or thyroglobulin (Tg-Abs) are detectable in most children with autoimmune thyroiditis and many patients with Graves disease. TPO-Abs are involved in activation of the complement cascade and antibody-dependent, cell-mediated cytotoxicity. Tg-Abs do not appear to play a role in the autoimmune destruction of the gland. TSH receptor-blocking antibodies (TRBAbs) may cause thyroid atrophy and have been demonstrated in 18% of patients with severe hypothyroidism (TSH >20 mU/L) caused by autoimmune thyroiditis.

Clinical Manifestations

Autoimmune thyroiditis is 4-6 times more common in females than in males. It can occur during the first 3 years of life but becomes more common after 6 years of age and reaches its peak incidence during adolescence. The most common clinical manifestations are goiter and growth deceleration. Goiter is primarily caused by thyroid inflammation and fibrosis, and it can appear insidiously and may be variable in size. In most patients, the thyroid is diffusely enlarged, firm, and nontender. In some patients the gland may be asymmetric. Most affected children are euthyroid and asymptomatic. Children who develop hypothyroidism may be symptomatic, but others may have no symptoms despite laboratory evidence of overt hypothyroidism. In some cases, autoimmune thyroiditis can cause transient thyroiditis as a result of autoimmune thyroid destruction (so-called *Hashitoxicosis*). Such children may present with manifestations of thyrotoxicosis, such as tremulousness, irritability, increased sweating, and hyperactivity. Ophthalmopathy can occur in autoimmune thyroiditis even in the absence of Graves disease, although this is rare in childhood.

The clinical course of autoimmune thyroiditis is variable. Goiter may persist or regress spontaneously. Most children who are euthyroid at presentation remain euthyroid, but a subset of patients develop hypothyroidism within months or years. In children who have subclinical hypothyroidism at diagnosis (elevated TSH, normal free thyroxine [T_4]), approximately 35% revert to euthyroidism, 50% continue to have subclinical hypothyroidism, and approximately 15% develop overt hypothyroidism (elevated serum TSH, subnormal free T_4) within 5 years. There are few reliable predictors of progression to hypothyroidism, so periodic monitoring of TSH levels is indicated in children with autoimmune thyroiditis.

Familial clusters of autoimmune thyroiditis are common, and the incidence in siblings or parents of affected children may be as high as 25%. The concurrence within families of patients with autoimmune thyroiditis and Graves disease reflects a fundamental pathophysiologic relationship among these autoimmune thyroid disorders.

Autoimmune thyroiditis is associated with other autoimmune disorders. Autoimmune thyroiditis occurs in 10% of patients with **type 1 autoimmune polyglandular syndrome (APS-1),** characterized by autoimmune

polyendocrinopathy, candidiasis, and ectodermal dysplasia **(APECED)**, a rare autosomal recessive disorder caused by pathogenic variants in the autoimmune regulator *(AIRE)* gene (see Chapter 608). Autoimmune thyroiditis occurs in 70% of patients with **type 2 autoimmune polyglandular syndrome (APS-2)**, including type 1 diabetes mellitus, autoimmune primary adrenal insufficiency, pernicious anemia, vitiligo, and alopecia. TPO-Abs are found in approximately 20% of White and 4% of Black children with type 1 diabetes mellitus. The onset of APS-2 typically occurs in late childhood or early adulthood. Its cause is unknown but may be related to predisposing genetic factors shared among these autoimmune conditions (see Chapter 608). Autoimmune thyroiditis has also been described in children with **immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome**, including early-onset diabetes and colitis (see Chapter 608).

Autoimmune thyroiditis is common in patients with celiac disease or certain chromosomal disorders, particularly Turner syndrome (8–30%) and trisomy 21 (7–10%). Males with Klinefelter syndrome also appear to be at increased risk for autoimmune thyroid disease.

Table 604.1 compares the characteristics of autoimmune thyroiditis to other forms of thyroiditis.

Laboratory and Imaging Findings

Thyroid function tests are often normal. Elevation of serum TSH indicates hypothyroidism, which may be subclinical (normal free T_4) or overt (low free T_4). TPO-Abs are present in most children with autoimmune thyroiditis. Tg-Abs are present in many adolescents but are somewhat less sensitive in young children. Testing for both antibodies will detect about 95% of children with autoimmune thyroiditis. Antibody levels are lower in children than in adults, so repeated measurements of borderline levels may be indicated. Measurement of thyroid autoantibody levels is useful only for diagnosing autoimmune thyroiditis; antibody levels do not correlate with thyroid function and should not be monitored routinely after the initial diagnosis. In adolescent females with overt hypothyroidism, measurement of TSH receptor antibodies may identify patients at future risk of having babies with transient congenital hypothyroidism caused by transplacental passage of TRBAbs.

Thyroid scintigraphy and ultrasonography usually are not necessary for the diagnosis of autoimmune thyroiditis. If performed, thyroid scintigraphy reveals decreased radioisotope uptake that is patchy and irregular. Thyroid ultrasonography shows diffusely heterogeneous echogenicity and frequently an increased number of hyperplastic, benign-appearing cervical lymph nodes. Thyroid ultrasound is indicated for patients with a palpable thyroid nodule or significant thyroid asymmetry.

Treatment

If hypothyroidism is overt (elevated TSH with low free T_4) or symptomatic, treatment with levothyroxine is indicated at doses specific to size and age. Goiter may decrease in size but can persist for years. In a euthyroid patient, treatment with levothyroxine is unlikely to significantly decrease the goiter's size, and doses of levothyroxine sufficient to suppress TSH should be avoided because of potential adverse effects. Because autoimmune thyroiditis is self-limited in some instances, the need for continued therapy may be reevaluated periodically, particularly after growth and pubertal development are complete. Untreated euthyroid patients should have periodic monitoring for risk of progression to hypothyroidism. There is some controversy about the management of patients with subclinical hypothyroidism. Subclinical hypothyroidism has not been demonstrated to have clinically significant adverse effects, but studies are small and of limited quality. Therefore observation without treatment is acceptable, but some clinicians prefer to treat until growth and puberty are complete and then reevaluate their thyroid function.

OTHER CAUSES OF THYROIDITIS

Painless thyroiditis (silent thyroiditis) is characterized by transient thyrotoxicosis, followed sometimes by hypothyroidism, and then recovery. It accounts for 1–5% of cases of thyrotoxicosis. It can also occur in the postpartum period and in response to certain types of drugs.

Drug-induced thyroiditis can be caused by medications including lithium, amiodarone, interferon-α, interleukin-2, and tyrosine kinase inhibitors. Patients taking lithium are susceptible to both lithium-induced hypothyroidism and painless thyroiditis. The antiarrhythmic drug amiodarone contains a high concentration of iodine and can cause two types of thyrotoxicosis. Type 1 is caused by increased synthesis of thyroid hormone (hyperthyroidism), typically occurs in patients with underlying thyroid autoimmunity, and is amenable to treatment with antithyroid drugs (methimazole). Type 2 is a destructive thyroiditis causing excessive release of preformed thyroid hormone, which can be treated with glucocorticoids (prednisone).

Fibrous thyroiditis (invasive or Riedel thyroiditis) is quite rare in children and is characterized by extensive fibrosis and macrophage and eosinophil infiltration of the thyroid gland. The thyroid becomes enlarged, hard, and affixed to surrounding structures. Thyroid function tests are normal, and a biopsy is required to confirm the diagnosis. Glucocorticoids may alleviate symptoms.

Table 604.1 Characteristics of Thyroiditis Syndromes

CHARACTERISTIC	AUTOIMMUNE THYROIDITIS	PAINLESS THYROIDITIS	SUBACUTE THYROIDITIS	ACUTE INFECTIOUS THYROIDITIS	FIBROUS THYROIDITIS
Sex ratio (F:M)	4-6:1	2:1	5:1	1:1	3-4:1
Cause	Autoimmune	Autoimmune	Unknown (probably viral)	Infectious (bacterial)	Unknown
Pathologic findings	Lymphocytic infiltration, germinal centers, fibrosis	Lymphocytic infiltration	Giant cells, granulomas	Abscess formation	Dense fibrosis
Thyroid function	Usually euthyroidism; some hypothyroidism	Thyrotoxicosis, hypothyroidism, or both	Thyrotoxicosis, hypothyroidism, or both	Usually euthyroidism	Usually euthyroidism
TPO antibodies	Present, persistent	Present, persistent	Low titer, absent, or transient	Absent	Usually present
ESR	Normal	Normal	High	High	Normal
^{123}I uptake	Usually low	Low	Low	Normal	Low or normal

ESR, Erythrocyte sedimentation rate; ^{123}I, iodine 123; TPO, thyroid peroxidase.
Data from Farwell AP, Braverman LE. Inflammatory thyroid disorders. *Otolaryngol Clin North Am.* 1996;4:541–556.

Chapter 605

Goiter

Jessica R. Smith and Ari J. Wassner

A goiter is an enlargement of the thyroid gland. Average thyroid volume is approximately 1 mL at birth and increases with age and body mass index. For clinical assessment of thyroid size, the "rule of thumb" states that in older children (>5 years) each lobe of the thyroid gland is approximately the size of the distal phalanx of the child's thumb. Children with an enlarged thyroid can have normal thyroid function **(euthyroidism)**, underproduction of thyroid hormone **(hypothyroidism)**, or overproduction of thyroid hormone **(hyperthyroidism)**. Most goiters are discovered by the patient or a caregiver or on physical examination. Detection of a goiter should prompt an investigation of its cause and assessment of thyroid function.

Goiter may be congenital or acquired, endemic or sporadic. Goiter often results from increased pituitary secretion of thyroid-stimulating hormone (TSH) in response to decreased circulating levels of thyroid hormone. The most common causes of pediatric goiter are inflammation (autoimmune thyroiditis) and, in endemic areas, iodine deficiency (endemic goiter). Other causes include inborn errors in thyroid hormone synthesis (dyshormonogenesis), maternal ingestion of antithyroid drugs, goitrogens, abnormal activation of the TSH receptor by circulating antibodies (TRSAb) in Graves disease or by genetic gain-of-function pathogenic variants, or disorders of inappropriate TSH secretion. Thyroid enlargement can also result from thyroid nodules or infiltrative processes.

605.1 Congenital Goiter

Ari J. Wassner and Jessica R. Smith

Congenital goiter usually results from a defect in fetal thyroxine (T_4) synthesis that leads to neonatal hypothyroidism. This defect may be intrinsic to the fetal thyroid or may be caused by transplacental transfer from the mother of substances that decrease fetal thyroid hormone synthesis. Antithyroid drugs (methimazole or propylthiouracil) administered during pregnancy to treat maternal thyrotoxicosis cross the placenta and can interfere with fetal synthesis of thyroid hormone. The neonatal consequences are most severe when overtreatment with antithyroid drugs causes concomitant hypothyroidism in the mother, which reduces the supply of maternal thyroid hormone to the fetus. Fetal effects can occur even with low doses of antithyroid drugs; therefore infants born to women treated with such drugs in the third trimester should undergo serum thyroid studies at birth, even if they appear clinically euthyroid. Levothyroxine treatment may be indicated for severe hypothyroidism or to reduce the size of goiter that causes airway obstruction. Hypothyroidism caused by maternal antithyroid drugs is transient and resolves once the antithyroid drug has been excreted by the neonate, usually after 1-2 weeks. Like antithyroid drugs, other medications containing large amounts of iodine can cause congenital goiter, including amiodarone and some cough preparations.

In cases of congenital goiter and hypothyroidism in which no cause is identifiable from the maternal or medication history, an intrinsic defect in synthesis of thyroid hormone **(dyshormonogenesis)** should be suspected. Such disorders are caused by genetic defects in one of the proteins critical to thyroid hormone synthesis and are usually inherited in autosomal recessive fashion. Neonatal screening programs detect congenital hypothyroidism caused by such a defect in about 1 in 25,000 infants. Treatment with levothyroxine should be initiated immediately. If a specific defect is suspected, genetic testing to identify a mutation may be considered (see Chapter 603). Monitoring subsequent pregnancies with ultrasonography can be useful to detect fetal goiter (see Chapter 117).

Iodine deficiency is an important cause of congenital goiter that is rare in countries that have adopted universal salt iodization, but iodine deficiency persists in endemic areas (see Chapter 605.3). Severe maternal iodine deficiency early in pregnancy can cause neurologic damage during fetal development because maternal hypothyroidism reduces the transfer of maternal thyroid hormones that typically protect neurodevelopment in a fetus unable to synthesize its own thyroid hormone.

Goiter is almost always present in the infant with **neonatal Graves disease**. Thyroid enlargement results from transplacental passage of maternal TSH receptor-stimulating antibodies that promote thyroid hyperplasia (see Chapter 606.2). These goiters usually are not large, and the infant manifests clinical symptoms of hyperthyroidism. The diagnosis of maternal Graves disease is usually known but occasionally may be discovered by evaluating unexpected neonatal hyperthyroidism. Activating pathogenic variants of the TSH receptor are a rare cause of congenital goiter with hyperthyroidism.

A very large congenital goiter of any cause can lead to tracheal compression and respiratory distress that interferes with feeding and can even be fatal. Therefore intervening to reduce the size of a large fetal goiter may be necessary before delivery. Treatment should be directed at the underlying cause. Iodine deficiency should be treated if present. In pregnant women treated with antithyroid drugs, reducing the dose of maternal medication is appropriate. In severe cases, fetal goiter caused by fetal hypothyroidism (including dyshormonogenesis) may be reduced by intraamniotic injections of levothyroxine. If the fetal goiter is caused by fetal hyperthyroidism (e.g., fetal Graves disease), treatment with antithyroid drugs administered to the mother is indicated. Large obstructing fetal goiters are often managed with the ex utero intrapartum treatment (EXIT) procedure during elective delivery (see Chapter 117). When postnatal respiratory obstruction is severe, endotracheal intubation, hormone therapy, and occasionally partial thyroidectomy is indicated (Fig. 605.1).

When a palpable congenital goiter is lobulated, asymmetric, firm, or unusually large, a teratoma in or near the thyroid must be considered (see Chapter 607).

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

605.2 Intratracheal Goiter

Ari J. Wassner and Jessica R. Smith

One of the many potential ectopic locations of thyroid tissue is within the trachea. When present, intraluminal thyroid tissue lies beneath the tracheal mucosa and is often continuous with the normally located extratracheal thyroid gland. Both eutopic and ectopic thyroid tissue are susceptible to goitrous enlargement. Therefore when airway obstruction is associated with a goiter, it must be ascertained whether the obstruction is extratracheal or intratracheal. If obstructive manifestations are mild, administration of levothyroxine usually decreases the size of the goiter. When symptoms are severe, surgical removal of the intratracheal goiter is indicated.

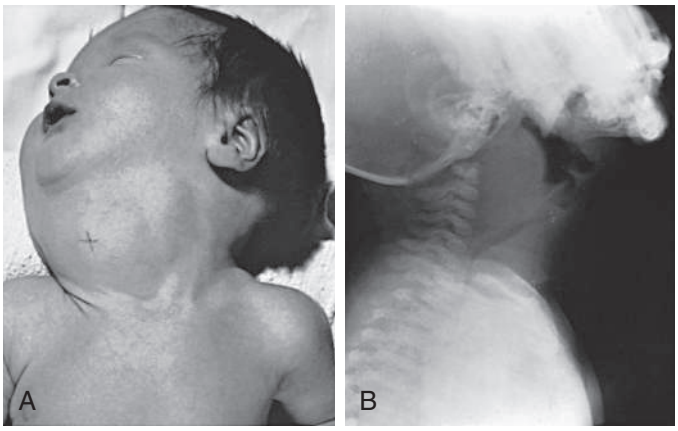

Fig. 605.1 Congenital goiter in infancy. **A,** Large congenital goiter in an infant born to a mother with thyrotoxicosis who had been treated with iodides and methimazole during pregnancy. **B,** A different infant, 6 wk old, with increasing respiratory distress and cervical mass since birth. Notice the anterior deviation and posterior compression of the trachea.

605.3 Endemic Goiter and Cretinism

Ari J. Wassner and Jessica R. Smith

ETIOLOGY

Goiter caused by iodine deficiency is termed *endemic goiter,* whereas *cretinism* refers to the clinical manifestations of severe hypothyroidism in early life. The association of dietary iodine deficiency with endemic goiter and cretinism is well established. The thyroid gland can overcome a moderate deficiency of iodine by increasing the efficiency of thyroid hormone synthesis. This increased activity is achieved by compensatory thyroid hypertrophy and hyperplasia (goiter). In cases of severe iodine deficiency, these compensatory mechanisms are insufficient, and hypothyroidism can result. The World Health Organization estimates that nearly 2 billion individuals have insufficient iodine intake, including one third of the world's school-age children. Thus despite significant progress in the global effort to reduce iodine deficiency, it remains a leading cause of preventable intellectual disability worldwide.

Because seawater is rich in iodine, endemic goiter is rare in coastal populations that consume much of their diet from the sea. In areas of iodine deficiency, iodized salt provides excellent prophylaxis, and endemic goiter has effectively disappeared in the United States and other countries that have introduced salt iodization programs. The U.S. recommended dietary allowance of iodine is:

- Infants under 6 months: 110 μg/day
- Infants 7-12 months: 130 μg/day
- Children 1-8 years: 90 μg/day
- Children 9-13 years: 120 μg/day
- Children 14 years and older: 150 μg/day
- Pregnant women: 220 μg/day
- Lactating women: 290 μg/day

Although the overall dietary iodine intake in the United States is considered adequate, recent data indicate that the median urinary iodine concentration among pregnant U.S. women has dropped to <150 μg/L (mild iodine deficiency). This highlights the re-emerging risk of iodine deficiency even in industrialized countries. These risks can be mitigated by the continued monitoring of iodine status, the adjustment of salt iodization levels, and the targeted supplementation of vulnerable subpopulations (e.g., promoting iodine-containing prenatal vitamins).

CLINICAL MANIFESTATIONS

In mild iodine deficiency, thyroid enlargement generally is not noticeable except when demand for thyroid hormone synthesis is increased, such as during rapid growth in adolescence and pregnancy. In regions of moderate iodine deficiency, goiter in school children can disappear with maturity and reappear during pregnancy or lactation. Iodine-deficient goiter is more common in girls than in boys. In areas of severe iodine deficiency, nearly half the population may have large goiters, and endemic cretinism is common (Fig. 605.2).

Serum T_4 levels are often low in individuals with endemic goiter, although clinical hypothyroidism is rare. Despite low serum T_4 levels, serum TSH concentrations are often normal or only mildly increased because of the elevated circulating levels of T_3 produced in response to iodine deficiency.

Endemic cretinism is the most severe consequence of iodine deficiency and occurs only in association with endemic goiter. The term *endemic cretinism* includes two distinct but overlapping syndromes (neurologic and myxedematous). The incidence of the two syndromes varies among different populations, but both syndromes are found in all endemic areas, and some individuals have intermediate or mixed features.

The **neurologic syndrome** is characterized by intellectual disability; deaf-mutism; disturbances in standing and gait; and pyramidal signs such as clonus of the foot, Babinski sign, and patellar hyperreflexia. Affected persons have a goiter but minimally impaired thyroid function and have normal pubertal development and adult stature. Persons with the **myxedematous syndrome** also have intellectual disability, deafness, and neurologic symptoms. In contrast to the neurologic type, they also have delayed growth and pubertal development and myxedema. Serum T_4 levels are low, TSH levels are markedly elevated, goiter is absent, and ultrasound demonstrates thyroid atrophy.

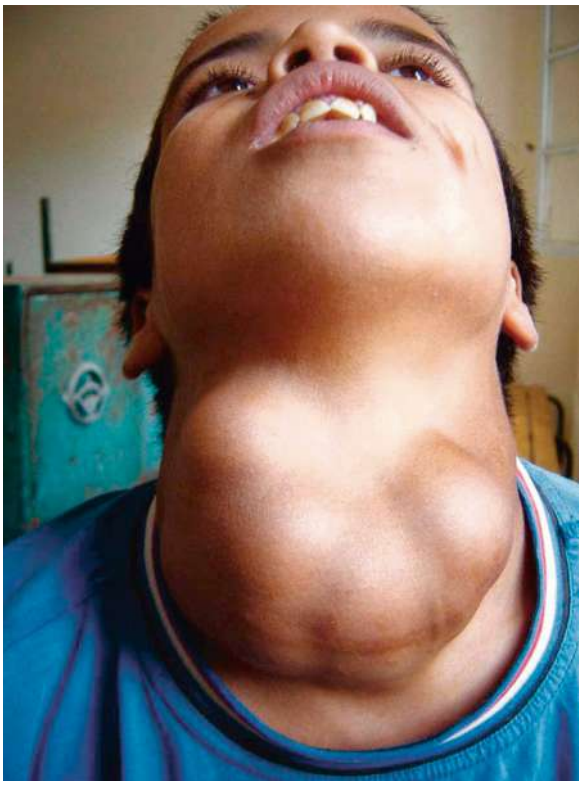

Fig. 605.2 A 14-yr-old male with a large nodular goiter was seen in 2004, in an area of severe iodine-deficiency disorders in northern Morocco. He had tracheal and esophageal compression and hoarseness, probably as a result of damage to the recurrent laryngeal nerves. *(From Zimmermann MB, Jooste PL, Pandav CS. Iodine-deficiency disorders. Lancet. 2008;372:1251–1262, Fig. 2.)*

PATHOGENESIS

The pathogenesis of the **neurologic syndrome** is attributed to maternal iodine deficiency and hypothyroidism during pregnancy, leading to fetal and postnatal hypothyroidism. Maternal thyroid hormone is critical for early fetal neurodevelopment. Thyroid hormone receptors are expressed in the fetal brain as early as 7 weeks of gestation. Although the fetal thyroid gland does not produce significant amounts of thyroid hormone until midgestation, as early as 6 weeks there is measurable T_4 in the coelomic fluid that is of maternal origin. In addition, there is transplacental passage of maternal thyroid hormone into the fetus throughout gestation, which ameliorates the neurologic effects of fetal hypothyroidism in the second half of pregnancy. Thus maternal iodine deficiency affects fetal neurodevelopment throughout pregnancy. However, iodine intake after birth is often sufficient for the infant to maintain (near-)normal thyroid function.

The pathogenesis of the **myxedematous syndrome** and its persistent postnatal hypothyroidism is not well understood. Multiple environmental factors have been implicated (Table 605.1), as have thyroid autoimmunity and TSH receptor-blocking antibodies, but studies are conflicting, and the pathogenesis remains obscure.

TREATMENT

The optimal treatment of endemic goiter is prevention by ensuring iodine sufficiency in women before pregnancy. A single intramuscular injection of iodinated poppy seed oil administered to women prevents iodine deficiency during future pregnancies for approximately 5 years. This therapy is also effective in children younger than 4 years with myxedematous cretinism. However, older children and adults respond poorly, indicating a progressive inability of the thyroid gland to synthesize hormone, and these patients require treatment with levothyroxine. Large-scale prevention efforts include universal salt iodization in many countries, as well as

Table 605.1 Goitrogens and Their Mechanisms

GOITROGEN	MECHANISM
FOODS	
Cassava, lima beans, linseed, sorghum, sweet potato	Contain cyanogenic glucosides that are metabolized to thiocyanates that compete with iodine for uptake by the thyroid
Cruciferous vegetables (cabbage, kale, cauliflower, broccoli, turnips)	Contain glucosinolates; metabolites compete with iodine for uptake by the thyroid
Soy, millet	Flavonoids impair thyroid peroxidase activity
INDUSTRIAL POLLUTANTS	
Perchlorate	Competitive inhibitor of the sodium-iodide symporter, decreasing iodide transport into the thyroid
Others (e.g., disulfides from coal processes)	Reduce thyroidal iodine uptake
Smoking	Smoking during breastfeeding is associated with reduced iodine concentrations in breast milk; high serum concentration of thiocyanate from smoking might compete with iodine for active transport into the secretory epithelium of the lactating breast
NUTRIENTS	
Selenium deficiency	Accumulated peroxides can damage the thyroid, and deiodinase deficiency impairs thyroid hormone activation
Iron deficiency	Reduces heme-dependent thyroperoxidase activity in the thyroid and may blunt the efficacy of iodine prophylaxis
Vitamin A deficiency	Increases TSH stimulation and goiter through decreased vitamin A–mediated suppression of the pituitary TSH-β gene

TSH, Thyroid-stimulating hormone.
From Zimmermann MB, Jooste PL, Pandav CS. Iodine-deficiency disorders. *Lancet.* 2008;372:1251–1262, Table 1.

iodination of irrigation water in some areas. Nevertheless, political, economic, and practical obstacles have limited iodization efforts in many parts of the world.

605.4 Acquired Goiter

Jessica R. Smith and Ari J. Wassner

Acquired goiter is usually sporadic and may develop from a variety of causes. The most common cause of acquired goiter is autoimmune thyroiditis (see Chapter 604). Other causes in children include painless sporadic thyroiditis and subacute thyroiditis (de Quervain disease; see Chapter 604). Ingestion of excess iodide or certain medications can cause goiter, as can congenital defects in thyroid hormone synthesis. The occurrence of goiter in siblings, onset in early life, and possible association with hypothyroidism are important clues to diagnosing congenital dyshormonogenesis.

IODIDE GOITER

Excessive iodine ingestion can result in a goiter. Large amounts of iodine are found in certain foods (such as seaweed) and some expectorants for chronic reactive airway disease or cystic fibrosis. Some children with iodine-induced goiter have underlying autoimmune thyroiditis or a subclinical congenital defect in thyroid hormone synthesis. In a normal thyroid gland, the acute intake of large doses of iodine inhibits thyroid hormone synthesis (Wolff-Chaikoff effect). However, this effect is short-lived and normally does not lead to hypothyroidism. If iodine administration continues, an autoregulatory mechanism limits iodide uptake by the thyroid, allowing thyroid hormone synthesis to resume. This "escape" from the Wolff-Chaikoff effect may not occur in individuals with underlying thyroid abnormalities (such as autoimmune thyroid disease or thyroid irradiation) or in neonates, potentially leading to hypothyroidism and iodine-induced goiter.

Iodine-Deficiency Goiter

Iodine deficiency is the most common cause of goiter worldwide, but salt iodization has nearly eradicated this entity in the United States and many other countries. A severely iodine-restricted diet can result in a goiter and hypothyroidism in children, adolescents, or neonates born to mothers with severe iodine deficiency (urine iodine concentration <50 mcg/L). Children with moderate or severe iodine deficiency and goiter have subclinical or mild hypothyroidism, but their serum T_3 concentrations may be normal or high because of preferential thyroidal T_3 secretion. Acquired iodine deficiency can be treated with either iodine or levothyroxine supplementation.

Goitrogens

Certain foods contain goitrogenic substances (see Table 605.1). When consumed alone, these substances are unlikely to cause goiter but can contribute to goiter formation when iodine intake is marginal.

Lithium carbonate can cause goiter and hypothyroidism in children. Lithium decreases T_4 and T_3 synthesis and release; the mechanism producing the goiter or hypothyroidism is similar to that described for iodide goiter. Lithium and iodide act synergistically to produce goiter, so their combined use should be avoided.

Amiodarone, a drug used to treat cardiac arrhythmias, can cause thyroid dysfunction with goiter because it is rich in iodine. Amiodarone can often cause hypothyroidism, particularly in patients with underlying autoimmune thyroid disease. In other patients, it can cause thyrotoxicosis through either transient thyroiditis or the Jod-Basedow effect.

SIMPLE GOITER (COLLOID GOITER)

Some children with euthyroid goiters have a simple goiter, a condition of unknown cause not associated with thyroid dysfunction and not caused by inflammation or neoplasia. Simple goiter is more common in girls, may be familial, and has its peak incidence during adolescence. Histologic examination of the thyroid either is normal or reveals variable follicular size, dense colloid, and flattened epithelium. The size of the goiter is variable. It can occasionally be firm, asymmetric, or nodular. Levels of TSH are normal, thyroid scintigraphy is normal, and thyroid antibodies are absent. Simple goiters usually decrease in size gradually over several years, without treatment. Patients should be reevaluated periodically because some have antibody-negative autoimmune thyroiditis and therefore are at risk for changes in thyroid function (see Chapter 604).

MULTINODULAR GOITER

Multinodular goiter is usually a firm goiter with a lobulated surface and one or more palpable nodules. Areas of cystic change, hemorrhage, and fibrosis may be present. The incidence of this condition has decreased markedly with the use of iodine-enriched salt. Ultrasonographic examination can reveal multiple nodules that are nonfunctioning on thyroid scintigraphy. Thyroid function is usually normal. Some children with autoimmune thyroiditis develop a multinodular goiter, and in such cases, thyroid antibodies may be present, and TSH may be elevated. If hypofunctioning nodules within a multinodular goiter grow to a significant size (≥1 cm) or have suspicious sonographic features, fine needle aspiration should be considered to rule out malignancy (see Chapter 607). Children with **McCune-Albright syndrome** or TSH receptor–activating mutations can develop a toxic multinodular goiter, characterized by suppressed TSH, hyperthyroidism, and multiple hyperfunctioning nodules.

TOXIC GOITER (HYPERTHYROIDISM)

See Chapter 606.

Chapter 606

Thyrotoxicosis

Jessica R. Smith and Ari J. Wassner

Although the terms *hyperthyroidism* and *thyrotoxicosis* are often interchanged in the literature, they are not synonymous. **Hyperthyroidism** specifically refers to the synthesis and secretion of excess thyroid hormone from the thyroid gland; in contrast, **thyrotoxicosis** refers to any state of excess circulating thyroid hormone (and its clinical manifestations) regardless of its source. This distinction is physiologically and clinically relevant because different therapies may be indicated depending on the mechanism of thyroid hormone excess.

Graves disease is the most common cause of hyperthyroidism in children (Table 606.1). It is an autoimmune disorder that results in the production of thyrotropin (TSH) receptor–stimulating antibodies (TRSAbs) that bind and activate the G protein–coupled TSH receptor (TSHR) to cause increased thyroid hormonogenesis and diffuse glandular growth. In infants born to mothers with Graves disease, hyperthyroidism can be caused by transplacental passage of TRSAbs, but this is transitory and resolves when TRSBAbs are cleared from the neonate's circulation. Etiologies of nonautoimmune hyperthyroidism include hyperfunctioning thyroid nodules and germline gain-of-function pathogenic variants in the TSHR (either autosomal dominant or sporadic). Hyperthyroidism can also occur in patients with **McCune-Albright syndrome** because of an activating pathogenic variant of the stimulatory α-subunit of the G protein. These patients can also develop a multinodular goiter. Other rare causes of hyperthyroidism include iodine-induced hyperthyroidism, TSH-secreting adenomas, toxic multinodular goiters, and hyperfunctioning thyroid carcinoma. Thyrotoxicosis not caused by hyperthyroidism (i.e., not the result of overproduction of thyroid hormone by the gland) can be caused by thyroiditis (see Chapter 604) or ingestion of exogenous thyroid hormone. Choriocarcinoma, hydatidiform mole, and struma ovarii can cause hyperthyroidism but are rarely diagnosed in children.

Laboratory evaluation of primary thyrotoxicosis reveals suppression of serum TSH and elevation of serum total thyroxine (T_4) and/or total triiodothyronine (T_3) levels. Elevated T_4 and T_3 with normal or elevated TSH suggests hyperthyroidism caused by inappropriate TSH secretion, which may be caused by a dominant-negative pathogenic variant in thyroid hormone receptor-β *(THRB)* resulting in **resistance to thyroid hormone (RTH)**. TSH-secreting pituitary tumors are extremely rare in the pediatric population. Elevated T_4 and/or T_3 levels with normal TSH may also be caused by abnormalities of thyroid hormone–binding proteins such as **thyroxine-binding globulin** excess or **familial dysalbuminemic hyperthyroxinemia**. In such cases, free T_4 levels are normal, and patients are euthyroid.

606.1 Graves Disease

Jessica R. Smith and Ari J. Wassner

EPIDEMIOLOGY

Graves disease occurs in approximately 0.02% of children (1:5,000) and is the most common cause of pediatric hyperthyroidism. It has a peak incidence in the 11- to 15-year-old age-group, and there is a 5:1 female:male ratio. Many children with Graves disease have a family history of autoimmune thyroid disease. Although rare in very young children, Graves disease has been reported between 6 weeks and 2 years of age in children born to mothers without a history of hyperthyroidism.

ETIOLOGY

Graves disease is a form of autoimmune thyroid disease characterized by infiltration of the thyroid gland by T-helper cells ($CD4^+$), cytotoxic T cells ($CD8^+$), and activated B lymphocytes. A postulated failure of T suppressor cells allows the expression of T helper cells sensitized to the TSH antigen to interact with B cells, which

Table 606.1 Pathogenic Mechanisms and Causes and Effects of Thyrotoxicosis

Thyrotoxicosis with hyperthyroidism (normal or high radioactive iodine uptake)	
EFFECT OF INCREASED THYROID STIMULATORS	
TSH-receptor antibody	Graves disease
Inappropriate TSH secretion	TSH-secreting pituitary adenoma; resistance to thyroid hormone β
Excess hCG secretion	Trophoblastic tumors (choriocarcinoma or hydatidiform mole); hyperemesis gravidarum
AUTONOMOUS THYROID FUNCTION	
Activating pathogenic variant in TSH receptor or $G_s\alpha$ protein	Solitary hyperfunctioning adenoma; multinodular goiter; familial nonautoimmune hyperthyroidism
Thyrotoxicosis without hyperthyroidism (low radioactive iodine uptake)	
INFLAMMATION AND RELEASE OF STORED HORMONE	
Autoimmune destruction of thyroid gland	Autoimmune thyroiditis; postpartum thyroiditis
Viral infection*	Subacute (painful) thyroiditis (de Quervain thyroiditis)
Toxic drug effects	Drug-induced thyroiditis (amiodarone, lithium, interferon-α)
Bacterial or fungal infection	Acute suppurative thyroiditis
Radiation	Radiation thyroiditis
EXTRATHYROIDAL SOURCE OF HORMONE	
Excess intake of thyroid hormone	Excess exogenous thyroid hormone (iatrogenic or factitious)
Ectopic hyperthyroidism (thyroid hormone produced outside the thyroid gland)	Struma ovarii; functional thyroid cancer
Ingestion of contaminated food	Hamburger thyrotoxicosis
EXPOSURE TO EXCESSIVE IODINE	
Jod-Basedow effect	Iodine-induced hyperthyroidism (radiocontrast agents or iodine in medications)

*Etiology is not definitive.
$G_s\alpha$, G protein alpha subunit; hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone.
Modified from De Leo S, Lee SY, Braverman LE. Hyperthyroidism. *Lancet.* 2016;388:906–916, Table 1.

Table 606.2 Conditions Associated with Graves Disease

Trisomy 21
Turner syndrome

differentiate into plasma cells that produce TRSAbs. TRSAbs bind to and activate the TSHR, resulting in thyroid hyperplasia and unregulated thyroid hormone synthesis. Some patients with Graves disease also produce TSH receptor–blocking antibodies (TRBAbs) that bind to and block activation of the TSHR. In these cases, the clinical course of the disease correlates to the ratio between stimulating and blocking antibodies.

Ophthalmopathy may occur in Graves disease and appears to be caused primarily by autoimmunity to the TSHR, which is also expressed in orbital adipocytes and fibroblasts. TRSAb-mediated activation of these cells stimulates the synthesis of glycosaminoglycans and cytokines, resulting in retro-orbital inflammation and edema. Although 50–75% of children with Graves disease have some eye findings, the symptoms are much milder than in adults; significant ophthalmopathy is rare.

Graves disease is associated with specific human leukocyte antigen (HLA) haplotypes. It is also associated with other HLA-related disorders, such as autoimmune adrenal insufficiency, type 1 diabetes mellitus, myasthenia gravis, and celiac disease (Table 606.2). Systemic lupus erythematosus, rheumatoid arthritis, vitiligo, idiopathic thrombocytopenic purpura, and pernicious anemia have also been described in children with Graves disease. In family clusters, the condition associated most commonly with Graves disease is autoimmune thyroiditis. Polymorphisms in the *TSHR* gene and numerous immunomodulatory genes—including *FOXP3, IL2RA, CD40, CTLA4, PTPN22,* and *FCRL3*—have also been associated with increased susceptibility to Graves disease.

CLINICAL MANIFESTATIONS

The clinical course of Graves disease is variable, and children typically take longer to remit than adults. Because symptoms develop gradually, the interval between onset and diagnosis is typically 6-12 months and may be longer in prepubertal children than in adolescents.

Signs and symptoms of Graves disease in children are shown in Figure 606.1 and Table 606.3. Tremulousness, headaches, mood disturbances, behavioral swings, difficulties with sleep, decreased attention span, hyperactivity, and a decline in school performance are all common findings in childhood. Many hyperthyroid children are referred for evaluation of attention-deficit/hyperactivity disorder (ADHD). Children with hyperthyroidism may show acceleration in growth velocity and advanced skeletal maturation. The effect on growth may be more pronounced if hyperthyroidism presents earlier in childhood. The onset of puberty does not appear to be altered by hyperthyroidism, but postmenarchal females can develop secondary amenorrhea. There may also be an increase in appetite with either failure to gain weight or overt weight loss. Polyuria and more frequent defecation (although not usually frank diarrhea) contribute to changes in weight. Because of the increased risk

Fig. 606.1 A 15-yr-old female with classic Graves disease. Clinical features include a goiter and exophthalmos. She was treated with antithyroid drugs, to which she had a good response.

of comorbid autoimmune disorders, screening for type 1 diabetes, celiac disease, and inflammatory bowel disease should be considered in patients who present with these symptoms.

Most children with Graves disease have a diffuse goiter. The size of the thyroid is variable, but it is typically smooth and without nodules. A bruit can occasionally be auscultated over a markedly enlarged gland. Ocular manifestations can produce proptosis, pain, eyelid erythema, chemosis, decreased extraocular muscle function and decreased visual acuity (corneal or optic nerve involvement) (Table 606.4). In children with thyrotoxicosis and diffuse goiter, identifying these signs of ophthalmopathy on physical examination strongly suggests the diagnosis of Graves disease. However, stare and lid lag are eye findings caused by increased sympathetic activity and can be seen in thyrotoxicosis of any cause, not only Graves disease (Fig. 606.2). In general, ocular symptoms in children with Graves disease tend to be mild and improve with the restoration of euthyroidism.

Children with hyperthyroidism have an increase in cardiac output. Tachycardia, palpitations, increased systolic blood pressure, and a widened pulse pressure are common cardiac manifestations, whereas cardiac enlargement and insufficiency and atrial fibrillation are rare complications.

The skin is smooth and flushed, with excessive sweating. Occasionally, associated vitiligo or psoriasis can be present. Graves dermopathy, characterized by indurated, nonpitting edema often on the anterior shins (pretibial myxedema), is rare in children. Proximal muscular weakness may be present. Thyroid hormone stimulates bone resorption, leading to low bone density and increased fracture risk in patients with chronic hyperthyroidism. Bone density returns to normal with treatment.

Table 606.3 Clinical Manifestation of Thyrotoxicosis

	SYMPTOMS	SIGNS
Constitutional	Weight loss despite increased appetite; heat-related symptoms (heat intolerance, sweating, and polydipsia)	Weight loss
Neuromuscular	Tremor; nervousness; anxiety; fatigue; weakness; disturbed sleep; poor concentration	Tremor of the extremities; hyperactivity; hyperreflexia; pelvic and girdle muscle weakness
Cardiovascular	Palpitations	Tachycardia; systolic hypertension
Pulmonary	Dyspnea, shortness of breath	Tachypnea
Gastrointestinal	Hyperdefecation; nausea, vomiting	Abdominal tenderness
Skin	Increased perspiration	Warm and moist skin
Reproductive		Menstrual disturbances
Ocular (Graves disease)	Diplopia; sense of irritation in the eyes; eyelid swelling; retro-orbital pain or discomfort	Proptosis; eyelid retraction and lag; periorbital edema; conjunctival injection and chemosis; ophthalmoplegia

From De Leo S, Lee SY, Braverman LE. Hyperthyroidism. *Lancet.* 2016;388:906–916, Table 2.

Table 606.4 Clinical Assessment of the Patient with Graves Ophthalmopathy

ACTIVITY MEASURES*
- Spontaneous retrobulbar pain
- Pain on attempted up or down gaze
- Redness of the eyelids
- Redness of the conjunctivae
- Swelling of the eyelids
- Inflammation of the caruncle and/or plica
- Conjunctival edema

SEVERITY MEASURES
- Lid aperture (distance between the lid margins in millimeters with the patient looking in the primary position, sitting relaxed, and with distant fixation)
- Swelling of the eyelids (absent/equivocal, moderate, severe)
- Redness of the eyelids (absent/present)
- Redness of the conjunctivae (absent/present)
- Conjunctival edema (absent, present)
- Inflammation of the caruncle or plica (absent, present)
- Exophthalmos (measured in millimeters using the same Hertel exophthalmometer and the same intercanthal distance for an individual patient)
- Subjective diplopia score†
- Eye muscle involvement (ductions in degrees)
- Corneal involvement (absent/punctate keratopathy/ulcer)
- Optic nerve involvement (best corrected visual acuity, color vision, optic disc, relative afferent pupillary defect (absent/present), plus visual fields if optic nerve compression is suspected

*Based on the classic features of inflammation in Graves ophthalmopathy.
†Subjective diplopia score: 0, no diplopia; 1, intermittent (i.e., diplopia in primary position of gaze, when tired or when first awakening); 2, inconstant (i.e., diplopia at extremes of gaze); 3, constant (i.e., continuous diplopia in primary or reading position). The clinical activity score (CAS) is the sum (1 point each) of all items present; a CAS ≥3/7 indicates active ophthalmopathy.
From Davies TF, Laurberg P, Bahn RS. Hyperthyroid disorders. In: Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, eds. *Williams Textbook of Endocrinology,* 13th ed. Philadelphia: Elsevier; 2016: Table 12.4.

Thyroid storm is an extreme form of hyperthyroidism characterized by severely elevated thyroid hormone levels, hyperthermia, tachycardia, heart failure, altered mental status, and GI symptoms (Table 606.5). If untreated, there may be rapid progression to delirium, coma, and death. Precipitating events include trauma, infection, radioactive iodine (RAI) treatment, or surgery.

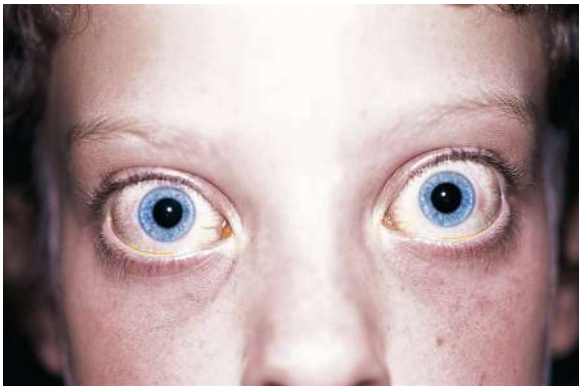

Fig. 606.2 Retraction of upper eyelids in the primary gaze (Dalrymple sign). *(From Kanski JJ. Systemic Diseases and the Eye: Signs and Differential Diagnosis. London: Mosby; 2001.)*

LABORATORY FINDINGS

In Graves disease, serum TSH is suppressed and free T_4 and T_3 are elevated. Most patients with Graves disease have measurable TRSAbs at diagnosis. TRSAbs can be measured either by a functional assay (thyroid-stimulating immunoglobulin [TSI]) that assesses the presence of antibodies capable of stimulating TSHR-mediated cyclic adenosine monophosphate (cAMP) generation, or by a competitive binding assay (thyrotropin-binding inhibitory immunoglobulin [TBII]) that assesses the presence of antibodies that bind to the TSHR, regardless of their effect on receptor activity. In a patient with thyrotoxicosis, both assays are highly sensitive and specific for Graves disease.

When the diagnosis cannot be established by history, physical examination, and laboratory evaluation, RAI uptake can be measured, preferably using ^{123}I. RAI uptake is elevated in Graves disease, whereas it is low in other causes of thyrotoxicosis like thyroiditis or exogenous thyroid hormone ingestion. If scintigraphy is also performed, the increased RAI uptake in Graves disease is present diffusely throughout the gland, whereas focally increased uptake is observed in hyperfunctioning thyroid nodules.

DIFFERENTIAL DIAGNOSIS

Elevated serum levels of T_4 or free T_4 and T_3 in association with suppressed levels of TSH are diagnostic of thyrotoxicosis (see Table 606.1).

Table 606.5 Diagnostic Criteria for Thyroid Storm

	POINTS
TEMPERATURE °F (°C)	
99-99.9 (37.2-37.7)	5
100-100.9 (37.8-38.2)	10

In adults, a score ≥45 is highly suggestive of thyroid storm; a score of 25-44 is suggestive of impending thyroid storm; a score of <25 is unlikely to represent thyroid storm.
Data are from HB Burch, L Wartofsky. Life-threatening thyrotoxicosis. Thyroid storm. *Endocrinol Metab Clin North Am.* 1993;22:263–277. From De Leo S, Lee SY, Braverman LE. Hyperthyroidism. *Lancet.* 2016;388:906–916, Table 3.

The combination of diffuse goiter and prolonged thyrotoxicosis (>8 weeks) is most often caused by Graves disease; the presence of circulating TSHR antibodies or characteristic eye or skin changes is diagnostic.

If the etiology of thyrotoxicosis is unclear, ^{123}I radioiodine uptake can distinguish hyperthyroidism (increased uptake) from other causes of thyrotoxicosis, which will determine the appropriateness of antithyroid medication. If a discrete thyroid nodule is palpated, ^{123}I scintigraphy should be performed to assess for a hyperfunctioning nodule. Some children with toxic multinodular goiter may have a TSHR-activating pathogenic variant or McCune-Albright syndrome. If precocious puberty, polyostotic fibrous dysplasia, or café-au-lait macules are present, then McCune-Albright syndrome is likely.

Patients with thyroid hormone resistance have elevated levels of free T_4 and T_3, but levels of TSH are inappropriately elevated or normal. They must be differentiated from patients with TSH-secreting pituitary tumors who have elevated serum levels of the common α-subunit shared by TSH, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and human chorionic gonadotropin (hCG). Most other causes of elevated serum T_4 are uncommon but can result in an erroneous diagnosis. Patients with elevated thyroxine-binding globulin levels or familial dysalbuminemic hyperthyroxinemia have high serum T_4 but normal levels of free T_4 and TSH and are clinically euthyroid. Rare patients with pathogenic variants in *SLC16A2* (encoding the MCT8 thyroid hormone transporter) or *THRA* (encoding thyroid hormone receptor α) can present with high serum T_3, inappropriately normal or high TSH, and low or low-normal serum T_4 concentrations.

When thyrotoxicosis is caused by exogenous thyroid hormone, free T_4 and TSH levels are the same as those seen in Graves disease, but in contrast to Graves disease, thyroid size is small, serum thyroglobulin is very low, and ^{123}I radioiodine uptake is suppressed.

TREATMENT

Antithyroid Drugs

In most cases, antithyroid drugs (ATDs) are the preferred initial therapy for Graves disease in children. Alternative treatments include radioiodine ablation (in children older than 10 years of age) and thyroidectomy. Each therapeutic option has advantages and disadvantages (Table 606.6). Methimazole is the first-line ATD for children with Graves disease and functions by blocking the organification of iodide necessary to synthesize thyroid hormone. Methimazole has a long serum half-life (6-8 hours) that allows once- or twice-daily dosing. Propylthiouracil is similar to methimazole, but its use is not recommended in children because of its potential to cause liver failure. However, in rare instances of severe hyperthyroidism in which methimazole cannot be used, a short course of propylthiouracil may be offered to restore euthyroidism before definitive therapy.

Adverse reactions can occur with ATDs and range from mild to life-threatening. Minor adverse effects occur in approximately 10–20% of patients, and severe adverse effects occur in 2–5%. Reactions most commonly occur during the first 3 months of therapy but can occur at any time. Transient urticaria is common and may be managed with antihistamines or by a short period off therapy followed by restarting ATD. Agranulocytosis is a severe adverse reaction that occurs in 0.1–0.5% of patients and can lead to a fatal infection. Therefore during any episode of significant fever, pharyngitis, or oral ulcers, patients should stop taking methimazole and have an absolute neutrophil count checked. On the other hand, transient, asymptomatic granulocytopenia (<2,000/mm^3) is common in Graves disease; it is not a harbinger of agranulocytosis and is not a reason to discontinue treatment. Other severe reactions include hepatitis (0.2–1.0%), a lupus-like polyarthritis syndrome, glomerulonephritis, and antineutrophilic cytoplasmic antibody–positive vasculitis. Severe liver disease, including liver failure requiring transplantation, has been reported with propylthiouracil. The most common liver disease associated with methimazole is cholestatic jaundice, which is reversible when the drug is discontinued. Patients with severe adverse effects should be treated with radioiodine or thyroidectomy. Importantly, methimazole and propylthiouracil have been associated with congenital malformations in infants exposed to these drugs in utero. Methimazole exposure may be associated with aplasia cutis, omphalocele, choanal atresia,

Table 606.6 Treatments for Graves Disease

TREATMENT	ADVANTAGE	DISADVANTAGE	COMMENT
Antithyroid drugs	Noninvasive Less initial cost No risk of permanent hypothyroidism Possible remission	Remission rate 30–50% (with long-term treatment) Adverse drug reactions Drug compliance required	First-line treatment in children and adolescents
Radioactive iodine (^{131}I)	Cure of hyperthyroidism	Permanent hypothyroidism Might worsen ophthalmopathy Pregnancy must be deferred for 6-12 mo, mother cannot breastfeed; small potential risk of exacerbation of hyperthyroidism	No evidence for infertility or birth defects with currently recommended doses
Surgery	Rapid, effective (especially in patients with large goiter)	Most invasive therapy Potential complications (recurrent laryngeal nerve damage, hypoparathyroidism) Permanent hypothyroidism Pain, surgical scar	Useful when coexisting suspicious nodule is present or thyromegaly is massive Option for patients who do not desire radioiodine

Modified from Cooper DS. Hyperthyroidism. *Lancet.* 2003;362:459–468.

Table 606.7 Management of Thyroid Storm in Adolescents

GOAL	TREATMENT
Inhibition of thyroid hormone formation and secretion	Propylthiouracil 400 mg q8h PO/IV/NGT Saturated solution of potassium iodide, 3 drops every 8 hr
Sympathetic blockade	Propranolol 20-40 mg q4-6h or 1 mg IV slowly (repeat doses until heart rate slows); not indicated in patients with asthma or heart failure that is not rate related
Glucocorticoid therapy	Prednisone 20 mg bid
Supportive therapy	Intravenous fluids (depending on indication: glucose, electrolytes, multivitamins) Temperature control (cooling blankets, acetaminophen; avoid salicylates) O_2 if required Digitalis for heart failure and to slow ventricular response; pentobarbital for sedation Treatment of precipitating event (e.g., infection)

From Goldman L, Ausiello D, eds. *Cecil Textbook of Medicine,* 22nd ed. Philadelphia: WB Saunders; 2004:1401.

and urinary system malformations, whereas propylthiouracil may be associated with malformations of the head, neck, and urinary system.

The initial dosage of methimazole is 0.5-1.0 mg/kg/24 hr (max 40 mg/day) administered once or twice daily. Smaller initial dosages should be used in early childhood or for mild disease. Careful surveillance is required after treatment is initiated. Low serum free T_4 or elevated serum TSH indicates overtreatment and warrants a dose reduction. The clinical response becomes apparent in 3-4 weeks, and adequate control is typically evident within 2-4 months. The dose is slowly decreased to the minimal level required to maintain a euthyroid state.

Most studies report a remission rate of approximately 25% after 2 years of ATD treatment in children. However, extended treatment appears to be associated with higher remission rates of 30–50% after 4-10 years of drug treatment. Among patients who remit, relapse may occur, often within 6-12 months after therapy has been discontinued. In cases of relapse, ATD therapy may be resumed, or definitive therapy with radioiodine or thyroidectomy can be pursued. Rituximab has been used as an adjuvant therapy for difficult-to-treat Graves disease.

Thyroid hormones potentiate the actions of catecholamines, leading to symptoms of tachycardia, tremor, excessive sweating, lid lag, and stare. *To ameliorate cardiovascular symptoms, a β-adrenergic blocking agent such as propranolol or atenolol is a useful initial supplement to ATDs.* However, these agents do not alter thyroid function or treat Graves ophthalmopathy. Table 606.7 lists additional therapies for **thyroid storm**.

Definitive Therapy

Radioiodine ablation or thyroidectomy is indicated when medical management is not possible because of patient nonadherence or severe side effects of ATDs, when an adequate trial of medical management has failed to result in remission, or if the patient prefers definitive therapy.

Radioiodine ablation with ^{131}I is an effective therapy for Graves disease in children. In patients with severe hyperthyroidism, euthyroidism should be restored with methimazole before radioiodine ablation to deplete the gland of preformed hormone and reduce the risk of a thyrotoxic flare from radiation thyroiditis. If a patient is taking methimazole, it should be stopped 3-5 days before radioiodine administration. The goal of radioiodine ablation is to administer a sufficient dose of radioiodine to ensure complete ablation of thyroid tissue. Some centers measure radioiodine uptake before treatment and use this to calculate an ^{131}I dose that delivers an absorbed thyroid dose of >150 μCi/g thyroid tissue (based on thyroid gland mass estimated by clinical examination or ultrasound). Alternatively, an empiric fixed dose of ^{131}I (usually 10-15 mCi) can be offered. The theoretical advantage of calculated doses is that they define the lowest administered dose for each patient who achieves the therapeutic target. This benefit is most important in small children because the absorbed radiation dose to the bone marrow and other normal tissues is inversely proportional to body size. Based on this concept and theoretical modeling of radiation exposure, ^{131}I therapy should be avoided in children younger than 5 years of age. It should be used in children between 5 and 10 years of age if the administered dose is <10 mCi. Radioiodine ablation has a low failure rate (5–20%), and

patients with persistent hyperthyroidism more than 6 months after their first ^{131}I therapy can be offered retreatment.

Thyroidectomy is a safe procedure when performed by an experienced surgeon. Thyroid surgery should be performed only after the patient has been rendered euthyroid with methimazole. A saturated solution of potassium iodide (SSKI; 1-3 drops, 2-3 times per day) may be added for 7-14 days before surgery to decrease the vascularity of the gland. Complications of surgical treatment include hypoparathyroidism (transient or permanent) and paralysis of the vocal cords. Total or near-total thyroidectomy should be performed rather than a less extensive subtotal resection. Patients become hypothyroid postoperatively, and recurrence of hyperthyroidism is rare. Referral to a surgeon with extensive experience in thyroidectomy and a low personal complication rate is paramount.

Graves **ophthalmopathy** usually remits gradually and independently of hyperthyroidism, but control of ophthalmopathy is facilitated by maintaining consistent euthyroidism. Severe ophthalmopathy can require treatment with high-dose glucocorticoids, orbital radiotherapy, or orbital decompression surgery. Teprotumumab, a human monoclonal antibody against the insulin-like growth factor 1 receptor (IGF-1R) is effective in adults with ophthalmopathy. Cigarette smoking is a risk factor for thyroid eye disease and should be avoided or discontinued to avoid progression of eye involvement.

Fig. 606.3 Twins with neonatal hyperthyroidism confirmed by abnormal thyroid function tests. Clinical features include lack of subcutaneous tissue owing to a hypermetabolic state and a wide-eyed, anxious stare. They were given the diagnosis of neonatal Graves disease, but, in fact, their mother did not have Graves disease; they had persistent, not transient, hyperthyroidism. At age 8 years, they were treated with radioiodine. They are now believed to have had some other form of neonatal hyperthyroidism, such as a constitutive activation of the thyroid-stimulating hormone receptor.

606.2 Congenital Hyperthyroidism

Jessica R. Smith and Ari J. Wassner

Neonatal Graves disease is caused by transplacental passage of TRSAbs from mothers with a history of Graves disease. These mothers can have active Graves disease, Graves disease in remission, or a prior history of Graves disease treated with radioiodine ablation or thyroidectomy. Occasionally, there is a maternal history of autoimmune thyroiditis. High levels of TRSAb typically result in fetal and neonatal hyperthyroidism. However, if the mother has been treated with ATDs, the onset of hyperthyroidism may be delayed by 3-7 days postnatally until the ATD is metabolized by the neonate. If TRBAbs are also present, they may delay the onset of hyperthyroidism for several weeks or even cause neonatal hypothyroidism. Neonatal Graves disease typically remits spontaneously within 6-12 weeks but can persist longer, depending on the titer and rate of clearance of the TRSAbs (and TRBAbs, if present).

Neonatal hyperthyroidism occurs in approximately 2% of infants born to mothers with a history of Graves disease. Fetal tachycardia and goiter may suggest the diagnosis prenatally, and close ultrasound surveillance is recommended in mothers with uncontrolled hyperthyroidism, particularly in the third trimester. Elevated serum titers of TRSAb (more than 3 times the upper limit of normal) or a history of a prior child with neonatal thyroid dysfunction increases the likelihood of neonatal Graves disease.

CLINICAL MANIFESTATIONS

Many infants born with neonatal Graves disease are premature and have intrauterine growth restriction. Many infants also have a goiter, and tracheal compression can occur if the goiter is very large. Other signs and symptoms of neonatal Graves disease include stare, periorbital edema, retraction of the eyelids, hyperthermia, irritability, diarrhea, feeding difficulties, poor weight gain, tachycardia, heart failure, hypertension, hepatomegaly, splenomegaly, cholestasis, jaundice, thrombocytopenia, and hyperviscosity (Fig. 606.3). Laboratory evaluation shows suppressed serum TSH and elevated serum levels of T_4, free T_4, and T_3. TRSAbs are elevated at birth and typically resolve within 3 months of life. If symptoms and signs are not recognized and treated promptly, cardiac failure and death can occur. Permanent sequelae of neonatal hyperthyroidism can include craniosynostosis and developmental delay.

TREATMENT

Treatment should be initiated at the onset of symptoms to avoid short-term and long-term complications. Therapy consists of methimazole (0.5-1.0 mg/kg/24 hr given every 12 hr) and oral or intravenous administration of a nonselective β-adrenergic blocker such as propranolol to decrease sympathetic hyperactivity. In refractory cases, Lugol solution or potassium iodide (1-2 drops per day) can be added. The first dose of iodide should be given at least 1 hour after the first dose of ATD to prevent the iodide from being used for further thyroid hormone synthesis. If severe hyperthyroidism induces heart failure, parenteral fluid therapy, corticosteroids, and digitalization may be indicated. Once serum thyroid hormone levels begin to decrease, ATDs should be gradually tapered to keep the infant euthyroid. Occasionally, a block-and-replace method with concurrent ATD and thyroid hormone replacement therapy may be required to ensure euthyroidism.

Most cases of neonatal Graves disease remit by 3 months of age, but occasionally neonatal hyperthyroidism persists into childhood. Typically, there is a family history of hyperthyroidism. **Neonatal hyperthyroidism** *without* evidence for autoimmune disease in mother or infant may be caused by a gain-of-function pathogenic variant in the *TSHR* gene that results in constitutive activation of the receptor. This can be transmitted in an autosomal dominant manner or can occur sporadically. Neonatal hyperthyroidism has also been reported in patients with McCune-Albright syndrome because of an activating pathogenic variant of the G protein stimulatory α-subunit. Under these circumstances, hyperthyroidism recurs when ATDs are discontinued, and these children eventually must be treated with radioiodine or surgery.

PROGNOSIS

Advanced osseous maturation, microcephaly, and cognitive impairment occur when treatment of neonatal hyperthyroidism is delayed. Intellectual development is normal in most treated infants with neonatal Graves disease, although some have neurocognitive problems likely caused by in utero hyperthyroidism. Therefore neurocognitive development should be monitored throughout childhood. After the resolution of neonatal hyperthyroidism, some infants develop transient or permanent central hypothyroidism that requires thyroid hormone replacement, likely resulting from poorly understood changes in hypothalamic-pituitary-thyroid feedback caused by in utero hyperthyroidism.

Resistance to Thyroid Hormone

The actions of thyroid hormones are mediated by two thyroid hormone receptors (α and β), each with a unique tissue distribution. Inactivating pathogenic variants in each of these receptors gives rise to a distinct syndrome of resistance to thyroid hormone. Resistance to thyroid hormone β (RTHβ) is an *autosomal dominant* disorder caused by pathogenic variants in the *THRB* gene. Because this receptor mediates the normal feedback of thyroid hormone on the hypothalamus and pituitary, patients have elevated serum levels of T_4 and T_3, but serum TSH levels are inappropriately normal or elevated. Goiter is almost always present, but symptoms of thyroid dysfunction are variable among individuals. There may be clinical features of hypothyroidism such as developmental delay, growth retardation, delayed skeletal maturation, and some features of hyperthyroidism like tachycardia and hyperreflexia. Affected children have an increased prevalence of learning disabilities and ADHD. The clinical symptoms, goiter, and elevated thyroid hormone levels may be mistaken for Graves disease, but RTHβ is confirmed by the presence of normal or elevated (not suppressed) TSH levels. This condition must also be differentiated from a pituitary TSH-secreting tumor, which is not familial and in which serum levels of the common α-subunit are elevated.

More than 100 distinct variants in *THRB* have been identified in patients with RTHβ, and genotype-phenotype correlation is poor even among affected members of the same family. Nearly all mutations have a dominant-negative effect in which the variant receptor interferes with normal receptor action, leading to disease even in heterozygotes. Individuals carrying two mutant alleles are severely affected. A very rare *autosomal recessive* form of this disorder has been reported in individuals homozygous for a deletion of the *THRB* gene.

Treatment usually is not required unless growth and skeletal stunting are present. Different therapies, including levothyroxine and triiodothyroacetic acid, have been successful in some patients. Intermittent administration of T_3 may be useful for reducing goiter size. Symptoms of hyperthyroidism can be treated with β blockers, but ATDs or radioiodine ablation are generally not used because they increase TSH levels and goiter size.

Pathogenic variants in the *THRA* gene, which encodes thyroid hormone receptor α, have also been reported. *THRA* variants are dominant negative and cause RTHα in heterozygous individuals. Clinical symptoms are those of untreated primary hypothyroidism, including skeletal dysplasia with short stature and macrocephaly, developmental delay, constipation, bradycardia, and macrocytic anemia. Serum thyroid function tests show subtle abnormalities of low or low-normal T_4, high or high-normal T_3 (with elevated T_3/T_4 ratio), and normal TSH, as well as the unique finding of markedly low reverse T_3. Treatment has not been clearly established for RTHα.

Chapter 607

Carcinoma of the Thyroid

Jessica R. Smith and Ari J. Wassner

Carcinoma of the thyroid is rare in childhood, with an annual incidence in children younger than 15 years of approximately 4-5 in 100,000 cases. The incidence of childhood thyroid cancer increases with age and peaks in adolescence. Females are more commonly affected than males. Compared to adults, childhood thyroid cancers are characterized by significantly higher rates of metastasis and recurrence. Despite often being metastatic at discovery, most pediatric thyroid cancers with adequate treatment have a favorable outcome.

PATHOGENESIS

The majority of differentiated thyroid cancers are of follicular cell origin; **papillary carcinoma** (85–90%) is the most common subtype. Although their histologic features are similar, papillary thyroid cancers of childhood are genetically distinct from their adult counterparts. About 70% of adults with papillary thyroid cancer exhibit pathogenic somatic variants in *BRAF* or *RAS*; pediatric papillary thyroid cancers are more commonly caused by somatic gene fusion events involving the oncogenic tyrosine kinases *RET* or *NTRK1/3*. **Follicular carcinoma** (8%) is the next most common type of childhood thyroid cancer and is also derived from thyroid follicular cells. **Medullary carcinoma** (4%), derived from thyroid C cells, and anaplastic thyroid cancers are relatively rare.

Up to 10% of cases of follicular cell–derived thyroid cancers may be familial. Genetic syndromes associated with an increased risk of thyroid neoplasia include ***PTEN* hamartoma tumor syndromes** (Cowden, Bannayan-Riley-Ruvalcaba, and Proteus syndromes) characterized by macrocephaly, mucocutaneous lesions (fibromas), and breast cancer and endometrial tumors; **familial adenomatous polyposis** (pathogenic variant in *APC*); and ***DICER1* syndrome**, which includes tumors of the lung, kidney, female reproductive tract, and other organs. The evaluation of a child with a thyroid nodule should include a medical and family history to assess for features of these syndromes. In addition, some families have a strong history of nonsyndromic nonmedullary thyroid cancer, but no specific genetic causes have been confirmed.

The thyroid gland of children is susceptible to radiation exposure, particularly in very young patients. Even a low dose (1 Gy) of radiation exposure results in a 7.7-fold increased relative risk of thyroid cancer. In past decades, irradiation of the cervical region for benign conditions (e.g., enlarged thymus or tonsils, adenitis) was a predominant cause of thyroid cancer in children. Currently, therapeutic irradiation for other regional neoplasms or bone marrow transplantation and the increased survival of these children have made this cause of thyroid cancer increasingly prevalent. Higher radiation dose, younger age at the time of treatment, and female sex are additional risk factors for the development of thyroid cancer. The relative risk of thyroid cancer is highest after radiation doses of 5-30 Gy, above which the excess risk declines but does not disappear. In studies of cancer survivors treated with radiation, ~10–30% develop benign thyroid nodules. There is an increased incidence of thyroid cancer beginning within 3-5 years after radiation treatment and peaking after 15-25 years.

Autoimmune thyroiditis and Graves disease may be associated with an increased risk of thyroid cancer, but data remain conflicting.

Therefore thyroid nodules detected in patients with these disorders should be evaluated for possible thyroid cancer. Thyroid cancer has been reported rarely in children with congenital goiter or ectopic thyroid tissue.

CLINICAL MANIFESTATIONS

Thyroid cancer usually presents as a *painless nodule* in the anterior neck. Rapid growth and large size, firmness, fixation to adjacent tissues, hoarseness, dysphagia, or neck lymphadenopathy should heighten the concern for thyroid cancer. Cervical lymph node metastasis is common, so any unexplained cervical lymphadenopathy warrants examination of the thyroid.

The lungs are the most common site of distant metastasis. Pulmonary metastases are usually asymptomatic, and pulmonary function testing may be normal even with widespread metastases. Radiologically, metastases may appear as diffuse miliary or nodular infiltrations, typically greatest in the posterior basal lung fields. Other sites of metastasis, including bones and brain, are rare in children. Almost all children with thyroid cancer are euthyroid, but rarely is the carcinoma functional and produces clinical and laboratory evidence of hyperthyroidism.

DIAGNOSIS

Patients usually present with a neck mass, and thyroid ultrasound demonstrates a thyroid nodule and/or diffuse infiltration of the thyroid. Although several imaging features (including calcifications, irregular margins, and the presence of abnormal lymph nodes) are significantly associated with thyroid cancer risk, the absence of these features does not exclude the possibility of thyroid cancer. The appropriate technique for evaluating sonographically suspicious nodules is fine needle aspiration (FNA), which can detect the characteristic nuclear abnormalities of papillary thyroid carcinoma, which is the most common form. In most cases, operative pathology is required to confirm the diagnosis of thyroid cancer and to determine the extent of disease.

TREATMENT

The primary therapy for thyroid cancer is surgical resection. Because intrathyroidal spread is common in papillary thyroid cancer, near-total thyroidectomy is recommended. Before surgery, neck ultrasonography should be performed to assess for abnormal lymph nodes, and suspicious lymph nodes may be biopsied preoperatively to determine the need for lymph node dissection. In patients with metastatic thyroid cancer, adjunctive therapy may be required with radioactive iodine (^{131}I) to ablate unresectable thyroid cancer and thyroid-stimulating hormone (TSH) suppression with supraphysiologic levothyroxine to reduce TSH-stimulated growth of residual cancer cells.

PROGNOSIS

Although regional and distant metastases are more common in the pediatric population than in adults, most children with thyroid cancer have an excellent prognosis. Long-term survival from pediatric thyroid cancer is >97%, although the disease may recur in up to 15–20%. Even in children with pulmonary metastasis at diagnosis, 30-year survival is 90%, and many patients who cannot achieve complete cure remain asymptomatic with stable or slowly progressive cancer burden over many years. For rare children with aggressive cancers that progress despite conventional therapy, targeted molecular therapies directed at the underlying genetic pathogenic variants are available and effective in many cases. Psychosocial supports, including access to social work and mental health professionals, are essential in caring for children with thyroid cancer.

Children with thyroid cancer require lifelong monitoring because of the risk of disease recurrence years or decades after initial treatment. For most patients, serum thyroglobulin is a sensitive and specific cancer marker. Circulating autoantibodies to thyroglobulin can confound the measurement of thyroglobulin levels and should be measured whenever serum thyroglobulin is assayed. Because most thyroid cancer recurrences occur in the thyroid bed or cervical lymph nodes, surveillance should include serial neck ultrasounds. Patients with a higher risk of recurrence or with distant metastases may require additional anatomic imaging (such as chest CT), whole-body radioactive iodine scanning (^{123}I), or combined anatomic and functional imaging (SPECT/CT).

MEDULLARY THYROID CARCINOMA

Medullary thyroid carcinoma (MTC) arises from the parafollicular cells (C cells) of the thyroid and accounts for approximately 4% of thyroid malignancies in children. In children, the majority of MTC cases are hereditary, as part of the syndrome of **multiple endocrine neoplasia type 2** (MEN2; see Chapter 609). Activating pathogenic variants in the *RET* proto-oncogene are responsible for most cases of MTC. These variants occur in the germline in patients with MEN2, but somatic *RET* changes are present in many sporadic cases of MTC.

The most common presentation of sporadic MTC is an asymptomatic thyroid nodule. When MTC occurs sporadically, it is usually unicentric, but in the familial form it may be multicentric. MTC begins as hyperplasia of the parafollicular cells (*C cell hyperplasia*), which is often present histologically in thyroid glands removed prophylactically from patients with MEN2. The diagnosis of MTC can also be made by cytology after FNA of a thyroid nodule. Because C cells produce calcitonin, a high calcitonin concentration in an FNA specimen or in a patient's serum can help confirm the diagnosis of MTC. The diagnosis warrants genetic testing for a germline *RET* variant, and in variant-positive patients, screening for pheochromocytoma and hyperparathyroidism should be obtained before anesthesia for thyroidectomy.

The most important treatment for MTC is surgical resection. Preoperative evaluation should include neck ultrasound to identify potential lymph node metastases. Baseline serum levels of calcitonin and carcinoembryonic antigen (CEA) should be measured preoperatively, and higher levels are correlated with a greater likelihood of metastatic disease. Surgical treatment includes total thyroidectomy and lymph node dissection of any involved lymph node compartments. Complete resection is often curative, but this can be difficult to achieve in patients with metastatic disease. Surveillance with neck ultrasound and serum levels of calcitonin and CEA can assess for the presence or progression of residual disease. Other treatment modalities for advanced or metastatic disease include specific *RET* inhibitors, external beam radiation, and radiofrequency ablation.

607.1 Thyroid Nodules

Jessica R. Smith and Ari J. Wassner

The frequency of thyroid nodules increases with age. Sonographically detectable thyroid nodules are present in 19–67% of adults but in only 1–2% of children. Although the risk of malignancy in a thyroid nodule is higher in children (20–25%) than in adults (5–15%), the majority of thyroid nodules in children are benign.

Benign disorders that can present as a thyroid mass include benign adenomatous or colloid nodules and various congenital cysts (Table 607.1). A thyroid mass that appears suddenly or enlarges rapidly can indicate hemorrhage into a cyst, a benign adenoma, or an infectious process.

Evaluation of a child with a thyroid nodule should begin by measuring serum TSH. A low serum TSH suggests a possible hyperfunctioning (autonomous) thyroid nodule, which should be evaluated by scintigraphy (^{123}I or ^{99m}Tc-pertechnetate). Autonomous nodules generally are not malignant and do not require biopsy. Patients with a normal or elevated TSH should undergo neck ultrasound, and any sonographically suspicious nodule(s) of significant size should be evaluated by ultrasound-guided FNA

Table 607.1 Etiologic Classification of Solitary Thyroid Nodules

Lymphoid follicle, as part of autoimmune thyroiditis

Anaplastic carcinoma
Medullary carcinoma
Nonthyroidal
Lymphoma
Teratoma

(Fig. 607.1). Thyroid cytology is evaluated using a standardized system, most commonly the Bethesda System for Reporting Thyroid Cytopathology. Cytology may be interpreted as benign, positive for papillary thyroid cancer, indeterminate, or nondiagnostic. The predictive value of cytology for thyroid cancer varies by category and to some degree among institutions. In general, cytology positive for papillary thyroid cancer confers a >98% likelihood of cancer, and near-total thyroidectomy is appropriate. For a nodule of indeterminate cytology, lobectomy is commonly performed for definitive diagnosis; this may be followed by completion thyroidectomy if pathology shows a significant thyroid cancer. Molecular testing for oncogenic mutations may inform the management of certain indeterminate cytology. Patients with cytologically benign nodules have a low likelihood of malignancy and should be monitored with serial neck ultrasound. Surgical resection may be offered for benign nodules that cause symptoms, including dysphagia, globus sensation, or undesired appearance.

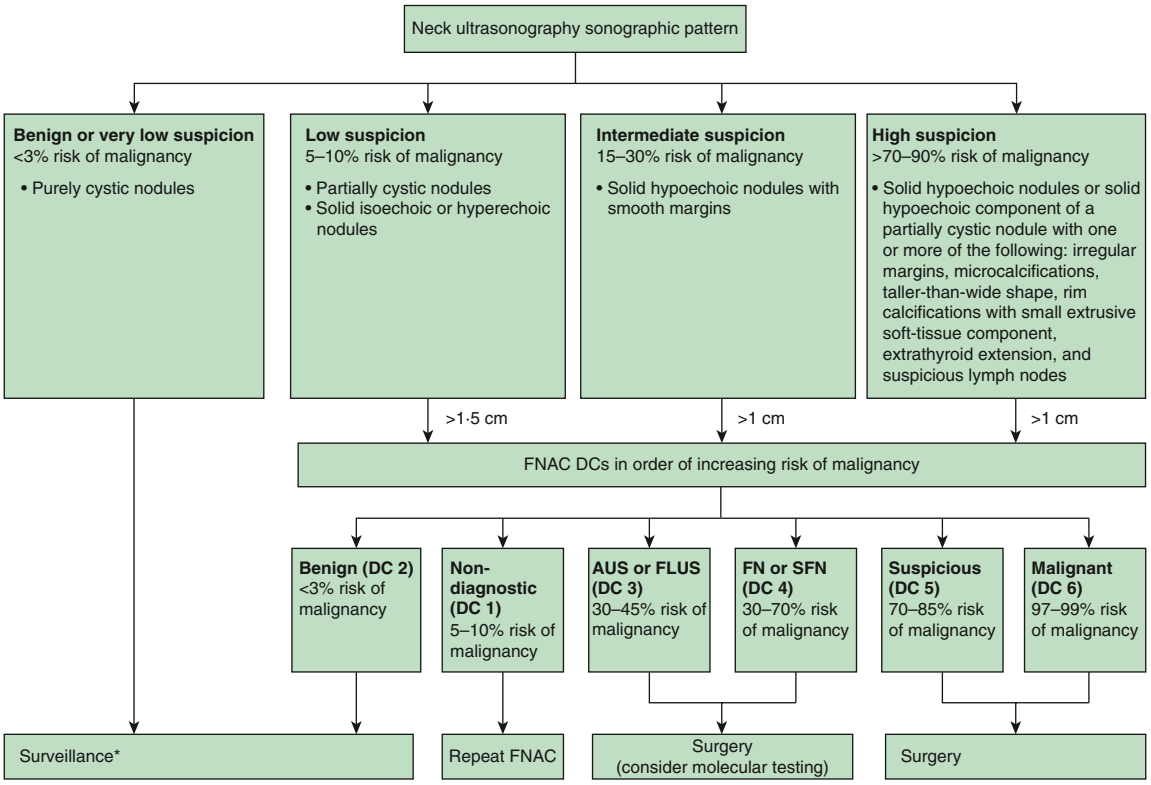

Fig. 607.1 Management algorithm for thyroid nodules based on sonographic patterns and cytology diagnostic categories of the Bethesda System. *Fine-needle aspiration can be considered (1) for nodules with a low-suspicion sonographic pattern and the largest diameter greater than 2 cm and (2) if there are suspicious clinical findings (e.g., firm mass, neck pain, cough, voice change, and a history of childhood neck irradiation or familial thyroid cancer), regardless of the sonographic appearances. AUS, Atypia of undetermined significance; DC, diagnostic category; FLUS, follicular lesion of undetermined significance; FN, follicular neoplasm; FNAC, fine needle aspiration cytology; SFN, suspicious for follicular neoplasm. *(From Cabanillas ME, McFadden DG, Durante C. Thyroid cancer. Lancet. 2016;388:2783–2794, Fig. 2.)*

Chapter 608

Autoimmune Polyglandular Syndromes

Christina M. Astley, Jessica R. Smith, and Ari J. Wassner

An **autoimmune polyglandular syndrome (APS)** occurs when autoimmunity is directed at multiple glands and/or nonendocrine organs, sometimes associated with **immune dysregulation**. Endocrine glands and other organs commonly affected by APS have unique autoantigens that increase these tissues' susceptibility to damage by an untamed immune response. Most autoimmune endocrinopathies are caused by cell-mediated immunity from autoreactive T cells. Antibodies to one or more autoantigens are commonly associated with specific autoimmune manifestations and are markers of immune dysregulation. These autoantibodies are directly pathogenic in some nonendocrine tissues, but this is rarely the case in autoimmune endocrine disease. A notable exception is the autoantibodies in Graves disease that cause primary hyperthyroidism by activating the thyroid-stimulating hormone receptor (TSHR).

APS caused by monogenic disorders of immune dysregulation (including APS type 1 [**APS-1**]) have heritable lesions in key aspects of immune tolerance (Table 608.1). Polygenic disorders associated with APS (APS type 2 [**APS-2**]) and some chromosomal abnormalities (e.g., trisomy 21) also result in an aberrant immune response that causes multiorgan autoimmunity. Nongenetic factors (e.g., immune **checkpoint inhibitors** for cancer therapy) may lead to autoimmune polyglandular disease. Although APS is uncommon, patients can experience significant morbidity, particularly if the syndrome is not identified early and managed appropriately. There may be 1-2 decades between the presentations of the first and subsequent endocrinopathy. *The presence of hypoparathyroidism, primary adrenal insufficiency, neonatal type 1 diabetes mellitus, chronic mucocutaneous candidiasis, immune dysregulation, or a family history should raise particular suspicion for APS.*

MONOGENIC AUTOIMMUNE POLYGLANDULAR SYNDROMES

The number of recognized monogenic defects of immune regulation leading to APS continues to grow (see Table 608.1). The best-characterized monogenic APSs are caused by pathogenic genetic variants that primarily affect central immune tolerance **(APS-1)** or the development of regulatory T cells (immune dysregulation polyendocrinopathy enteropathy X-linked, or **IPEX**). Other monogenic APSs (the so-called IPEX-like disorders) are caused by defects in regulatory T-cell suppression or signaling.

AUTOIMMUNE POLYGLANDULAR SYNDROME TYPE 1

APS-1 is an archetypal monogenic polyendocrinopathy syndrome. It is a rare, autosomal recessive disorder caused by loss-of-function variants in the autoimmune regulator gene *(AIRE)* on chromosome 21q22.3. *AIRE* plays a critical role in the presentation of self-antigens to developing T cells in the thymus, which normally leads to central immune tolerance by inducing apoptosis of T cells specific for these autoantigens (negative selection). *AIRE* also plays a role in the development of regulatory T cells (see Chapter 174). Therefore patients with APS-1 develop autoreactive T cells and autoantibodies directed at multiple tissues.

APS-1 is defined by the presence of at least two of three classic clinical features **(Whitaker triad)** of **chronic mucocutaneous candidiasis**, **hypoparathyroidism**, and primary **adrenal insufficiency**. These three manifestations tend to emerge over time—candidiasis before around 5 years of age, hypoparathyroidism around 10 years, and adrenal insufficiency around 15 years—but the precise order and age of onset of each component are variable. Most patients develop additional autoimmune manifestations over time, with skin and gastrointestinal disorders typically emerging before age 20 and other endocrine disorders after the second decade (see Table 608.1).

Nearly every endocrine gland may be affected by APS-1. The commonly affected glands include parathyroids and adrenals. Other glands affected, in decreasing order of frequency, are the ovaries, testes, thyroid, pancreatic β cells, and pituitary. A wide range of nonendocrine tissues can be affected, sometimes before the first endocrinopathy is detected. The commonly affected nonendocrine tissues are teeth and nails, and ectodermal dystrophy is present in most patients. For this reason, APS-1 has also been called **autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED)**. Other manifestations include gastrointestinal malabsorption, autoimmune hepatitis, pernicious anemia, vitiligo, and alopecia. APS-1 patients are at increased risk of infection, possibly related to a combination of cytokine autoantibodies, splenic dysfunction, and compromised gastrointestinal mucosal integrity. Mucocutaneous candidiasis is quite common and can lead to oral or esophageal cancer if not diagnosed and treated. Esophageal cancer, autoimmune hepatitis, adrenal crisis, and severe hypocalcemia are important causes of mortality in APS-1 patients. Therefore APS-1 patients require close clinical follow-up with a multidisciplinary team to manage disease manifestations. (Treatment of individual endocrinopathies and other manifestations are reviewed separately in the relevant chapters, including Chapters 280, 611, and 615).

The initial diagnosis of APS-1 generally is made clinically. Pathogenic *AIRE* variants can be detected in the majority of patients with clinical APS-1, and confirmation of the diagnosis by *AIRE* sequencing is indicated for any patient with known or suspected APS-1. APS-1 caused by pathogenic *AIRE* variants is more common in certain founder populations (e.g., Iranian Jews, Sardinians, Finns, and Norwegians reported a prevalence ranging from 1 in 9,000 to 1 in 90,000). Knowledge of the specific pathogenic variant facilitates clinical and genetic counseling, including testing of family members. *AIRE* variants with autosomal dominant inheritance and an atypical APS-2–like clinical presentation (especially with pernicious anemia or vitiligo) have been reported. APS-1 patients without identifiable *AIRE* variants may benefit from further evaluation (e.g., immune dysregulation gene panel, whole exome sequencing, imaging for thymoma).

The clinical presentation of APS-1 is variable, even within families with the same *AIRE* variant, making it difficult to predict the disease course for affected individuals. Therefore patients with APS-1 should have regular screening for the development of new clinical manifestations. The importance of screening is illustrated by unexplained deaths in APS-1 patients or their siblings, presumably the result of undiagnosed manifestations such as adrenal insufficiency.

Multiple autoantibodies may be detectable in patients with APS-1 (Table 608.2). Many of these autoantibodies are also present in the corresponding single-organ autoimmune disease, but autoantibodies to some antigens (e.g., NALP5, interleukin-17 family cytokine, and type 1 interferons) are unique to APS-1. Measuring organ-specific autoantibodies has variable utility for predicting the onset of endocrine gland failure or other APS-1 manifestations. Therefore clinical suspicion, laboratory screening, and education about symptoms of evolving endocrinopathies and/or other APS-1 manifestations are paramount regardless of autoantibody status.

IMMUNE DYSREGULATION-POLYENDOCRINOPATHY-ENTEROPATHY X-LINKED

IPEX is caused by loss-of-function variants in *FOXP3,* which is located on the X chromosome (Xp11.23) (see Chapter 174). The inactivation of *FOXP3* results in impaired peripheral immune tolerance caused by impaired development of regulatory T cells, leading to the emergence of autoreactive T cells. The endocrinopathies commonly associated with IPEX are early-onset type 1 diabetes mellitus and autoimmune thyroiditis. *Any diagnosis of type 1 diabetes mellitus*

before 6-9 months of age should prompt consideration of a monogenic APS or a genetic cause of β-cell dysfunction. Patients with IPEX often have autoimmune enteropathy and eczematous dermatitis. They may also have other autoimmunity (e.g., liver, kidney, cytopenias) and allergic dysregulation (e.g., food allergy, peripheral eosinophilia). Therapy for IPEX consists of immune modulation with immunosuppressants (e.g., glucocorticoids, tacrolimus), novel therapeutics (e.g., abatacept), or stem cell transplantation.

OTHER MONOGENIC IMMUNE DYSREGULATION DISORDERS

Several other disorders involve failure of peripheral tolerance and emergence of autoimmunity, often with some degree of immune dysregulation. These disorders include loss-of-function genetic variants in *IL2RA* (CD25), *LRBA, CTLA4, STAT5b,* and gain-of-function variants in *STAT1* and *STAT3* that are pathophysiologically similar to IPEX. Broadly, patients with these **IPEX-like disorders** are at high risk of type 1 diabetes mellitus and autoimmune thyroiditis (see Table 608.1). They also have multiple nonendocrine diseases, especially autoimmunity and immunodeficiency affecting the skin, lungs, and gastrointestinal tract. *STAT5b* participates in the IL2/STAT5 signal transduction axis necessary for growth hormone signaling and may also affect prolactin secretion. Therefore patients with **STAT5b** defects may have nonautoimmune growth hormone insensitivity and hyperprolactinemia in addition to immune dysregulation, hypergammaglobulinemia, and multiple autoimmunity. ***STAT1*** gain-of-function variants inhibit the normal production of Th17 cytokines, which leads to chronic mucocutaneous candidiasis. These patients also have increased risk of infection, squamous cell cancer, enteropathy, and arterial aneurysms. Patients with **CD25** defects are also at increased risk of infection because interleukin (IL)-2 signaling plays a role in Th17 responses. Many IPEX-like patients develop nonautoimmune endocrinopathies, including iatrogenic adrenal insufficiency, dysglycemia, hypocalcemia, poor bone health from high-dose glucocorticoid therapy, chronic inflammation/infection, and/or malabsorption/malnutrition.

POLYGENIC AUTOIMMUNE POLYGLANDULAR SYNDROME

APS-2 is a clinical syndrome defined by the presence of two or more syndrome-specific endocrinopathies: autoimmune primary adrenal insufficiency (Addison disease), autoimmune thyroid disease (Hashimoto thyroiditis or Graves disease), and/or type 1 diabetes mellitus. Some classification systems subdivide APS-2 according to the particular glands affected (e.g., subtype 2, 3, and 4 if adrenal, thyroid, or neither gland, respectively) or other autoimmune manifestations present (e.g., subtype 3A, 3B, and 3C if additional endocrine, gastrointestinal, or systemic autoimmunity are present, respectively). However, because there is no clear pathophysiologic distinction between these subtypes, they can be considered collectively as APS-2. When describing the characteristics of APS-2, it is important to recognize some degree of overlap between patients with clinical APS-2 and those with a single autoimmune endocrinopathy who may later develop another and be classified as APS-2.

Unlike monogenic APSs, which are rare diseases with early-childhood onset and a mendelian inheritance pattern, APS-2 is a common polygenic disease that usually manifests after the second decade in a patient with a personal or family history of autoimmune disease. APS-2 is most common in middle-age females (prevalence near 1 in 20,000). Primary gonadal insufficiency, vitiligo, alopecia, and chronic atrophic gastritis (with or without pernicious anemia) can occur. Autoimmune hypoparathyroidism and candidiasis are not typical of APS-2 and should prompt consideration of APS-1.

Addison disease is uncommon in the general population (prevalence near 1 in 10,000). However, patients with this condition are at high risk of developing additional endocrine autoimmunity constituting APS-2. Two thirds will have evidence of additional subclinical or clinical autoimmunity. Patients with Addison disease should have close follow-up, screening, and education about other autoimmune manifestations. About half of patients with Addison disease have autoimmune thyroid disease (**Schmidt syndrome**), and about 10% have type 1 diabetes mellitus **(Carpenter syndrome**). Less frequent comorbid autoimmune manifestations include Graves disease, ovarian insufficiency, alopecia, vitiligo, pernicious anemia, or celiac disease.

APS-2 develops less frequently in patients with type 1 diabetes mellitus than in those with Addison disease. Nevertheless, many patients with type 1 diabetes develop additional autoimmunity, and comorbid autoimmune thyroid and gastrointestinal disease are much more common (each about 20%) than comorbid adrenal disease (<1%). Because thyroxine and cortisol affect insulin sensitivity, metabolism, and appetite, unexplained hypoglycemia or deterioration in glycemic control may be the first clinical sign of APS-2 in a patient with preexisting type 1 diabetes mellitus. Unexplained hypoglycemia may also signal the onset of celiac disease. Indeed, **celiac disease** often precedes the onset of autoimmune endocrinopathies, including type 1 diabetes mellitus, hypothyroidism, and Addison disease.

The development of APS-2 in individuals with autoimmune thyroid disease is relatively infrequent. Nevertheless, the clinician should consider the possibility of adrenal insufficiency before treating

Table 608.2 Autoantibodies Present in Autoimmune Polyglandular Syndromes and in Isolated Autoimmune Endocrinopathies

TISSUE OR GLAND	AUTOANTIGEN	DISEASE MANIFESTATION	NOTE
AUTOIMMUNE ENDOCRINOPATHIES			
Adrenal	CYP21A2, CYP11A1, CYP17A1	Primary adrenal insufficiency	Of the adrenal autoantibodies, CYP21A2 is most strongly associated with adrenal insufficiency. Higher risk of progression to adrenal insufficiency in children with positive adrenal autoantibodies (over 80%) compared with adults (near 20%). Adrenal autoantibodies detected in 50% of pediatric hypoparathyroidism and 1% of pediatric type 1 diabetes
Thyroid	TPO, Tg	Autoimmune thyroiditis (hypothyroidism)	Frequently positive without clinical thyroid disease
	TSHR	Graves disease (hyperthyroidism)	Only endocrine autoantibody that directly causes autoimmune endocrinopathy
Pancreatic β cell	IA-2, GAD65, insulin, ZnT8	Type 1 diabetes mellitus	Risk of type 1 diabetes increases with the number of positive autoantibodies; IA-2, but not GAD65, autoantibodies associated with time to type 1 diabetes diagnosis in APS-1
Parathyroid	NALP5, CaSR	Hypoparathyroidism	NALP5 antibodies are present only in hypoparathyroidism caused by APS-1
Gonad	CYP11A1, CYP17A1, NALP5 and TSGA10	Gonadal insufficiency	CYP11A1 antibodies associated with gonadal insufficiency in APS-1
Pituitary	TDRD6	Hypophysitis	Poorly predictive of clinical pituitary disease
NONENDOCRINE DISEASE			
Cytokines	IFN-ω, IFN-α, IL-22, IL-17F	APS-1	IFN-ω autoantibodies are 100% sensitive and 99% specific for APS-1; IL-22 autoantibodies associated with time to diagnosis and diagnosis of candidiasis in APS-1
Gastric	IF, H+/K+ ATPase	Pernicious anemia, autoimmune gastritis	IF autoantibodies associated with time to B_{12} deficiency in APS-1
Small intestine	TTG, gliadin	Celiac disease	
Gastrointestinal	TPH, GAD65	Intestinal dysfunction	TPH autoantibodies associated with time to intestinal dysfunction in APS-1. Both autoantibodies associated with diagnosis of intestinal dysfunction in APS-1

Continued

Table 608.2 Autoantibodies Present in Autoimmune Polyglandular Syndromes and in Isolated Autoimmune Endocrinopathies—cont'd

TISSUE OR GLAND	AUTOANTIGEN	DISEASE MANIFESTATION	NOTE
Liver	CYP1A2, TPH, AADC	Autoimmune hepatitis	TPH autoantibodies associated with diagnosis of autoimmune hepatitis in APS-1
Skin melanocytes	Tyrosinase, SOX9, SOX10, AADC	Vitiligo	
Hair follicle	Tyrosine hydroxylase	Alopecia	
Lung	KCNRG, BPIFB1	Interstitial lung disease	Both autoantibodies present in 90–100% of APS-1 patients with interstitial lung disease and are associated with time to diagnosis

AADC, Aromatic L-amino acid decarboxylase; BPIFB1, bactericidal/permeability-increasing fold-containing B1; CaSR, calcium sensing receptor; CYP11A1, side chain cleavage enzyme; CYP17A1, 17-α-hydroxylase; CYP1A2, cytochrome P450 1A2; CYP21A2, 21-hydroxylase; GAD65, glutamic acid decarboxylase; IA-2, islet antigen-2; IF, intrinsic factor; IFN, interferon; IL, interleukin; KCNRG, potassium channel-regulating protein; NALP5, NACHT leucine-rich-repeat protein 5; TDRD6, Tudor domain containing protein 6; Tg, thyroglobulin; TPH, tryptophan hydroxylase; TPO, thyroid peroxidase; TSGA10, testis-specific gene 10 protein; TSHR, thyroid-stimulating hormone receptor; TTG, tissue transglutaminase; ZnT8, zinc transporter 8.

hypothyroidism in a patient with features suggestive of APS-2 because thyroid hormone replacement may precipitate **adrenal crisis** in this setting. Autoantibodies to specific tissues may be detectable and may prompt functional screening before the onset of overt clinical disease (see Table 608.2); however, the predictive value of these autoantibodies for the development of clinical disease is variable.

Aberrant T-cell responses probably play a role in the pathogenesis of multiple gland destruction present in APS-2. The risk of autoimmunity directed against the adrenal glands, thyroid gland, and islet cells appears to be shared across certain human leukocyte antigen (HLA) haplotypes and other immune-related genetic loci. However, the magnitude of this risk varies substantially for each endocrinopathy. The prevalence of HLA-D3 and HLA-D4 alleles is increased in patients with APS-2, and they appear to confer an increased risk for the development of this disease. Particular alleles of the major histocompatibility complex class I chain-related genes A and B (*MICA* and *MICB*) also are associated with APS-2. Polymorphisms in other genes (e.g., *PTPN22*, *CTLA4*) have been associated with individual autoimmune endocrinopathies that constitute APS-2, but the contribution of these genes to the pathogenesis of APS-2 itself is uncertain. Although not well defined, there are likely environmental factors that promote the development of autoimmunity in genetically susceptible individuals, and many of the risk factors associated with endocrine and nonendocrine autoimmunity overlap (see individual chapters on these diseases for more detailed discussions of risk factors). Next-generation immune therapies combined with an understanding of autoimmunity pathways may lead to targeted treatments to prevent new endocrinopathies (e.g., type 1 diabetes mellitus) among those at high risk.

CHROMOSOMAL ABNORMALITIES ASSOCIATED WITH AUTOIMMUNE POLYGLANDULAR SYNDROME

Many genetic syndromes involving chromosomal deletions, duplications, and other copy number variations are associated with an increased risk of autoimmunity, particularly endocrine autoimmunity affecting the thyroid and pancreatic β cells (see Table 608.1). Clinical practice guidelines for many of these genetic syndromes recommend routine screening for autoimmune and endocrine manifestations. Males with **Klinefelter syndrome** and females with **Turner syndrome** have an increased risk of autoimmunity in multiple systems, including autoimmune endocrine disease. The mechanism of autoimmunity in **trisomy 21** remains unclear, although differences in *AIRE* gene expression, HLA susceptibility, and autoantibody profiles have been described. Thymic dysplasia is a typical feature of **DiGeorge syndrome** (22q11.2 deletion), and the resulting **immune dysregulation** may play a role in the increased risk of autoimmunity in this disorder. Patients with genetic syndromes and chromosomal abnormalities may have nonautoimmune endocrinopathies such as abnormal growth, primary gonadal failure, and hypoparathyroidism.

Mitochondrial diseases such as Kearns-Sayre syndrome (progressive external ophthalmoplegia, retinal pigmentation, cardiac conduction defects) and MELAS (mitochondrial encephalomyopathy, lactic acidosis, strokelike episodes) have been associated with polyendocrinopathy syndromes, with some rare cases reported to be associated with autoimmunity. Endocrine manifestations of mitochondrial disease include diabetes mellitus, hypogonadism, adrenal insufficiency, hypoparathyroidism, and hypothyroidism. These manifestations may develop before neurologic and other organ injury and could be an early clue of mitochondrial dysfunction.

NONGENETIC AUTOIMMUNE CAUSES OF MULTIPLE ENDOCRINOPATHY

Rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation **(ROHHAD)** is a rare pediatric syndrome diagnosed by its cardinal clinical features (see Chapter 468.3). Children with ROHHAD abruptly develop rapid weight gain and associated autonomic deficits (e.g., ophthalmologic findings, gastrointestinal dysmotility, thermal dysregulation, bradycardia), central hypoventilation, and/or hypothalamic dysfunction. Patients have progressive dysfunction of hypothalamic-pituitary axes such as central hypothyroidism, growth hormone deficiency, hyperprolactinemia, and vasopressin dysregulation (see Chapter 468.3). It is hypothesized that ROHHAD is an autoimmune paraneoplastic neurologic syndrome based on the presence of cerebrospinal fluid inflammatory markers, response to immunosuppressive therapy in some patients, and identification of neuroblastic tumors in about half. Antineural autoantibody profiling and genetic testing have not yet identified the underlying cause of ROHHAD.

Novel immune-modulating biologic compounds are used increasingly in the treatment of malignancies and immune disorders. Monoclonal antitumor drugs that *inhibit immune checkpoints* such as CLTA4, PD1, and PD-L1 are associated with immune-related adverse effects (IRAEs). Clinically important IRAEs include acute onset of multiple autoimmune endocrinopathies, including hypophysitis with hypopituitarism (especially with CTLA4-directed therapies), thyroiditis with hyperthyroidism or hypothyroidism, type 1 diabetes mellitus, and primary adrenal insufficiency. Anti-CD52 antibodies used to treat multiple sclerosis have been linked to the development of Graves disease and other antibody-mediated autoimmune diseases (e.g., immune thrombocytopenic purpura). Preexisting autoimmunity may be a risk factor for developing autoimmune disease after exposure to a wide range of immunomodulatory therapies.

Chapter 609

Multiple Endocrine Neoplasia Syndromes

Ari J. Wassner and Jessica R. Smith

Multiple endocrine neoplasia (MEN) syndromes are characterized by the development of tumors in two or more endocrine glands. These syndromes are divided clinically into two types based on the specific endocrine organs involved (Table 609.1). MEN type 1 is characterized by tumors of the parathyroid glands, anterior pituitary, and endocrine pancreas. In contrast, MEN type 2 is characterized by medullary thyroid cancer and pheochromocytoma. Both types of MEN are usually inherited in an autosomal dominant fashion, but sporadic cases can occur.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

Multiple endocrine neoplasia type 1 (MEN1) most commonly presents in the fourth or fifth decade of life, but endocrine tumors can develop as early as 5 years of age. The endocrine tissues most frequently involved include the parathyroid glands, pituitary, and cells of the endocrine pancreas.

Primary hyperparathyroidism caused by a parathyroid adenoma or multigland hyperplasia is the most common manifestation of MEN1, with a lifetime cumulative incidence of 90–95%. In children with MEN1, hyperparathyroidism usually presents after 10 years of age and is often the first endocrine disorder to develop (in about 50% of cases). The diagnosis and management of hyperparathyroidism are discussed in Chapter 613. In patients with MEN1, bilateral surgical exploration is generally recommended over focused, minimally invasive approaches because of the tendency for multiple parathyroid glands to be hyperplastic. In such cases, subtotal (3- or 3.5-gland) parathyroidectomy may be required. MEN1 may be present in 15–70% of pediatric cases of primary hyperparathyroidism, and this syndrome should be considered in any child or adolescent with primary hyperparathyroidism, particularly if multigland hyperplasia is present.

Pituitary adenomas are the presenting feature of pediatric MEN1 in about 20% of cases and usually occur after age 10 years, although they have been reported in patients as young as 5 years. Although these adenomas most commonly secrete prolactin (60–70%), a few secrete growth hormone (5–10%) or adrenocorticotrophic hormone (5%), and the remainder are nonfunctioning (~25%). Diagnosis and management are similar to that of sporadic pituitary adenomas except that adenomas associated with MEN1 may be more locally aggressive and are more likely to cosecrete multiple pituitary hormones (see Chapter 598).

Patients with MEN1 can develop neoplasia of various **enteropancreatic endocrine** cells. Such tumors may occur in up to 70% of patients by adulthood but are found in only about 5–20% of affected children. Nonfunctioning pancreatic neuroendocrine tumors are the most common pancreatic lesions found in children with MEN1 and are usually detected by screening imaging. Insulinomas are the most common functional pancreatic tumor in children with MEN1, occurring in 3–10% of cases, and present with symptoms of hypoglycemia. These tumors may present before age 10 years but are more common in adolescence. Although gastrinomas represent over 50% of pancreatic tumors in adults with MEN1, they are rare in children (~2%) and occur after age 15 years. Rarer pancreatic tumors can secrete other hormones such as glucagon or vasoactive intestinal peptide (VIP).

MEN1 is also associated with several other rare tumors. Adrenocortical tumors in children with MEN1 may be benign or malignant, and they

Table 609.1 Clinical Manifestation of MEN Syndromes

SYNDROME	MEN 1	MEN 2

MEN, Multiple endocrine neoplasia; NET, neuroendocrine tumor.
Modified from Al-Salameh, A, Baudry C, Cohen R. Update on multiple endocrine neoplasia type 1 and 2. *La Presse Médicale*. 2018;47(9):722–731, Table 1.

may be nonfunctional or hypersecrete cortisol, androgens, or aldosterone. Pheochromocytomas have been reported rarely. Meningiomas, carcinoid tumors, and neuroendocrine tumors of the thymus, bronchopulmonary tree, or stomach can also occur, usually in older adolescents. Older patients with MEN1 frequently manifest cutaneous angiofibromas or collagenomas, which are benign but may be a useful diagnostic clue.

The diagnosis of MEN1 can be made clinically based on the presence of at least two of the classical endocrine tumor types (parathyroid, pituitary, pancreas) or the presence of one of these tumors in a first-degree relative of a patient with known MEN1. Genetic testing should be used to confirm a clinical diagnosis of MEN1 or to diagnose the condition preclinically in a relative of an affected individual. The *MEN1* gene on chromosome 11q13 encodes the tumor suppressor menin. A single germline inactivating pathogenic variant in *MEN1* is inherited but is not sufficient to cause tumorigenesis; a second *somatic* variant that inactivates the remaining normal allele then leads to tumor formation in a specific tissue. MEN1 is generally inherited in an autosomal dominant fashion, although sporadic variants account for about 10% of cases. Over 1,000 *MEN1* variants have been described, including deletions and changes in noncoding regions; therefore genetic testing should include analysis for deletions in patients in whom MEN1 sequencing does not reveal a pathogenic variant. Children diagnosed with MEN1 should undergo routine age-based clinical, laboratory, and imaging surveillance for disease manifestations.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2

Multiple endocrine neoplasia type 2 (MEN2) is a rare genetic disorder that occurs in about 1 in 2 million individuals and is characterized by the development of **medullary thyroid carcinoma (MTC)** and **pheochromocytoma**. MEN2 is an autosomal dominant disorder caused by activating pathogenic variants in the *RET* proto-oncogene, a tyrosine kinase encoded on chromosome 10q11.2. The clinical features of the syndrome are related to the specific *RET* mutation present, although disease manifestations can vary even among family members carrying the same mutation.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2A

Multiple endocrine neoplasia type 2A (MEN2A) is characterized by MTC, pheochromocytoma, and primary hyperparathyroidism. At least 50 different *RET* pathogenic variants have been described in patients with MEN2A, the majority occurring in exons 10 or 11 (codons 609, 611, 618, 620, or 634) in the *RET* extracellular domain. Almost all patients with MEN2A develop MTC, but the occurrence of other manifestations is more variable. MTC, or its precursor C cell hyperplasia, is usually the first manifestation to occur, but the age at which it develops is variable. Pheochromocytomas are often bilateral and may be multiple, and they usually develop in the third decade or later but may occur in childhood. Hyperparathyroidism is caused by hyperplasia that may involve one or more parathyroid glands. Hyperparathyroidism occurs at an average age of about 30 years but can occur in childhood or adolescence. Variants in *RET* codon 634 confer a relatively high risk of pheochromocytoma and hyperparathyroidism compared to variants at other sites.

Additional clinical conditions associated with MEN2A include cutaneous lichen amyloidosis and Hirschsprung disease. **Cutaneous lichen amyloidosis** is a dermatologic lesion consisting of pruritic hyperpigmented papules that are usually distributed in the interscapular region and on extensor surfaces. These skin lesions may develop before MTC and may provide an early clue to the diagnosis of MEN2A. Some patients with **Hirschsprung** disease have variants in *RET,* particularly in exon 10. Although the *RET* variants that cause Hirschsprung disease are generally loss-of-function variants, some of these can nevertheless cause MEN2A. Therefore individuals with Hirschsprung disease who carry such *RET* pathogenic variants should be evaluated for MEN2A.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2B

Multiple endocrine neoplasia type 2B (MEN2B) is characterized by MTC and pheochromocytoma, but *not* hyperparathyroidism. Rather, the distinguishing features of MEN2B are the presence of **multiple neuromas** and a characteristic phenotype that includes **Marfan-like habitus**. Nearly all patients with MEN2B have a specific missense pathogenic variant (M918T) in the tyrosine kinase catalytic domain of *RET*. Although MEN2B can be inherited, about 75% of cases are caused by de novo variants.

MTC in MEN2B can develop early in childhood, including in infancy, and metastasis of MTC to local and distant sites is often present at diagnosis. Pheochromocytomas occur in about half of patients. The neuromas of MEN2B can occur throughout the digestive tract, most commonly on the tongue, buccal mucosa, lips, and conjunctivae. Diffuse proliferation of nerves and ganglion cells is found in mucosal, submucosal, myenteric, and subserosal plexuses throughout the digestive tract and may be associated with gastrointestinal symptoms. Peripheral neurofibromas and café-au-lait patches may be present. Affected individuals may be tall, with arachnodactyly and a Marfan-like appearance, including scoliosis, pectus excavatum, pes cavus, and muscular hypotonia. The eyelids may be thickened and everted, lips thickened, and jaw prognathic. Feeding difficulties, poor sucking, diarrhea, constipation, and failure to thrive can begin in infancy or early childhood, sometimes years before the appearance of neuromas or endocrine symptoms.

FAMILIAL MEDULLARY THYROID CARCINOMA

The familial occurrence of MTC without other clinical manifestations of MEN2 has been termed *familial medullary thyroid carcinoma* (FMTC). *RET* variants are commonly present in individuals with FMTC, and although some families appear to have truly isolated MTC, in other kindreds, the pattern of apparent FMTC may represent MEN2A in which other manifestations have not yet occurred or have not been diagnosed. FMTC is frequently regarded as a form of MEN2A, and evaluation for other manifestations of MEN2A is warranted in patients with FMTC.

MANAGEMENT OF MULTIPLE ENDOCRINE NEOPLASIA TYPE 2

Genetic testing of affected family members often leads to the diagnosis of MEN2 in a child before the development of any disease manifestations. MTC is highly likely to develop in these individuals. Although thyroidectomy is curative if performed before the development of MTC or while it is still localized to the thyroid gland, the prognosis is poor once MTC has metastasized beyond the thyroid. Therefore prophylactic thyroidectomy is required in most individuals with MEN2. However, the timing of prophylactic thyroidectomy must be determined for each patient based on balancing the likelihood of developing metastatic MTC against the need to minimize the risks of surgery, which are higher in younger children.

Factors influencing the risk of MTC include the specific *RET* variants present, the history of MTC in the family, and serum levels of calcitonin. The first two factors are not entirely predictive, as MTC behavior can vary significantly even in family members with the same variant. Some *RET* variants are associated with earlier-onset MTC, and consensus guidelines categorize *RET* variants as highest risk (M918T, usually associated with MEN2B), high risk (codon 634 and 883 mutations), or moderate risk (other variants) for MTC. Patients at highest risk should undergo thyroidectomy within the first year of life. Those with high-risk variants should undergo thyroidectomy at 5 years of age or earlier if calcitonin levels begin to rise. Patients at moderate risk should be monitored by neck ultrasound and serum calcitonin levels beginning at age 5 years, and thyroidectomy should be performed if calcitonin levels rise. However, the timing of surgery may be influenced by other factors, including family history or desire to avoid prolonged monitoring by proceeding with thyroidectomy. For patients who do not wish to undergo prophylactic thyroidectomy, regular careful surveillance is mandatory. Thyroidectomy should be performed by an experienced thyroid surgeon, especially in the youngest patients, to minimize the risk of surgical complications. Prophylactic thyroidectomy reduces morbidity and mortality from MTC in patients with MEN2, many of whom are found to have C cell hyperplasia, or even MTC, at the time of prophylactic thyroidectomy. The management of MTC is described in detail in Chapter 607.

Screening for pheochromocytoma and hyperparathyroidism should be performed in children with MEN2. The age at which screening should commence depends on the specific RET variant (11 years for high and highest risk; 16 years for moderate risk). Management of pheochromocytoma (see Chapters 555.4 and 613) and hyperparathyroidism (see Chapter 621) are discussed elsewhere.

Section 3

Disorders of the Parathyroid Gland

Chapter 610

Hormones and Peptides of Calcium Homeostasis and Bone Metabolism

Evan G. Graber and Daniel A. Doyle

Parathyroid hormone (PTH) and vitamin D are the principal regulators of calcium homeostasis (see Chapters 69 and 746). Calcitonin and PTH-related peptide (PTHrP) are important primarily in the fetus.

PARATHYROID HORMONE

PTH is an 84–amino acid chain (95 kDa), but its biologic activity resides in the first 34 residues. In the parathyroid gland, a pre–pro-PTH (115–amino acid chain) and a pro-PTH (90 amino acids) are synthesized. Pre–pro-PTH is converted to pro-PTH and pro-PTH to PTH. PTH (consisting of amino acids 1-84) is the major secretory product of the gland, but it is rapidly cleaved in the liver and kidney into smaller COOH-terminal, midregion, and NH_2-terminal fragments.

The occurrence of these fragments in serum has led to the development of a variety of assays. The 1-34 aminoterminal (N-terminus) fragments possess biologic activity but are present in low amounts in the circulation; assay of these fragments is most useful for detecting acute secretory changes. The carboxyterminal (C-terminus) and midregion fragments, although biologically inert, are cleared more slowly from the circulation and represent 80% of plasma immunoreactive PTH; concentrations of the C-terminal fragment are 50-500 times the level of the active hormone. The C-terminal assays are effective in detecting hyperparathyroidism, but because C-terminal fragments are removed from the circulation by glomerular filtration, these assays are less useful for evaluating the secondary hyperparathyroidism characteristic of renal disease. Only certain sensitive radioimmunoassays for PTH can differentiate the subnormal concentrations that occur in hypoparathyroidism from normal levels.

When serum levels of calcium fall, the signal is transduced through the calcium-sensing receptor, and secretion of PTH increases (Fig. 610.1). PTH stimulates activity of 1α-hydroxylase in the kidney, enhancing production of 1,25-dihydroxycholecalciferol, also written as $1,25(OH)_2D_3$. The increased level of $1,25(OH)_2D_3$ induces synthesis of a calcium-binding protein (calbindin-D) in the intestinal mucosa, with resultant absorption of calcium. PTH also mobilizes calcium by directly enhancing bone resorption, an effect that requires $1,25(OH)_2D_3$. The effects of PTH on bone and kidney are mediated through binding to specific receptors on the membranes of target cells and through activation of a transduction pathway involving a G-protein coupled to the adenylate cyclase system (see Chapter 594).

The calcium-sensing receptor regulates the secretion of PTH and the reabsorption of calcium by the renal tubules in response to alterations in serum calcium concentrations. The gene for the receptor is located on chromosome 3q13.3-q21 and encodes a cell surface protein that is expressed in parathyroid glands and kidneys and belongs to the family of G-protein–coupled receptors. In the normally functioning calcium-sensing receptor, hypocalcemia induces increased secretion of PTH and hypercalcemia depresses PTH secretion. Loss-of-function pathogenic variants cause an increased set point with respect to serum calcium, resulting in hypercalcemia and in the conditions of familial hypocalciuric hypercalcemia and neonatal severe hyperparathyroidism. There is a close genotype/phenotype relationship that determines severity of illness. Acquired hypocalciuric hypercalcemia may be a result of autoantibodies to the calcium-sensing receptor and manifests with hypercalcemia and hyperparathyroidism. Gain-of-function variants result in depressed secretion of PTH in response to hypocalcemia, leading to the syndrome of familial hypocalcemia with hypercalciuria (see Fig. 610.1).

PARATHYROID HORMONE–RELATED PEPTIDE

PTHrP is homologous to PTH only in the first 13 amino acids of its amino terminus, 8 of which are identical to PTH. Its gene is on the short arm of chromosome 12 and that of PTH is on the short arm of chromosome 11.

PTHrP, like PTH, activates PTH receptors in kidney and bone cells and increases urinary cyclic adenosine monophosphate and renal production of $1,25(OH)_2D_3$. It is produced in almost every type of cell of the body, including every tissue of the embryo at some stage of development. PTHrP is critical for normal fetal development. Inactivating variants of the receptor for PTH/PTHrP results in a lethal bone disorder characterized by short limbs and markedly advanced bone maturation known as **Blomstrand chondrodysplasia** (see Fig. 610.1). PTHrP appears to have a paracrine or autocrine role because serum levels are low except in a few clinical situations. Cord blood contains levels of PTHrP that are threefold higher than in serum from adults; it is produced by the fetal parathyroid glands and appears to be the main agent stimulating maternal-fetal calcium transfer. PTHrP appears to be essential for normal skeletal maturation of the fetus, which requires 30 g of calcium during a normal gestation. During pregnancy, maternal absorption of calcium increases from about 150 mg daily to 400 mg during the second trimester.

PTHrP levels are increased during lactation and in patients with benign breast hypertrophy. Breast milk and pasteurized bovine milk have levels of PTHrP that are 10,000 times higher than those of normal plasma. Most instances of the hormonal **hypercalcemia syndrome of malignancy** are caused by elevated concentrations of PTHrP.

VITAMIN D

See Chapter 69.

CALCITONIN

Calcitonin is a 32–amino acid polypeptide. Its gene is on chromosome 11p and is tightly linked to that of PTH. The gene for calcitonin encodes three peptides: calcitonin, a 21–amino acid carboxyterminal flanking peptide (katacalcin), and a calcitonin gene–related peptide. Katacalcin and calcitonin are cosecreted in equimolar amounts by the parafollicular cells (C cells) of the thyroid gland. Calcitonin appears to be of little consequence in children and adults because very high levels in patients with medullary carcinoma of the thyroid (a tumor arising from the C cells) do not cause hypercalcemia. In the fetus, circulating levels are high and appear to augment bone metabolism and skeletal growth; these high levels are probably stimulated by the normally high fetal calcium levels. Unlike the high levels in cord blood and circulating concentrations in young children, levels in older children and adults are low. Infants and children with congenital hypothyroidism (and presumed deficiency of C cells) have lower levels of calcitonin than normal children.

Its action appears to be independent of PTH and vitamin D. Its main biologic effect appears to be the inhibition of bone resorption by decreasing the number and activity of bone-resorbing osteoclasts. This action of calcitonin is the rationale for its use in treatment of Paget disease. Calcitonin is synthesized in other organs, such as the gastrointestinal tract, pancreas, brain, and pituitary. In these organs, calcitonin is thought to behave as a neurotransmitter to impose a local inhibitory effect on cell function.

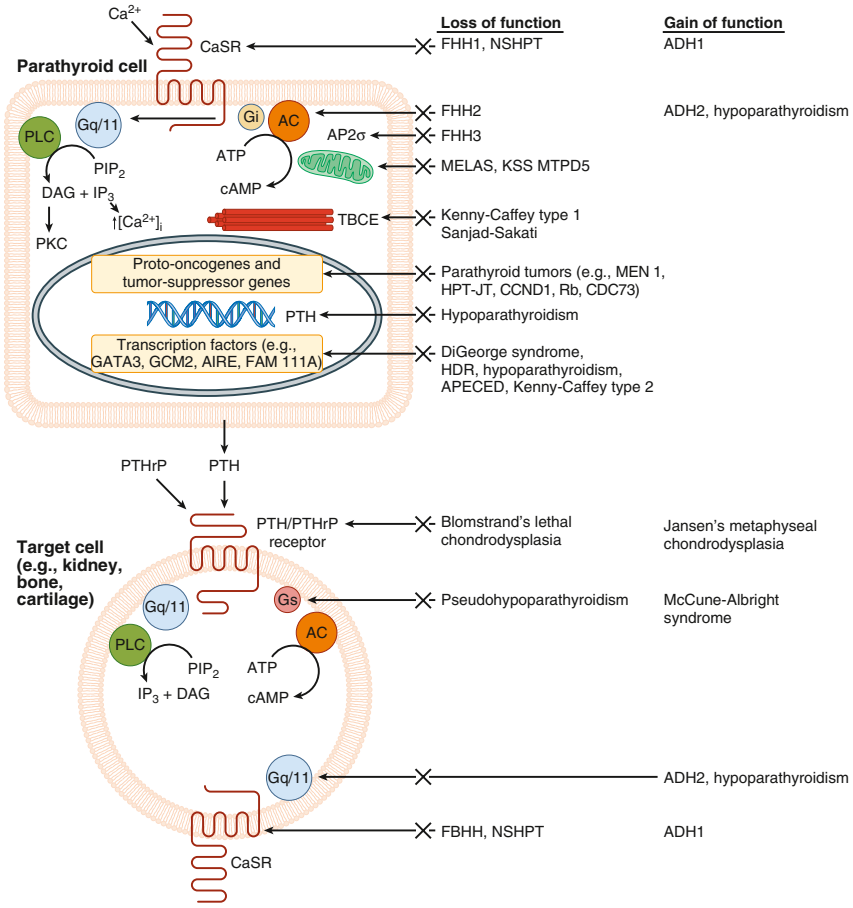

Fig. 610.1 Schematic representation of some of the components involved in calcium homeostasis. Alterations in extracellular calcium are detected by the calcium-sensing receptor *(CaSR)*, which is a 1078–amino acid, G protein–coupled receptor. The parathyroid hormone (PTH)/parathyroid hormone-related peptide (PTHrP) receptor, which mediates the actions of and PTHrP, is also a G protein–coupled receptor. Thus Ca^{2+}, PTH, and PTHrP involve G protein–coupled signaling pathways, and interaction with their specific receptors can lead to activation of Gs, Gi, and Gq, respectively. Gs stimulates adenylcyclase *(AC)*, which catalyzes the formation of cyclic adenosine monophosphate *(cAMP)* from adenosine triphosphate *(ATP)*. Gi inhibits AC activity. cAMP stimulates protein kinase A *(PKA)*, which phosphorylates cell-specific substrates. Activation of Gq stimulates phospholipase C *(PLC)*, which catalyzes the hydrolysis of the phosphoinositide *(PIP_2)* to inositol triphosphate *(IP_3)*, which then increases intracellular calcium, and diacylglycerol *(DAG)*, activating protein kinase C *(PKC)*. These proximal signals modulate downstream pathways, which results in specific physiologic effects. Loss of function in several genes, shown with their respective sites of action on the right, has been identified in specific disorders of calcium homeostasis. ADH, autosomal dominant hypocalcemia; APECED, autoimmune polyendocrinopathy candidiasis ectodermal dystrophy; FBHH, familial benign hypocalciuric hypercalcemia; FHH, familial hypocalciuric hypercalcemia; HDR, hypoparathyroidism, sensorineural deafness, and renal anomaly; HPT-JT, hyperparathyroidism-jaw tumor syndrome; KSS, Kearns-Sayre syndrome; MELAS, Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; MEN, multiple endocrine neoplasia; MTPD, mitochondrial trifunctional protein deficiency; NSHPT, neonatal severe hyperparathyroidism. TBCE, tubulin-specific chaperone E. *(From Thakkerf RV. The parathyroid glands, hypercalcemia and hypocalcemia. In: Goldman L, Schafer AI, eds. Goldman-Cecil Medicine, 25th ed. Philadelphia: Elsevier; 2016: Fig. 245.2, p. 1651.)*

Chapter 611

Hypoparathyroidism

Patrick C. Hanley and Daniel A. Doyle

Hypocalcemia is common in neonates between 12 and 72 hours of life, especially in premature infants, in infants with asphyxia, and in infants of diabetic mothers (**early neonatal hypocalcemia**; see Chapter 121.4; Table 611.1 and Fig. 611.1). After the second to third day and during the first week of life, the type of feeding also is a determinant of the level of serum calcium **(late neonatal hypocalcemia)**. The role played by the parathyroid glands in these hypocalcemic infants is unclear, although functional immaturity of the parathyroid glands is invoked as one pathogenetic factor. In a group of infants with **transient idiopathic hypocalcemia** (1-8 weeks of age), serum levels of parathyroid hormone (PTH) are significantly lower than those in unaffected infants. It is possible that the functional immaturity is a manifestation of a delay in development of the enzymes that convert glandular PTH to secreted PTH; other mechanisms are possible.

APLASIA OR HYPOPLASIA OF THE PARATHYROID GLANDS

Aplasia or hypoplasia of the parathyroid glands is often associated with **DiGeorge/velocardiofacial syndrome**. This syndrome occurs in 1 in 4,000 newborns. In 90% of patients, the condition is caused by a deletion of chromosome 22q11.2 with involvement of the *TBX1* gene. Approximately 25% of these patients inherit the chromosomal abnormality from a parent. Neonatal hypocalcemia occurs in 60% of affected patients, but it is transitory in the majority; hypocalcemia may recur or can have its onset later in life. Associated abnormalities of the third and fourth pharyngeal pouches are common; these include conotruncal defects of the heart in 25%, velopharyngeal insufficiency in 32%, cleft palate in 9%, renal anomalies in 35%, and aplasia of the thymus with severe immunodeficiency in 1%. This syndrome has also been reported in a small number of patients with a deletion of chromosome 10p13 thought to affect the *NEBL* gene, in infants of diabetic mothers, and in infants born to mothers treated with retinoic acid for acne early in pregnancy. Loss-of-function pathogenic variants in the *GCM2* gene, which is a key regulator of parathyroid gland development, leads to isolated parathyroid aplasia and hypoparathyroidism.

Table 611.1 Causes of Hypocalcemia

I. NEONATAL
A. Maternal Disorders
1. Diabetes mellitus
2. Toxemia of pregnancy
3. Vitamin D deficiency
4. High intake of alkali or magnesium sulfate
5. Use of anticonvulsants
6. Hyperparathyroidism
B. Neonatal Disorders
1. Low birthweight: prematurity, intrauterine growth restriction
2. Peripartum asphyxia, sepsis, critical illness
3. Hyperbilirubinemia, phototherapy, exchange transfusion
4. Hypomagnesemia, hypermagnesemia
5. Acute/chronic renal failure
6. Nutrients/medications: high phosphate intake, fatty acids, phytates, bicarbonate infusion, citrated blood, anticonvulsants, aminoglycosides
7. Hypoparathyroidism
8. Vitamin D deficiency or resistance
9. Osteopetrosis type II

II. HYPOPARATHYROIDISM
A. Congenital
1. Transient neonatal
2. Congenital hypoparathyroidism
   a. Familial isolated hypoparathyroidism
      (i) Autosomal recessive hypoparathyroidism *(GMC2, PTH)*
      (ii) Autosomal dominant hypoparathyroidism *(CASR, GNA11)*
      (iii) X-linked hypoparathyroidism *(SOX3)*
   b. DiGeorge syndrome types 1 and 2 *(TBX1, NEBL)*
   c. Sanjad-Sakati syndrome (short stature, retardation, dysmorphism; HRD) *(TBCE)*
   d. Kenny-Caffey syndrome type 1 (short stature, medullary stenosis, retardation) *(TBCE)*
   e. Kenny-Caffey syndrome type 2 (short stature, medullary stenosis) *(FAM111A)*
   f. Barakat syndrome (sensorineural deafness, renal dysplasia; HDR) *(GATA3)*
   g. Lymphedema-Hypoparathyroidism syndrome (nephropathy, mitral valve prolapse and brachytelephalangy).
   h. Mitochondrial disorders (Kearns-Sayre, Pearson, MELAS, trifunctional protein deficiency)
3. Insensitivity to PTH
   a. Blomstrand chondrodysplasia *(PTHR1)*
   b. Pseudohypoparathyroidism type IA *(GNAS)*
      (i) Pseudohypoparathyroidism type IB *(STX16, GNAS-A1)*
      (ii) Pseudohypoparathyroidism type IC *(GNAS)*
      (iii) Pseudohypoparathyroidism type II
      (iv) Pseudopseudohypoparathyroidism
   c. Acrodysostosis with hormone resistance *(PRKAR1A)*
   d. Hypomagnesemia
4. CaSR-activating mutation
   a. Sporadic
   b. Autosomal dominant (G protein subunit α11 mutation)

II. HYPOPARATHYROIDISM—cont'd
B. Acquired
1. Autoimmune polyglandular syndrome type I (*AIRE* gene mutation)
2. Activating antibodies to the CaSR
3. Postsurgical, radiation destruction
4. Infiltrative—excessive iron (hemochromatosis, thalassemia) or copper (Wilson disease) deposition; granulomatous inflammation, neoplastic invasion; amyloidosis, sarcoidosis
5. Hypomagnesemia/hypermagnesemia

III. VITAMIN D DEFICIENCY
IV. OTHER CAUSES OF HYPOCALCEMIA
A. Calcium Deficiency
1. Nutritional deprivation
2. Hypercalciuria
B. Disorders of Magnesium Homeostasis
1. Congenital hypomagnesemia
2. Acquired
   a. Acute renal failure
   b. Chronic inflammatory bowel disease, intestinal resection
   c. Diuretics
C. Hyperphosphatemia
1. Renal failure
2. Phosphate administration (intravenous, oral, rectal)
3. Tumor cell lysis
4. Muscle injuries (crush, rhabdomyolysis)
D. Miscellaneous
1. Hypoproteinemia
2. Hyperventilation
3. Drugs: furosemide, aminoglycosides, bisphosphonates, calcitonin, anticonvulsants, ketoconazole, antineoplastic agents (plicamycin, asparaginase, cisplatinum, cytosine arabinoside, doxorubicin), citrated blood products
4. Hungry bone syndrome
5. Acute and critical illness: sepsis, acute pancreatitis, toxic shock
   a. Organic acidemia: propionic, methylmalonic, isovaleric

CaSR, Ca^2-sensing receptor; HDR, hypoparathyroidism, sensorineural deafness, and renal anomaly; HRD, hypoparathyroidism, retardation, dysmorphism; MELAS, mitochondrial encephalomyopathy with lactic acidosis and strokelike episode; PTH, parathyroid hormone.
Modified from Root AW, Diamond Jr FB. Disorders of mineral homeostasis in children and adolescents. In: Sperling MA. *Pediatric Endocrinology*, 4th ed. Philadelphia: Elsevier; 2014: Table 18.2A.

X-LINKED RECESSIVE HYPOPARATHYROIDISM

Familial clusters of hypoparathyroidism with various patterns of transmission have been described. In two large North American pedigrees, this disorder appears to be transmitted by an X-linked recessive gene located on Xq26-q27, which has a key role in the development of the parathyroid glands. In these families, the onset of afebrile hypocalcemic seizures characteristically occurs in infants from 2 weeks to 6 months of age. The absence of parathyroid tissue after detailed examination of a male with this condition suggests a defect in embryogenesis.

AUTOSOMAL RECESSIVE HYPOPARATHYROIDISM WITH DYSMORPHIC FEATURES

Autosomal recessive hypoparathyroidism with dysmorphic features has been described in Middle Eastern children. Parental consanguinity occurred for most of several dozen affected patients. Profound hypocalcemia occurs early in life, and dysmorphic features include microcephaly, deep-set eyes, beaked nose, micrognathia, and large floppy ears. Intrauterine and postnatal growth restriction are severe, and cognitive impairment is common. The putative gene *(TBCE)* is on chromosome 1q42-43. In a few patients with autosomal recessive inheritance of isolated hypoparathyroidism, pathologic variants of the *PTH* gene have been found.

HYPOPARATHYROIDISM, SENSORINEURAL DEAFNESS, AND RENAL ANOMALY SYNDROME

Hypoparathyroidism, sensorineural deafness, and renal anomaly (HDR) occur owing to pathologic variants of the *GATA3* gene. The protein encoded by this gene is essential in the development of the

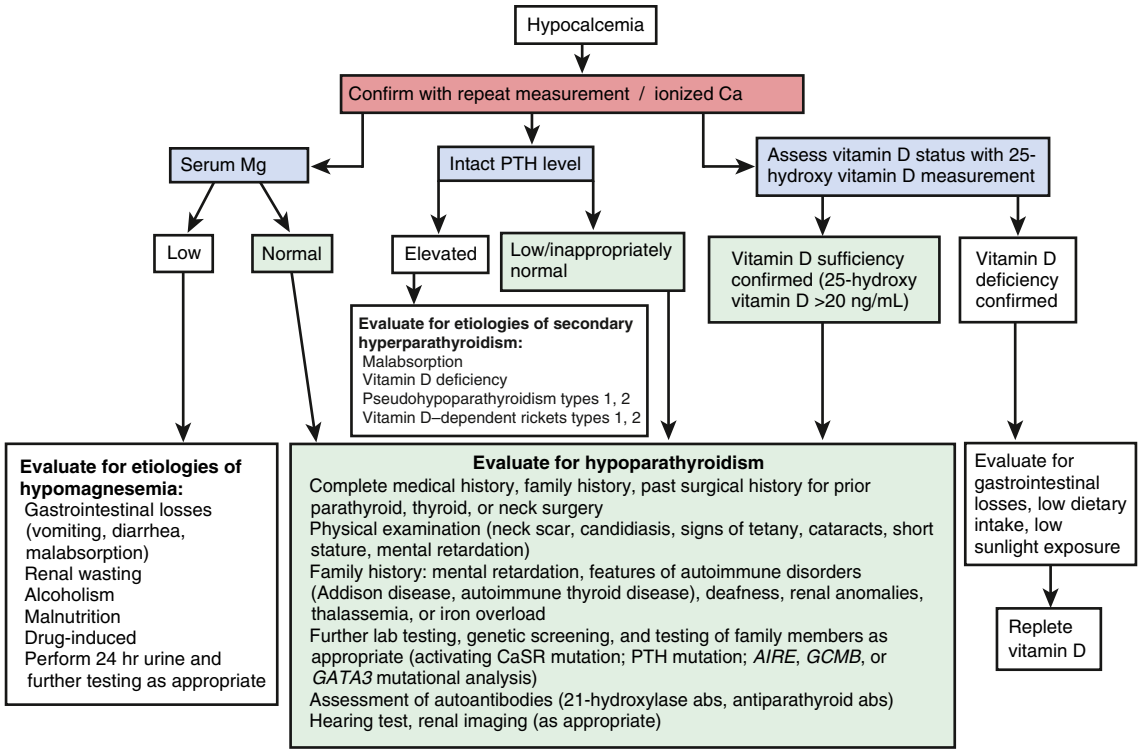

Fig. 611.1 Algorithm for the evaluation of hypocalcemia. Abs, autoantibodies; CaSR, Ca^2-sensing receptor; PTH, parathyroid hormone. *(From Bilezikian JP, Khan A, Potts Jr JT, et al. Hypoparathyroidism in the adult: epidemiology, diagnosis, pathophysiology, target-organ involvement, treatment, and challenges for future research. J Bone Miner Res. 2011;26:2317–2337, Fig. 1.)*

parathyroids, auditory system, and kidneys. The *GATA3* gene is located at chromosome 10p14 and is nonoverlapping with the DiGeorge critical region at 10p13 (see Fig. 610.1). Congenital ichthyosis and HDR have also been reported.

SUPPRESSION OF NEONATAL PARATHYROID HORMONE SECRETION BECAUSE OF MATERNAL HYPERPARATHYROIDISM OR MATERNAL FAMILIAL HYPOCALCIURIC HYPERCALCEMIA

Neonatal PTH secretion can be suppressed by maternal hyperparathyroidism, resulting in transient hypocalcemia in the newborn infant. It appears that neonatal hypocalcemia results from suppression of the fetal parathyroid glands by exposure to elevated levels of calcium in maternal and hence fetal serum. Tetany usually develops within 3 weeks but may be delayed by 1 month or more if the infant is breastfed. Seizures may occur within 1 week with familial hypocalciuric hypercalcemia (FHH1) because of maternal Ca^2-sensing receptor (CaSR) loss-of-function pathogenic variants. Hypocalcemia can persist for weeks or months. When the cause of hypocalcemia in an infant is unknown, measurements of calcium, phosphorus, and PTH should be obtained from the mother. Most affected mothers are asymptomatic, and the cause of their hyperparathyroidism is usually a parathyroid adenoma.

AUTOSOMAL DOMINANT HYPOPARATHYROIDISM

Patients with autosomal dominant hypoparathyroidism have an activating (gain-of-function) pathogenic variant of the Ca^{2+}-sensing receptor, forcing the receptor to an on state with subsequent depression of PTH secretion even during hypocalcemia. The patients have hypercalciuria. The hypocalcemia is usually mild and might not require treatment beyond childhood (see Fig. 610.1).

HYPOPARATHYROIDISM ASSOCIATED WITH MITOCHONDRIAL DISORDERS

Mitochondrial DNA pathogenic variants in Kearns-Sayre syndrome, MELAS (mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes) syndrome, and mitochondrial trifunctional protein–deficiency syndrome are associated with hypoparathyroidism. A diagnosis of mitochondrial cytopathy should be considered in patients with unexplained symptoms, such as ophthalmoplegia, sensorineural hearing loss, cardiac conduction disturbances, and tetany (see Fig. 610.1).

SURGICAL OR INFILTRATIVE HYPOPARATHYROIDISM

Removal or damage of the parathyroid glands can complicate thyroidectomy. Hypoparathyroidism has developed even when the parathyroid glands have been identified and left undisturbed at the time of operation. This may be the result of interference with the blood supply or of postoperative edema and fibrosis. Symptoms of tetany can occur abruptly postoperatively and may be temporary or permanent. In some instances, symptoms develop insidiously and go undetected until months after thyroidectomy. Occasionally, the first evidence of surgical hypoparathyroidism may be the development of cataract. The status of parathyroid function should be carefully monitored in all patients undergoing thyroidectomy.

Deposition of iron pigment or of copper in the parathyroid glands (thalassemia, Wilson disease) can also produce hypoparathyroidism.

AUTOIMMUNE HYPOPARATHYROIDISM

An autoimmune mechanism for hypoparathyroidism is strongly suggested by the finding of parathyroid antibodies and by its frequent association with other autoimmune disorders or organ-specific antibodies. Autoimmune hypoparathyroidism is often associated with Addison disease and chronic mucocutaneous candidiasis. The association of at least two of these three conditions has been classified as **autoimmune polyglandular disease type I** (see Chapter 608). It is also known as *autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy* (APECED). This syndrome is inherited in an autosomal recessive fashion and is not related to any single human leukocyte antigen–associated haplotype. Approximately one third of pediatric patients with this syndrome have all three components; 66% have only two of three conditions. The candidiasis almost always precedes the other disorders (70% of cases

occur in children *younger* than 5 years of age); the hypoparathyroidism (90% of cases occur *after* 3 years of age) usually occurs before Addison disease (90% of cases occur *after* 6 years of age). A variety of other disorders, including alopecia areata or totalis, malabsorption disorder, asplenia, pernicious anemia, gonadal failure, autoimmune hepatitis, vitiligo, dental enamel hypoplasia, nail dystrophy, keratoconjunctivitis, and insulin-dependent diabetes, occur at various times. Some of these associations might not appear until adult life. Autoimmune thyroid disease is a rare concomitant finding in pediatric patients.

Affected siblings can have the same or different constellations of disorders (hypoparathyroidism, Addison disease). The disorder is exceptionally prevalent among Finns and Iranian Jews. The gene for this disorder is designated *AIRE* (autoimmune regulator); it is located on chromosome 21q22. It appears to be a transcription factor that plays an essential role in the development of immunologic tolerance. Patients with Addison disease as part of polyendocrinopathy syndrome type I have demonstrated adrenal-specific autoantibody reactivity directed against the side-chain cleavage enzyme.

IDIOPATHIC HYPOPARATHYROIDISM

The term *idiopathic hypoparathyroidism* should be reserved for the small residuum of children with hypoparathyroidism for whom no causative mechanism can be defined. Most children in whom onset of hypoparathyroidism occurs after the first few years of life have an **autoimmune condition**. Autoantibodies to the extracellular domain of the Ca^2-sensing receptor have been identified in some patients with acquired hypoparathyroidism. One should always consider incomplete forms of DiGeorge syndrome or an activating Ca^2-sensing receptor pathogenic variant in the differential diagnosis.

Clinical Manifestations

There is a spectrum of parathyroid deficiencies with clinical manifestations varying from no symptoms to those of complete and long-standing deficiency. Mild deficiency may be revealed only by appropriate laboratory studies. Muscular pain and cramps are early manifestations; they progress to numbness, stiffness, and tingling of the hands and feet. There may be only a positive Chvostek or Trousseau sign or laryngeal and carpopedal spasms. Seizures with or without loss of consciousness can occur at intervals of days, weeks, or months. These episodes can begin with abdominal pain, followed by tonic rigidity, retraction of the head, and cyanosis. Hypoparathyroidism is often mistaken for epilepsy. Headache, vomiting, increased intracranial pressure, and papilledema may be associated with seizures and might suggest a brain tumor.

In patients with long-standing hypocalcemia, the teeth erupt late and irregularly. Enamel formation is irregular, and the teeth may be unusually soft. The skin may be dry and scaly, and the nails might have horizontal lines. Mucocutaneous candidiasis, when present, antedates the development of hypoparathyroidism; the candidal infection most often involves the nails, the oral mucosa, the angles of the mouth, and less often, the skin; it is difficult to treat.

Cataracts in patients with long-standing untreated disease are a direct consequence of hypoparathyroidism; other autoimmune ocular disorders such as keratoconjunctivitis can also occur. Manifestations of Addison disease, lymphocytic thyroiditis, pernicious anemia, alopecia areata or totalis, hepatitis, and primary gonadal insufficiency may also be associated with those of hypoparathyroidism.

Permanent physical and mental deterioration occurs if initiation of treatment is long delayed.

Laboratory Findings

The serum calcium level is low (5-7 mg/dL), and the phosphorus level is elevated (7-12 mg/dL). Blood levels of ionized calcium (usually approximately 45% of the total) more nearly reflect physiologic adequacy but also are low. The serum level of alkaline phosphatase is normal or low, and the level of $1,25(OH)_2D_3$ is usually low, but high levels have been found in some children with severe hypocalcemia. The level of magnesium is normal but should always be checked in hypocalcemic patients. Levels of PTH are low relative to the calcium level when measured by immunometric assay. Radiographs of the bones occasionally reveal an increased density limited to the metaphyses, suggesting heavy metal poisoning, or an increased density of the lamina dura. Radiographs or CT scans of the skull can reveal calcifications in the basal ganglia. There is a prolongation of the QT interval on the electrocardiogram, which disappears when the hypocalcemia is corrected. The electroencephalogram usually reveals widespread slow activity; the tracing returns to normal after the serum calcium concentration has been within the normal range for a few weeks, unless irreversible brain damage has occurred or unless the parathyroid insufficiency is associated with epilepsy. When hypoparathyroidism occurs concurrently with Addison disease, the serum level of calcium may be normal, but hypocalcemia appears after effective treatment of the adrenal insufficiency.

Treatment

Emergency treatment of neonatal tetany consists of intravenous injections of 5-10 mL or 1-3 mg/kg of a 10% solution of calcium gluconate (elemental calcium 9.3 mg/mL) at the rate of 0.5-1.0 mL/min while the heart rate is monitored and a total dose not to exceed 20 mg of elemental calcium/kg. Additionally, 1,25-dihydroxycholecalciferol (calcitriol) should be given. The initial dosage is 0.25 μg/24 hr; the maintenance dosage ranges from 0.01-0.10 g/kg/24 hr to a maximum of 1-2 μg/24 hr. Calcitriol has a short half-life and should be given in two equally divided doses; it has the advantages of rapid onset of effect (1-4 days) and rapid reversal of hypercalcemia after discontinuation in the event of overdosage (calcium levels begin to fall in 3-4 days). Calcitriol is supplied as an oral solution.

An adequate intake of calcium should be ensured. Supplemental calcium can be given in the form of calcium gluconate or calcium glubionate to provide 800 mg of elemental calcium daily or 25-50 mg/kg day dosing of elemental calcium as needed. Foods with high phosphorus content such as milk, eggs, and cheese should be *reduced* in the diet. Other therapies used for some children with hypoparathyroidism in studies include hormone replacement with recombinant PTH 1-34 or recombinant PTH 1-84 given via a pump or subcutaneous injections in adult patients who do not respond to conventional therapy.

Clinical evaluation of the patient and frequent determinations of the serum calcium levels are indicated in the early stages of treatment to determine the requirement for calcitriol, calcium supplementation, or vitamin D_2. If hypercalcemia occurs, therapy should be discontinued and resumed at a lower dose after the serum calcium level has returned to normal. In long-standing cases of hypercalcemia, repair of cerebral and dental changes is not likely. Pigmentation, lowering of blood pressure, or weight loss can indicate adrenal insufficiency, which requires specific treatment. Patients with autosomal dominant hypocalcemic hypercalciuria can develop nephrocalcinosis and renal impairment if treated with vitamin D.

Differential Diagnosis

Magnesium deficiency must be considered in patients with unexplained hypocalcemia. Concentrations of serum magnesium <1.5 mg/dL (1.2 mEq/L) are usually abnormal (Table 611.2). Administration of calcium is ineffective, but administration of magnesium promptly corrects both calcium and magnesium levels. Oral supplements of magnesium are necessary to maintain levels of magnesium in the normal range.

Hypomagnesemia also occurs in malabsorption syndromes such as Crohn disease and cystic fibrosis. Patients with autoimmune polyglandular disease type I and hypoparathyroidism can also have concurrent

Table 611.2 Genetic Causes of Hypomagnesemia

CATEGORIES/NAMES OF DISORDERS*	GENE	INHERITANCE	DISTINCTIVE FINDINGS OTHER THAN HYPOMAGNESEMIA†
HYPERCALCIURIC HYPOMAGENESEMIAS			Hypercalciuria, nephrocalcinosis
FHHNC type 1	*CLDN16*	R	Polyuria/polydipsia, elevated serum iPTH, renal failure
FHHNC type 2	*CLDN19*	R	Same as FHHNC type 1, plus ocular abnormalities
ADHH Bartter syndrome type 5	*CASR*	D	Hypocalcemia with normal or low PTH
Bartter syndrome, type 3 (classical type)	*CLCNKB*	R	Gitelman-like phenotype possible, rarely nephrocalcinosis
GITELMAN-LIKE HYPOMAGNESEMIAS			Hypocalciuria, hypokalemia, metabolic alkalosis
Gitelman syndrome	*SLC12A3*	R	Chondrocalcinosis at older age
Bartter syndrome, type 4	*BSND*	R	Prenatal complications, renal failure early in life possible
EAST syndrome	*KCNJ10*	R	Sensorineural deafness, seizures, ataxia
IDH	*FXYD2*	D	
ADTKD/RCAD	*HNF1B*	D	Renal, genital, and pancreatic abnormalities and MODY5 in highly variable combination and presentation
HPABH4D/RCAD-like	*PCBD1*	R	MODY5-like
MITOCHONDRIAL HYPOMAGNESEMIAS			Variable
HHH	*MT-TI*	Mt	Hypertension and hypercholesterolemia
HUPRAS	*SARS2*	R	Hyperuricemia, pulmonary hypertension, renal failure, and alkalosis
KSS	Mitochondrial deletion	Mt	External ophthalmoplegia, retinopathy and cardiac conduction defects
OTHER HYPOMAGNESEMIAS			Variable
HSH	*TRPM6*	R	Neonatal presentation with severe hypomagnesemia
IRH	*EGF*	R	Intellectual disability
NISBD2	*EGFR*	R	Severe inflammation of skin and bowel from birth
HSMR	*CNNM2*	D/R	Intellectual disability, seizures
ADH/EA1	*KCNA1*	D	Episodic myokymia
KCS2	*FAM111A*	D	Impaired skeletal development and hypocalcemic hypoparathyroidism

*ADH, Autosomal dominant hypomagnesemia; ADHH, autosomal dominant hypocalcemia with hypocalciuria; ADTKD, autosomal dominant tubulointerstitial kidney disease; EA1, episodic ataxia type 1; EAST, epilepsy, ataxia, sensorineural deafness and tubulopathy; FHHNC, familial hypomagnesemia with hypocalcemia and nephrocalcinosis; HHH, hypertension, hypercholesterolemia and hypomagnesemia; HPABH4D, hyperphenylalaninemia BH4-deficient; HSH, hypomagnesemia with secondary hypocalcemia; HSMR, hypomagnesemia with seizures and mental retardation; HUPRAS, hyperuricemia, pulmonary hypertension, renal failure and alkalotic syndrome; IDH, isolated dominant hypomagnesemia; IRH, isolated recessive hypomagnesemia; KCS2, Kenny-Chaffey syndrome type 2; KSS, Kearns-Sayre syndrome; NISBD2, neonatal inflammatory skin and bowel disease type 2; RCAD, renal cysts and diabetes.

†iPTH, Intact parathyroid hormone; MODY5, maturity onset diabetes of the young type 5.

Modified from Viering DHHM, de Baaij JHF, Walsh SB. et al. Genetic causes of hypomagnesemia, a clinical overview. *Pediatr Nephrol.* 2017;32:1123–1135.

steatorrhea and low magnesium levels. Therapy with aminoglycosides causes hypomagnesemia by increasing urinary losses.

It is not clear how low levels of magnesium lead to hypocalcemia. Evidence suggests that hypomagnesemia impairs release of PTH and induces resistance to the effects of the hormone, but other mechanisms also may be operative.

Poisoning with inorganic phosphate leads to hypocalcemia and tetany. Infants administered large doses of inorganic phosphates, either as laxatives or as sodium phosphate enemas, have had sudden onset of tetany, with serum calcium levels <5 mg/dL and markedly elevated levels of phosphate. Symptoms are quickly relieved by intravenous administration of calcium. The mechanism of the hypocalcemia is not clear (see Chapter 73.6).

Hypocalcemia can occur early in treatment of acute lymphoblastic leukemia. Hypocalcemia is usually associated with hyperphosphatemia resulting from destruction of lymphoblasts.

Episodic symptomatic hypocalcemia occurs in **Kenny-Caffey syndrome**, which is characterized by medullary stenosis of the long bones, short stature, delayed closure of the fontanel, delayed bone age, and eye abnormalities. Idiopathic hypoparathyroidism and abnormal PTH levels have been found. Autosomal dominant and autosomal recessive modes of inheritance have been reported. Pathogenic variants of the *TBCE* gene (1q43-44) perturb microtubule organization in diseased cells in Kenny-Caffey syndrome type 1.

Chapter 612

Pseudohypoparathyroidism

Patrick C. Hanley and Daniel A. Doyle

In pseudohypoparathyroidism (PHP, also known as *Albright hereditary osteodystrophy*), the parathyroid glands are normal or hyperplastic, and they can synthesize and secrete parathyroid hormone (PTH). Serum levels of immunoreactive PTH are elevated even when the patient is hypocalcemic and may be elevated when the patient is normocalcemic. Neither endogenous nor administered PTH raises the serum levels of calcium or lowers the levels of phosphorus. The genetic defects in the **hormone receptor adenylate cyclase system** are classified into various types depending on the phenotypic and biochemical findings (Table 612.1).

TYPE Ia

Type Ia accounts for the majority of patients with PHP. Affected patients have a genetic defect of the α subunit of the stimulatory guanine nucleotide-binding protein ($G_s\alpha$). This coupling factor is required for PTH bound to cell surface receptors to activate cyclic adenosine monophosphate (cAMP). Heterogeneous pathogenic variants of the $G_s\alpha$ gene have been documented; the gene is located on chromosome 20q13.2. Deficiency of the $G_s\alpha$ subunit is a generalized cellular defect and accounts for the association of other endocrine disorders with type Ia PHP. The defect is inherited as an autosomal dominant trait, and the paucity of father-to-son transmissions is thought to be a result of decreased fertility in males.

Tetany is often the presenting sign. Affected children have a short, stocky build and a round face. Brachydactyly with dimpling of the dorsum of the hand is usually present. The second metacarpal is involved least often. As a result, the index finger occasionally is longer than the middle finger. Likewise, the second metatarsal is only rarely affected. There may be other skeletal abnormalities such as short and wide phalanges, bowing, exostoses, and thickening of the calvaria. These patients often have obesity, calcium deposits, and metaplastic bone formation subcutaneously. Moderate degrees of cognitive impairment, calcification of the basal ganglia, and lenticular cataracts are common in patients whose disease is diagnosed late.

Some members of affected kindreds may have the usual anatomic stigmata of PHP type Ia, but serum levels of calcium and phosphorus are normal despite reduced $G_s\alpha$ activity; however, PTH levels may be slightly elevated. Such patients have been labeled as having **pseudopseudohypoparathyroidism (PPHP)**. Affected patients with PPHP have pathologic variants in the *GNAS* gene inherited in an autosomal dominant pattern. PPHP patients have inactivating *GNAS* variants encoding the $G_s\alpha$ subunit that are paternally inherited. The signs and symptoms of PPHP are similar to those of patients with PHP type Ia, except patients with PPHP do not have the characteristic PTH resistance seen in PHP type Ia.

Patients with **PHP type Ic** also have the usual anatomic stigmata of PHP along with the laboratory abnormalities associated with PTH resistance, including elevated phosphorus and PTH in the setting of hypocalcemia. PHP type Ic is differentiated from PHP type Ia and PPHP in that patients do not have abnormal $G_s\alpha$ activity.

Transition from normocalcemia to hypocalcemia often occurs with increasing age of the patient. These phenotypically similar but metabolically dissimilar patients may be in the same family and have the same pathogenic variants of $G_s\alpha$ protein. It is not known what other factors cause clinically overt hypocalcemia in some

affected patients and not in others. There is evidence that the $G_s\alpha$ variant is paternally transmitted in PPHP and maternally transmitted in patients with type Ia disease. The gene may be imprinted in a tissue-specific manner and have different methylation patterns.

In addition to resistance to PTH, resistance to other G protein–coupled receptors for thyroid-stimulating hormone (TSH), gonadotropins, growth hormone–releasing hormone (GHRH), calcitonin, and glucagon can result in various metabolic effects. Clinical hypothyroidism is uncommon, but basal levels of TSH are elevated and thyrotropin-releasing hormone–stimulated TSH responses are exaggerated. Moderately decreased levels of thyroxine and increased levels of TSH have been demonstrated by newborn thyroid-screening programs, leading to the detection of type Ia PHP in infancy. In adults, gonadal dysfunction is common, as manifested by sexual immaturity, amenorrhea, oligomenorrhea, and infertility. Each of these abnormalities can be related to deficient synthesis of cAMP secondary to a deficiency of $G_s\alpha$, but it is not clear why resistance to other G protein–dependent hormones (corticotropin, vasopressin) are much less affected.

Serum levels of calcium are low, and those of phosphorus and alkaline phosphatase are elevated. Clinical diagnosis can be confirmed by demonstration of a markedly attenuated response in urinary phosphate and cAMP after intravenous infusion of the synthetic 1-34 fragment of human PTH (teriparatide acetate). Definitive diagnosis is established by demonstration of the pathogenic variant in the G protein gene.

Type Ia with Precocious Puberty

Two males have been reported with both type Ia PHP and gonadotropin-independent precocious puberty (see Chapter 600.7). They were found to have a temperature-sensitive variant of the G_s protein. Thus at normal body temperature (37°C), the G_s is degraded, resulting in PHP, but in the cooler temperature of the testes (33°C) the G_s variant results in constitutive activation of the luteinizing hormone receptor and precocious puberty.

TYPE Ib

Affected patients have normal levels of G protein activity and a normal phenotypic appearance. These patients have tissue-specific resistance to PTH but not to other hormones. Serum levels of calcium, phosphorus, and immunoreactive PTH are the same as those in patients with type Ia PHP. These patients also show no rise in cAMP in response to exogenous administration of PTH. Bioactive PTH is not increased. The pathophysiology of the disorder in this group of patients is caused by paternal uniparental isodisomy of chromosome 20q and resulting *GNAS1* methylation. This, along with the loss of the maternal *GNAS1* gene, leads to PTH resistance in the proximal renal tubules, which leads to impaired mineral ion homeostasis. Pathologic genetic deletions in the *STX16* gene are also associated with PHP type Ib.

ACRODYSOSTOSIS WITH HORMONE RESISTANCE

Patients with acrodysostosis resemble those with PHP type Ia, but defects in the $G_s\alpha$ subunit are not present. Instead, in one subgroup of patients there is a defect in the gene encoding *PRKAR1A,* the cAMP-dependent regulatory subunit of protein kinase A that confers resistance to multiple hormones, including PTH. Another subgroup has a defect in a phosphodiesterase gene *Pde4d.* This subgroup also carries the phenotype of PHP type Ia but rarely exhibits the hormone resistance. **Acroscyphodysplasia** is a distinctive form of metaphyseal dysplasia characterized by the distal femoral and proximal tibial epiphyses embedded in cup-shaped, large metaphyses known as *metaphyseal scypho* or *cup deformity* and is a phenotypic variation of PHP and acrodysostosis.

Chapter 613

Hyperparathyroidism

Evan G. Graber and Daniel A. Doyle

Excessive production of parathyroid hormone (PTH) can result from a primary defect of the parathyroid glands such as an **adenoma** or hyperplasia **(primary hyperparathyroidism)**.

More often, the increased production of PTH is compensatory, usually aimed at correcting hypocalcemic states of diverse origins **(secondary hyperparathyroidism)**. In vitamin D–deficient rickets and the malabsorption syndromes, intestinal absorption of calcium is deficient, but hypocalcemia and tetany may be averted by increased activity of the parathyroid glands. In **pseudohypoparathyroidism**, PTH levels are elevated because a pathogenic variant in the $G_s\alpha$ protein interferes with response to PTH. Early in chronic renal disease, hyperphosphatemia results in a reciprocal fall in the calcium concentration with a consequent increase in PTH, but in advanced stages of renal failure, production of $1,25(OH)_2D_3$ is also decreased, leading to worsening hypocalcemia and further stimulation of PTH. In some instances, if stimulation of the parathyroid glands has been sufficiently intense and protracted, the glands continue to secrete increased levels of PTH for months or years after kidney transplantation, with resulting hypercalcemia.

ETIOLOGY

Childhood hyperparathyroidism is uncommon. Onset during childhood is usually the result of a single benign adenoma. It usually becomes manifested after 10 years of age. There have been some kindreds in which multiple members have hyperparathyroidism transmitted in an autosomal dominant fashion. Most of the affected family members are adults, but children have been involved in approximately 30% of the pedigrees. Some affected patients in these families are asymptomatic, and disease is detected only by careful study. In other kindreds, hyperparathyroidism occurs as part of the constellation known as the **multiple endocrine neoplasia** (MEN) syndromes (see Chapter 609) or of **hyperparathyroidism–jaw tumor syndrome**.

Neonatal severe hyperparathyroidism is rare. Symptoms develop shortly after birth and consist of anorexia, irritability, lethargy, constipation, and failure to thrive. Radiographs reveal subperiosteal bone resorption, osteoporosis, and pathologic fractures. Symptoms may be mild, resolving without treatment, or can have a rapidly fatal course if diagnosis and treatment are delayed. Histologically, the parathyroid glands show diffuse hyperplasia. Affected siblings have been observed in some kindreds, and parental consanguinity has been reported in several kindreds. Most cases have occurred in kindreds with the clinical and biochemical features of **familial hypocalciuric hypercalcemia**. Infants with neonatal severe hyperparathyroidism may be homozygous or heterozygous for the pathogenic variant in the Ca^{2+}-sensing receptor gene, whereas most persons with one copy of this variant exhibit autosomal dominant familial hypocalciuric hypercalcemia.

MEN type 1 (see Chapter 609) is an autosomal dominant disorder characterized by hyperplasia or neoplasia of the endocrine pancreas (which secretes gastrin, insulin, pancreatic polypeptide, and occasionally glucagon), the anterior pituitary (which usually secretes prolactin), and the parathyroid glands. In most kindreds, hyperparathyroidism is usually the presenting manifestation, with a prevalence approaching 100% by 50 years of age and occurring only rarely in children younger than 18 years of age. With genetic testing, it is possible to detect carriers of the gene with 99% accuracy at birth, avoiding unnecessary biochemical screening programs.

The gene for MEN type 1 is on chromosome 11q13; it appears to function as a tumor-suppressor gene and follows the two-hit hypothesis of tumor development. The first variant *(germinal)* is inherited and is recessive to the dominant allele; this does not result in tumor formation. A second variant *(somatic)* is required to eliminate the normal allele, which then leads to tumor formation.

Hyperparathyroidism–jaw tumor syndrome is an autosomal dominant (*CDC73*) disorder characterized by parathyroid adenomas and fibro-osseous jaw tumors. Affected patients can also have polycystic kidney disease, renal hamartomas, and Wilms tumor. Although the condition affects adults primarily, it has been diagnosed as early as age 10 years. **MEN type 2** may also be associated with hyperparathyroidism (see Chapter 609).

Transient neonatal hyperparathyroidism has occurred in a few infants born to mothers with hypoparathyroidism (idiopathic or surgical) or with pseudohypoparathyroidism. In each case, the maternal disorder had been undiagnosed or inadequately treated during pregnancy. The cause of the condition is chronic intrauterine exposure to hypocalcemia with resultant hyperplasia of the fetal parathyroid glands. In the newborn, manifestations involve the bones primarily, and healing occurs between 4 and 7 months of age.

CLINICAL MANIFESTATIONS

At all ages, the clinical manifestations of hypercalcemia of any cause include muscle weakness, fatigue, headache, hyporeflexia, anorexia, abdominal pain, nausea, vomiting, constipation, polydipsia and polyuria **(nephrogenic diabetes insipidus)**, weight loss, and fever. When hypercalcemia is of long duration, calcium may be deposited in the renal parenchyma (nephrocalcinosis), with progressively diminished renal function. Renal calculi can develop and can cause renal colic and hematuria. Osseous changes can produce pain in the back or extremities, disturbances of gait, genu valgum, fractures, and tumors. Height can decrease from compression of vertebrae; the patient can become bedridden. Detection of completely asymptomatic patients is increasing with the advent of automated panel assays that include serum calcium determinations.

Abdominal pain is occasionally prominent and may be associated with **acute pancreatitis**. Parathyroid crisis can occur, manifested by serum calcium levels >15 mg/dL and progressive oliguria, azotemia, stupor, and coma. In infants, failure to thrive, poor feeding, and hypotonia are common. Cognitive impairment, convulsions, and blindness can occur as sequelae of long-standing hypercalcemia. Psychiatric manifestations include depression, confusion, dementia, stupor, and psychosis.

LABORATORY FINDINGS

The serum calcium level is elevated; 39 of 45 children with adenomas had levels >12 mg/dL. The hypercalcemia is more severe in infants with parathyroid hyperplasia; concentrations ranging from 15 to 20 mg/dL are common, and values as high as 30 mg/dL have been reported. Even when the total serum calcium level is borderline or only slightly elevated, ionized calcium levels are often increased. The serum phosphorus level is reduced to approximately 3 mg/dL or less, and the level of serum magnesium is low. The urine can have a low and fixed specific gravity, and serum levels of nonprotein nitrogen and uric acid may be elevated. In patients with adenomas who have skeletal involvement, serum phosphatase levels are elevated, but in infants with hyperplasia, the levels of alkaline phosphatase may be normal even when there is extensive involvement of bone.

The ECG may demonstrate a prolonged PR interval, short QT interval, widened QRS complex and bradycardia.

Serum levels of intact PTH are elevated, especially in relation to the level of calcium. Calcitonin levels are normal. Acute hypercalcemia can stimulate calcitonin release, but with prolonged hypercalcemia, hypercalcitoninemia does not occur.

The most consistent and characteristic radiographic finding is resorption of subperiosteal bone, best seen along the margins of the phalanges of the hands. In the skull, there may be gross trabeculation or a granular appearance resulting from focal rarefaction; the lamina dura may be absent. In more advanced disease, there may be generalized rarefaction, cysts, tumors, fractures, and deformities. Approximately 10% of patients have radiographic signs of rickets. Radiographs of the abdomen can reveal renal calculi or nephrocalcinosis.

DIFFERENTIAL DIAGNOSIS

Other causes of hypercalcemia can result in a similar clinical pattern and must be differentiated from hyperparathyroidism (Table 613.1 and Fig. 613.1). A low serum phosphorus level with hypercalcemia is characteristic of primary hyperparathyroidism; elevated levels of PTH are also diagnostic. With hypercalcemia of any cause except hyperparathyroidism and familial hypocalciuric hypercalcemia, PTH levels are suppressed. Pharmacologic doses of corticosteroids lower the serum calcium level to normal in patients with hypercalcemia from other causes but generally do not affect the calcium level in patients with hyperparathyroidism.

TREATMENT

When hyperparathyroidism is clearly established, imaging and possibly surgical exploration are indicated. All glands should be carefully inspected and if an adenoma is discovered, it should be removed. Very few instances of carcinoma are known in children. Most neonates with severe hypercalcemia require total parathyroidectomy; less severe hypercalcemia remits spontaneously in others. Still others have been treated successfully with bisphosphonates and calcimimetics. The patient should be carefully observed postoperatively for the development of hypocalcemia and tetany; intravenous administration of calcium gluconate may be required for a few days. The serum calcium level then gradually returns to normal, and, under ordinary circumstances, a diet high in calcium and phosphorus must be maintained for only several months after operation.

CT, real-time ultrasonography, and subtraction scintigraphy using sestamibi/technetium-pertechnetate alone and in combination have proved effective in localizing a single adenoma versus diffuse hyperplasia in 50–90% of adults. Parathyroid surgeons often rely on intraoperative selective venous sampling with intraoperative assay of PTH for localizing and removing the source of increased PTH secretion.

PROGNOSIS

The prognosis is good if the disease is recognized early and there is appropriate surgical treatment. When extensive osseous lesions are present, deformities may be permanent. A search for other affected family members is indicated.

613.1 Other Causes of Hypercalcemia

Evan G. Graber and Daniel A. Doyle

FAMILIAL HYPOCALCIURIC HYPERCALCEMIA (FAMILIAL BENIGN HYPERCALCEMIA)

Patients with familial hypocalciuric hypercalcemia are usually asymptomatic, and the hypercalcemia is identified by chance during routine investigation for other conditions. Adults may have recurrent pancreatitis, chondrocalcinosis, or premature vascular calcification. The parathyroid glands are normal, PTH levels are inappropriately normal, and subtotal parathyroidectomy does not correct the hypercalcemia. Serum levels of magnesium are high-normal or mildly elevated. The ratio of calcium-to-creatinine clearance is usually decreased despite hypercalcemia.

The disorder is inherited in an autosomal dominant manner and is caused by a pathogenic variant *(CASR)* on chromosome 3q2 in ~65% of patients **(type 1)**. In **type 2**, there is a pathogenic variant in *GNA11,* and in **type 3**, the variant is on *AP2S1*. The disorder can be diagnosed early in childhood by serum and urinary calcium concentrations. Detection of other affected family members is important to avoid inappropriate parathyroid surgery. The defect in type 1 is an inactivating mutation in the Ca^{2+}-sensing receptor gene. This G-protein–coupled receptor senses the level of free Ca^{2+} in the blood and triggers the pathway to increase extracellular Ca^{2+} in the face of hypocalcemia. This receptor functions in the parathyroid and kidney to regulate calcium homeostasis; inactivating mutations lead to an increased set point with respect to serum Ca^{2+}, resulting in mild to moderate hypercalcemia in heterozygotes.

GRANULOMATOUS DISEASES

Hypercalcemia occurs in 30–50% of children with sarcoidosis and less often in patients with other granulomatous diseases such as tuberculosis. Levels of PTH are suppressed, and levels of $1,25(OH)_2D_3$ are elevated. The source of ectopic $1,25(OH)_2D_3$ is the activated macrophage, through stimulation by interferon-α from T lymphocytes, which are present in abundance in granulomatous lesions. Unlike renal tubular cells, the 1α-hydroxylase in macrophages is unresponsive to homeostatic regulation. Oral administration of prednisone lowers serum levels of $1,25(OH)_2D_3$ to normal and corrects the hypercalcemia.

Table 613.1 Causes of Hypercalcemia

I. NEONATE/INFANT
A. Maternal Disorders
1. Excessive vitamin D ingestion, hypoparathyroidism, pseudohypoparathyroidism
B. Neonate/Infant
1. Iatrogenic: excessive intake of calcium, vitamin D, vitamin A
2. Phosphate depletion
3. Subcutaneous fat necrosis
4. Williams syndrome (del7q11.23/WBSCR1)
5. Neonatal severe hyperparathyroidism *(CaSR)*
6. Metaphyseal chondrodysplasia, Murk-Jansen type *(PTH1R)*
7. Idiopathic infantile hypercalcemia *(CYP24A1)* (25-hydroxyvitamin D 24-hydroxylase)
8. Persistent parathyroid hormone–related protein
9. Lactase/disaccharidase deficiency *(LCT)*
10. Infantile hypophosphatasia *(TNSALP)*
11. Mucolipidosis type II *(GNPTAB)*
12. Blue diaper syndrome
13. Antenatal Bartter syndrome types 1 and 2 *(SLC12A1, KCNJ1)*
14. Distal renal tubular acidosis
15. IMAGe syndrome *(CDKN1C)*
16. Post bone marrow transplantation for osteopetrosis
17. Endocrinopathies: primary adrenal insufficiency, severe congenital hypothyroidism, hyperthyroidism

II. HYPERPARATHYROIDISM
A. Sporadic
1. Parathyroid hyperplasia, adenoma, carcinoma
B. Familial
1. Neonatal severe hyperparathyroidism *(CaSR)*
2. Multiple endocrine neoplasia, type 1 *(MEN1)*
3. Multiple endocrine neoplasia, type 2A *(RET)*
4. Multiple endocrine neoplasia, type 2B *(RET)*
5. Multiple endocrine neoplasia, type 4 *(CDKN1B)*
6. McCune-Albright syndrome *(GNAS)*
7. Familial isolated hyperparathyroidism 1 *(CDC73)*
8. Familial isolated hyperparathyroidism 2 (jaw tumor syndrome) *(CDC73)*
9. Familial isolated hyperparathyroidism 3
10. Jansen metaphyseal dysplasia *(PTH1R)*
C. Secondary/tertiary
1. Postrenal transplantation
2. Chronic hyperphosphatemia
D. Hypercalcemia of malignancy
1. Ectopic production of parathyroid hormone–related peptide
2. Metastatic dissolution of bone

III. FAMILIAL HYPOCALCIURIC HYPERCALCEMIA
A. Familial hypocalciuric hypercalcemia I (CaSR)
1. Loss-of-function mutations in *CaSR*
- Monoallelic: familial benign hypercalcemia
- Biallelic: neonatal severe hyperparathyroidism
B. Familial hypocalciuric hypercalcemia II (GNA11)
C. Familial hypocalciuric hypercalcemia III, Oklahoma variant (AP2S1)
D. CaSR-blocking autoantibodies

IV. EXCESSIVE CALCIUM OR VITAMIN D
A. Milk-alkali syndrome
B. Exogenous ingestion of calcium or vitamin D or topical application of vitamin D (calcitriol or analog)
C. Ectopic production of calcitriol associated with granulomatous diseases (sarcoidosis, cat scratch fever; tuberculosis, histoplasmosis, coccidioidomycosis, cryptococcosis, leprosy; human immunodeficiency virus; cytomegalovirus; chronic inflammatory bowel disease, Blau syndrome, granulomatosis with polyangiitis)
D. Neoplasia
1. Primary bone tumors
2. Metastatic tumors with osteolysis
3. Lymphoma, leukemia
4. Dysgerminoma
5. Pheochromocytoma
6. Langerhans cell histiocytosis
7. Tumors secreting parathyroid hormone–related peptide, growth factors, cytokines, prostaglandins, and osteoclast-activating factors
E. Williams-Beuren syndrome (del7q11.23)

V. IMMOBILIZATION
VI. OTHER CAUSES
A. Drugs: thiazides, lithium, vitamin A and analogs, calcium, alkali, antiestrogens, aminophylline, teriparatide, abaloparatide
B. Total parenteral nutrition
C. Endocrinopathies: hyperthyroidism, congenital hypothyroidism, Addison disease, pheochromocytoma
D. Vasoactive intestinal polypeptide–secreting tumor
E. Acute or chronic renal failure/administration of aluminum
F. Hypophosphatasia
G. Juvenile idiopathic arthritis: cytokine mediated
H. Late phase of rhabdomyolysis

Hypercalcemia in children. *Pediatr Endocrinol Rev.* 2008;5:778–784; Davies JH. A practical approach to the problems of hypercalcaemia. *Endocr Dev.* 2009;16:93–114.

HYPERCALCEMIA OF MALIGNANCY

Hypercalcemia often occurs in adults with a wide variety of solid tumors but is identified much less often in children. It has been reported in infants with malignant rhabdoid tumors of the kidney or congenital mesoblastic nephroma and in children with neuroblastoma, medulloblastoma, leukemia, Burkitt lymphoma, dysgerminoma, and rhabdomyosarcoma. Serum levels of PTH are rarely elevated. In most patients, the hypercalcemia associated with malignancy is caused by elevated levels of parathyroid hormone–related peptide and not PTH. Rarely, tumors produce $1,25(OH)_2D_3$ or PTH ectopically.

MISCELLANEOUS CAUSES OF HYPERCALCEMIA

Hypercalcemia can occur in infants with **subcutaneous fat necrosis**. Levels of PTH are normal. In one infant, the level of $1,25(OH)_2D_3$ was elevated, and biopsy of the skin lesion revealed granulomatous infiltration, suggesting that the mechanism of the hypercalcemia was akin to that seen in patients with other granulomatous disease. In another infant, although the level of $1,25(OH)_2D_3$ was normal, PTH was suppressed, suggesting the hypercalcemia was not related to PTH. Treatment with prednisone is effective. Bisphosphonate therapy has also been effective in severe cases.

Hypophosphatasia, especially the severe infantile form, is usually associated with mild to moderate hypercalcemia (see Chapter 747). Serum levels of phosphorus are normal, and those of alkaline phosphatase are subnormal. The bones exhibit rachitic-like lesions on radiographs. Urinary levels of phosphoethanolamine, inorganic pyrophosphate, and pyridoxal 5′-phosphate are elevated; each is a natural substrate to a tissue-nonspecific (liver, bone, kidney) alkaline phosphatase enzyme. Missense variants of the tissue-nonspecific alkaline phosphatase enzyme gene result in an inactive enzyme in this autosomal recessive disorder.

Idiopathic hypercalcemia of infancy is manifested by failure to thrive and hypercalcemia during the first year of life, followed by spontaneous remission. Serum levels of phosphorus and PTH are normal. The condition has been defined as resulting from increased absorption of calcium from decreased degradation of $1,25(OH)_2D_3$. Pathogenic variants in the *CYP24A1* gene that encodes 25-hydroxyvitamin D 24-hydroxylase, the key enzyme in $1,25(OH)_2D_3$ degradation, cause excessive levels of the active vitamin D metabolite, which, in turn, causes hypercalcemia in a subset of infants who receive supplemental vitamin D. An excessive rise in the level of $1,25(OH)_2D_3$ in response to PTH administration has been reported years after the hypercalcemic phase.

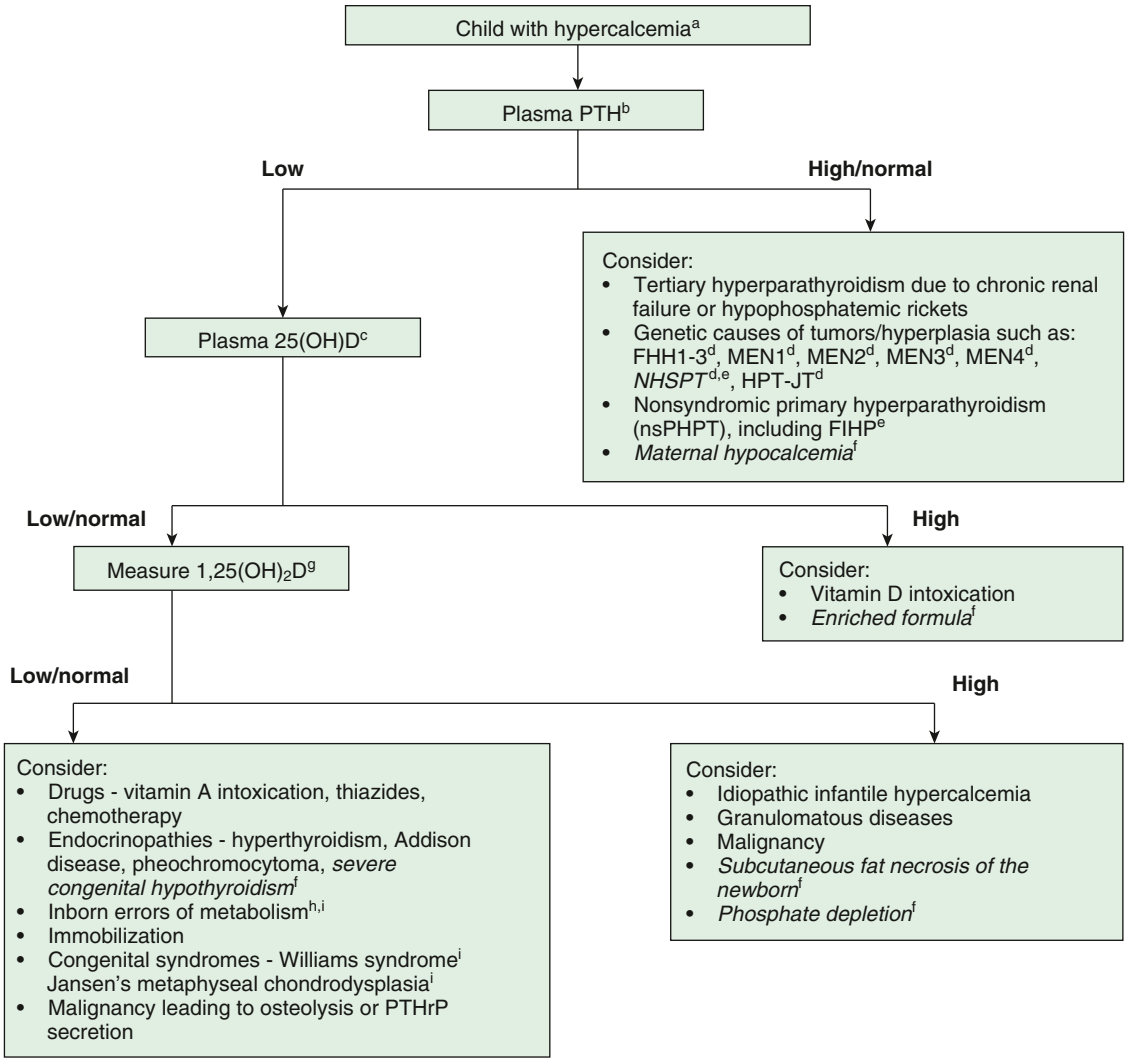

Fig. 613.1 Algorithm illustrating the clinical approach to investigation of causes of hypercalcemia in a child. [e]FIHP, Familial isolated hyperparathyroidism. [f]Conditions affecting neonates (shown in italics). [g]1,25$(OH)_2$D, 1,25-dihydroxyvitamin D. [h]Inborn errors of metabolism, for example, hypophosphatasia, congenital lactase deficiency (CLD), and blue diaper syndrome. [i]These syndromes may be associated with dysmorphic features, for example, Williams syndrome, Jansen metaphyseal chondrodysplasia, and hypophosphatasia. PTHrP, parathyroid hormone-related peptide. *(From Stokes VJ, Nielsen MF, Hannan FM, Thaller RV. Hypercalcemic disorders in children. J Bone Miner Res. 2017;32:2157–2170, Fig. 2.)*

Approximately 15% of patients with **Williams syndrome** may exhibit hypercalcemia. Hypercalcemia is more common in patients <24 months of age. It is often transient and usually does not require treatment. The phenotype consists of feeding difficulties, slow growth, elfin facies (small mandible, prominent maxilla, upturned nose), renovascular disorders, and a gregarious "cocktail party" personality. Cardiac lesions include supravalvular aortic stenosis, peripheral pulmonic stenosis, aortic hypoplasia, coronary artery stenosis, and atrial or ventricular septal defects. **Nephrocalcinosis** can develop if hypercalcemia persists. The IQ score of 50-70 is curiously accompanied by enhanced quantity and quality of vocabulary, auditory memory, and social use of language. A contiguous gene deletion syndrome with a submicroscopic deletion at chromosome 7q11.23, which includes deletion of one elastin allele, occurs in 90% of patients and seems to account for the vascular problems. Definitive diagnosis can be established by specific fluorescence in situ hybridization. The hypercalcemia and central nervous system symptoms may be caused by deletion of adjacent genes. Hypercalcemia has been successfully controlled with either prednisone or calcitonin.

Hypervitaminosis D resulting in hypercalcemia from drinking milk that has been incorrectly fortified with excessive amounts of vitamin D has been reported. Not all patients with hypervitaminosis D develop hypercalcemia. Affected infants can manifest failure to thrive, nephrolithiasis, poor renal function, and osteosclerosis. Serum levels of 25(OH)D are a better indicator of hypervitaminosis D than levels of 1,25$(OH)_2D_3$ because 25(OH)D has a longer half-life.

Prolonged immobilization can lead to hypercalcemia and occasionally to decreased renal function, hypertension, and encephalopathy. Children who have hypophosphatemic rickets and undergo surgery with subsequent long-term immobilization are at risk for hypercalcemia and should therefore have their vitamin D supplementation decreased or discontinued.

Jansen-type metaphyseal chondrodysplasia is a rare genetic disorder characterized by short-limbed dwarfism and severe but asymptomatic hypercalcemia (see Chapter 735). Circulating levels of PTH and parathyroid hormone–related peptide are undetectable. These patients have an activating PTH–parathyroid hormone–related peptide receptor mutation that results in aberrant calcium homeostasis and abnormalities of the growth plate.

Section 4

Disorders of the Adrenal Gland

Chapter 614

Physiology of the Adrenal Gland

614.1 Histology and Embryology

Perrin C. White

The adrenal gland is composed of two endocrine tissues: the medulla and the cortex. The chromaffin cells of the adrenal medulla are derived from neuroectoderm, whereas the cells of the adrenal cortex are derived from mesoderm. Mesodermal cells also contribute to the development of the gonads. The adrenal glands and gonads have certain common enzymes involved in steroid synthesis; an inborn error in steroidogenesis in one tissue can also be present in the other.

The adrenal cortex of the older child or adult consists of three zones: the **zona glomerulosa**, the outermost zone located immediately beneath the capsule; the **zona fasciculata**, the middle zone; and the **zona reticularis**, the innermost zone, lying next to the adrenal medulla. The zona fasciculata is the largest zone, constituting approximately 75% of the cortex; the zona glomerulosa constitutes approximately 15%; and the zona reticularis approximately 10%. Glomerulosa cells are small, with a lower cytoplasmic:nuclear ratio, an intermediate number of lipid inclusions, and smaller nuclei containing more condensed chromatin than the cells of the other two zones. The cells of the zona fasciculata are large, with a high cytoplasmic:nuclear ratio and many lipid inclusions that give the cytoplasm a foamy, vacuolated appearance. The cells are arranged in radial cords. The cells of the zona reticularis are arranged in irregular anastomosing cords. The cytoplasmic:nuclear ratio is intermediate, and the compact cytoplasm has relatively little lipid content.

The zona glomerulosa synthesizes **aldosterone**, the most potent natural **mineralocorticoid** in humans. The zona fasciculata produces **cortisol**, the most potent natural **glucocorticoid** in humans, and the zona fasciculata and zona reticularis synthesize the adrenal androgens.

The adrenal medulla consists mainly of neuroendocrine (chromaffin) cells and glial (sustentacular) cells with some connective tissue and vascular cells. Neuroendocrine cells are polyhedral, with abundant cytoplasm and small, pale-staining nuclei. Under the electron microscope, the cytoplasm contains many large secretory granules that contain catecholamines. Glial cells have less cytoplasm and more basophilic nuclei.

The adrenogonadal primordium differentiates from the coelomic mesothelium at 4 weeks of gestation at the urogenital ridge, just cephalad to the developing mesonephros. At 5-6 weeks, it develops into the steroidogenic cells of the gonads and adrenal cortex; the adrenal and gonadal cells separate, the adrenal cells migrate retroperitoneally, and the gonadal cells migrate caudad. At 6-8 weeks of gestation, the gland rapidly enlarges, the cells of the inner cortex differentiate to form the fetal zone, and the outer subcapsular rim remains as the definitive zone. The primordium of the adrenal cortex is invaded at this time by sympathetic neural elements of ectodermal origin that differentiate into the chromaffin cells capable of synthesizing and storing catecholamines. Catechol *O*-methyltransferase, which converts norepinephrine to epinephrine, is expressed later in gestation. By the end of the eighth week of gestation, the encapsulated adrenal gland is associated with the upper pole of the kidney. By 8-10 weeks of gestation, the cells of the fetal zone are capable of active steroidogenesis.

In the full-term infant, the combined weight of both adrenal glands is 7-9 g. At birth, the inner fetal zone of the cortex makes up approximately 80% of the gland and the outer definitive zone 20%. Within a few days the fetal cortex begins to involute, undergoing a 50% reduction by 1 month of age. Conversely, the adrenal medulla is relatively small at birth and undergoes a proportionate increase in size over the first 6 months after birth. By 1 year, the adrenal glands each weigh <1 g. Adrenal growth thereafter results in adult adrenal glands reaching a combined weight of 8 g. The zonae fasciculata and glomerulosa are fully differentiated by about 3 years of age. The zona reticularis is not fully developed until puberty.

Adrenocorticotropic hormone (ACTH) is essential for fetal adrenal growth and maturation; feedback regulation of ACTH by cortisol is apparently established by 8-10 weeks of gestation. Additional factors important in fetal growth and steroidogenesis include placental chorionic gonadotropins and a number of peptide growth factors produced by the placenta and fetus.

Many transcription factors are critical for the development of the adrenal glands. At least four, EMX2, LHX1 (also termed LIM1), WT1, and WNT4, are required for development of the adrenogonadal primordium. WT1 upregulates expression of steroidogenic factor-1 (SF-1, encoded by the *NR5A1* gene). NR5A1 is one of at least three transcription factors associated with **adrenal hypoplasia** in humans; the others are *NR0B1* (dosage-sensitive sex reversal, adrenal hypoplasia congenita, X chromosome; *DAX1*), and the *GLI3* oncogene. Disruption of *NR5A1,* encoded on chromosome 9q33, results in gonadal and often adrenal agenesis, absence of pituitary gonadotropes, and an underdeveloped ventral medial hypothalamus. In-frame deletions and frameshift and missense pathogenic variants of this gene are associated with **46,XX ovarian insufficiency** and **46,XY gonadal dysgenesis**. Pathogenic variants in the *NR0B1* gene, encoded on Xp21, result in **adrenal hypoplasia congenita** and **hypogonadotropic hypogonadism** (see Chapter 615.1). Pathogenic variants in *GLI3* on chromosome 7p13 cause **Pallister-Hall syndrome**, other features of which include hypothalamic hamartoblastoma, hypopituitarism, imperforate anus, and postaxial polydactyly.

The postnatal adrenal cortex is not static but is continually regenerated from a population of stem or progenitor cells under the adrenal capsule. These cells move radially inward (i.e., centripetally) and can differentiate into zona glomerulosa or fasciculata cells as needed in response to the appropriate trophic stimuli (see Chapter 614.3). Several signaling pathways, including sonic hedgehog (SHH) and WNT, regulate this process. SHH expression is restricted to the peripheral cortical cells that do not express high levels of steroidogenic genes but give rise to the underlying differentiated cells of the cortex. Wnt/β-catenin signaling maintains the undifferentiated state and adrenal fate of adrenocortical stem/progenitor cells, in part through induction of its target genes *DAX1* and inhibin-α, respectively. Adrenal tumors can result from constitutive activation of the WNT signaling pathway (see Chapter 617).

614.2 Adrenal Steroid Biosynthesis

Perrin C. White

Cholesterol is the starting substrate for all steroid biosynthesis (Fig. 614.1). Although adrenal cortex cells can synthesize cholesterol de novo from acetate, circulating plasma lipoproteins provide most of the cholesterol for adrenal cortex hormone formation. Receptors for both low-density lipoprotein and high-density lipoprotein cholesterol are expressed on the surface of adrenocortical cells; the receptor for high-density lipoprotein is termed *scavenger receptor class B, type I* (SR-BI). Patients with **homozygous familial hypercholesterolemia**

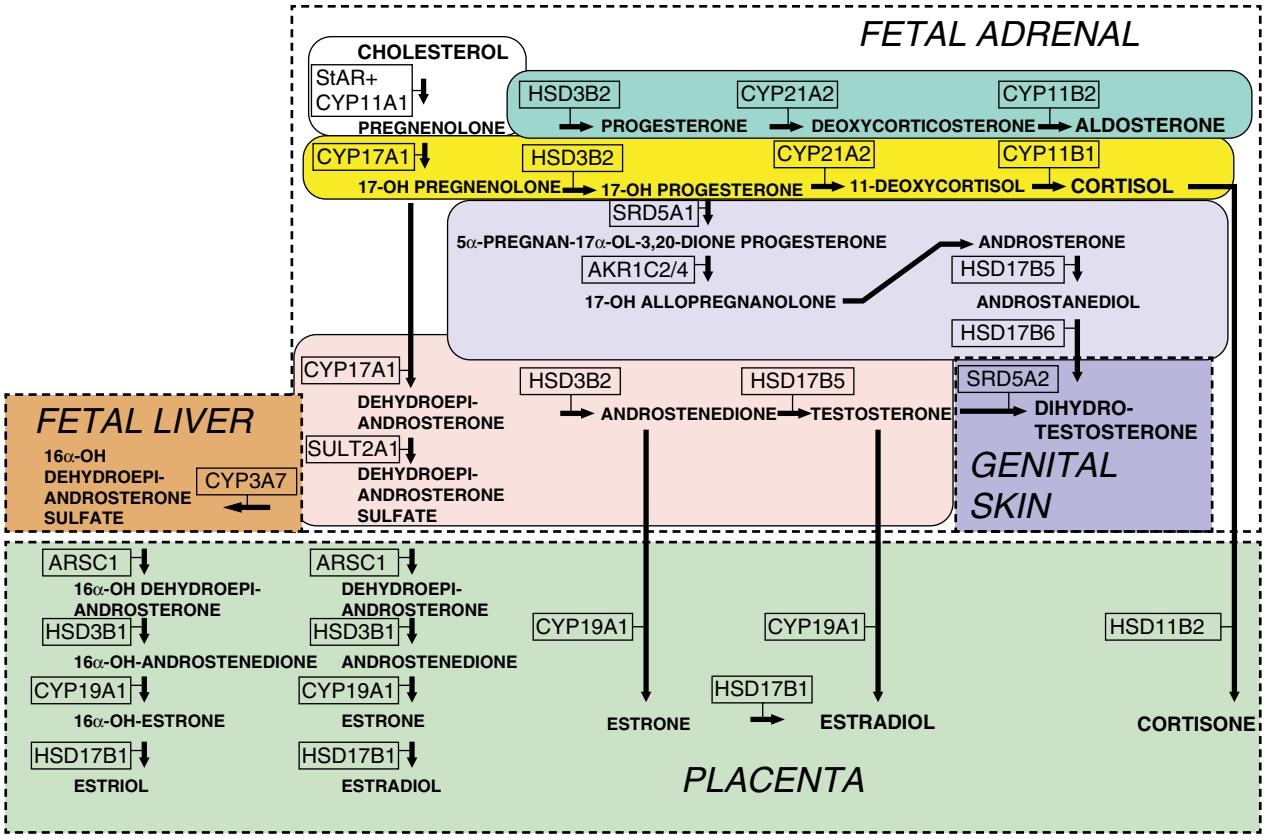

Fig. 614.1 Steroid biosynthesis and metabolism during gestation. Conversions within the fetal adrenal cortex, fetal liver *(brown rectangle),* male (i.e., testosterone-exposed) genital skin *(purple rectangle),* and placenta *(green rectangle)* are denoted by *arrows;* the enzyme mediating each conversion is also shown. Enzymatic conversions in the adrenal cortex are the same postnatally as prenatally, but cortisol and aldosterone biosynthesis (denoted by *yellow and turquoise boxes,* respectively) are more prominent, and normally little testosterone is synthesized *(pink rectangle).* A "backdoor pathway" *(lavender rectangle)* to convert 17-hydroxyprogesterone to dihydrotestosterone is active in the fetal adrenal and may assume particular importance in congenital adrenal hyperplasia (see Chapter 616). Many of the involved enzymes are cytochromes P450 (CYPs). The first step in all steroid biosynthesis is importation of cholesterol into mitochondria *(white rectangle)* mediated by the steroidogenic acute regulatory (StAR) protein. Adrenal enzymes include CYP11A1, cholesterol side-chain cleavage enzyme (P450scc in older terminology); HSD3B2, 3β-hydroxysteroid dehydrogenase/Δ5,Δ4 isomerase type 2; CYP17A1, 17β-hydroxylase/17,20-lyase (P450c17); CYP21A2, 21-hydroxylase (P450c21); CYP11B1, 11β-hydroxylase (P450c11); CYP11B2, aldosterone synthase (P450aldo; this enzyme mediates successive 11β-hydroxylase, 18-hydroxylase, and 18-oxidase reactions in the zona glomerulosa for the conversion of deoxycorticosterone to aldosterone); and AKR1C2/4, aldo-ketoreductases 1C2 and 1C4. Other enzymes important in the fetoplacental unit include ARSC1, arylsulfatase; CYP19, aromatase (P450arom); HSD3B1, 3β-hydroxysteroid dehydrogenase/Δ5,Δ4 isomerase type 1; HSD11B2, 11β-hydroxysteroid dehydrogenase type 2; HSD17B1, HSD17B5, and HSD17B6 are three different 17-hydroxysteroid dehydrogenase enzymes; SRD5A1 and SRD5A2, steroid 5α-reductase types 1 and 2, respectively; and SULT2A1, steroid sulfotransferase.

who lack low-density lipoprotein receptors have only mildly impaired adrenal steroidogenesis, suggesting that high-density lipoprotein is the more important source of cholesterol. Cholesterol is stored as cholesteryl esters in vesicles and subsequently hydrolyzed by cholesteryl ester hydrolases to liberate free cholesterol for steroid hormone synthesis.

The rate-limiting step of adrenal steroidogenesis is importation of cholesterol across the mitochondrial outer and inner membrane. This requires several proteins, particularly the steroidogenic acute regulatory (StAR) protein. The StAR protein has a very short half-life, and its synthesis is rapidly induced by trophic factors (corticotropin); it is the main short-term (minutes to hours) regulator of steroid hormone biosynthesis.

At the mitochondrial inner membrane, the side chain of cholesterol is cleaved to yield pregnenolone. This is catalyzed by the cholesterol side-chain cleavage enzyme (cholesterol desmolase, side-chain cleavage enzyme, P450scc, CYP11A1—the last term is the current systematic nomenclature), a cytochrome P450 (CYP) enzyme. Like other CYP enzymes, this is a membrane-bound hemoprotein with a molecular mass of approximately 50 kDa. It accepts electrons from a reduced nicotinamide adenine dinucleotide phosphate–dependent mitochondrial electron transport system consisting of two accessory proteins: adrenodoxin reductase (also called *ferredoxin reductase,* a flavoprotein) and adrenodoxin (or ferredoxin; a small protein containing nonheme iron). CYP enzymes use electrons and O_2 to hydroxylate the substrate and form H_2O. In the case of cholesterol side-chain cleavage, three successive oxidative reactions are performed to cleave the C20,22 carbon bond. Pregnenolone then diffuses out of mitochondria and enters the endoplasmic reticulum. The subsequent reactions that occur depend on the zone of the adrenal cortex.

ZONA GLOMERULOSA

In the zona glomerulosa, pregnenolone is converted to progesterone by 3β-hydroxysteroid dehydrogenase type 2, an oxidized nicotinamide adenine dinucleotide–dependent enzyme of the short-chain dehydrogenase type. Progesterone is converted to 11-deoxycorticosterone by steroid 21-hydroxylase (CYP21A2, P450c21), which is another CYP enzyme. Like other such enzymes in the endoplasmic reticulum, it uses an electron transport system with only one accessory protein: P450 oxidoreductase.

Deoxycorticosterone then reenters mitochondria and is converted to aldosterone by aldosterone synthase (CYP11B2, P450aldo), a CYP enzyme structurally related to cholesterol side-chain cleavage enzyme. Aldosterone synthase also carries out three successive oxidations: 11β-hydroxylation, 18-hydroxylation, and further oxidation of the 18-methyl carbon to an aldehyde.

ZONA FASCICULATA

In the endoplasmic reticulum of the zona fasciculata, pregnenolone and progesterone are converted by 17α-hydroxylase (CYP17A1, P450c17) to 17-hydroxypregenolone and 17-hydroxyprogesterone, respectively. This enzyme is not expressed in the zona glomerulosa, which consequently cannot synthesize 17-hydroxylated steroids. 17-Hydroxypregnenolone is converted to 17-hydroxyprogesterone and 11-deoxycortisol by the same 3β-hydroxysteroid and 21-hydroxylase enzymes, respectively, as are active in the zona glomerulosa. Thus inherited disorders in these enzymes affect both aldosterone and cortisol synthesis (see Chapter 616). Finally, 11-deoxycortisol reenters mitochondria and is converted to cortisol by steroid 11β-hydroxylase CYP11B1 (P450c11). This enzyme is closely related to aldosterone synthase but has low 18-hydroxylase and nonexistent 18-oxidase activity. Thus under normal circumstances the zona fasciculata cannot synthesize aldosterone.

ZONA RETICULARIS

In the zona reticularis and to some extent in the zona fasciculata, the 17-hydroxylase (CYP17A1) enzyme has an additional activity: cleavage of the 17,20 carbon-carbon bond. This converts 17-hydroxypregnenolone to dehydroepiandrosterone (DHEA). DHEA is converted to androstenedione by HSD3B2. This may be further converted in other tissues to testosterone and estrogens.

The Alternative or "Backdoor" Pathway to Dihydrotestosterone

In addition to the classic pathway via DHEA, androstenedione, and testosterone, the most potent endogenous androgen, 5-dihydrotestosterone (DHT), can also be synthesized via an alternative or "backdoor" pathway, which is physiologically active during the major period of human sexual differentiation in the 6th to 10th week of human fetal development and into the second trimester. To enter the alternative pathway, progesterone or 17-hydroxyprogesterone is 5α-reduced by steroid 5α-reductase type 1 (SRD5A1) to yield 5α-dihydroprogesterone and 17α-hydroxydihydroprogesterone. These three ketosteroids are subsequently 3α-reduced to allopregnanolone and 17α-hydroxyallopregnanolone by isoforms of the AKR1C enzyme family. CYP17A1 converts allopregnanolone to 17α-hydroxyallopregnanolone and then to androsterone by its 17,20-lyase activity. Androsterone can then be activated to DHT by sequential 17β-reduction and 3α-oxidase reactions.

FETOPLACENTAL UNIT

Steroid synthesis in the fetal adrenal varies during gestation (see Figs. 614.1 and 614.2). Shortly after the fetal adrenal gland forms (weeks 8-10), it efficiently secretes cortisol, which is able to negatively feed back on the fetal pituitary and hypothalamus to suppress ACTH secretion. This is a critical time for differentiation of the external genitalia in both sexes (see Chapter 616.1); to prevent virilization, the female fetus must not be exposed to high levels of androgens of adrenal origin, and placental aromatase activity must remain low during this time to minimize conversion of testosterone to estradiol in male fetuses, which would interfere with masculinization. After week 12, HSD3B activity in the fetal adrenal gland decreases and steroid sulfokinase activity increases. Major steroid products of the midgestation fetal adrenal gland are DHEA and DHEA sulfate (DHEAS) and, by 16α-hydroxylation in the liver, 16α-hydroxy DHEAS. Aromatase activity increases in the placenta at the same time, and steroid sulfatase activity is high as well. The placenta uses DHEA and DHEAS as substrates for estrone and estradiol synthesis and 16α-OH DHEAS as a substrate for estriol synthesis. Cortisol activity is low during the second trimester, which might serve to prevent premature secretion of surfactant by the developing fetal lungs; surfactant levels can affect the timing of parturition. As term approaches, fetal cortisol concentration increases because of increased cortisol secretion and decreased conversion of cortisol to cortisone by 11β-hydroxysteroid dehydrogenase type 2 (HSD11B2). Low levels of aldosterone are produced in midgestation, but aldosterone secretory capacity increases near term.

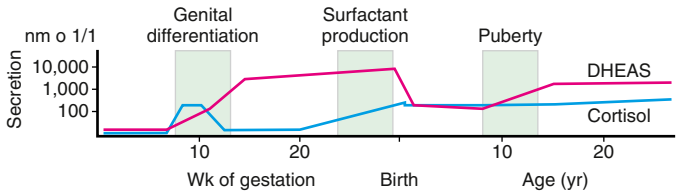

Fig. 614.2 Relative levels of cortisol and dehydroepiandrosterone sulfate (DHEAS) secretion by the fetal adrenal cortex during gestation and postnatally. Approximate times of several events are shown. Vertical axis is logarithmic, but values are approximate. Horizontal axis is not to scale.

614.3 Regulation of the Adrenal Cortex

Perrin C. White

REGULATION OF CORTISOL SECRETION

Glucocorticoid secretion is regulated mainly by ACTH (corticotropin), a 39–amino acid peptide that is produced in the anterior pituitary (see Fig. 594.2). It is synthesized as part of a larger-molecular-weight precursor peptide known as *pro-opiomelanocortin*. This precursor peptide is also the source of β-lipotropin. ACTH and β-lipotropin are cleaved further to yield α- and β-melanocyte–stimulating hormone, corticotropin-like intermediate lobe peptide, γ-lipotropin, β- and γ-endorphin, and enkephalin (see Chapter 594).

ACTH is released in secretory bursts of varying amplitude throughout the day and night. The normal diurnal rhythm of cortisol secretion is caused by the varying amplitudes of ACTH pulses. Pulses of ACTH and cortisol occur every 30-120 minutes, are highest at about the time of waking, are low in late afternoon and evening, and reach their lowest point 1 or 2 hours after sleep begins.

Corticotropin-releasing hormone (CRH), synthesized by neurons of the parvicellular division of the hypothalamic paraventricular nucleus, is the most important stimulator of ACTH secretion. Arginine vasopressin (AVP) augments CRH action. Neural stimuli from the brain cause the release of CRH and AVP (see Chapter 594). AVP and CRH are secreted in the hypophyseal-portal circulation in a pulsatile manner. This pulsatile secretion appears to be responsible for the pulsatile (ultradian) release of ACTH. The circadian rhythm of ACTH release is probably induced by the corresponding circadian rhythm of hypothalamic CRH secretion, regulated by the suprachiasmatic nucleus with input from other areas of the brain. Cortisol exerts a negative feedback effect on the synthesis and secretion of ACTH, CRH, and AVP. ACTH inhibits its own secretion, a feedback effect mediated at the level of the hypothalamus. Finally, the adrenal cortex has intrinsic rhythmicity in its responses to the ACTH. Thus the secretion of cortisol is a result of the interaction of the hypothalamus, pituitary, and adrenal glands and other neural stimuli.

ACTH acts through a specific G protein–coupled receptor (also termed *melanocortin receptor-2,* encoded by the *MCR2* gene) to activate adenylate cyclase and increase levels of cyclic adenosine monophosphate. Cyclic adenosine monophosphate has short-term (minutes to hours) effects on cholesterol transport into mitochondria by increasing expression of StAR protein. The long-term effects (hours to days) of ACTH stimulation are to increase the uptake of cholesterol and the expression of genes encoding the enzymes required to synthesize cortisol. These transcriptional effects occur at least in part through increased activity of protein kinase A, which phosphorylates several transcriptional regulatory factors. MC2R trafficking and signaling are dependent on the MC2R accessory protein (MRAP). Pathogenic variants in either MC2R or MRAP can cause **familial glucocorticoid deficiency** (see Chapter 615).

REGULATION OF ALDOSTERONE SECRETION

The rate of aldosterone synthesis, which is normally 100- to 1,000-fold less than that of cortisol synthesis, is regulated mainly by the renin-angiotensin system and by potassium levels, with ACTH having only a short-term effect. In response to decreased intravascular volume, renin is secreted by the juxtaglomerular apparatus of the kidney. Renin is a proteolytic enzyme that cleaves angiotensinogen (renin substrate), an α_2-globulin produced by the liver, to yield the inactive decapeptide angiotensin I. Angiotensin-converting enzyme in the lungs and other tissues rapidly cleaves angiotensin I to the biologically active octapeptide angiotensin II. Cleavage of angiotensin II produces the heptapeptide angiotensin III. Angiotensins II and III are potent stimulators of aldosterone secretion; angiotensin II is a more potent vasopressor agent. Angiotensins II and III occupy a G protein–coupled receptor activating phospholipase C. This protein hydrolyzes phosphatidylinositol bisphosphate to produce inositol triphosphate and diacylglycerol, which raise intracellular calcium levels and activate protein kinase C and calmodulin-activated kinases. Similarly, increased levels of extracellular potassium depolarize the cell membrane and increase calcium influx through voltage-gated L-type calcium channels. Phosphorylation of transcriptional regulatory factors by calmodulin-activated kinases increases transcription of the aldosterone synthase (CYP11B2) enzyme required for aldosterone synthesis.

REGULATION OF ADRENAL ANDROGEN SECRETION

The mechanisms by which the adrenal androgens DHEA and androstenedione are regulated are not completely understood. **Adrenarche** is a maturational process in the adrenal gland that results in increased adrenal androgen secretion between the ages of 5 and 20 years. The process begins before the earliest signs of puberty and continues throughout the years when puberty is occurring. Histologically, it is associated with the appearance of the zona reticularis. Whereas ACTH stimulates adrenal androgen production acutely and clearly is the primary stimulus for cortisol release, additional factors have been implicated in the stimulation of the adrenal androgens. These include a relative decrease in expression of HSD3B2 in the zona reticularis and possibly increases in 17,20-lyase activity owing to phosphorylation of CYP17 or increased cytochrome b5 expression.

614.4 Adrenal Steroid Hormone Actions

Perrin C. White

Steroid hormones act through several distinct receptors corresponding to the known biologic activities of the steroid hormones: glucocorticoid, mineralocorticoid, progestin, estrogen, and androgen. These receptors belong to a larger superfamily of nuclear transcription factors that include, among others, thyroid hormone and retinoic acid receptors. They have a common structure that includes a carboxyterminal ligand-binding domain and a midregion DNA-binding domain. The latter domain contains two zinc fingers, each of which consists of a loop of amino acids stabilized by four cysteine residues chelating a zinc ion.

Unliganded glucocorticoid and mineralocorticoid receptors are found mainly in the cytosol in complexes with other proteins. Hormone molecules diffuse through the cell membrane and bind receptors, changing their conformation and causing them to release their cytosolic binding proteins and translocate to the nucleus, where they bind DNA at specific hormone-response elements. Bound receptors can recruit other transcriptional coregulatory factors to DNA.

Whereas different steroids can share bioactivities because of their ability to bind to the same receptor, a given steroid can exert diverse biologic effects in different tissues. The diversity of hormonal responses is determined by the different genes that are regulated by each hormone in different tissues. Additionally, different combinations of coregulators are expressed in different tissues, allowing each steroid hormone to have many different effects. Moreover, enzymes can increase or decrease the affinity of steroids for their receptors and thus modulate their activity. 11β-Hydroxysteroid dehydrogenase type 1 (HSD11B1) converts cortisone, which is not a ligand for the glucocorticoid receptor, to cortisol, which is an active glucocorticoid. This increases local glucocorticoid concentrations in several tissues, especially the liver, where glucocorticoids maintain hepatic glucose output (see Chapter 615.4). Overexpression of this enzyme in adipose tissue can predispose to the development of obesity. Conversely, HSD11B2 oxidizes cortisol to cortisone, particularly in the kidney, preventing mineralocorticoid receptors from being occupied by high levels of cortisol (see Chapter 615.4).

Although corticosteroid receptors mainly act in the nucleus, some responses to both glucocorticoids and mineralocorticoids begin within minutes, an interval too short to be accounted for by increased gene transcription and protein synthesis. Such nongenomic effects can in some cases be mediated by cell membrane–associated isoforms of the classic glucocorticoid and mineralocorticoid receptors, which can couple to a variety of rapid intracellular signaling pathways such as G proteins. Direct interactions with other proteins, such as ion channels, have been documented as well, particularly in the nervous system.

ACTIONS OF GLUCOCORTICOIDS

Glucocorticoids are essential for survival. The term *glucocorticoid* refers to the glucose-regulating properties of these hormones. However, glucocorticoids have multiple effects on carbohydrate, lipid, and protein metabolism. They also regulate immune, circulatory, and renal function. They influence growth, development, bone metabolism, and central nervous system activity.

In stress situations, glucocorticoid secretion can increase up to 10-fold. This increase is believed to enhance survival through increased cardiac contractility, cardiac output, sensitivity to the pressor effects of catecholamines and other pressor hormones, work capacity of the skeletal muscles, and capacity to mobilize energy stores.

METABOLIC EFFECTS

The primary action of the glucocorticoids on carbohydrate metabolism is to increase glucose production by increasing hepatic gluconeogenesis. Glucocorticoids also increase cellular resistance to insulin, thereby decreasing entry of glucose into the cell. This inhibition of glucose uptake occurs in adipocytes, muscle cells, and fibroblasts. In addition to opposing insulin action, glucocorticoids can work in parallel with insulin to protect against long-term starvation by stimulating glycogen deposition and production in the liver. Both hormones stimulate glycogen synthetase activity and decrease glycogen breakdown. Glucocorticoid excess can cause hyperglycemia, and glucocorticoid deficiency can cause hypoglycemia.

Glucocorticoids increase free fatty acid levels by enhancing lipolysis, decreasing cellular glucose uptake, and decreasing glycerol production, which is necessary for reesterification of fatty acids. This increase in lipolysis is also stimulated through the permissive enhancement of lipolytic action of other factors such as epinephrine. This action affects adipocytes differently according to their anatomic locations. In the patient with glucocorticoid excess, fat is lost in the extremities, but it is increased in the trunk (centripetal obesity), neck, and face (moon facies). This may involve effects on adipocyte differentiation.

Glucocorticoids generally exert a catabolic or antianabolic effect on protein metabolism. Proteolysis in fat, skeletal muscle, bone, lymphoid, and connective tissue increases amino acid substrates that can be used in gluconeogenesis. Cardiac muscle and the diaphragm are almost entirely spared from this catabolic effect.

Circulatory and Renal Effects

Glucocorticoids have a positive inotropic influence on the heart, increasing the left ventricular work index. They have a permissive effect on the actions of epinephrine and norepinephrine on both the heart and the blood vessels. In the absence of glucocorticoids, decreased cardiac output and shock can develop; in states of glucocorticoid excess,

hypertension is often observed. This may be a result of activation of the mineralocorticoid receptor (see Chapter 615.4), which occurs when renal HSD11B2 is saturated by excessive levels of glucocorticoids.

Growth

In excess, glucocorticoids inhibit linear growth and skeletal maturation in children, apparently through direct effects on the epiphyses. However, glucocorticoids are also necessary for normal growth and development. In the fetus and neonate, they accelerate the differentiation and development of various tissues, including the hepatic and gastrointestinal systems, along with the production of surfactant in the fetal lung. Glucocorticoids are often given to pregnant women at risk for delivery of premature infants to accelerate these maturational processes.

Immunologic Effects

Glucocorticoids play a major role in immune regulation. They inhibit synthesis of glycolipids and prostaglandin precursors and the actions of bradykinin. They also block secretion and actions of histamine and proinflammatory cytokines (tumor necrosis factor-α, interleukin-1, and interleukin-6), thus diminishing inflammation. High doses of glucocorticoids deplete monocytes, eosinophils, and lymphocytes, especially T cells. They do so at least in part by inducing cell-cycle arrest in the G_1 phase and by activating apoptosis through glucocorticoid receptor–mediated effects. The effects on lymphocytes are primarily exerted on T-helper 1 cells and hence on cellular immunity, whereas the T-helper 2 cells are spared, leading to a predominantly humoral immune response. Pharmacologic doses of glucocorticoids can also decrease the size of immunologic tissues (spleen, thymus, and lymph nodes).

Glucocorticoids increase circulating polymorphonuclear cell counts, mostly by preventing their egress from the circulation. Glucocorticoids decrease diapedesis, chemotaxis, and phagocytosis of polymorphonuclear cells. Thus the mobility of these cells is altered such that they do not arrive at the site of inflammation to mount an appropriate immune response. High levels of glucocorticoids decrease inflammatory and cellular immune responses and increase susceptibility to certain bacterial, viral, fungal, and parasitic infections.

Effects on Skin, Bone, and Calcium

Glucocorticoids inhibit fibroblasts, leading to increased bruising and poor wound healing through cutaneous atrophy. This effect explains the thinning of the skin and striae that are seen in patients with Cushing syndrome.

Glucocorticoids have the overall effect of decreasing serum calcium and have been used in emergency therapy for certain types of hypercalcemia. This hypocalcemic effect probably results from a decrease in the intestinal absorption of calcium and a decrease in the renal reabsorption of calcium and phosphorus. Serum calcium levels, however, generally do not fall below normal because of a secondary increase in parathyroid hormone secretion.

The most significant effect of long-term glucocorticoid excess on calcium and bone metabolism is osteoporosis. Glucocorticoids inhibit osteoblastic activity by decreasing the number and activity of osteoblasts. Glucocorticoids also decrease osteoclastic activity but to a lesser extent, leading to low bone turnover with an overall negative balance. The tendency of glucocorticoids to lower serum calcium and phosphate levels causes secondary hyperparathyroidism. These actions decrease bone accretion and cause a net loss of bone mineral.

Central Nervous System Effects

Glucocorticoids readily penetrate the blood-brain barrier and have direct effects on brain metabolism. They decrease certain types of central nervous system edema and are often used to treat increased intracranial pressure. In large doses, they stimulate appetite and cause insomnia with a reduction in rapid eye movement sleep. There is an increase in irritability and emotional lability, with an impairment of memory and ability to concentrate. Mild to moderate glucocorticoid excess for a limited period often causes a feeling of euphoria or well-being, but glucocorticoid excess and deficiency can both be associated with clinical depression. *Glucocorticoid excess produces psychosis in some patients.*

Glucocorticoid effects in the brain are mediated largely through interactions with both the mineralocorticoid and glucocorticoid receptors (sometimes referred to in this context as *type I* and *type II corticosteroid receptors,* respectively). Activation of type II receptors increases sensitivity of hippocampal neurons to the neurotransmitter serotonin, which might help explain the euphoria associated with high doses of glucocorticoids. Glucocorticoids suppress release of CRH in the anterior hypothalamus, but they stimulate it in the central nucleus of the amygdala and lateral bed nucleus of the stria terminalis, where it can mediate fear and anxiety states. Glucocorticoids and other steroids might have nongenomic effects by modulating activities of both γ-aminobutyric acid and *N*-methyl-D-aspartate receptors.

ACTIONS OF MINERALOCORTICOIDS

The most important mineralocorticoids are aldosterone and, to a lesser degree, 11-deoxycorticosterone; corticosterone and cortisol are normally not important as mineralocorticoids unless secreted in excess. Mineralocorticoids have more limited actions than glucocorticoids. Their major function is to maintain intravascular volume by conserving sodium and eliminating potassium and hydrogen ions. They exert these actions in the kidney, gut, and salivary and sweat glands. Aldosterone can have distinct effects in other tissues. Mineralocorticoid receptors are found in the heart and vascular endothelium, and aldosterone increases myocardial fibrosis in heart failure.

Mineralocorticoids have their most important actions in the distal convoluted tubules and cortical collecting ducts of the kidney, where they induce reabsorption of sodium and secretion of potassium. In the medullary collecting duct, they act in a permissive fashion to allow vasopressin to increase osmotic water flux. Thus patients with mineralocorticoid deficiency can develop weight loss, hypotension, hyponatremia, and hyperkalemia, whereas patients with mineralocorticoid excess can develop hypertension, hypokalemia, and metabolic alkalosis (see Chapters 615, 616, and 620).

The mechanisms by which aldosterone affects sodium excretion are incompletely understood. Most effects of aldosterone are presumably the result of changes in gene expression mediated by the mineralocorticoid receptor, and indeed levels of subunits of both the Na^+, K^+-adenosine triphosphatase and the epithelial sodium channel increase in response to aldosterone. Additionally, aldosterone increases expression of the serum- and glucocorticoid-regulated kinase, which indirectly reduces turnover of epithelial sodium channel subunits and thus increases the number of open sodium channels.

The mineralocorticoid receptor has similar affinities in vitro for cortisol and aldosterone, yet cortisol is a weak mineralocorticoid in vivo. This discrepancy results from the action of HSD11B2, which converts cortisol to cortisone. Cortisone is not a ligand for the receptor, whereas aldosterone is not a substrate for the enzyme. Pharmacologic inhibition (as occurs with excessive consumption of licorice) or genetic deficiency of this enzyme allows cortisol to occupy renal mineralocorticoid receptors and produce sodium retention and hypertension; the genetic condition is termed **apparent mineralocorticoid excess syndrome**.

ACTIONS OF THE ADRENAL ANDROGENS

Many actions of adrenal androgens are exerted through their conversion to active androgens or estrogens such as testosterone, dihydrotestosterone, estrone, and estradiol. In males, <2% of the biologically important androgens are derived from adrenal production, whereas in females approximately 50% of androgens are of adrenal origin. The adrenal contribution to circulating estrogen levels is mainly important in pathologic conditions such as feminizing adrenal tumors. Adrenal androgens contribute to the physiologic development of pubic and axillary hair during normal puberty. They also play an important role in the pathophysiology of **congenital adrenal hyperplasia**, **premature**

adrenarche, **adrenal tumors,** and **Cushing syndrome** (see Chapters 616-619).

In humans, circulating levels of DHEA and DHEAS, the chief adrenal androgen precursors, reach a peak in early adulthood and then decline. This has led to speculation that some age-related physiologic changes might be reversed by DHEA administration, and beneficial effects have been suggested (but not proved) on insulin sensitivity, bone mineral density, muscle mass, cardiovascular risk, obesity, cancer risk, autoimmunity, and the central nervous system.

Synthetic Corticosteroids

Many synthetic analogs of cortisone and hydrocortisone are available. Prednisone and prednisolone are derivatives with an additional double bond in ring A. Similar to cortisone, prednisone is not an active steroid, but it is converted to prednisolone by HSD11B1 in the liver. Prednisone and prednisolone are 4-5 times as potent in antiinflammatory and carbohydrate activity but have slightly less effect on retention of water and sodium than cortisol. Halogenated derivatives have different effects. Betamethasone and dexamethasone have 25-40 times the glucocorticoid potency of cortisol but have little mineralocorticoid effect. These analogs are usually used in pharmacologic doses for their antiinflammatory or immunosuppressive properties. The antiinflammatory activity of fludrocortisone is about 15 times that of hydrocortisone, but fludrocortisone is more than 125 times as active a mineralocorticoid; it is used to treat aldosterone deficiency.

614.5 Adrenal Medulla

Perrin C. White

The principal hormones of the adrenal medulla are the physiologically active catecholamines: dopamine, norepinephrine, and epinephrine (Fig. 614.3). Catecholamine synthesis also occurs in the brain, in sympathetic nerve endings, and in chromaffin tissue outside the adrenal medulla. Metabolites of catecholamines are excreted in the urine, principally 3-methoxy-4-hydroxymandelic acid, metanephrine, and normetanephrine. Urinary metanephrines and catecholamines are measured to detect pheochromocytomas of the adrenal medulla and sympathetic nervous system (see Chapter 621).

The proportions of epinephrine and norepinephrine in the adrenal gland vary with age. In early fetal stages, there is practically no epinephrine; at birth, norepinephrine remains predominant. However, in adults, norepinephrine accounts for only 10–30% of the pressor amines in the medulla.

The effects of catecholamines are mediated through a series of G protein–coupled adrenergic receptors. Both epinephrine and norepinephrine raise the mean arterial blood pressure, but only epinephrine increases cardiac output. By increasing peripheral vascular resistance, norepinephrine increases systolic and diastolic blood pressures with only a slight reduction in the pulse rate. Epinephrine increases the pulse rate and, by decreasing the peripheral vascular resistance, decreases the diastolic pressure. The hyperglycemic and calorigenic effects of norepinephrine are much less pronounced than are those of epinephrine.

Chapter 615

Adrenocortical Insufficiency and Altered Sensitivity to Corticosteroids

Perrin C. White

In primary adrenal insufficiency, congenital or acquired lesions of the adrenal cortex prevent production of cortisol and often aldosterone (Table 615.1). Acquired primary adrenal insufficiency is termed **Addison disease**. Dysfunction of the anterior pituitary gland or hypothalamus can cause a deficiency of corticotropin (adrenocorticotropic hormone [ACTH]) and lead to hypofunction of the adrenal cortex, termed *secondary adrenal insufficiency;* the term *tertiary adrenal insufficiency* is sometimes used to denote cases arising from hypothalamic dysfunction (Tables 615.2 and 615.3).

615.1 Primary Adrenal Insufficiency

Perrin C. White

Primary adrenal insufficiency in children is most frequently caused by genetic conditions that are often, but not always, manifested in infancy and, less often, by acquired problems such as autoimmune conditions (Table 615.4) or syndromes (Table 615.5). Susceptibility to autoimmune conditions often has a genetic basis, and so these distinctions are not absolute.

INHERITED ETIOLOGIES

Inborn Defects of Steroidogenesis

The most common causes of adrenocortical insufficiency in *infancy* are the salt-losing forms of congenital adrenal hyperplasia (CAH, see Chapter 616). Approximately 75% of infants with 21-hydroxylase deficiency, almost all infants with lipoid adrenal hyperplasia, and most infants with a deficiency of 3β-hydroxysteroid dehydrogenase manifest salt-losing symptoms in the newborn period because they are unable to synthesize either cortisol or aldosterone. Relatively mild pathogenic variants in *STAR* (which controls cholesterol importation into mitochondria) or *CYP11A1* (which encodes the cholesterol side-chain cleavage enzyme) can cause adrenal insufficiency manifesting in childhood.

Aside from CAH and autoimmune adrenalitis, a genetic cause can be identified in >65% of patients with primary adrenal insufficiency presenting in *childhood*. These can be grouped into several categories: (1) ACTH unresponsiveness (familial glucocorticoid deficiency); (2) adrenal hypoplasia congenita caused by pathogenic variants in orphan nuclear hormone receptors that affect expression of other genes; (3) defects in lipid metabolism, particularly adrenoleukodystrophy; (4) syndromes associated with intrauterine growth restriction, adrenal hypoplasia, and disorders of sexual development, such as IMAGe and MIRAGE syndromes (activating variants of *CDKN1C* and *SAMD9,* respectively), and type 2 IMAGe syndrome (*POLE1* gene); and (5) deficiency of mitochondrial reactive oxygen species detoxification (*NNT* and *TXNRD2* genes).

Familial Glucocorticoid Deficiency

Familial glucocorticoid deficiency is a form of chronic adrenal insufficiency characterized by isolated deficiency of glucocorticoids, elevated levels of ACTH, and generally normal aldosterone production, although salt-losing manifestations present in most other forms of adrenal insufficiency occasionally occur. Patients may have hypoglycemia, seizures, and increased pigmentation during the first decade of life. The disorder affects both sexes equally and is inherited in an autosomal recessive manner. There is marked adrenocortical atrophy with relative sparing of the zona glomerulosa. Pathogenic variants in the gene for the ACTH receptor *(MCR2)* have been described in approximately 25% of these patients, most of which affect trafficking of receptor molecules from the endoplasmic reticulum to the cell surface. Another 10–20% of cases are caused by variants in *MRAP,* which encodes a melanocyte receptor accessory protein required for this trafficking.

Another syndrome of ACTH resistance occurs in association with achalasia and alacrima (**triple A** or **Allgrove syndrome**). These patients often have a progressive neurologic disorder that includes autonomic dysfunction, intellectual disability, motor neuropathy, and occasional deafness. This syndrome is autosomal recessive; the *AAAS* gene has been mapped to chromosome 12q13. The encoded protein, aladin, might help to regulate nucleocytoplasmic transport of other proteins.

Adrenal Hypoplasia Congenita

Adrenal hypoplasia congenita (AHC) is a relatively frequent cause of adrenal insufficiency in males, along with CAH, autoimmune disease, and adrenoleukodystrophy (ALD). AHC is predominantly a failure of development of the definitive zone of the adrenal cortex; the fetal zone may be relatively normal. Consequently, adrenal insufficiency generally becomes evident as the fetal zone involutes postnatally (see Chapter 614), with onset in infancy or in the first 2 years of life but occasionally in later childhood or even adulthood. In some cases, aldosterone deficiency becomes evident before cortisol deficiency.

The disorder is caused by pathogenic variants of *NR0B1 (DAX1)*, a member of the nuclear hormone receptor family, located on Xp21. Males with AHC often do not undergo puberty as a result of hypogonadotropic hypogonadism caused by the same variant of *NR0B1*. **Cryptorchidism**, sometimes noted in these males, is probably an early manifestation of hypogonadotropic hypogonadism, but often testicular function in infants is normal, with a typical or even an unusually prolonged testosterone surge in the first month of life.

AHC occasionally occurs as part of a *contiguous gene deletion* syndrome together with Duchenne muscular dystrophy, glycerol kinase deficiency, cognitive impairment, or a combination of these conditions.

The transcription factor NR5A1 (steroidogenic factor-1, SF-1) is required for adrenal and gonadal development (see Chapter 614). Males with heterozygous variants in *NR5A1* have impaired development of the testes despite the presence of a normal copy of the gene on the other chromosome and can appear to be female, similar to patients with lipoid adrenal hyperplasia (see Chapter 616). Rarely, such patients also have adrenal insufficiency.

Adrenal hypoplasia is also occasionally seen in patients with **Pallister-Hall syndrome** caused by pathogenic variants in *GLI3*.

Disorders of Lipid Metabolism

In **adrenal leukodystrophy (ALD)**, adrenocortical deficiency is associated with demyelination in the central nervous system (see Chapters 106.2 and 639.3). High levels of **very long-chain fatty acids** are found in tissues and body fluids, resulting from their impaired β-oxidation in the peroxisomes.

The most common form of ALD is an X-linked disorder with various presentations. The most common clinical picture is of a degenerative neurologic disorder appearing in childhood or adolescence and progressing to severe dementia and deterioration of vision, hearing, speech, and gait, with death occurring within a few years. Neurologic symptoms may be subtle at onset, sometimes consisting only of behavioral changes or deteriorating academic performance. Generalized but incomplete alopecia, resembling that of chemotherapy, is a characteristic but inconsistent finding. A milder form of X-linked ALD is **adrenomyeloneuropathy**, which begins in later adolescence or early adulthood. Patients may have evidence of adrenal insufficiency before, at the time of, or after neurologic symptoms develop, often with years

Table 615.1 Causes of Primary Adrenal Insufficiency

	GENE (OMIM*)	ASSOCIATED CLINICAL SIGNS AND SYMPTOMS
ADRENAL DESTRUCTION		
Autoimmunity		
Autoimmune primary adrenal insufficiency and autoimmune polyendocrine syndrome type 2	*HLA-DR3, DR4, CTLA4, BACH2, PTPN22, GATA3, CLEC16, MIC-A, MIC-B, NALP1,* and *AIRE*	Hypothyroidism, hyperthyroidism, premature ovarian insufficiency, vitiligo, type 1 diabetes, pernicious anemia, other organ-specific autoimmune features
Autoimmune polyendocrine syndrome type 1	*AIRE* (240300)	Hypoparathyroidism, chronic mucocutaneous candidiasis, other autoimmune disorders, lymphomas (rarely)
Immunodeficiency 31C	*STAT1* (614162)	Chronic mucocutaneous candidiasis, susceptibility to *Staphylococcus aureus* and other bacterial, viral, and fungal infections, polyendocrinopathy (including hypothyroidism and type 1 diabetes), cerebral aneurysms
Peroxisomal Defects		
X-linked adrenoleukodystrophy	*ABCD1* (300100)	Progressive neurodegeneration, behavioral changes, cognitive decline, loss of speech, hearing, and vision, dementia, spasticity, seizures
Refsum disease	*PEX7* (266500)	Least severe form of peroxisome biosynthesis defects
Neonatal adrenoleukodystrophy (autosomal recessive)	*PEX1* (601539)	Craniofacial abnormalities, liver dysfunction, absence of peroxisomes
Zellweger syndrome	*PEX1* (214100)	Craniofacial abnormalities, hepatomegaly, severe intellectual disability and growth failure, hypotonia, deafness, blindness, genitourinary abnormalities, stippled epiphyses
Mitochondrial Defects		
Kearns-Sayre syndrome	Mitochondrial DNA deletions (530000)	External ophthalmoplegia, retinal degeneration, cardiac conduction defects, other endocrinopathies
Hemorrhage	—	Bilateral adrenal hemorrhage of the newborn baby, primary antiphospholipid syndrome, anticoagulation
Trauma or Surgery	—	Bilateral adrenalectomy
Infection	—	Septic shock, meningococcal sepsis (Waterhouse-Friderichsen syndrome), tuberculosis, fungal infections (e.g., histoplasmosis, cryptococcosis, coccidioidomycosis, and blastomycosis), African trypanosomiasis, cytomegalovirus, HIV-1, syphilis
Infiltration	—	Metastatic cancers, primary adrenal lymphoma, amyloidosis, sarcoidosis (rare), hemochromatosis
DRUGS	—	Ketoconazole, rifampicin, phenytoin, phenobarbital, aminoglutethimide, mitotane, abiraterone acetate, etomidate, suramin, mifepristone, nivolumab, pembrolizumab
IMPAIRED STEROIDOGENESIS		
Impaired Cholesterol Transport		
Steroidogenic acute regulatory protein (congenital lipoid adrenal hyperplasia)	*StAR* (201710)	46,XY DSD, gonadal insufficiency
Steroidogenic Enzyme or Cofactor Deficiency Causing Congenital Adrenal Hyperplasia		
3β-hydroxysteroid dehydrogenase type 2	*HSD3B2* (201810)	46,XX and 46,XY DSD, gonadal insufficiency
21-hydroxylase	*CYP21A2* (201 910)	46,XX DSD, hyperandrogenism
11β-hydroxylase	*CYP11B1* (202 010)	46,XX DSD, arterial hypertension
CYP17A1 deficiency	*CYP17A1* (202 110)	46,XY DSD, arterial hypertension, gonadal insufficiency
P450 oxidoreductase	*POR* (201 750)	46,XX and 46,XY DSD, gonadal insufficiency, bone malformation, dysfunction of all endoplasmic CYP450 enzymes
Steroidogenic Enzyme Deficiency (Noncongenital Adrenal Hyperplasia)		
P450 side-chain cleavage enzyme	*CYP11A1* (118 485)	46,XY DSD, gonadal insufficiency
Aldosterone synthase	*CYP11B2* (124 080)	Isolated mineralocorticoid deficiency
Defects of Cholesterol Synthesis or Metabolism		
Wolman disease (lysosomal acid lipase deficiency, and cholesterol ester storage disease)	*LIPA* (278 000)	Diffuse punctate adrenal calcification, xanthomatous changes in multiple organs, hypercholesterolemia, steatorrhea, poor prognosis

Continued

Table 615.1 Causes of Primary Adrenal Insufficiency—cont'd

	GENE (OMIM*)	ASSOCIATED CLINICAL SIGNS AND SYMPTOMS
Smith-Lemli-Opitz disease	*DHCR7* (270 400)	Intellectual disability, craniofacial malformations, limb abnormalities, growth failure
Abetalipoproteinemia	*MTP* (200 100)	Ataxia, retinopathy, acanthocytosis, fat malabsorption
ADRENAL DYSGENESIS		
X-linked adrenal hypoplasia congenital	*NROB1* (300 200)	Combined primary and secondary hypogonadism, Duchenne muscular dystrophy in contiguous gene syndrome
Adrenal hypoplasia steroidogenic factor-1 deficiency	*NR5A1* (184757)	46,XY DSD, gonadal insufficiency
IMAGe syndrome	*CDKN1C* (300 290)	Intrauterine growth restriction, metaphyseal dysplasia, adrenal insufficiency, genital anomalies
MIRAGE syndrome	*SMAD9* (617 053)	Myelodysplasia, infection, adrenal hypoplasia, growth restriction, genital anomalies, enteropathy
Pallister-Hall syndrome	*GLI3* (165 240)	Hypothalamic hamartoblastoma, hypopituitarism, imperforate anus, postaxial polydactyly
Meckel syndrome	*MKS1* (249 000)	CNS malformation, polycystic kidneys with fibrotic liver changes, polydactyly
Pseudotrisomy 13	(264 480)	Holoprosencephaly, severe facial anomalies, postaxial polydactyly, various other congenital defects, and normal chromosomes
Hydrolethalus syndrome	*HYLS1* (236 680)	Severe prenatal-onset hydrocephalus, polydactyly
Galloway-Mowat syndrome	*WDR73* (251 300)	Early-onset severe encephalopathy, intractable epilepsy, nephrotic syndrome, microcephaly, hiatal hernia
ACTH RESISTANCE		
Familial glucocorticoid deficiency type 1	*MC2R* (202 200)	Tall stature, isolated deficiency of glucocorticoids, generally normal aldosterone production
Familial glucocorticoid deficiency type 2	*MRAP* (607398)	Isolated deficiency of glucocorticoids, generally normal aldosterone production
IMPAIRED REDOX HOMEOSTASIS		
Triple A syndrome (Allgrove syndrome)	*AAAS* (231550)	Alacrimia, achalasia, neurologic impairment, deafness, intellectual disability, hyperkeratosis
Mitochondrial deficiency of free radical detoxification	*NNT* (614736) and *TRXR2* (606448)	*NNT*: hypoglycemia, hyperpigmentation, low cortisol concentration, increased ACTH concentration, isolated deficiency of glucocorticoids; *TRXR2*: isolated deficiency of glucocorticoids
MISCELLANEOUS		
Defects in DNA repair	*MCM4* (609981)	Natural killer cell deficiency, growth failure, increased chromosomal breakage
Bioinactive ACTH	*POMC* (201400)	—
Sphingosine-1-phosphate lyase 1	*SGPL1* (617575)	Steroid-resistant nephrotic syndrome, ichthyosis, primary hypothyroidism, cryptorchidism, immunodeficiency, neurologic defects

separating their presentation. X-linked ALD is caused by pathogenic variants in *ABCD1* located on Xq28. The gene encodes a transmembrane transporter involved in the importation of very long-chain fatty acids into peroxisomes. Clinical phenotypes can vary even within families, perhaps owing to modifier genes or other unknown factors. There is no correlation between the degree of neurologic impairment and severity of adrenal insufficiency. Prenatal diagnosis by DNA analysis and family screening by very long-chain fatty acid assays and gene analysis are available. Females who are heterozygous carriers of the X-linked ALD gene can develop neurologic symptoms in midlife or later; adrenal insufficiency is rare. This condition is part of the newborn screening panel.

Neonatal ALD is a rare *autosomal recessive* disorder. Infants have neurologic deterioration and have or acquire evidence of adrenocortical dysfunction. Most patients have severe, progressive cognitive impairment and die before 5 years of age. This disorder is a subset of **Zellweger (cerebrohepatorenal) syndrome**, in which peroxisomes do not develop at all owing to pathogenic variants in any of several genes (*PEX5*, *PEX1*, *PEX10*, *PEX13*, and *PEX26*) controlling the development of peroxisomes.

Patients with disorders of cholesterol synthesis or metabolism, including abetalipoproteinemia with deficient lipoprotein B–containing lipoproteins (such as low-density lipoprotein), and homozygous **familial hypercholesterolemia**, with impaired or absent low-density lipoprotein receptors, have mildly impaired adrenocortical function. Heterozygous familial hypercholesterolemia patients have normal adrenocortical function, which is unaffected by treatment with statin (HMG-CoA reductase inhibitor) drugs. Adrenal insufficiency has been reported in patients with **Smith-Lemli-Opitz syndrome**, an autosomal recessive disorder manifesting with facial anomalies, microcephaly, limb anomalies, and developmental delay (see Chapter 106.3), caused by pathogenic variants in the gene coding for sterol Δ^7-reductase on chromosome 11q12-q13.

Table 615.2 Causes of Secondary Adrenal Insufficiency in the Form of Pituitary Disorders

	GENE (OMIM*)	ASSOCIATED CLINICAL SIGNS AND SYMPTOMS
ACQUIRED CAUSES		
Steroid withdrawal syndrome	*PDGFD*	Endogenous glucocorticoid hypersecretion caused by Cushing syndrome and exogenous glucocorticoid administration for more than 2 wk
Opioids	—	Hypogonadotropic hypogonadism
Tumor	—	Craniopharyngioma, glioma, meningioma, ependymoma, germinoma, intrasellar or suprasellar metastases, adenoma, carcinoma
Trauma	—	Pituitary stalk lesions, battered child syndrome, vehicular trauma
Pituitary apoplexy (Sheehan syndrome)	—	High blood loss or hypotension
CONGENITAL CAUSES		
Aplasia or Hypoplasia		
PROP1 deficiency	*PROP1* (262600)	Additional deficiency of growth hormone, prolactin, thyroid-stimulating hormone, and luteinizing hormone or follicle-stimulating hormone, or both
LHX4 deficiency	*LHX4* (262700)	Additional deficiency of growth hormone and thyroid-stimulating hormone
SOX3 deficiency	*SOX3* (312000)	Additional deficiencies of pituitary hormones
Isolated ACTH Deficiency		
TBX19 deficiency	*TBX19* (201400)	Severe neonatal-onset adrenal insufficiency
Proopiomelanocortin	*POMC* (609734)	Adrenal insufficiency, early-onset obesity, red hair pigmentation
Proprotein convertase 1	*PCSK1* (600955)	Hypoglycemia, malabsorption, hypogonadotropic hypogonadism

This impairs the final step in cholesterol synthesis with marked elevation of 7-dehydrocholesterol and abnormally low cholesterol. **Wolman disease** is a rare autosomal recessive disorder caused by pathogenic variants in the gene encoding human lysosomal acid lipase on chromosome 10q23.2-23.3. Cholesteryl esters accumulate in lysosomes in most organ systems, leading to organ failure. Infants during the first or second month of life have hepatosplenomegaly, steatorrhea, abdominal distention, and failure to thrive. Adrenal insufficiency and bilateral adrenal calcification are present, and death usually occurs in the first year of life.

Multisystem Syndromes Associated with Growth Restriction

Pathogenic variants in genes that affect DNA replication may be associated with primordial dwarfism, immune deficiency, and adrenal insufficiency. Minichromosome maintenance-deficient 4 homolog *(MCM4)* functions to integrate several protein kinase signals that regulate progression of DNA replication through the S phase. Homozygous deficiency of MCM4 causes a primary **immunodeficiency syndrome** characterized by severe intrauterine and extrauterine growth

Table 615.4 Frequencies of Etiologies of Primary Adrenal Insufficiency

ETIOLOGY	%	AGE AT DIAGNOSIS
Congenital adrenal hyperplasia	59	Infancy
Autoimmune	16	Childhood to adolescence
APECED (autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy)	6	Childhood to adolescence
Adrenoleukodystrophy	4	Childhood to adolescence
Other genetic causes	14*	
Hemorrhage	1	Infancy

Primary adrenal insufficiency in children: twenty years' experience at the Sainte-Justine Hospital, Montreal. *J Clin Endocrinol Metab.* 2005;90:3243–3250; Hsieh S, White PC. Presentation of primary adrenal insufficiency in childhood. J Clin Endocrinol Metab. 2011;96:E925–E928.

Table 615.5 Other Genetic Etiologies for Primary Adrenal Insufficiency

GENE	FUNCTION	SYNDROME	FREQUENCY* %
MC2R	Melanocortin (ACTH) receptor	Familial glucocorticoid deficiency type 1	22
MRAP	Melanocortin receptor accessory protein	Familial glucocorticoid deficiency type 2	4
NROB1	DAX1 orphan nuclear receptor	X-linked adrenal hypoplasia congenita	6†
NR5A1	SF-1 orphan nuclear receptor	Gonadal dysgenesis	<1
STAR	Steroidogenic acute regulatory protein	Nonclassic lipoid adrenal hyperplasia	8
CYP11A1	Cholesterol side-chain cleavage enzyme	Nonclassic lipoid adrenal hyperplasia	8
NNT	Nicotinamide nucleotide transhydrogenase	Familial glucocorticoid deficiency type 4	8
AAAS	Aladin (nuclear transport protein)	Triple A syndrome	5
SAMD9	Factor inhibiting cell proliferation	MIRAGE syndrome	3
CDKN1C	Cyclin-dependent kinase inhibitor	IMAGE syndrome	1
POLE	Subunit of DNA polymerase	IMAGE syndrome type 2	rare

*Frequencies are from 95 Turkish and 155 United Kingdom patients in whom congenital adrenal hyperplasia, autoimmune etiologies, and metabolic disorders (e.g., adrenoleukodystrophy) had been excluded.
†Many cases of X-linked adrenal hypoplasia congenita had already been identified, so this frequency is an underestimate.

restriction, microcephaly, decreased numbers of natural killer (NK) cells, recurrent viral infections, and adrenal insufficiency. It is relatively frequent (1 in 2,506) in the Irish Traveller population.

MIRAGE syndrome is a form of syndromic adrenal hypoplasia, characterized by myelodysplasia, infections, restriction of growth, adrenal hypoplasia, genital abnormalities, and enteropathy. It is often fatal within the first decade of life, usually because of invasive infection. It is caused by pathogenic variants in *SAMD9* on chromosome 7q21, which encodes a protein that inhibits cell proliferation. Disease-causing variants are heterozygous and usually arise de novo. When expressed in cultured cells, the abnormal proteins strongly inhibit cell proliferation. There is a risk that affected cells will attempt to escape growth inhibition by selectively losing chromosome 7 carrying the variant causing haploinsufficiency of *SAMD9*. This can cause myelodysplastic syndrome.

IMAGE syndrome consists of intrauterine growth restriction, metaphyseal dysplasia, adrenal hypoplasia, and genital anomalies. Two forms have been identified: an autosomal dominant form caused by pathogenic variants in *CDKN1C* and an autosomal recessive form caused by variants in *POLE*. Adrenal insufficiency in cases associated with *CDKN1C* variants tends to present in early infancy, whereas in cases caused by *POLE* variants, it is manifested during early childhood. The recessive form is also associated with immunodeficiency and is therefore sometimes termed *IMAGEI syndrome.*

The *CDKN1C* gene product, also called *p57(KIP2),* binds G1 cyclin/CDK complexes and thus inhibits cell proliferation. It is located in the imprinted region of chromosome 11p15 and is preferentially expressed from the maternal allele. Inactivating variants in this gene cause some cases of Beckwith-Wiedemann syndrome (see Chapter 113), which is associated with macrosomia and tumor risk. Variants that interfere with binding of CDKN1C to DNA polymerase delta auxiliary protein enhance the growth inhibitory effect of CDKN1C (gain of function) and cause IMAGE syndrome when maternally inherited. Thus both genes involved in IMAGE syndrome have roles in DNA replication and repair.

Deficiency of Mitochondrial Reactive Oxygen Species Detoxification

Nicotinamide nucleotide transhydrogenase *(NNT)* is a mitochondrial protein that catalyzes transfer of a hydride ion between nicotinamide adenine dinucleotide, NAD(H), and oxidized nicotinamide dinucleotide phosphate, NADP(H). Its deficiency manifests generally in infancy or early childhood, and most patients have both mineralocorticoid and glucocorticoid deficiencies. A pathogenic variant in *TXNRD2* has been identified in a single kindred with glucocorticoid deficiency.

Type 1 Autoimmune Polyendocrinopathy Syndrome

Although autoimmune Addison disease most often occurs sporadically, it can occur as a component of two syndromes, each consisting of a constellation of autoimmune disorders (see Chapter 608). **Type 1 autoimmune polyendocrinopathy syndrome (APS-1)**, also known as *autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy* (APECED) syndrome, is inherited in a mendelian autosomal recessive manner, whereas APS-2 has complex inheritance. Patients with APS-1

may have autoantibodies to the adrenal cytochrome P450 enzymes CYP21A2, CYP17A1, and CYP11A1. The presence of such antibodies indicates a high likelihood of the development of Addison disease or, in female patients, ovarian failure. Adrenal failure can evolve rapidly in APS-1; death in patients with a previous diagnosis and unexplained deaths in siblings of patients with APS-1 have been reported, indicating the need to closely monitor patients with APS-1 (or any child with unexplained hypoparathyroidism) and to thoroughly evaluate apparently unaffected siblings of patients with this disorder.

Corticosteroid-Binding Globulin Deficiency and Decreased Cortisol-Binding Affinity

Corticosteroid-binding globulin deficiency (*SERPINA6* pathogenic variant) and decreased cortisol-binding affinity result in low levels of plasma cortisol but normal urinary free cortisol and normal plasma ACTH levels. A high prevalence of hypotension and fatigue has been reported in some adults with abnormalities of corticosteroid-binding globulin deficiency.

ACQUIRED ETIOLOGIES

Autoimmune Addison Disease

The most common cause of Addison disease is autoimmune destruction of the glands. The glands may be so small that they are not visible at autopsy, and only remnants of tissue are found in microscopic sections. Usually, the medulla is not destroyed, and there is marked lymphocytic infiltration in the area of the former cortex. In advanced disease, all adrenocortical function is lost, but early in the clinical course, isolated cortisol deficiency can occur. Most patients have **antiadrenal cytoplasmic antibodies** in their plasma; 21-hydroxylase (CYP21A2) is the most commonly occurring biochemically defined autoantigen.

Addison disease can occur as a component of two autoimmune polyendocrinopathy syndromes. Type 1 (APS-1) was discussed previously. **Type 2 autoimmune polyendocrinopathy (APS-2)** consists of Addison disease associated with autoimmune thyroid disease **(Schmidt syndrome)** or type 1 diabetes **(Carpenter syndrome)** (see Chapter 608). Frequencies of the human leukocyte antigen (HLA)-D3 and HLA-D4 alleles are increased in these patients and appear to confer an increased risk for development of this disease; particular alleles at the major histocompatibility complex class I chain–related genes A and B (*MICA* and *MICB*) also are associated with this disorder. Polymorphisms in genes involved in other autoimmune disorders have been inconsistently associated with primary adrenal insufficiency, and their contribution to its pathogenesis must be regarded as uncertain. These include the class II, major histocompatibility complex, transactivator *(CIITA),* C-type lectin domain family 16, member A (*CLEC16A*), and protein tyrosine phosphatase, nonreceptor type 22 *(PTPN22).* The disorder is most common in middle-age females and can occur in many generations of the same family. Antiadrenal antibodies, specifically antibodies to the CYP21A2, CYP17A1, and CYP11A1 enzymes, are also found in these patients. Autoimmune adrenal insufficiency may also be seen in patients with celiac disease and mitochondrial gene mutations.

Adrenal insufficiency remains a risk among patients previously treated with a prolonged course of steroids when stressed with an infection or trauma. Despite being "tapered or weaned" from the steroids, subclinical adrenal insufficiency may develop weeks to months later if stressed (see Chapter 615.2).

Infection

Tuberculosis was a common cause of adrenal destruction in the past but is currently much less prevalent. The most common infectious etiology for adrenal insufficiency is meningococcemia (see Chapter 237); adrenal crisis from this cause is referred to as **Waterhouse-Friderichsen syndrome**. Patients with AIDS can have a variety of subclinical abnormalities in the hypothalamic-pituitary-adrenal (HPA) axis, but frank adrenal insufficiency is rare. However, drugs used in the treatment of AIDS can affect adrenal hormone homeostasis.

Drugs

Ketoconazole, an antifungal drug, can cause adrenal insufficiency by inhibiting adrenal enzymes. Mitotane (o,p′-DDD), used in the treatment of adrenocortical carcinoma and refractory Cushing syndrome (see Chapters 617 and 619), is cytotoxic to the adrenal cortex and can also alter extraadrenal cortisol metabolism. Signs of adrenal insufficiency occur in a substantial percentage of patients treated with mitotane. **Etomidate**, used in the induction and maintenance of general anesthesia, inhibits 11β-hydroxylase (CYP11B1), and a single induction dose can block cortisol synthesis for 4-8 hours or longer. This may be problematic in severely stressed patients, particularly if repeated doses are used in a critical care setting. Abiraterone acetate, an androgen biosynthesis inhibitor that is used to treat metastatic prostate carcinoma, inhibits cortisol biosynthesis but leaves corticosterone biosynthesis unimpaired. This drug is not currently encountered in pediatric practice. **Immune checkpoint inhibitors** may rarely cause primary adrenal insufficiency. Although not themselves a cause of adrenal insufficiency, rifampicin and anticonvulsive drugs such as phenytoin and phenobarbital reduce the effectiveness and bioavailability of corticosteroid replacement therapy by inducing steroid-metabolizing enzymes in the liver.

Hemorrhage into Adrenal Glands

Hemorrhage into adrenal glands can occur in the neonatal period as a result of a difficult labor (especially breech presentation), or its etiology might not be apparent (Fig. 615.1). An incidence rate of 3 in 100,000 live births has been suggested. The hemorrhage may be sufficiently extensive to result in death from exsanguination or hypoadrenalism. An abdominal mass, anemia, unexplained jaundice, or scrotal hematoma may be the presenting sign. Often, the hemorrhage is asymptomatic initially and is identified later by calcification of the adrenal gland. Fetal adrenal hemorrhage has also been reported. Postnatally, adrenal hemorrhage most often occurs in patients being treated with anticoagulants. It can also occur as a result of child abuse.

CLINICAL MANIFESTATIONS

Primary adrenal insufficiency leads to cortisol and often aldosterone deficiencies. The signs and symptoms of adrenal insufficiency are most easily understood in the context of the normal actions of these hormones (see Chapter 614; Table 615.6).

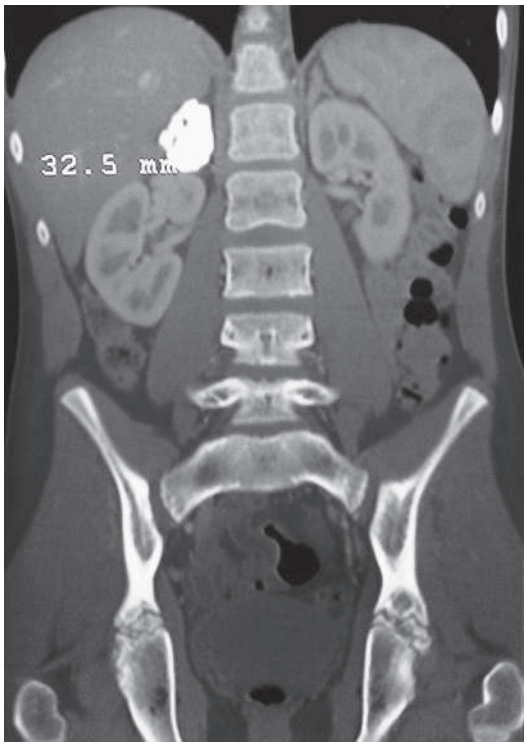

Fig. 615.1 Contrast-enhanced coronal CT confirming intraadrenal localization of a round hyperdense lesion compatible with a large calcification. *(From Llano JP, Beaufils E, Nicolino M. Uncommon cause of large paravertebral calcification in a child. J Pediatr. 2013;162:881, Fig. 2.)*

Table 615.6 Clinical Manifestations and Biochemical Findings in Adrenal Insufficiency

	PATHOPHYSIOLOGIC MECHANISM	PREVALENCE (%)*
SYMPTOMS		
Fatigue	Glucocorticoid deficiency	90
Anorexia, weight loss	Glucocorticoid deficiency	90
Nausea, vomiting	Glucocorticoid deficiency, mineralocorticoid deficiency	90
Salt craving (primary adrenal insufficiency only)	Mineralocorticoid deficiency	20
Myalgia or joint pain	Glucocorticoid deficiency	
SIGNS		
Low blood pressure, orthostatic hypotension	Mineralocorticoid deficiency, glucocorticoid deficiency	70-100
Skin or mucosal hyperpigmentation (primary adrenal insufficiency only)	Excess of proopiomelanocortin-derived peptides	70
LABORATORY FINDINGS		
Hyponatremia	Mineralocorticoid deficiency, glucocorticoid deficiency (leading to decreased free water excretion)	90
Hyperkalemia (primary adrenal insufficiency only)	Mineralocorticoid deficiency	50
Hypoglycemia	Glucocorticoid deficiency	30
Ketosis	Glucocorticoid deficiency	30
Low random cortisol level	Glucocorticoid deficiency	80
Eosinophilia, lymphocytosis	Glucocorticoid deficiency	
High ACTH level (primary adrenal insufficiency only)	Glucocorticoid deficiency	100
High plasma renin activity (primary adrenal insufficiency only)	Mineralocorticoid deficiency	100

*Prevalence data are for primary insufficiency only. Blanks indicate that no pediatric prevalence data are available.
Data from Hsieh S, White PC. Presentation of primary adrenal insufficiency in childhood J Clin Endocrinol Metab. 2011;96:E925–E928.

Cortisol deficiency decreases cardiac output and vascular tone; moreover, catecholamines such as epinephrine have decreased inotropic and pressor effects in the absence of cortisol. These problems are initially manifested as orthostatic hypotension in older children and can progress to frank shock in patients of any age. They are exacerbated by aldosterone deficiency, which causes hypovolemia owing to decreased resorption of sodium in the distal nephron.

Hypotension and decreased cardiac output decrease glomerular filtration and thus decrease the ability of the kidney to excrete free water. Vasopressin (AVP) is secreted by the posterior pituitary in response to hypotension and as a direct consequence of lack of inhibition by cortisol. These factors decrease plasma osmolality and lead to hyponatremia. Hyponatremia is also caused by aldosterone deficiency and may be much worse when both cortisol and aldosterone are deficient.

In addition to hypovolemia and hyponatremia, aldosterone deficiency causes hyperkalemia by decreasing potassium excretion in the distal nephron. Cortisol deficiency alone does not cause hyperkalemia.

Cortisol deficiency decreases negative feedback on the hypothalamus and pituitary, leading to increased secretion of ACTH. Hyperpigmentation is caused by ACTH and other peptide hormones (γ-melanocyte–stimulating hormone) arising from the ACTH precursor, proopiomelanocortin. In patients with a fair complexion, the skin can have a bronze cast. Pigmentation may be more prominent in skin creases, mucosa, and scars. In dark-skinned patients, it may be most readily appreciated in the gingival and buccal mucosa.

Hypoglycemia is a feature of adrenal insufficiency. It is often accompanied by ketosis as the body attempts to use fatty acids as an alternative energy source. Ketosis may cause or be aggravated by anorexia, nausea, and vomiting, all of which occur frequently.

The clinical presentation of adrenal insufficiency depends on the age of the patient, whether both cortisol and aldosterone secretion are affected, and to some extent on the underlying etiology. The most common causes in early infancy are inborn errors of steroid biosynthesis, sepsis, AHC, and adrenal hemorrhage. Infants have a relatively greater requirement for aldosterone than do older children, possibly owing to immaturity of the kidney and to the low sodium content of human breast milk and infant formula. Hyperkalemia, hyponatremia, and hypoglycemia are prominent presenting signs of adrenal insufficiency in infants. Ketosis is not consistently present because infants generate ketones less well than do older children. Hyperpigmentation is not usually seen because this takes weeks or months to develop, and orthostatic hypotension is obviously difficult to demonstrate in infants.

Infants can become ill very quickly. There may be only a few days of decreased activity, anorexia, and vomiting before critical electrolyte abnormalities develop.

In older children with Addison disease, symptoms include muscle weakness, malaise, anorexia, vomiting, weight loss, and orthostatic hypotension. These may be of insidious onset. It is not unusual to elicit, in retrospect, an episodic history spanning years with symptoms being noticeable only during intercurrent illnesses. Such patients can present with acute decompensation **(adrenal crisis)** during relatively minor infectious illnesses. *Some of these patients have been initially misdiagnosed with chronic fatigue syndrome, postmononucleosis syndrome, chronic Lyme disease, or psychiatric disorders (depression or anorexia nervosa).*

Hyperpigmentation is often, but not necessarily, present. **Hyponatremia** is present at diagnosis in almost 90% of patients. **Hyperkalemia** tends to occur later in the course of the disease in older children than in infants and is present in only half of patients at diagnosis. *Normal potassium levels must never be presumed to rule out primary adrenal insufficiency.*

Hypoglycemia and ketosis are common. The clinical presentation can be easily confused with gastroenteritis or other acute infections. Chronicity of symptoms can alert the clinician to the possibility of Addison disease, but this diagnosis should be considered in any child with

orthostatic hypotension, hyponatremia, hypoglycemia, and ketosis. Salt craving is seen in primary adrenal insufficiency with mineralocorticoid deficiency. Fatigue, myalgias, fever, eosinophilia, lymphocytosis, hypercalcemia, and anemia may be noted with glucocorticoid deficiency.

LABORATORY FINDINGS

Hypoglycemia, ketosis, hyponatremia, and hyperkalemia have been discussed. An electrocardiogram is useful for quickly detecting hyperkalemia in a critically ill child. Acidosis is often present, and the blood urea nitrogen level is elevated if the patient is dehydrated.

Cortisol levels are sometimes at the low end of the normal range but are invariably low when the patient's degree of illness is considered. ACTH levels are high in primary adrenal insufficiency but can take time to be reported by the laboratory. Similarly, aldosterone levels may be within the normal range but inappropriately low considering the patient's hyponatremia, hyperkalemia, and hypovolemia. Plasma renin activity is elevated. Blood eosinophils may be increased in number, but this is rarely useful diagnostically.

Urinary excretion of sodium and chloride is increased and urinary potassium is decreased, but these are difficult to assess in random urine samples. Accurate interpretation of urinary electrolytes requires more prolonged (24 hours) urine collections and knowledge of the patient's sodium and potassium intake.

The most definitive test for adrenal insufficiency is measurement of serum levels of cortisol before and after administration of ACTH; resting levels are low and do not increase normally after administration of ACTH. Occasionally, normal resting levels that do not increase after administration of ACTH indicate an absence of adrenocortical reserve. A low initial level followed by a significant response to ACTH can indicate secondary adrenal insufficiency. Traditionally, this test has been performed by measuring cortisol levels before and 30 or 60 minutes after giving 0.250 mg of cosyntropin (ACTH 1-24) by rapid intravenous infusion. Aldosterone will transiently increase in response to this dose of ACTH and may also be measured. A low-dose test (1 μg ACTH 1-24/1.73 m^2) is a more sensitive test of pituitary-adrenal reserve but has somewhat lower specificity (more false-positive tests).

DIFFERENTIAL DIAGNOSIS

Upon presentation, Addison disease often needs to be distinguished from more acute illnesses such as gastroenteritis with dehydration or sepsis. Additional testing is directed at identifying the specific cause for adrenal insufficiency. When CAH is suspected, serum levels of cortisol precursors (17-hydroxyprogesterone) should be measured along with cortisol in an ACTH stimulation test (see Chapter 616) (Fig. 615.2). Elevated levels of very long-chain fatty acids are diagnostic of ALD (see Chapter 639.3). Many genetic etiologies for primary adrenal insufficiency may be identified by direct genetic testing, but it can take weeks for results to become available. The presence of antiadrenal antibodies suggests an autoimmune pathogenesis. Patients with autoimmune Addison disease must be closely observed for the development of other autoimmune disorders. In children, hypoparathyroidism is a commonly associated disorder, and it is suspected if hypocalcemia and elevated phosphate levels are present.

Ultrasonography, CT, or MRI can help to define the size of the adrenal glands, but this is not usually necessary.

TREATMENT

Treatment of acute adrenal insufficiency must be immediate and vigorous. If the diagnosis of adrenal insufficiency has not been established, a blood sample should be obtained before therapy to determine electrolytes, glucose, ACTH, cortisol, aldosterone, and plasma renin activity. If the patient's condition permits, an ACTH stimulation test can be performed while initial fluid resuscitation is underway. An intravenous solution of 5% glucose in 0.9% saline should be administered to correct hypoglycemia, hypovolemia, and hyponatremia. Hypotonic fluids (e.g., 5% glucose in water or 0.2% saline) must be avoided because they can precipitate or exacerbate hyponatremia. If hyperkalemia is severe, it can require treatment with intravenous calcium and/or bicarbonate, intrarectal potassium-binding resin (sodium polystyrene sulfonate, Kayexalate), or intravenous infusion of glucose and insulin. A water-soluble form of hydrocortisone, such as hydrocortisone sodium succinate, should be given intravenously. As much as 10 mg for infants, 25 mg for toddlers, 50 mg for older children, and 100 mg for adolescents should be administered as a bolus and a similar total amount then given in divided doses at 6-hour intervals for the first 24 hours. These doses may be reduced during the next 24 hours if progress is satisfactory. Adequate fluid and sodium repletion is achieved by intravenous saline administration, aided by the mineralocorticoid effect of high doses of hydrocortisone.

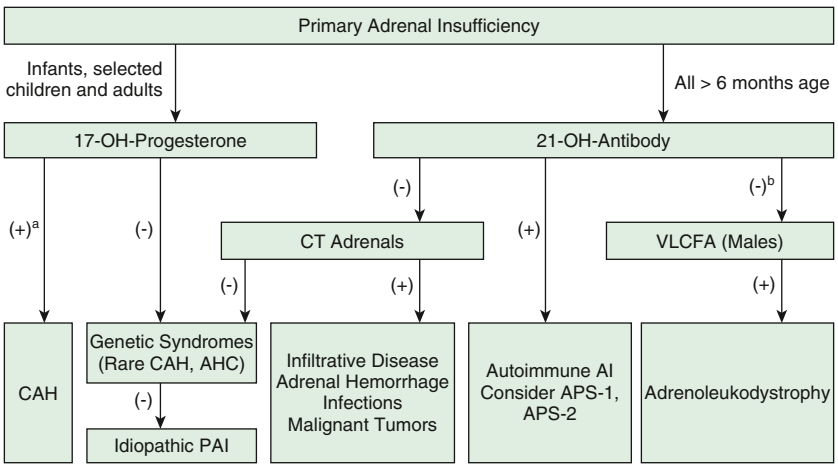

Fig. 615.2 Algorithm for the diagnostic approach to the patient with primary adrenal insufficiency (PAI). The most common causes of PAI are autoimmune destruction of the adrenal cortex in adults and congenital adrenal hyperplasia (CAH) in children. These etiologies can be screened for using 21-hydroxylase antibodies and a baseline serum 17-hydroxyprogesterone level, respectively. Males with negative 21-hydroxylase antibodies should be tested for adrenoleukodystrophy with plasma VLCFAs. If these diagnoses are excluded, a CT scan of the adrenals may reveal evidence of adrenal infiltrative processes or metastases, but this is of low yield in children and adolescents. The individual's clinical picture and family history may render some steps in the algorithm redundant or suggest specific genetic syndromes. The latter includes subtypes of autoimmune polyglandular syndromes or specific rare genetic disorders where adrenal failure is part of a broader phenotype. AHC, Adrenal hypoplasia congenita; AI, adrenal insufficiency; APS-1, type 1 autoimmune polyendocrinopathy syndrome; VLCFA, very long-chain fatty acid. [a]17-OH-progesterone >1,000 ng/dL is diagnostic for 21-OH deficiency. [b]VLCFA should be measured in the initial evaluation of preadolescent boys. *(Adapted from Husebye ES, Allolio B, Arlt W, et al. Consensus statement on the diagnosis, treatment, and follow-up of patients with primary adrenal insufficiency. J Intern Med. 2014;275:104–115.)*

Caution should be exercised in the rare patient with concomitant adrenal insufficiency and hypothyroidism, because thyroxine can increase cortisol clearance. Thus an adrenal crisis may be precipitated if hypothyroidism is treated without first ensuring adequate glucocorticoid replacement.

After the acute manifestations are under control, most patients require chronic replacement therapy for their cortisol and aldosterone deficiencies. Hydrocortisone (cortisol) may be given orally in daily doses of 10 mg/m^2/24 hr in three divided doses; some patients require 15 mg/m^2/24 hr to minimize fatigue, especially in the morning. Dividing the hydrocortisone into four doses daily may yield more physiologic drug profiles, but adherence to such frequent dosing may be problematic. Timed-release preparations of hydrocortisone are available in Europe and are undergoing clinical trials in the United States as of 2021. Subcutaneous infusion of hydrocortisone with a pump has also been examined in clinical trials; although this has the advantage that it can very closely mimic normal diurnal variation in cortisol secretion, it is expensive and has not yet entered routine clinical practice. Equivalent doses (20–25% of the hydrocortisone dose) of prednisone or prednisolone may be divided and given twice daily. ACTH levels may be used to monitor adequacy of glucocorticoid replacement in primary adrenal insufficiency; in CAH, levels of precursor hormones are used instead. Blood samples for monitoring should be obtained at a consistent time of day and in a consistent relation to (i.e., before or after) the hydrocortisone dose. Normalizing ACTH levels is unnecessary and can require excessive doses of hydrocortisone; in general, morning ACTH levels high in the normal range to 3-4 times normal are satisfactory. Because untreated or severely undertreated patients can acutely decompensate during relatively minor illnesses, assessment of symptoms (or lack thereof) should not be used as a substitute for biochemical monitoring. During situations of stress, such as periods of infection or minor operative procedures, the dose of hydrocortisone should be increased twofold to threefold. Major surgery under general inhalation anesthesia requires high intravenous doses of hydrocortisone similar to those used for acute adrenal insufficiency.

If aldosterone deficiency is present, fludrocortisone, a synthetic mineralocorticoid, is given orally in doses of 0.05-0.2 mg daily. Measurements of plasma renin activity are useful in monitoring the adequacy of mineralocorticoid replacement. Chronic overdosage with glucocorticoids leads to obesity, short stature, and osteoporosis, whereas overdosage with fludrocortisone results in hypertension and occasionally hypokalemia.

Replacement of dehydroepiandrosterone (DHEA) in adults remains controversial; prepubertal children do not normally secrete large amounts of DHEA. Many adults with Addison disease complain of having decreased energy, and replacing DHEA can improve this problem, particularly in women in whom adrenal androgens represent approximately 50% of total androgen secretion.

Additional therapy might need to be directed at the underlying cause of the adrenal insufficiency regarding infections and certain metabolic defects. Previous therapeutic approaches to ALD included administration of glycerol trioleate and glycerol trierucate (Lorenzo's oil), bone marrow transplantation, and lovastatin (see Chapter 639.3). Introducing a normal *ABCD1* gene into autologous stem cells with a lentiviral vector (officially termed *elivaldogene autotemcel*) has shown excellent results in preventing neurologic progression, but it remains investigational as of 2021.

615.2 Secondary and Tertiary Adrenal Insufficiency

Perrin C. White

ABRUPT CESSATION OF ADMINISTRATION OF CORTICOSTEROIDS

Secondary adrenal insufficiency most commonly occurs when the HPA axis is suppressed by prolonged administration of high doses of a potent glucocorticoid and that agent is suddenly withdrawn or the dose is tapered too quickly. Patients at risk for this problem include those with leukemia, asthma (particularly when patients are transitioned from oral to inhaled corticosteroids), and collagen vascular disease or other autoimmune conditions and those who have undergone tissue transplants or neurosurgical procedures. The maximal duration and dosage of glucocorticoid that can be administered before encountering this problem is not known, but it is assumed that high-dose glucocorticoids (the equivalent of >10 times physiologic cortisol secretion) can be administered for less than 1 week without requiring a subsequent taper of dose. On the other hand, when high doses of dexamethasone are given to children with leukemia, it can take 6 months or longer after therapy is stopped before tests of adrenal function return to normal. Signs and symptoms of adrenal insufficiency are most likely in patients who are subsequently subjected to stresses such as severe infections or additional surgical procedures.

Corticotropin (Adrenocorticotropic Hormone) Deficiency

Pituitary or hypothalamic dysfunction can cause corticotropin deficiency (see Chapter 595), usually associated with deficiencies of other pituitary hormones such as growth hormone and thyrotropin. Destructive lesions in the area of the pituitary, such as craniopharyngioma and germinoma, are the most common causes of corticotropin deficiency. In many cases the pituitary or hypothalamus is further damaged during surgical removal or radiotherapy of tumors in the midline of the brain. Traumatic brain injury (see Chapter 750) frequently causes pituitary dysfunction, especially in the first days after the injury. However, corticotropin deficiency is difficult to detect in that period owing to frequent use of high doses of dexamethasone to minimize brain swelling, and permanent corticotropin deficiency is unusual after traumatic brain injury. In rare instances, autoimmune hypophysitis is the cause of corticotropin deficiency.

Congenital lesions of the pituitary also occur. The pituitary alone may be affected, or additional midline structures may be involved, such as the optic nerves or septum pellucidum. The latter type of abnormality is termed **septo-optic dysplasia**, or de Morsier syndrome (see Chapter 631.9). More severe developmental anomalies of the brain, such as anencephaly and holoprosencephaly, can also affect the pituitary. These disorders are usually sporadic, although a few cases of autosomal recessive inheritance have occurred. Isolated deficiency of corticotropin has been reported, including in several sets of siblings. Patients with multiple pituitary hormone deficiencies caused by pathogenic variants in the *PROP1* gene may develop progressive ACTH/cortisol deficiency. Isolated deficiency of corticotropin-releasing hormone has been documented in an Arab kindred as an autosomal recessive trait.

Up to 60% of children with **Prader-Willi syndrome** (see Chapter 99.8) have some degree of secondary adrenal insufficiency as assessed by provocative testing with metyrapone, although diurnal cortisol levels are normal. The clinical significance of this finding is uncertain, but it might contribute to the relatively high incidence of sudden death with infectious illness that occurs in this population. Although it is not yet a standard of care, some endocrinologists advocate treating patients who have Prader-Willi syndrome with hydrocortisone during febrile illness.

CLINICAL PRESENTATION

Aldosterone secretion is unaffected in secondary adrenal insufficiency because the adrenal gland is, by definition, intact and the renin-angiotensin system is not involved. Thus signs and symptoms are those of cortisol deficiency. Newborns often have hypoglycemia. Older children can have orthostatic hypotension or weakness. Hyponatremia may be present.

When secondary adrenal insufficiency is the consequence of an inborn or acquired anatomic defect involving the pituitary, there may be signs of associated deficiencies of other pituitary hormones. The penis may be small in male infants if gonadotropins are also deficient. Infants with secondary hypothyroidism are often jaundiced. Children with associated growth hormone deficiency grow poorly after the first year of life.

Some children with pituitary abnormalities have hypoplasia of the midface. Children with optic nerve hypoplasia can have obvious visual impairment. They usually have a characteristic wandering nystagmus, but this is often not apparent until several months of age.

LABORATORY FINDINGS

Because the adrenal glands themselves are not directly affected, the diagnosis of secondary adrenal insufficiency is sometimes challenging. The most commonly used test to diagnose secondary adrenal insufficiency is **low-dose ACTH stimulation testing** (1 μg/1.73 m^2 of cosyntropin given intravenously), the rationale being that there will be some degree of atrophy of the adrenal cortex if normal physiologic ACTH stimulation is lacking. Thus this test may be falsely negative in cases of acute compromise of the pituitary (e.g., injury or surgery). Such circumstances rarely pose a diagnostic dilemma; in general, this test provides excellent sensitivity and specificity. Although assays vary somewhat, a threshold cortisol level of 18-20 μg/dL 30 minutes after cosyntropin administration may be used to dichotomize normal and abnormal responses.

There seems to be little reason to use stimulation with corticotropin-releasing hormone instead of ACTH; although the corticotropin-releasing hormone test has the theoretical advantage of testing the ability of the anterior pituitary to respond to this stimulus by secreting ACTH (thus distinguishing secondary and tertiary adrenal insufficiency), in practice it does not provide improved sensitivity and specificity, and the agent is not as widely available.

TREATMENT

Iatrogenic secondary adrenal insufficiency (caused by chronic glucocorticoid administration) is best avoided by use of the smallest effective doses of systemic glucocorticoids for the shortest period. When a patient is thought to be at risk, tapering the dose rapidly to a level equivalent to or slightly less than the physiologic replacement (~10 mg/m^2/24 hr of hydrocortisone) and further tapering over several weeks can allow the adrenal cortex to recover without the patient developing signs of adrenal insufficiency. Patients with anatomic lesions of the pituitary should be treated indefinitely with glucocorticoids. Mineralocorticoid replacement is not required. In patients with panhypopituitarism, treating cortisol deficiency can increase free water excretion, thus unmasking central diabetes insipidus. Electrolytes must be monitored carefully when initiating cortisol therapy in panhypopituitary patients.

615.3 Adrenal Insufficiency in the Critical Care Setting

Perrin C. White

Critical illness–related corticosteroid insufficiency (CIRCI) is encountered in up to 20–50% of critically ill pediatric patients, often as a transient condition. In many cases, it is considered functional or relative in nature, meaning that cortisol levels are within normal limits but cannot increase sufficiently to meet the demands of critical illness. The causes are heterogeneous (see Chapter 615.1). They include adrenal hypoperfusion from shock, particularly septic shock, as is often seen in meningococcemia. Inflammatory mediators during septic shock, particularly interleukin-6, can suppress ACTH secretion, directly suppress cortisol secretion, or both. Etomidate, used as sedation for intubation, inhibits steroid 11β-hydroxylase and thus blocks cortisol biosynthesis. Neurosurgical patients with closed head trauma or with tumors that involve the hypothalamus or pituitary might have ACTH deficiency in the context of panhypopituitarism. Some children have been previously treated with systemic corticosteroids (e.g., children with leukemia) and have suppression of the HPA axis for that reason. In the intensive care nursery, premature infants have not yet developed normal cortisol biosynthetic capacity and thus may not be able to secrete adequate amounts of this hormone when ill.

Additionally, plasma clearance of cortisol is markedly reduced during critical illness, owing to decreased activity of cortisol-metabolizing enzymes in the liver and kidney. Although this may help defend plasma levels of cortisol in the context of decreased cortisol secretion, the inflammation associated with sepsis may increase glucocorticoid resistance through activation of mitogen-activated protein kinases (MAPKs) and decreased activity of their regulators, dual-specific phosphatases (DUSPs).

CLINICAL MANIFESTATIONS

Cortisol is required for catecholamines to have their normal pressor effects on the cardiovascular system (see Chapters 614.4 and 614.5). Accordingly, adrenal insufficiency is often suspected in hypotensive patients who do not respond to intravenous pressor agents. Patients may be at increased risk for hypoglycemia or a presentation resembling the syndrome of inappropriate antidiuretic hormone secretion, but these conditions commonly occur in the context of sepsis, and the contribution of adrenal insufficiency may be difficult to distinguish.

LABORATORY FINDINGS

Although low random cortisol levels in severely stressed patients are certainly abnormal, very high levels are also associated with a poor outcome in such patients; the latter situation presumably reflects a maximally stimulated adrenal cortex with diminished reserve. ACTH (cosyntropin) stimulation testing is generally considered the best way to diagnose adrenal insufficiency in this setting (see Chapter 615.1); evidence suggests that the low-dose (1 μg/1.73 m^2) test may be superior to the 250-μg standard dose test, although this remains controversial. In general, a peak cortisol level <18 μg/dL or an increment of <9 μg/dL from baseline is considered suggestive for adrenal insufficiency in this context. In evaluating cortisol levels, cortisol in the circulation is mostly bound to cortisol-binding globulin; in hypoproteinemic states, total cortisol levels may be decreased, whereas free cortisol levels might be normal. It may be prudent to measure free cortisol before initiating treatment when total cortisol is low and albumin is <2.5 g/dL, but such measurements are not readily available in all institutions.

TREATMENT

It is likely that stress doses of hydrocortisone (e.g., 100 mg/m^2/day) improve responses to pressor agents in patients with shock *and* documented adrenal insufficiency (Waterhouse-Friderichsen syndrome). In adults with sepsis, corticosteroids probably reduce intensive care unit (ICU) and hospital length of stay and 28-day and hospital mortality, but there are limited data regarding treatment efficacy in critically ill children. The Surviving Sepsis Guidelines suggest using IV hydrocortisone (or not using it) to treat pediatric septic shock only if fluids and vasopressor therapy are unable to restore hemodynamic stability. This is a weak recommendation with low-quality evidence.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

615.4 Altered End-Organ Sensitivity to Corticosteroids

Perrin C. White

Diseases can result from altered actions of hormones at their physiologic targets. These may be caused by abnormal metabolism of hormones, mutations in hormone receptors, or defects in cellular effectors (such as ion channels) that are targets of hormone action.

GENERALIZED GLUCOCORTICOID RESISTANCE

Patients with generalized glucocorticoid resistance have target-tissue insensitivity to glucocorticoids. The condition is usually inherited in an autosomal dominant manner, but sporadic cases occur. Impairment of normal negative feedback of cortisol at the levels of the hypothalamus and pituitary activates the HPA axis, with consequent increases in ACTH and cortisol concentrations. Generalized glucocorticoid resistance is caused by pathogenic variants in the glucocorticoid receptor *(NR3C1)*. Most variants are heterozygous; glucocorticoid receptors usually bind DNA as dimers, and three out of four dimers will contain at least one abnormal receptor molecule when a heterozygous variant is present.

Clinical Manifestations

The excess ACTH secretion causes adrenal hyperplasia with increased production of adrenal steroids with mineralocorticoid activity, including cortisol, deoxycorticosterone, and corticosterone, and also androgens and precursors, including androstenedione, DHEA, and DHEA sulfate. The high cortisol concentrations do not cause Cushing syndrome (see Chapter 619) because of the insensitivity to glucocorticoids; conversely, most signs and symptoms of adrenal insufficiency are absent except for the frequent occurrence of chronic fatigue and occasional anxiety (neonatal hypoglycemia was reported in one very unusual patient with a homozygous null variant). The mineralocorticoid and androgen receptors are normally sensitive to their ligands. Signs of **mineralocorticoid excess**, such as hypertension and hypokalemic alkalosis, are frequently noted. The increased concentrations of adrenal androgens may cause ambiguous genitalia in females and gonadotropin-independent precocious puberty in children of either gender; acne, hirsutism, and infertility in both sexes; menstrual irregularities in females; and oligospermia in males. Testicular adrenal rest tumors and ACTH-secreting pituitary adenomas occasionally occur.

Laboratory Findings

The diagnosis of generalized glucocorticoid resistance is suggested by elevated serum cortisol concentrations and increased 24-hour urinary free cortisol excretion in the absence of Cushing syndrome. Levels of other adrenal steroids are also increased. Plasma concentrations of ACTH may be normal or high. The circadian pattern of ACTH and cortisol secretion is preserved, although at higher-than-normal concentrations, and there is resistance of the HPA axis to dexamethasone suppression. Sequencing of the *NR3C1* gene can confirm the diagnosis.

Differential Diagnosis

Generalized glucocorticoid resistance should be distinguished from relatively mild cases of Cushing syndrome (whether caused by a pituitary adenoma or adrenal tumor, see Chapter 619); the latter is more likely to be associated with excessive weight gain or poor linear growth. Adrenocortical tumors may secrete mineralocorticoids such as deoxycorticosterone and also androgens, but ACTH levels are often suppressed and, of course, the tumor can usually be visualized with appropriate imaging techniques. CAH (see Chapter 616), particularly 11β-hydroxylase deficiency, may present with hypertension and signs of androgen excess, but in that condition cortisol levels are low and levels of cortisol precursors (17-hydroxyprogesterone, 11-deoxycortisol) are elevated. Obese patients may be hypertensive and have hyperandrogenism, but cortisol secretion should be readily suppressed by dexamethasone.

Treatment

The goal of treatment is to suppress the excess secretion of ACTH, thereby suppressing the increased production of adrenal steroids with mineralocorticoid and androgenic activity. This requires administration of high doses of a pure glucocorticoid agonist such as dexamethasone (typically ~20-40 μg/kg/day) with careful titration to suppress endogenous corticosteroid secretion without causing signs of glucocorticoid excess such as excessive weight gain or suppression of linear growth.

CORTISONE REDUCTASE DEFICIENCY

Levels of active glucocorticoids in target tissues are modulated by two isozymes of 11β-hydroxysteroid dehydrogenase. The HSD11B2 isozyme converts cortisol to an inactive metabolite, cortisone; the two steroids differ in the presence of an 11β-hydroxyl versus an 11-oxo group, respectively. Pathogenic variants in this enzyme cause the syndrome of **apparent mineralocorticoid excess**. Conversely, the HSD11B1 isozyme converts cortisone to cortisol, and so it is sometimes referred to as *cortisone reductase*. This isozyme is expressed at high levels in glucocorticoid target tissues, particularly the liver, where it ensures adequate levels of active glucocorticoids (cortisol and corticosterone) to meet metabolic demands without requiring excessive adrenal cortisol secretion.

The HSD11B1 isozyme is located in the endoplasmic reticulum (i.e., it is a microsomal enzyme) and functions as a dimer. It accepts electrons from reduced nicotine–adenine dinucleotide phosphate, which is generated within the endoplasmic reticulum by hexose-6-phosphate dehydrogenase, an enzyme distinct from cytoplasmic glucose-6-phosphate dehydrogenase.

Apparent cortisone reductase deficiency is caused by homozygous pathogenic variants in hexose-6-phosphate dehydrogenase that prevent generation of reduced nicotine–adenine dinucleotide phosphate within the endoplasmic reticulum and thus starve HSD11B1 of its essential cofactor for the reductase reaction. Very rare patients have been reported to have heterozygous variants in *HSD11B1* itself and thus have "true" cortisone reductase deficiency; because the enzyme functions as a homodimer, heterozygous variants are able to impair three fourths of all dimers.

Clinical Manifestations

Because circulating cortisone is not converted to cortisol, the circulating half-life of cortisol is decreased, and the adrenal cortex must secrete additional cortisol to compensate. This leads to adrenocortical overactivity analogous to, but generally much milder than, that seen in generalized glucocorticoid resistance. This is usually not severe enough to cause hypertension, presenting instead with mild to moderate signs of androgen excess such as hirsutism, oligomenorrhea or amenorrhea, and infertility in females and precocious pseudopuberty (axillary and pubic hair and penile enlargement, but not testicular enlargement) in males.

Laboratory Findings

The ratio of cortisol to cortisone in blood is lower than usual. The same is true of urinary metabolites, typically measured as a ratio of the sum of the tetrahydrocortisol and allotetrahydrocortisol excretion to that of tetrahydrocortisone. These determinations are best accomplished by gas chromatography followed by mass spectrometry and are available in specialized reference laboratories. Absolute levels of cortisol and ACTH are within normal limits.

Differential Diagnosis

Cortisone reductase deficiency should be distinguished from and is much less common than other causes of androgen excess such as polycystic ovarian syndrome and nonclassical CAH as a result of 21-hydroxylase deficiency.

Treatment

Treatment is aimed at decreasing adrenal overactivity and thus reducing secretion of androgens. This can be accomplished by administration of hydrocortisone.

ALTERED END-ORGAN SENSITIVITY TO MINERALOCORTICOIDS

Pseudohypoaldosteronism

Pseudohypoaldosteronism type 1 (PHA1) is a monogenic disease in which aldosterone action is deficient and patients are thus unable

to resorb urinary sodium or excrete potassium properly. There are two forms. A relatively mild autosomal dominant form is caused by pathogenic variants in *NR3C2* encoding the human mineralocorticoid receptor. A heterozygous variant is sufficient to cause disease because the mineralocorticoid receptor interacts with DNA as a dimer, and three fourths of the dimers are defective in individuals carrying heterozygous variants (assuming mutant protein is synthesized). A more severe autosomal recessive form is usually the result of homozygous pathogenic variants in the α *(SCNN1A),* β *(SCNN1B),* or γ *(SCNN1G)* subunits of the epithelial Na^+ channel; one reported case of severe autosomal recessive disease was caused by homozygous variants in *NR3C2*.

PHA1 should not be confused with **pseudohypoaldosteronism type 2**, a rare mendelian syndrome characterized by hyperkalemia and, in contrast to PHA1, by hypertension from excessive renal sodium reabsorption. This disorder is caused by variants in the renal regulatory kinases WNK1 and WNK4 or components of an E3 ubiquitin ligase complex, Kelch-like 3 (KLHL3) and Cullin 3 (CUL3).

Transient or "secondary" (nongenetic) pseudohypoaldosteronism can occur in infants, mainly male, with urinary tract malformations and/or urinary tract infections.

Clinical Manifestations

Infants with PHA1 present with hyperkalemia, hyponatremia, hypovolemia, hypotension, and failure to thrive. In more severe (usually autosomal recessive) cases, salt loss is not confined to the kidney, but instead occurs from most epithelia. Mothers may report that the skin of their affected infants tastes salty. Some infants suffer from *cystic fibrosis–like pulmonary symptoms*. It is often difficult to control electrolyte abnormalities in patients with the autosomal recessive form, leading to frequent hospitalizations and a need for close clinical monitoring.

It is noteworthy that signs and symptoms of aldosterone deficiency tend to remit as the patients get older, particularly in the autosomal dominant form. This is similar to what is seen in actual aldosterone deficiency, as occurs in the salt-losing forms of CAH or aldosterone synthase deficiency. The kidney matures after early infancy to become more efficient at excreting potassium, and although breast milk and infant formula are low in sodium, the normal adult Western diet is relatively high in sodium, thus compensating for the renal salt wasting.

Laboratory Findings

Infants have marked hyperkalemia and hyponatremia. Both plasma renin and aldosterone are markedly elevated. Levels of cortisol and ACTH are normal. If hypovolemia is severe, patients may develop prerenal azotemia. With severe hyperkalemia, the electrocardiogram may include tall-peaked T waves or ventricular tachycardia.

Differential Diagnosis

PHA in infants should be distinguished from other causes of hyperkalemia and hyponatremia. These include renal failure of any cause, CAH, aldosterone synthase deficiency, and other causes of adrenocortical insufficiency such as AHC. Patients with renal failure will have elevated blood urea nitrogen and creatinine, but these may also be seen in severely dehydrated patients with PHA or adrenal insufficiency. Patients with any form of adrenal insufficiency in this clinical context will have low or low-normal aldosterone levels (with elevated plasma renin), in contrast to the elevated aldosterone levels seen in PHA. Patients with CAH have elevated levels of steroid precursors such as 17-hydroxyprogesterone (in patients with 21-hydroxylase deficiency), and patients with most forms of adrenal insufficiency have elevated ACTH levels.

Treatment

Infants must be given sodium supplementation (initially IV and then oral or enteral), typically approximately 8 mEq/kg/day. Potassium levels in the infant formula often need to be reduced, which may be accomplished by mixing the formula with polystyrene resin (Kayexalate) and then decanting the formula before feeding. Fludrocortisone, a synthetic mineralocorticoid, may be efficacious in milder autosomal dominant cases if administered in high doses (titrating up to ~0.5 mg daily). Significant electrolyte abnormalities require treatment with IV normal saline and rectal polystyrene resin. Severe hyperkalemia may require glucose and insulin infusions to keep it under control.

Secondary PHA owing to urinary tract infections or malformations generally resolves when the underlying condition is treated.

ACTIVATING PATHOGENIC VARIANTS IN THE MINERALOCORTICOID RECEPTOR

In contrast to PHA1, the S810L (serine-810 to leucine) variant of *NR3C2* causes autosomal dominant, severe, early-onset hypertension. This variant alters the ligand specificity of the mineralocorticoid receptor so that it is activated by cortisone and so HSD11B2 cannot protect it. It is also activated by progesterone, and consequently the hypertension is *exacerbated by pregnancy*. Conversely, the glucocorticoid and progesterone receptor antagonist mifepristone (RU-486) antagonizes the mutant receptor and might be useful therapeutically in nonpregnant individuals.

APPARENT MINERALOCORTICOID EXCESS

The syndrome of apparent mineralocorticoid excess is an autosomal recessive disorder caused by pathogenic variants in *HSD11B2* encoding the type 2 isozyme of 11β-hydroxysteroid dehydrogenase. The mineralocorticoid receptor has nearly identical affinities for aldosterone (the main mineralocorticoid hormone) and cortisol, yet cortisol is normally only a weak mineralocorticoid in vivo. This is because HSD11B2 is expressed along with the mineralocorticoid receptor in most target tissues such as the renal cortical collecting duct epithelium. It converts cortisol to cortisone, which is not an active steroid, thus preventing it from occupying the mineralocorticoid receptor. In contrast, aldosterone is not a substrate for the enzyme because its 11β-hydroxyl group forms a hemiketal with the 18-aldehyde group of the steroid and is thus not accessible to the enzyme. Thus in the absence of HSD11B2, cortisol efficiently occupies the mineralocorticoid receptor, and because cortisol concentrations are normally far higher than those of aldosterone, this results in signs and symptoms of mineralocorticoid excess.

A similar clinical picture occurs with excessive consumption of licorice or licorice-flavored chewing tobacco; licorice contains compounds, including glycyrrhetinic and glycyrrhizic acids, that inhibit HSD11B2. Carbenoxolone, an antihypertensive drug that is not marketed in the United States, has similar effects.

Clinical Manifestations

Affected infants often have some degree of intrauterine growth restriction, with birthweights of 2 kg typical for term infants. Infants and children often fail to thrive. Severe hypertension (to ~200/120 mm Hg) is almost always present. In some patients, the hypertension tends to be labile or paroxysmal with severe emotional stress as a precipitating factor. Complications of hypertension have included cerebrovascular accidents. Several patients have died during infancy or adolescence, either from electrolyte imbalances leading to cardiac arrhythmias or from vascular sequelae of hypertension. Hypokalemic alkalosis can eventually cause nephrocalcinosis (often visible on renal ultrasound) and nephrogenic diabetes insipidus leading to polyuria and polydipsia. Deleterious effects on muscle range from elevations in serum creatine phosphokinase to rhabdomyolysis. Electrocardiograms show left ventricular hypertrophy.

Laboratory Findings

Hypokalemia and alkalosis are common but not consistently present. Sodium levels are generally in the upper part of the reference range. Aldosterone and renin levels are very low because the

hypertension and hypervolemia are independent of aldosterone concentrations. Serum cortisol and ACTH levels are generally within normal limits. The serum half-life of cortisol is increased, but the test for this requires a radioactive tracer and is not clinically available. Total urinary excretion of cortisol metabolites is markedly decreased. The urinary ratio of free cortisol to free cortisone is elevated, as is the ratio of urinary tetrahydrocortisol plus allotetrahydrocortisol to tetrahydrocortisone.

Differential Diagnosis

The differential diagnosis includes other forms of severe childhood hypertension such as renal artery anomalies, but relatively few conditions present with suppressed renin and aldosterone levels. **Liddle syndrome** has a similar presentation but no abnormalities in the steroid profile, typically has an autosomal dominant mode of inheritance, and does not respond to treatment with mineralocorticoid receptor antagonists. Hypertensive forms of CAH (see Chapter 616) also have suppressed renin and aldosterone levels, but they present with signs of androgen excess (11β-hydroxylase deficiency) or androgen deficiency (17α-hydroxylase deficiency); the latter can be difficult to appreciate in young children. The steroid profiles in CAH differ from those seen in apparent mineralocorticoid excess syndrome.

Patients with severe Cushing syndrome may have high enough cortisol levels to overwhelm renal HSD11B2, leading to severe hypertension with alterations in urinary cortisol-to-cortisone ratios. This occurs most often in patients with ectopic ACTH syndrome. This generally does not present a diagnostic dilemma because other signs of Cushing syndrome are present, including high cortisol levels.

Treatment

Treatment includes a low-salt diet, potassium supplementation, and mineralocorticoid receptor blockade with spironolactone or eplerenone; a sodium channel blocker, such as amiloride or triamterene, may work at least as well. In principle, suppression of cortisol secretion with dexamethasone (which does not bind the mineralocorticoid receptor) should work, but in practice it is much less effective than mineralocorticoid receptor blockade.

LIDDLE SYNDROME

Liddle syndrome is a form of hypertension and hypokalemia that is clinically similar to the syndrome of apparent mineralocorticoid excess, but it is inherited in an autosomal dominant manner. It is caused by an activating pathogenic variant in the β *(SCNN1B)* or γ *(SCNN1G)* subunits of the epithelial sodium channel. Most of these mutations prevent the channel subunits from being ligated to ubiquitin and targeted to the proteasome for degradation, a process that is normally regulated indirectly by aldosterone. The net effect is to increase the number of open channels at the apical surface of epithelial cells of the renal collecting duct, thus facilitating sodium resorption and potassium excretion.

Clinical Manifestations, Laboratory Findings, and Differential Diagnosis

Liddle syndrome is characterized by severe early-onset hypertension and by hypokalemia, which may not be persistent. Aldosterone and renin levels are suppressed, but all steroid hormone levels are normal.

The differential diagnosis is the same as that for apparent mineralocorticoid excess.

Treatment

The mainstays of treatment are a low-salt diet, potassium supplementation, and a sodium channel blocker such as amiloride or triamterene. Mineralocorticoid receptor antagonists such as spironolactone are ineffective.

Chapter 616

Congenital Adrenal Hyperplasia and Related Disorders

Perrin C. White and Ming Yang

Congenital adrenal hyperplasia (CAH) is a family of autosomal recessive disorders of cortisol biosynthesis (normal adrenal steroidogenesis is discussed in Chapter 614). Cortisol deficiency increases secretion of corticotropin (adrenocorticotropic hormone [ACTH]), which, in turn, leads to adrenocortical hyperplasia and overproduction of intermediate metabolites. Depending on the enzymatic step that is deficient, there may be signs, symptoms, and laboratory findings of mineralocorticoid deficiency or excess; incomplete virilization or precocious puberty in affected males; and virilization or sexual infantilism in affected females (Figs. 616.1 and 616.2, Table 616.1).

616.1 Congenital Adrenal Hyperplasia Caused by 21-Hydroxylase Deficiency

Perrin C. White and Ming Yang

More than 90% of CAH cases are caused by 21-hydroxylase deficiency. This P450 enzyme (CYP21A2, P450c21) hydroxylates progesterone and 17-hydroxyprogesterone to yield 11-deoxycorticosterone and 11-deoxycortisol, respectively (see Fig. 614.1 in Chapter 614). These conversions are required for synthesis of aldosterone and cortisol, respectively. Both hormones are deficient in the most severe,

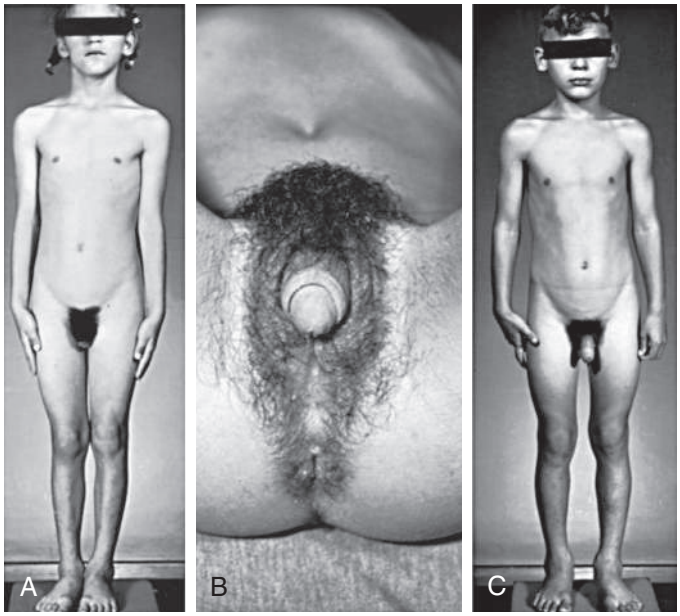

Fig. 616.1 **A,** A 6-yr-old female with congenital virilizing adrenal hyperplasia. The height age was 8.5 yr, and the bone age was 13 yr. **B,** Notice the clitoral enlargement and labial fusion. **C,** Her 5-yr-old brother was not considered to be abnormal by the parents. The height age was 8 yr, and the bone age was 12.5 yr.

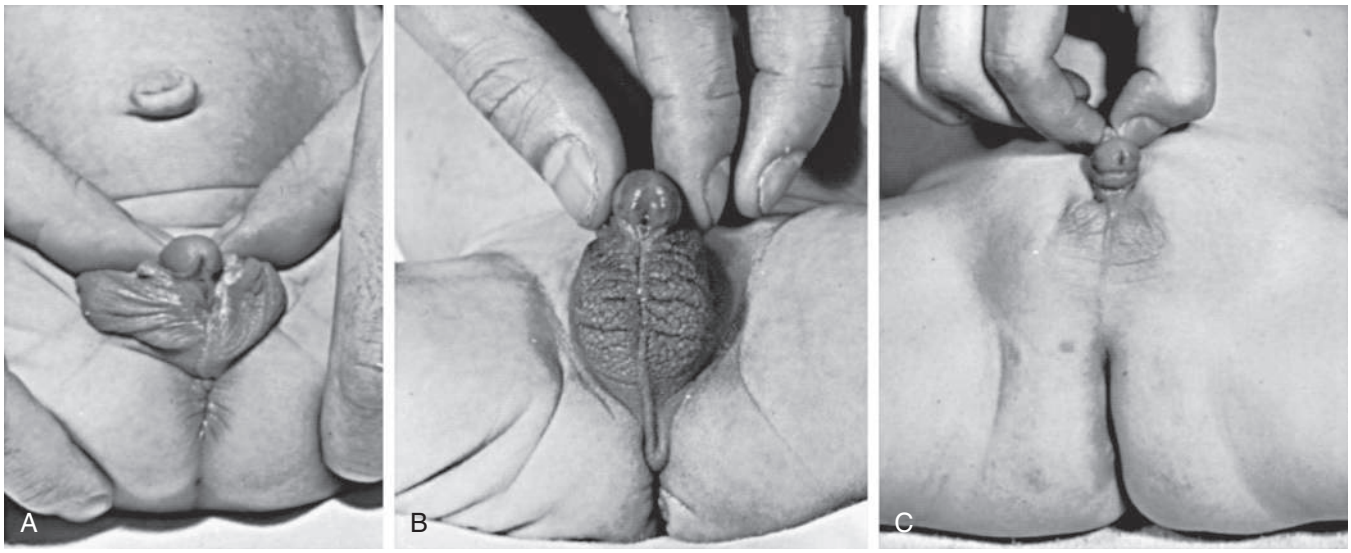

Fig. 616.2 Three virilized females with untreated congenital adrenal hyperplasia. All were erroneously assigned male sex at birth, and each had a normal female sex-chromosome complement. Infants A and B had the salt-wasting form and received the diagnosis early in infancy. Infant C was referred at 1 yr of age because of bilateral cryptorchidism. Notice the completely penile urethra; such complete masculinization in females with adrenal hyperplasia is rare; most of these infants have the salt-wasting form.

salt-wasting form of the disease. Slightly less severely affected patients are able to synthesize adequate amounts of aldosterone but have elevated levels of androgens of adrenal origin; this is termed **simple virilizing disease**. These two forms are collectively termed **classic 21-hydroxylase deficiency**. Patients with **nonclassic** disease have relatively mildly elevated levels of androgens and may be asymptomatic or have signs of androgen excess at any time after birth. Clinical presentation is dependent, in part, on the genotype (Table 616.2).

EPIDEMIOLOGY

Classic 21-hydroxylase deficiency occurs in approximately 1 in 14,000-18,000 births in most populations. Approximately 70% of affected infants have the salt-losing form, whereas 30% have the simple virilizing form of the disorder. In the United States, CAH is less common in African Americans compared with White children (1:42,000 vs 1:15,500). Nonclassic disease has a prevalence of approximately 1 in 1,000 in the general population but occurs more frequently in specific ethnic groups such as Ashkenazi Jews and Hispanics.

GENETICS

There are two steroid 21-hydroxylase genes—*CYP21P (CYP21A1P, CYP21A)* and *CYP21 (CYP21A2, CYP21B)*—which alternate in tandem with two genes for the fourth component of complement (C4A and C4B) in the human leukocyte antigen (HLA) major histocompatibility complex on chromosome 6p21.3 between the HLA-B and HLA-DR loci. Many other genes are in this cluster. *CYP21* is the active gene; *CYP21P* is 98% identical in DNA sequence to *CYP21* but is a pseudogene because of at least 10 different pathogenic variants. Although almost 300 variants have been reported, more than 90% of abnormal alleles causing 21-hydroxylase deficiency are the result of recombinations between *CYP21* and *CYP21P.* Approximately 20% are deletions generated by unequal meiotic crossing-over between *CYP21* and *CYP21P,* whereas the remainder are nonreciprocal transfers of deleterious variants from *CYP21P* to *CYP21,* a phenomenon termed *gene conversion.*

The deleterious variants in *CYP21P* have different effects on enzymatic activity when transferred to *CYP21.* Several variants completely prevent synthesis of a functional protein, whereas others are missense variants that yield enzymes with 1–50% of normal activity. Disease severity correlates well with the variants carried by an affected individual; patients with salt-wasting disease usually carry variants on both alleles that result in no enzymatic activity. Patients are frequently compound heterozygotes for different types of variants (i.e., one allele is less severely affected than the other), in which case the severity of disease expression is largely determined by the activity of the less severely affected of the two alleles.

Closely adjacent to, but on the opposite DNA strand from, *CYP21* is the tenascin-X *(TNX)* gene, which encodes a connective tissue protein. Rarely, deletions of *CYP21* extend into *TNX*. Such patients may have a contiguous gene syndrome (see Chapter 99.1) consisting of CAH and **Ehlers-Danlos syndrome** (see Chapter 744).

PATHOGENESIS AND CLINICAL MANIFESTATIONS

Aldosterone and Cortisol Deficiency

Because both cortisol and aldosterone require 21-hydroxylation for their synthesis, both hormones are deficient in the most severe, salt-wasting form of the disease. This form constitutes approximately 70% of cases of classic 21-hydroxylase deficiency. The signs and symptoms of cortisol and aldosterone deficiency, and the pathophysiology underlying them, are essentially those described in adrenal insufficiency (see Chapter 615). These include progressive weight loss, anorexia, vomiting, dehydration, weakness, hypotension, hypoglycemia, hyponatremia, and hyperkalemia. These problems typically first develop in affected infants at approximately 10-14 days of age. Without treatment, shock, cardiac arrhythmias, and death may occur within days or weeks.

CAH differs from other causes of primary adrenal insufficiency in that precursor steroids accumulate proximal to the blocked enzymatic conversion. Because cortisol is not synthesized efficiently, ACTH levels are high, leading to hyperplasia of the adrenal cortex and levels of precursor steroids that may be hundreds of times normal. In the case of 21-hydroxylase deficiency, these precursors include 17-hydroxyprogesterone and progesterone. Progesterone and perhaps other metabolites act as antagonists of the mineralocorticoid receptor and thus may exacerbate the effects of aldosterone deficiency in untreated patients.

It is not unusual for children with classic CAH to require hospitalization for intercurrent illnesses during childhood. This is most likely to occur in the first 2 years of life and to be precipitated by gastroenteritis, because such illnesses may cause fluid and electrolyte losses, and vomiting may interfere with medication dosing. Children requiring high fludrocortisone doses are most likely to be hospitalized, presumably because those patients have the greatest propensity to salt wasting.

Prenatal Androgen Excess

The most important problem caused by accumulation of steroid precursors is that 17-hydroxyprogesterone is shunted into the pathway for androgen biosynthesis, leading to high levels of androstenedione that

Table 616.1 Diagnosis and Treatment of Congenital Adrenal Hyperplasia

DISORDER	AFFECTED GENE AND CHROMOSOME	SIGNS AND SYMPTOMS	LABORATORY FINDINGS	THERAPEUTIC MEASURES
21-Hydroxylase deficiency, classic form	*CYP21* 6p21.3	Glucocorticoid deficiency	↓ Cortisol, ↑ACTH ↑↑ Baseline and ACTH-stimulated 17-hydroxyprogesterone	Glucocorticoid (hydrocortisone) replacement
		Mineralocorticoid deficiency (salt-wasting crisis)	Hyponatremia, hyperkalemia ↑ Plasma renin	Mineralocorticoid (fludrocortisone) replacement; sodium chloride supplementation
		Ambiguous genitalia in females	↑ Serum androgens	Vaginoplasty and clitoral recession
		Postnatal virilization in males and females	↑ Serum androgens	Suppression with glucocorticoids
21-Hydroxylase deficiency, nonclassic form	*CYP21* 6p21.3	May be asymptomatic; precocious adrenarche, hirsutism, acne, menstrual irregularity, infertility	↑ Baseline and ACTH-stimulated 17-hydroxyprogesterone ↑ Serum androgens	Suppression with glucocorticoids
11β-Hydroxylase deficiency	*CYP11B1* 8q24.3	Glucocorticoid deficiency	↓ Cortisol, ↑ ACTH ↑↑ Baseline and ACTH-stimulated 11-deoxycortisol and deoxycorticosterone	Glucocorticoid (hydrocortisone) replacement
		Ambiguous genitalia in females	↑ Serum androgens	Vaginoplasty and clitoral recession
		Postnatal virilization in males and females	↑ Serum androgens	Suppression with glucocorticoids
		Hypertension	↓ Plasma renin, hypokalemia	Suppression with glucocorticoids
3β-Hydroxysteroid dehydrogenase deficiency, classic form	*HSD3B2* 1p13.1	Glucocorticoid deficiency	↓ Cortisol, ↑ ACTH ↑↑ Baseline and ACTH-stimulated Δ5 steroids (pregnenolone, 17-hydroxypregnenolone, DHEA)	Glucocorticoid (hydrocortisone) replacement
		Mineralocorticoid deficiency (salt-wasting crisis)	Hyponatremia, hyperkalemia ↑ Plasma renin	Mineralocorticoid (fludrocortisone) replacement; sodium chloride supplementation
		Ambiguous genitalia in females and males	↑ DHEA, ↓ androstenedione, testosterone, and estradiol	Surgical correction of genitals and sex hormone replacement as necessary, consonant with sex of rearing
		Precocious adrenarche, disordered puberty	↑ DHEA, ↓ androstenedione, testosterone, and estradiol	Suppression with glucocorticoids
17α-Hydroxylase/17,20-lyase deficiency	*CYP17* 10q24.3	Cortisol deficiency (corticosterone is an adequate glucocorticoid)	↓ Cortisol, ↑ ACTH ↑ DOC, corticosterone Low 17α-hydroxylated steroids; poor response to ACTH	Glucocorticoid (hydrocortisone) administration
		Ambiguous genitalia in males	↓ Serum androgens; poor response to hCG	Orchidopexy or removal of intraabdominal testes; sex hormone replacement consonant with sex of rearing
		Sexual infantilism	↓ Serum androgens or estrogens	Sex hormone replacement consonant with sex of rearing
		Hypertension	↓ Plasma renin; hypokalemia	Suppression with glucocorticoids

Table 616.1 Diagnosis and Treatment of Congenital Adrenal Hyperplasia—cont'd

DISORDER	AFFECTED GENE AND CHROMOSOME	SIGNS AND SYMPTOMS	LABORATORY FINDINGS	THERAPEUTIC MEASURES
Congenital lipoid adrenal hyperplasia	*STAR* 8p11.2	Glucocorticoid deficiency	↑ ACTH Low levels of all steroid hormones, with decreased or absent response to ACTH	Glucocorticoid (hydrocortisone) replacement
		Mineralocorticoid deficiency (salt-wasting crisis)	Hyponatremia, hyperkalemia ↓ Aldosterone, ↑ plasma renin	Mineralocorticoid (fludrocortisone) replacement; sodium chloride supplementation
		Ambiguous genitalia in males	Decreased or absent response to hCG in males	Orchidopexy or removal of intraabdominal testes; sex hormone replacement consonant with sex of rearing
		Poor pubertal development or premature ovarian failure in females	↑ FSH, ↑ LH, ↓ estradiol (after puberty)	Estrogen replacement
P450 oxidoreductase deficiency	*POR* 7q11.3	Glucocorticoid deficiency	↓ Cortisol, ↑ ACTH ↑ Pregnenolone, ↑ progesterone	Glucocorticoid (hydrocortisone) replacement
		Ambiguous genitalia in males and females	↑ Serum androgens prenatally, ↓ androgens and estrogens at puberty	Surgical correction of genitals and sex hormone replacement as necessary, consonant with sex of rearing
		Maternal virilization Antley-Bixler syndrome	Decreased ratio of estrogens to androgens	

↓, Decreased; ↑, increased; ↑↑, markedly increased; ACTH, adrenocorticotropic hormone; DHEA, dehydroepiandrosterone; DOC, 11-deoxycorticosterone; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone.

Table 616.2 Genotype-Phenotype Correlations in Congenital Adrenal Hyperplasia Owing to 21-Hydroxylase Deficiency

VARIANT GROUP	A	B	C
Enzymatic activity, % normal	Nil	1–2%	20–50%
CYP21 variants (phenotype generally corresponds to the least affected allele)	Gene deletion Exon 3 del 8 bp Exon 6 cluster Q318X R356W Intron 2 splice*	I172N	P30L V281L P453S
Severity	Salt wasting	Simple virilizing	Nonclassic
Aldosterone synthesis	Low	Normal	Normal
Age at diagnosis (without newborn screening)	Infancy	Infancy (females) Childhood (males)	Childhood to adulthood, or asymptomatic
Virilization	Severe	Moderate to severe	None to mild
Incidence	1/20,000	1/50,000	1/500

*This variant is associated with both salt-wasting and simple virilizing disease.

are converted outside the adrenal gland to testosterone. This problem begins in affected fetuses by 8-10 weeks of gestation and leads to abnormal genital development in females (see Figs. 616.1 and 616.2).

The external genitalia of males and females normally appear identical early in gestation (see Chapter 622). Affected females who are exposed in utero to high levels of androgens of adrenal origin have masculinized external genitalia (see Figs. 616.1 and 616.2). This is manifested by enlargement of the clitoris and by partial or complete labial fusion. The vagina usually has a common opening with the urethra (urogenital sinus). The clitoris may be so enlarged that it resembles a penis; because the urethra opens below this organ, some affected females may be mistakenly presumed to be males with hypospadias and cryptorchidism. The severity of virilization is usually greatest in females with the salt-losing form of 21-hydroxylase deficiency (see Table 616.2). The internal genital organs are normal because affected females have normal ovaries and not testes and thus do not secrete antimüllerian hormone.

Prenatal exposure of the brain to high levels of androgens may influence subsequent sexually dimorphic behaviors in affected females. Females may demonstrate aggressive play behavior, tend to be interested in masculine toys such as cars and trucks, and often show decreased interest in playing with dolls. Women may have decreased interest in maternal roles. There is an increased frequency of homosexuality in affected females. Nonetheless, most function heterosexually and do not have gender identity confusion or dysphoria. It is unusual

for affected females to assign themselves a male role except in some with the severest degree of virilization.

Male infants appear normal at birth. The diagnosis may not be made in males until signs of adrenal insufficiency develop. Because patients with this condition can deteriorate quickly, infant males are more likely to die than infant females. For this reason, all 50 American states and many countries have instituted newborn screening for this condition (see Chapter 616.2).

Postnatal Androgen Excess

Untreated or inadequately treated children of both sexes develop additional signs of androgen excess after birth. Males with the simple virilizing form of 21-hydroxylase deficiency often have a delayed diagnosis because they appear normal and rarely develop adrenal insufficiency.

Signs of androgen excess include **rapid somatic growth** and **accelerated skeletal maturation**. Affected patients are tall in childhood, but premature closure of the epiphyses causes growth to stop relatively early, and adult stature is stunted (see Fig. 616.1). Muscular development may be excessive. Pubic and axillary hair may appear, and acne and a deep voice may develop. The penis, scrotum, and prostate may become enlarged in affected males; however, the testes are usually prepubertal in size so that they appear small relative to the enlarged penis. Occasionally, ectopic adrenocortical cells in the testes of patients become hyperplastic similarly to the adrenal glands, producing **testicular adrenal rest tumors** (see Chapter 624). The clitoris may become further enlarged in affected females (see Fig. 616.1). Although the internal genital structures are female, breast development and menstruation may not occur unless the excessive production of androgens is suppressed by adequate treatment.

Similar but usually milder signs of androgen excess may occur in **nonclassic 21-hydroxylase deficiency** (see Table 616.2). In this attenuated form, cortisol and aldosterone levels are normal and affected females have normal genitals at birth. Males and females may present with precocious pubarche and early development of pubic and axillary hair. Hirsutism, acne, menstrual disorders, and infertility may develop later in life, but many females and males are completely asymptomatic.

Adrenomedullary Dysfunction

Development of the adrenal medulla requires exposure to the extremely high cortisol levels normally present within the adrenal gland. Thus patients with classic CAH have abnormal adrenomedullary function, as evidenced by blunted epinephrine responses, decreased blood glucose, and lower heart rates with exercise. Ability to exercise is unimpaired, and the clinical significance of these findings is uncertain. Adrenomedullary dysfunction may exacerbate the cardiovascular effects of cortisol deficiency in untreated or undertreated patients.

LABORATORY FINDINGS

See Table 616.1.

Patients with salt-losing disease have typical laboratory findings associated with cortisol and aldosterone deficiency, including hyponatremia, hyperkalemia, metabolic acidosis, and, often, hypoglycemia, but these abnormalities can take 10-14 days or longer to develop after birth. Blood levels of 17-hydroxyprogesterone are markedly elevated. However, levels of this hormone are high during the first 2-3 days of life even in unaffected infants and especially if they are ill or premature. After infancy, once the circadian rhythm of cortisol is established, 17-hydroxyprogesterone levels vary in the same circadian pattern, being highest in the morning and lowest at night. Blood levels of cortisol are usually low in patients with the salt-losing type of disease. They are often normal in patients with simple virilizing disease but inappropriately low in relation to the ACTH and 17-hydroxyprogesterone levels. In addition to 17-hydroxyprogesterone, levels of androstenedione and testosterone are elevated in affected females; testosterone is not elevated in affected males because normal infant males have high testosterone levels compared with those seen later in childhood. Levels of urinary 17-ketosteroids and pregnanetriol are elevated but are now rarely used clinically because blood samples are easier to obtain than 24-hour urine collections. ACTH levels are elevated but have no diagnostic utility over 17-hydroxyprogesterone levels. Plasma levels of renin are elevated, and serum aldosterone is inappropriately low for the renin level. However, renin levels are high in normal infants in the first few weeks of life.

Diagnosis of 21-hydroxylase deficiency is most reliably established by measuring 17-hydroxyprogesterone before and 30 or 60 minutes after an intravenous bolus of 0.125-0.25 mg of cosyntropin (ACTH 1-24). Nomograms exist that readily distinguish between unaffected individuals and patients with nonclassic and classic 21-hydroxylase deficiency. Heterozygous carriers of this autosomal recessive disorder tend to have higher ACTH-stimulated 17-hydroxyprogesterone levels than genetically unaffected individuals, but there is significant overlap between subjects in these two categories. However, in infants with frank electrolyte abnormalities or circulatory instability, it may not be possible or necessary to delay treatment to perform this test, as levels of precursors will be sufficiently elevated on a random blood sample to make the diagnosis.

Genotyping is clinically available and may help to confirm the diagnosis. Because the gene conversions that generate most pathogenic alleles may transfer more than one variant, at least one parent should also be genotyped to determine which variants are on each allele.

DIFFERENTIAL DIAGNOSIS

Disorders of sexual development are discussed more generally in Chapter 628. The initial step in evaluating an infant with ambiguous genitalia is a thorough physical examination to define the anatomy of the genitals, locate the urethral meatus, palpate the scrotum or labia and the inguinal regions for testes (palpable gonads usually indicate the presence of testicular tissue and that the infant is a genetic male), and look for any other anatomic abnormalities. Ultrasonography is helpful in demonstrating the presence or absence of a uterus and can often locate the gonads. A rapid karyotype (such as fluorescence in situ hybridization of interphase nuclei for X and Y chromosomes) can quickly determine the genetic sex of the infant. These results are all likely to be available before the results of hormonal testing and together allow the clinical team to advise the parents as to the genetic sex of the infant and the anatomy of internal reproductive structures. Injection of contrast medium into the urogenital sinus of a virilized female demonstrates a vagina and uterus; surgeons use this information to formulate a plan for surgical management.

PRENATAL DIAGNOSIS

Prenatal diagnosis of 21-hydroxylase is possible late in the first trimester by analysis of DNA obtained by chorionic villus sampling or during the second trimester by amniocentesis. This is usually done because the parents already have an affected child. Most often, the *CYP21A2* gene is analyzed for frequently occurring pathogenic variants; less common variants may be detected by DNA sequencing. Cell-free fetal DNA may be an adjunctive noninvasive testing method to help guide decision-making for possible prenatal treatment with dexamethasone, given that prenatal sex typing can be performed as early as 6-9 weeks. As of 2021, cell-free fetal DNA testing for this disorder is not yet available as part of routine clinical care.

NEWBORN SCREENING

Because 21-hydroxylase deficiency is often undiagnosed in affected males until they have severe adrenal insufficiency, all states in the United States and many other countries have instituted newborn screening programs. These programs analyze 17-hydroxyprogesterone levels in dried blood obtained by heelstick and absorbed on filter paper cards; the same cards are screened in parallel for other congenital conditions, such as hypothyroidism and phenylketonuria. Potentially affected infants are typically quickly recalled for additional testing (electrolytes and repeat 17-hydroxyprogesterone determination) at approximately 2 weeks of age. Infants with salt-wasting disease often have abnormal electrolytes by this age but are usually not severely ill. Screening programs are effective in preventing many cases of adrenal crisis in affected males. The nonclassic form of the disease is not

reliably detected by newborn screening, but this is of little clinical significance because adrenal insufficiency does not occur in this type of 21-hydroxylase deficiency.

The main difficulty with current newborn screening programs is that to reliably detect all affected infants, the cutoff 17-hydroxyprogesterone levels for first-tier screening are set so low that there is a very high frequency of false-positive results (i.e., the test has a low positive predictive value of as little as 1%). This problem is worst in premature infants. Positive predictive value can be improved by using cutoff levels based on gestational age and by using more specific second-tier screening methods such as liquid chromatography followed by tandem mass spectrometry.

TREATMENT

Glucocorticoid Replacement

Cortisol deficiency is treated with glucocorticoids. Treatment also suppresses excessive production of androgens by the adrenal cortex and thus minimizes problems such as excessive growth and skeletal maturation and virilization. This often requires larger glucocorticoid doses than are needed in other forms of adrenal insufficiency, typically 12-15 mg/m^2/24 hr of hydrocortisone daily administered orally in 3 divided doses. Affected infants usually require dosing at the high end of this range. Double or triple doses are indicated during periods of stress, such as infection or surgery. Glucocorticoid treatment must be continued indefinitely in all patients with classic 21-hydroxylase deficiency but may not be necessary in patients with nonclassic disease unless signs of androgen excess are present. Therapy must be individualized. It is desirable to maintain linear growth along percentile lines; crossing to higher height percentiles may suggest undertreatment, whereas loss of height percentiles often indicates overtreatment with glucocorticoids. Overtreatment is also suggested by excessive weight gain. Pubertal development should be monitored by periodic examination, and skeletal maturation is evaluated by serial radiographs of the hand and wrist for bone age. Hormone levels, particularly 17-hydroxyprogesterone and androstenedione, should be measured early in the morning, before taking the morning medications, or at a consistent time in relation to medication dosing. Desirable 17-hydroxyprogesterone levels are in the high-normal range or several times normal; low-normal levels can usually be achieved only with excessive glucocorticoid doses. Hydrocortisone is the preferred glucocorticoid in growing children because its shorter half-life minimizes adverse side effects such as growth suppression, which is seen with longer half-life glucocorticoids. It is available as tablets, immediate-release granules, and a custom-compounded suspension. Use of continuous subcutaneous pump infusion devices to deliver hydrocortisone in a pattern more closely approximating the normal diurnal rhythm variation in cortisol secretion has been studied but has not entered clinical practice. Clinical trials for delayed-release hydrocortisone tablets are currently underway in the pediatric population.

Menarche occurs at the appropriate age in most females in whom good control has been achieved; it may be delayed in females with suboptimal control. Children with simple virilizing disease, particularly males, are frequently not diagnosed until 3-7 years of age, at which time skeletal maturation may be 5 years or more in advance of chronological age. In some children, especially if the bone age is 12 years or more, spontaneous central (i.e., gonadotropin-dependent) puberty may occur when treatment is instituted, because therapy with hydrocortisone suppresses production of adrenal androgens and thus stimulates release of pituitary gonadotropins if the appropriate level of hypothalamic maturation is present. This form of superimposed true precocious puberty may be treated with a gonadotropin hormone–releasing hormone analog such as leuprolide (see Chapter 600.1).

Males with 21-hydroxylase deficiency who have had inadequate corticosteroid therapy may develop **testicular adrenal rest tumors**, which may regress with increased steroid dosage. Testicular MRI, ultrasonography, and color flow Doppler examination help to define the character and extent of disease. Testis-sparing surgery to resect steroid-unresponsive tumors may be required in adult men to preserve fertility.

Mineralocorticoid Replacement

Patients with salt-wasting disease (i.e., aldosterone deficiency) require mineralocorticoid replacement with fludrocortisone. Infants may have very high mineralocorticoid requirements in the first few months of life, usually 0.1-0.3 mg daily in 2 divided doses, but occasionally up to 0.4 mg daily, and often require sodium supplementation (sodium chloride 8 mmol/kg) in addition to the mineralocorticoid. Older infants and children are usually maintained with 0.05-0.1 mg daily of fludrocortisone. In some patients, simple virilizing disease may be easier to control with a low dose of fludrocortisone in addition to hydrocortisone even when these patients have normal aldosterone levels in the absence of mineralocorticoid replacement. Therapy is evaluated by monitoring of vital signs; tachycardia and hypertension are signs of overtreatment with mineralocorticoids. Serum electrolytes should be measured frequently in early infancy as therapy is adjusted. Plasma renin activity is a useful way to determine adequacy of therapy; it should be maintained in or near the normal range but not suppressed.

Additional approaches to improve outcome have been proposed but have not yet become the standard of care. These include an antiandrogen such as flutamide to block the effects of excessive androgen levels and/or an aromatase inhibitor such as anastrozole or letrozole, which blocks conversion of androgens to estrogen and thus retards skeletal maturation, a process that is sensitive to estrogens in both males and females. Aromatase inhibitors generally should not be used in pubertal females, except in combination with a gonadotropin-releasing hormone agonist because this will expose the ovaries to excessive levels of gonadotropins. Growth hormone, with or without gonadotropin–releasing hormone agonists, has been suggested to improve adult height. Corticotropin-releasing hormone receptor antagonists such as crinecerfont and tildacerfont are in phase 2-3 studies as of 2021; they may reduce ACTH secretion, thus suppressing secretion of abnormal steroids at lower glucocorticoid doses than otherwise necessary. This strategy may reduce the adverse effects of high glucocorticoid doses. Abiraterone acetate, a CYP17A1 inhibitor that suppresses secretion of androgens and estrogens and is used for treatment of prostate cancer, may also permit reductions in glucocorticoid dosing and is in early-phase trials for CAH as of 2021.

Surgical Management of Ambiguous Genitals

Significantly virilized females usually undergo surgery between 2 and 6 months of age. If there is severe clitoromegaly, the clitoris is reduced in size, with partial excision of the corporal bodies and preservation of the neurovascular bundle; however, moderate clitoromegaly may become much less noticeable without surgery as the patient grows. Vaginoplasty and correction of the urogenital sinus usually are performed at the time of clitoral surgery; revision in adolescence is often necessary.

Risks and benefits of surgery should be fully discussed with parents of affected females. There is limited long-term follow-up of functional outcomes in patients who have undergone modern surgical procedures. It appears that female sexual dysfunction increases in frequency and severity in those with the most significant degrees of genital virilization and with the degree of enzymatic impairment (prenatal androgen exposure) caused by each patient's pathogenic variant (see Table 616.2). Sex assignment of infants with disorders of sexual differentiation (including CAH) is usually based on expected sexual functioning and fertility in adulthood, with early surgical correction of the external genitalia to conform with the sex assignment. The majority of females with CAH identify as female gender and are heterosexual. Gender dysphoria is not common with CAH; it occurs mostly in females with the salt-wasting form of the disease and the greatest degree of virilization.

Lay and medical opponents of genital surgery for other disorders of sexual differentiation raise the concern that it ignores any prenatally influenced gender role effects from androgen exposure and precludes the patient from having any decision as to the patient's own preferred sexual identity and what surgical correction of the genitals should be performed. They advocate that treatment should be aimed primarily at educating the patient, family, and others about the medical condition

and its treatment. They propose that surgery should be delayed until the patient decides on what, if any, surgery should be performed. There have not been any studies comparing early with late surgery. Not all lay groups support delaying surgery, and many agree with appropriate surgery during infancy. Severely virilized genotypic (XX) females raised as males have generally functioned well in the male gender as adults.

In adolescent and adult females with poorly controlled 21-hydroxylase deficiency (hirsutism, obesity, amenorrhea), bilateral laparoscopic adrenalectomy (with hormone replacement) may be an alternative to standard medical hormone replacement therapy, but because the adrenal glands have been removed, patients treated in this way may be more susceptible to acute adrenal insufficiency if treatment is interrupted. Moreover, they may exhibit signs of elevated ACTH levels such as abnormal pigmentation. There have also been reports of development of adrenal rest tumors in women after adrenalectomy, which defeats the purpose of adrenalectomy and allows the recurrence of androgen excess.

Prenatal Treatment

Besides genetic counseling, the main goal of prenatal diagnosis is to facilitate prenatal treatment of affected females. Mothers with pregnancies at risk may be given dexamethasone, a steroid that readily crosses the placenta, in an amount of 20 μg/kg pre-pregnancy maternal weight daily in 2 or 3 divided doses. This suppresses secretion of steroids by the fetal adrenal, including secretion of adrenal androgens. If started by 6 weeks of gestation, it ameliorates virilization of the external genitals in affected females. Chorionic villus biopsy is then performed to determine the sex and genotype of the fetus; therapy is continued only if the fetus is an affected female. DNA analysis of fetal cells isolated from maternal plasma for sex determination and *CYP21* gene analysis may permit earlier identification of the affected female fetus. Treatment should be considered only in affected female fetuses. Children exposed to this therapy have slightly lower birthweights. Reports of failure to thrive, stroke-like events, and midline defects have been observed in treated cases. Effects on personality or cognition, such as increased shyness, have been suggested but not consistently observed. At present there is insufficient information to determine whether the long-term risks are acceptable, particularly in the males and unaffected females who derive no direct benefit from the treatment. Maternal side effects of prenatal treatment have included edema, excessive weight gain, hypertension, glucose intolerance, cushingoid facial features, and severe striae. Consensus statements from professional societies recommend that prenatal treatment be carried out only under institutional protocols, but it is sometimes offered as an option outside the research setting by some high-risk obstetricians.

616.2 Congenital Adrenal Hyperplasia Caused by 11β-Hydroxylase Deficiency

Perrin C. White and Ming Yang

Deficiency of 11β-hydroxylase is caused by a pathologic variant in the *CYP11B1* gene located on chromosome 8q21-q22. *CYP11B1* mediates 11-hydroxylation of 11-deoxycortisol to cortisol. Because 11-deoxycortisol is not converted to cortisol, levels of corticotropin are high. In consequence, precursors—particularly 11-deoxycortisol and deoxycorticosterone—accumulate and are shunted into androgen biosynthesis in the same manner as occurs in 21-hydroxylase deficiency. The adjacent *CYP11B2* gene encoding aldosterone synthase is generally unaffected in this disorder, so patients are able to synthesize aldosterone normally.

EPIDEMIOLOGY

11β-Hydroxylase deficiency accounts for approximately 5% of cases of adrenal hyperplasia; its incidence in the general population has been estimated as 1 in 250,000 to 1 in 100,000. The disorder occurs relatively frequently in Israeli Jews of North African origin (1 in 5,000-7,000 live births). In this ethnic group, almost all alleles carry an Arg448 to His (R448H) variant in *CYP11B1,* but many other variants have been identified. This disorder presents in a classic, severe form and very rarely in a nonclassic, milder form.

CLINICAL MANIFESTATIONS

Although cortisol is not synthesized efficiently, aldosterone synthetic capacity is normal, and some corticosterone is synthesized from progesterone by the intact aldosterone synthase enzyme. Thus it is unusual for patients to manifest signs of adrenal insufficiency such as hypotension or hypoglycemia. On the contrary, approximately 65% of patients become *hypertensive,* although this can take several years to develop. Hypertension is probably a consequence of elevated levels of deoxycorticosterone, which has mineralocorticoid activity. Infants may transiently develop signs of mineralocorticoid deficiency after treatment with hydrocortisone is instituted. This is presumably from sudden suppression of deoxycorticosterone secretion in a patient with atrophy of the zona glomerulosa caused by chronic suppression of renin activity.

All signs and symptoms of androgen excess that are found in 21-hydroxylase deficiency may also occur in 11β-hydroxylase deficiency.

LABORATORY FINDINGS

Plasma levels of 11-deoxycortisol and deoxycorticosterone are elevated. Because deoxycorticosterone and some metabolites have mineralocorticoid activity, plasma renin activity is suppressed. Consequently, aldosterone levels are low even though the ability to synthesize aldosterone is intact. *Hypokalemic alkalosis occasionally occurs.*

TREATMENT

Patients are treated with hydrocortisone in doses similar to those used for 21-hydroxylase deficiency. Mineralocorticoid replacement is sometimes transiently required in infancy but is rarely necessary otherwise. Hypertension often resolves with glucocorticoid treatment but may require additional therapy if it is of long standing. Calcium channel blockers may be beneficial under these circumstances.

616.3 Congenital Adrenal Hyperplasia Caused by 3β-Hydroxysteroid Dehydrogenase Deficiency

Perrin C. White and Ming Yang

Deficiency of 3β-hydroxysteroid dehydrogenase (3β-HSD) occurs in less than 2% of patients with adrenal hyperplasia. This enzyme is required for conversion of Δ5 steroids (pregnenolone, 17-hydroxypregnenolone, dehydroepiandrosterone [DHEA]) to Δ4 steroids (progesterone, 17-hydroxyprogesterone, and androstenedione). Thus deficiency of the enzyme results in decreased synthesis of cortisol, aldosterone, and androstenedione but increased secretion of DHEA (see Fig. 614.1 in Chapter 614). The 3β-HSD isozyme expressed in the adrenal cortex and gonad is encoded by the *HSD3B2* gene located on chromosome 1p13.1. More than 30 pathogenic variants in *HSD3B2* have been described in patients with 3β-HSD deficiency.

CLINICAL MANIFESTATIONS

Because cortisol and aldosterone are not synthesized in patients with the classic form of the disease, infants are prone to **salt-wasting crises**. Because androstenedione and testosterone are not synthesized, *males*

are incompletely virilized; varying degrees of hypospadias may occur, with or without bifid scrotum or cryptorchidism. Because DHEA levels are elevated and this hormone is a weak androgen, females are mildly virilized, with slight to moderate clitoral enlargement. Postnatally, continued excessive DHEA secretion can cause precocious adrenarche. During adolescence and adulthood, hirsutism, irregular menses, and polycystic ovarian disease occur in females. Males manifest variable degrees of hypogonadism, although appropriate male secondary sexual development may occur. However, a persistent defect of testicular 3β-HSD is demonstrated by the high Δ5:Δ4 steroid ratio in testicular effluent.

LABORATORY FINDINGS

The hallmark of this disorder is the marked elevation of the Δ5 steroids (such as 17-hydroxypregnenolone and DHEA) preceding the enzymatic block. Patients may also have elevated levels of 17-hydroxyprogesterone because of the extraadrenal 3β-HSD activity that occurs in peripheral tissues; these patients may be mistaken for patients with 21-hydroxylase deficiency. The ratio of 17-hydrox ypregnenolone:17-hydroxyprogesterone is markedly elevated in 3β-HSD deficiency, in contrast to the decreased ratio in 21-hydroxylase deficiency. Plasma renin activity is elevated in the salt-wasting form.

DIFFERENTIAL DIAGNOSIS

It is not unusual for children with premature adrenarche, or females with signs of androgen excess, to have mild to moderate elevations in DHEA levels. It has been suggested that such individuals have *nonclassic 3β-HSD deficiency*. Variants in *HSD3B2* are usually not found in such individuals, and a nonclassic form of this deficiency may be quite rare. The activity of 3β-HSD in the adrenal zonae fasciculata and reticularis, relative to CYP17A1 (17-hydroxylase/17,20-lyase) activity, normally decreases during adrenarche to facilitate DHEA synthesis, and so modest elevations in DHEA in preteenage children or women usually represent a normal variant.

TREATMENT

Patients require glucocorticoid and mineralocorticoid replacement with hydrocortisone and fludrocortisone, respectively, as in 21-hydroxylase deficiency. Incompletely virilized genetic males in whom a male sex of rearing is contemplated may benefit from several injections of 25 mg of a depot form of testosterone every 4 weeks early in infancy to increase the size of the phallus. They may also require testosterone replacement at puberty.

616.4 Congenital Adrenal Hyperplasia Caused by 17-Hydroxylase Deficiency

Perrin C. White and Ming Yang

Less than 1% of CAH cases are caused by 17-hydroxylase deficiency, but the condition is apparently more common in Brazil and China. A single polypeptide, CYP17A1, catalyzes two distinct reactions: 17-hydroxylation of pregnenolone and progesterone to 17-hydroxypregnenolone and 17-hydroxyprogesterone, respectively, and the 17,20-lyase reaction–mediating conversion of 17-hydroxypregnenolone to DHEA and, to a lesser extent, 17-hydroxyprogesterone to Δ4-androstenedione. DHEA and androstenedione are steroid precursors of testosterone and estrogen (see Fig. 614.1 in Chapter 614). The enzyme is expressed in both the adrenal cortex and the gonads and is encoded by a gene on chromosome 10q24.3. Most pathogenic variants affect both the hydroxylase and lyase activities, but rare variants can affect either activity alone.

Pathogenic variants in genes other than *CYP17A1* can have the same phenotype as 17,20-lyase deficiency (i.e., deficient androgen synthesis with normal cortisol synthesis). These include an accessory electron transfer protein, cytochrome-b_5, (CYB5) and variants in two aldo-keto reductases AKR1C2 and AKR1C4. These AKR1C isozymes normally catalyze 3α-HSD activity, which allows synthesis of the potent androgen dihydrotestosterone through an alternative backdoor biosynthetic pathway that does not include testosterone as an intermediate (see Chapter 614).

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

Patients with 17-hydroxylase deficiency cannot synthesize cortisol, but their ability to synthesize corticosterone is intact. Because corticosterone is an active glucocorticoid, patients do not develop adrenal insufficiency. Deoxycorticosterone, the immediate precursor of corticosterone, is synthesized in excess. This can cause **hypertension**, **hypokalemia**, and suppression of renin and aldosterone secretion, as occurs in 11β-hydroxylase deficiency. However, in contrast to 11β-hydroxylase deficiency, patients with 17-hydroxylase deficiency are unable to synthesize sex hormones. *Affected males are incompletely virilized* and present as phenotypic females (but the gonads are usually palpable in the inguinal region or the labia) or with sexual ambiguity. Affected females usually present with *failure of sexual development* at the expected time of puberty. 17-Hydroxylase deficiency in females must be considered in the differential diagnosis of primary hypogonadism (see Chapter 626). Levels of deoxycorticosterone are elevated, and renin and aldosterone are consequently suppressed. Cortisol and sex steroids are unresponsive to stimulation with ACTH and human chorionic gonadotropin, respectively.

Patients with isolated 17,20-lyase deficiency have deficient androgen synthesis with normal cortisol synthesis and therefore do not become hypertensive.

TREATMENT

Patients with 17-hydroxylase deficiency require glucocorticoid replacement with hydrocortisone to suppress secretion of deoxycorticosterone and thus control hypertension. Additional antihypertensive medication may be required. Females require estrogen replacement at puberty. Genetic males may require either estrogen or androgen supplementation depending on the sex of rearing. Because of the possibility of malignant transformation of abdominal testes, genetic males with severe 17-hydroxylase deficiency being reared as females require gonadectomy at or before adolescence.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

616.5 Lipoid Adrenal Hyperplasia

Perrin C. White and Ming Yang

Lipoid adrenal hyperplasia is a rare disorder, most frequently found in Japanese persons. Patients with this disorder exhibit marked accumulation of cholesterol and lipids in the adrenal cortex and gonads associated with severe impairment of all steroidogenesis. Lipoid adrenal hyperplasia is usually caused by pathogenic variants in the gene for steroidogenic acute regulatory protein (StAR), a mitochondrial protein that promotes the movement of cholesterol from the outer to the inner mitochondrial membrane. However, pathogenic variants in *CYP11A1* (which encodes the cholesterol side-chain cleavage enzyme) have been reported in more than 30 patients. A milder, nonclassic form of StAR deficiency has been reported.

Some cholesterol is able to enter mitochondria even in the absence of StAR, so it might be supposed that this disorder would not completely impair steroid biosynthesis. However, the accumulation of cholesterol in the cytoplasm is cytotoxic, eventually leading to death of all steroidogenic cells in which StAR is normally expressed. This occurs prenatally in the adrenals and testes. The ovaries do not

normally synthesize steroids until puberty, so cholesterol does not accumulate, and the ovaries can retain the capacity to synthesize estrogens until adolescence.

Although estrogens synthesized by the placenta are required to maintain pregnancy, the placenta does not require StAR for steroid biosynthesis. Variants of StAR are not prenatally lethal.

CLINICAL MANIFESTATIONS

Patients with lipoid adrenal hyperplasia are usually unable to synthesize any adrenal steroids. Thus affected infants are likely to be confused with those with adrenal hypoplasia congenita. Salt-losing manifestations are typical, and many infants die in early infancy. Genetic males are unable to synthesize androgens and thus are **phenotypically female** but with gonads palpable in the labia majora or inguinal areas. Genetic females appear normal at birth and may undergo feminization at puberty with menstrual bleeding. They, too, progress to hypergonadotropic hypogonadism when accumulated cholesterol damages granulosa (i.e., steroid synthesizing) cells in the ovary.

LABORATORY FINDINGS

Adrenal and gonadal steroid hormone levels are low in lipoid adrenal hyperplasia, with a decreased or absent response to stimulation (ACTH, human chorionic gonadotropin). Plasma renin levels are increased.

Imaging studies of the adrenal gland demonstrating massive adrenal enlargement in the newborn help to establish the diagnosis of lipoid adrenal hyperplasia.

TREATMENT

Patients require glucocorticoid and mineralocorticoid replacement. Genetic males are usually assigned a female sex of rearing; thus both genetic males and females require estrogen replacement at the expected age of puberty.

616.6 Deficiency of P450 Oxidoreductase (Antley-Bixler Syndrome)

Perrin C. White and Ming Yang

P450 oxidoreductase (*POR*; gene located on chromosome 7q11.3) is required for the activity of all microsomal cytochrome P450 enzymes (see Chapter 614), including the adrenal enzymes CYP17 and CYP21. Complete *POR* deficiency abolishes all microsomal P450 activity. This is embryonically lethal in mice and presumably also in humans. Patients with pathogenic variants that decrease but do not abolish *POR* activity have partial deficiencies of 17-hydroxylase and 21-hydroxylase activities in the adrenals. A single recurrent variant A287P (alanine-287 to proline) is found on approximately 40% of alleles.

Deficiency of 17-hydroxylase leads to incomplete masculinization in males; 21-hydroxylase deficiency may lead to virilization in females. In addition, aromatase *(CYP19)* activity in the placenta is decreased, leading to unopposed action of androgens produced by the fetal adrenal. This exacerbates virilization of female fetuses and may **virilize the mother** of an affected fetus as well. Although it is puzzling that affected females could be virilized despite a partial deficiency in *CYP17* (which is required for androgen biosynthesis), an alternative (backdoor) biosynthetic pathway is used in which 17-hydroxyprogesterone is converted to 5α-pregnane-3α,17α-diol-20-one, a metabolite that is a much better substrate for the 17,20-lyase activity of *CYP17* than the usual substrate, 17-hydroxypregnenolone (see Chapter 614). The metabolite is then converted in several enzymatic steps to dihydrotestosterone, a potent androgen.

Because many other P450 enzymes are affected, patients may have other congenital anomalies collectively referred to as **Antley-Bixler syndrome**. These include craniosynostosis; brachycephaly; frontal bossing; severe midface hypoplasia with proptosis and choanal stenosis or atresia; humeroradial synostosis; medial bowing of ulnas; long, slender fingers with camptodactyly; narrow iliac wings; anterior bowing of femurs; and malformations of the heart and kidneys.

EPIDEMIOLOGY

More than 130 cases of *POR* deficiency have been reported. Although the prevalence is not known with certainty, it might be the second most common cause of CAH in some populations such as Korea and Japan.

LABORATORY FINDINGS

Serum steroids that are not 17- or 21-hydroxylated are most increased, including pregnenolone and progesterone. 17-Hydroxy and 21-deoxysteroids are also increased, including 17-hydroxypregnenolone, 17-hydroxyprogesterone, and 21-deoxycortisol. Urinary steroid metabolites may be determined by quantitative mass spectrometry. Metabolites excreted at increased levels include pregnanediol, pregnanetriol, pregnanetriolone, and corticosterone metabolites. Urinary cortisol metabolites are decreased. Genetic analysis demonstrates pathogenic variants in *POR*.

DIFFERENTIAL DIAGNOSIS

This disorder must be distinguished from other forms of CAH, particularly 21-hydroxylase deficiency in females, which is far more common and has similar laboratory findings. Suspicion for *POR* deficiency may be raised if the mother is virilized or if the associated abnormalities of Antley-Bixler syndrome are present. Conversely, virilization of both the mother and her daughter can result from a luteoma of pregnancy, but in this case postnatal abnormalities of corticosteroid biosynthesis should not be observed. Antley-Bixler syndrome may also occur without abnormalities of steroid hormone biosynthesis, resulting from pathogenic variants in the fibroblast growth factor receptor FGFR2.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

616.7 Aldosterone Synthase Deficiency

Perrin C. White and Ming Yang

This is an autosomal recessive disorder in which conversion of corticosterone to aldosterone is impaired; a group of Iranian Jewish patients has been the most thoroughly studied. Most cases result from pathogenic variants in *CYP11B2* coding for aldosterone synthase; however, linkage to *CYP11B2* has been excluded in other kindreds. When not caused by *CYP11B2* variants, the disorder has been termed **familial hyperreninemic hypoaldosteronism type 2**; the causative gene or genes have not yet been identified.

Aldosterone synthase mediates the three final steps in the synthesis of aldosterone from deoxycorticosterone (11β-hydroxylation, 18-hydroxylation, and 18-oxidation). Although 11β-hydroxylation is required to convert deoxycorticosterone to corticosterone, this conversion can also be catalyzed by the related enzyme, CYP11B1, located in the fasciculata, which is unaffected in this disorder. For the same reason, these patients have normal cortisol biosynthesis.

The disease has been classified into two types, termed **corticosterone methyloxidase deficiency types I and II**. They differ only in levels of the immediate precursor of aldosterone, 18-hydroxycorticosterone; levels are low in type I deficiency and elevated in type II deficiency.

CLINICAL MANIFESTATIONS

Infants with aldosterone synthase deficiency may have severe electrolyte abnormalities with **hyponatremia**, **hyperkalemia**, and

metabolic acidosis. Because cortisol synthesis is unaffected, infants rarely become as ill as untreated infants with salt-losing forms of CAH such as 21-hydroxylase deficiency. Thus some infants escape diagnosis. Later in infancy or in early childhood they may exhibit failure to thrive and poor growth. Adults often are asymptomatic, although they may develop electrolyte abnormalities when depleted of sodium through procedures such as bowel preparation for a barium enema.

LABORATORY FINDINGS

Infants have elevated plasma renin activity. Aldosterone levels are decreased; they may be at the lower end of the normal range but are always inappropriately low for the degree of hyperkalemia or hyperreninemia. Corticosterone levels are often elevated.

Some, but not all, patients have marked elevation of 18-hydroxycorticosterone; however, low levels of this steroid do not exclude the diagnosis. In those kindreds in which 18-hydroxycorticosterone levels are elevated in affected individuals, this biochemical abnormality persists in adults even when they have no electrolyte abnormalities.

DIFFERENTIAL DIAGNOSIS

It is important to distinguish aldosterone synthase deficiency from primary adrenal insufficiency in which both cortisol and aldosterone are affected (including salt-wasting forms of CAH), because the latter condition is usually associated with a much greater risk of shock and hyponatremia. This becomes apparent after the appropriate laboratory studies. **Adrenal hypoplasia congenita** may initially present with aldosterone deficiency; all male infants with apparently isolated aldosterone deficiency should be carefully monitored for subsequent development of cortisol deficiency. **Pseudohypoaldosteronism** (see Chapter 615.4) may have similar electrolyte abnormalities and hyperreninemia, but aldosterone levels are high, and this condition usually does not respond to fludrocortisone treatment.

TREATMENT

Treatment consists of giving enough fludrocortisone (0.05-0.2 mg daily) or sodium chloride, or both, to return plasma renin levels to normal. With increasing age, salt-losing signs usually improve, and drug therapy can often be discontinued.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

616.8 Glucocorticoid-Remediable Aldosteronism

Perrin C. White

Glucocorticoid-remediable aldosteronism (glucocorticoid-suppressible hyperaldosteronism, familial hyperaldosteronism type I) is an autosomal dominant form of *low-renin hypertension* in which hyperaldosteronism is rapidly suppressed by glucocorticoid administration. This unusual effect of glucocorticoids suggests that aldosterone secretion in this disorder is regulated by ACTH instead of by the renin-angiotensin system. In addition to abnormally regulated secretion of aldosterone, there is marked overproduction of 18-hydroxycortisol and 18-oxocortisol. The synthesis of these steroids requires both 17-hydroxylase (CYP17A1) activity, which is expressed only in the zona fasciculata, and aldosterone synthase (CYP11B2) activity, which is normally expressed only in the zona glomerulosa. These features imply that aldosterone synthase is being expressed in a manner similar to the closely related enzyme steroid 11-hydroxylase *(CYP11B1)*. The disorder is caused by unequal meiotic crossing-over events between the *CYP11B1* and *CYP11B2* genes, which are closely linked on chromosome 8q24. An additional "chimeric" gene is produced, having regulatory sequences of *CYP11B1* juxtaposed with coding sequences of *CYP11B2*. This results in the inappropriate expression of a *CYP11B2*-like enzyme with aldosterone synthase activity in the adrenal fasciculata.

CLINICAL MANIFESTATIONS

Some affected children have no symptoms, the diagnosis being established after incidental discovery of moderate hypertension, typically approximately 30 mm Hg higher than unaffected family members of the same age. Others have more symptomatic hypertension with headache, dizziness, and visual disturbances. A strong family history of early-onset hypertension or early strokes may alert the clinician to the diagnosis. Some patients have chronic hypokalemia, but this is not a consistent finding and is usually mild.

LABORATORY FINDINGS

Patients have elevated plasma and urine levels of aldosterone and suppressed plasma renin activity. *Hypokalemia is not consistently present.* Urinary and plasma levels of 18-oxocortisol and 18-hydroxycortisol are markedly increased. The hybrid *CYP11B1/CYP11B2* gene can be readily detected by molecular genetic methods.

DIFFERENTIAL DIAGNOSIS

This condition should be distinguished from primary aldosteronism based on bilateral hyperplasia or an aldosterone-producing adenoma (see Chapter 620). Most cases of primary aldosteronism are sporadic, although several affected kindreds have been reported. Patients with primary aldosteronism may also have elevated levels of 18-hydroxycortisol and 18-oxocortisol, and these biochemical tests should be used cautiously when attempting to distinguish primary and glucocorticoid-suppressible aldosteronism. By definition, a therapeutic trial of dexamethasone should suppress aldosterone secretion only in glucocorticoid-remediable aldosteronism, and genetic testing should identify the hybrid gene if it is present.

TREATMENT

Glucocorticoid-remediable aldosteronism is managed by daily administration of a glucocorticoid, usually dexamethasone 25 μg/kg/day in divided doses. If necessary, effects of aldosterone can be blocked with a potassium-sparing diuretic such as spironolactone, eplerenone, or amiloride. Hypertension resolves in patients in whom the hypertension is not severe or of long standing. If hypertension is long standing, additional antihypertensive medication may be required, such as a calcium channel blocker.

GENETIC COUNSELING

Because of the autosomal dominant mode of inheritance, at-risk family members should be investigated for this easily treated cause of hypertension.

Chapter 617

Adrenocortical Tumors and Masses

Perrin C. White

Adrenocortical tumors are rare in childhood, with an incidence of 0.3-0.5 cases per 1 million child-years. They occur in all age-groups but most commonly in children younger than 6 years of age and are slightly more frequent (1.6-fold) in females. In 2–10% of cases, the tumors are bilateral. Almost half of childhood adrenocortical tumors are carcinomas. Pathogenic variants in many genes can influence the risk of developing adrenal tumors (Table 617.1).

Tumors may be associated with hemihypertrophy, usually occurring during the first few years of life. They are also associated with other congenital defects, particularly genitourinary tract and central nervous system abnormalities and hamartomatous defects.

Many adrenocortical tumors secrete sex hormones, cortisol, or aldosterone; these are discussed in Chapters 618, 619, and 620, respectively.

617.1 Adrenocortical Carcinoma

Perrin C. White

ETIOLOGY

The incidence of adrenocortical carcinoma is increased in several familial cancer syndromes resulting from abnormalities in genes that encode transcription factors implicated in cell proliferation, differentiation, senescence, apoptosis, and genomic instability. These include tumor protein 53 *(TP53)*, menin (the *MEN1* gene involved in multiple endocrine neoplasia type 1; 1–2% of MEN1 patients develop adrenocortical carcinoma), the *APC* gene involved in familial adenomatous polyposis coli, and the *PRKAR1A* gene encoding a cyclic adenosine monophosphate–dependent protein kinase regulatory subunit (also see Chapter 619).

Germline pathogenic variants in *TP53* (on chromosome 17p13.1) occur in 50–80% of children with adrenocortical carcinoma. They have been found in patients with isolated adrenal carcinoma and in patients with familial clustering of unusual malignancies (choroid plexus tumors, sarcomas, early-onset breast cancers, brain cancers, and leukemias); this latter condition is termed **Li-Fraumeni syndrome**. A 15-fold increased incidence of childhood adrenocortical tumors is found in southern Brazil, associated with an R337H variant in *TP53*.

Overexpression of insulin-like growth factor (IGF) 2 (encoded by *IGF2,* on chromosome 11p15.5) occurs in 80% of sporadic childhood adrenocortical tumors and in those associated with **Beckwith-Wiedemann syndrome**, in which there is loss of the normal imprinting of genes in this chromosomal region, including *H19, CDKN1C, KCNQ1,* and *KCNQ1OT1*. However, whereas 5–10% of patients with Beckwith-Wiedemann syndrome develop tumors, <1% develop an adrenocortical carcinoma. Further implicating IGFs in pathogenesis, many pediatric adrenocortical tumors overexpress the IGF receptor, IGF1R.

Pathogenic variants in the *MENIN* gene on chromosome 11q13 cause **multiple endocrine neoplasia type 1**. Approximately 10% of MEN1 patients have adrenocortical tumors, of which ~14% are malignant. Adrenocortical carcinomas also occur in patients with **Lynch syndrome**, a hereditary cancer syndrome (mainly colorectal and endometrial cancer) caused by pathogenic variants in genes involved in DNA mismatch repair, including *MLH1, MSH2, MSH6,* and *PMS2,* or loss of expression of *MSH2* caused by deletion in the *EPCAM* gene. Occasional adrenocortical carcinomas occur in patients with familial adenomatous polyposis, neurofibromatosis type 1, Werner syndrome, and Carney complex.

In adult adrenocortical carcinoma samples, *somatic* pathogenic variants are detected in nine genes (*ZNRF3, CTNNB1, TP53, CDKN2A, RB1, MEN1, DAXX, MED12,* and *TERT*), most frequently (21%) in *ZNRF3*. This gene encodes a cell surface transmembrane E3 ubiquitin ligase that acts as a negative feedback regulator of Wnt/β-catenin signaling. There are also tumor-specific differences in DNA methylation and in micro-RNA (miRNA) expression that have prognostic significance in adults, but there are no corresponding data in children.

CLINICAL MANIFESTATIONS

Symptoms of endocrine hyperfunction are present in 80–90% of children with adrenal tumors. Tumors that secrete cortisol and aldosterone are discussed in Chapters 619 and 621. Other tumors are detected because of symptoms related to local tumor growth, such as abdominal pain, or as incidental findings on abdominal imaging.

Tumors can usually be detected by ultrasonography, CT, or MRI. Preoperatively, the presence of metastatic disease should be determined by MRI or CT of the chest, abdomen, and pelvis. Because these tumors are metabolically active, ^{18}F-fluorodeoxyglucose positron emission tomography (PET)/CT has very good sensitivity and specificity in distinguishing benign from malignant lesions, but it cannot distinguish adrenocortical carcinomas from other metabolically active tumors such as metastases, lymphoma, or pheochromocytoma. Radiochemical imaging of these tumors by PET may be improved with ^{11}C-metomidate or single photon emission CT or MRI with ^{123}I-iodometomidate.

PATHOLOGIC FINDINGS

Most pediatric adrenocortical tumors would be classified as malignant by the criteria used to classify adult tumors. Size is a useful prognostic factor, with tumors weighing less than 200 g, 200-400 g, and >400 g being classified, respectively, as low, intermediate, and high risk (>10 cm diameter has also been suggested as a high-risk category). Incomplete resection and gross local invasion or metastasis are also associated with a poor prognosis. However, most tumors occurring in children younger than 4 years of age have a favorable prognosis. Tumors associated with Cushing syndrome may have a poor prognosis, whereas the presence of germline *TP53* variants may be more favorable.

DIFFERENTIAL DIAGNOSIS

For functioning tumors, the differential diagnoses are those of the main presenting signs and symptoms. The differential diagnosis for Cushing syndrome is discussed in Chapter 619. For virilizing signs, the differential includes virilizing forms of adrenal hyperplasia (see Chapter 616) and factitious exposure to androgens, such as topical testosterone preparations. The differential diagnosis for hormonally

Table 617.1 Genes Involved in Adrenal Neoplasia

SYNDROME	ADRENAL NEOPLASIA TYPE	GENE	OTHER PHENOTYPE
Li-Fraumeni syndrome	Adrenocortical carcinoma	*TP53*	Sarcoma, choroid plexus tumor, brain cancer, early breast cancer, leukemia, lymphoma
Multiple endocrine neoplasia type 1	Diffuse hyperplasia, nodular hyperplasia, adrenal adenoma, adrenocortical carcinoma	*MENIN*	Foregut neuroendocrine tumors, pituitary tumors, parathyroid hyperplasia or tumors, collagenoma, angiofibroma
Lynch syndrome	Adrenocortical carcinoma	*MSH2, MSH6, MLH1, PMS2*	Colorectal cancer, endometrial cancer, sebaceous neoplasms, ovarian cancer, pancreatic cancer, brain cancer
Beckwith-Wiedemann syndrome	Adrenal adenoma, adrenocortical carcinoma	*IGF2, CDKN1C, H19* methylation changes on 11p15	Macrosomia, hemihypertrophy, macroglossia, omphalocele, ear pits; Wilms tumor, hepatoblastoma
Familial adenomatous polyposis coli	Bilateral macronodular adrenal hyperplasia, aldosterone-producing adenoma, adrenocortical carcinoma	*APC*	Intestinal polyps, colon cancer, duodenal carcinoma, thyroid cancer, desmoid tumor, supernumerary teeth, congenital hypertrophy of the retina, osteoma, epidermoid cysts
Neurofibromatosis type 1	Adrenocortical carcinoma, pheochromocytoma	*NF1*	Malignant peripheral nerve sheet tumor, café-au-lait spots, neurofibroma, optic glioma, Lisch nodule, skeletal abnormalities
ADRENAL ADENOMA AND CARCINOMA			
Carney complex	Primary pigmented nodular adrenal disease, adrenocortical carcinoma	*PRKAR1A*	Large-cell calcifying Sertoli cell tumors, thyroid adenoma, myxoma, somatotroph pituitary adenoma, lentigines
	Primary pigmented nodular adrenal disease	*PDE8B* or *PDE11A*	
Overexpression of steroidogenic factor-1	Adrenal adenoma, adrenocortical carcinoma	Somatic amplification of *NR5A1*	
McCune-Albright syndrome	Nodular hyperplasia, cortisol-secreting adenoma	Activating somatic mosaic variant of *GNAS*	Hyperfunction of bone (producing fibrous dysplasia), gonads, thyroid, and pituitary
	Cortisol-secreting adenomas	Activating somatic variant in *PRKACA*	
Somatic pathogenic variants	Adrenocortical carcinoma	*CDKN2A, CTNNB1, DAXX, MED12, MEN1, RB1,TERT, or TP53*	
PRIMARY ALDOSTERONISM			
Genetic causes of excess cortisol and aldosterone secretion	Hypertrophy of zona glomerulosa, aldosterone-producing adenoma	Germline or somatic activating variant in *KCNJ5*	
	Aldosterone-producing adenoma	Germline variants in *CYP11B2, CLCN2, or CACNA1H*	
	Aldosterone-producing adenoma	Germline and somatic activating variants in *CACNA1D*	
	Aldosterone-producing adenoma	Somatic variants in *ATP1A1, ATP2B3, CTNNB1, or APC*	
Pheochromocytoma			
von Hippel-Landau syndrome	Pheochromocytoma	*VHL*	Retinal and central nervous system hemangioblastomas, renal clear cell carcinomas
Multiple endocrine neoplasia syndromes *MEN2A* and *MEN2B*	Pheochromocytoma	*RET*	Medullary thyroid carcinoma and parathyroid tumors; type 2B also may include multiple mucosal neuromas and intestinal ganglioneuromas, a marfanoid habitus, and other skeletal abnormalities
	Pheochromocytoma, often malignant	*SDHB, SDHD, SDHC, SDHA, SDHAF2, MAX, TMEM127*	Paragangliomas, sometimes associated with gastrointestinal stromal tumors and/or pulmonary chondromas (Carney-Stratakis dyad or triad)

inactive adrenocortical adenomas includes pheochromocytomas (see Chapter 621), adrenocortical carcinoma, and metastasis from an extraadrenal primary carcinoma (very rare in children). Careful history, physical examination, and endocrine evaluation must be performed to seek evidence of autonomous cortisol, androgen, mineralocorticoid, or catecholamine secretion. Not infrequently, a low level of autonomous cortisol secretion is detected that does not cause clinically apparent symptoms; this condition is sometimes referred to as *subclinical Cushing syndrome.*

TREATMENT

Functioning adrenocortical tumors should be removed surgically. There are no data on which to base a recommendation regarding nonfunctioning childhood incidentalomas; in adults, such tumors may be closely observed with imaging and repeat biochemical studies if smaller than 4 cm in diameter, but it is not certain that this is prudent in children. Adrenalectomy should be performed transperitoneally to minimize the risk of surgical rupture of the capsule and consequent dissemination of malignant cells. Some adrenocortical neoplasms are highly malignant and metastasize widely, but less malignant, encapsulated tumors (stage I-II) are often curable if they can be resected without tumor spillage. Postoperatively, patients should be closely monitored biochemically, with frequent determinations of adrenal androgen levels and imaging studies. Recurrent symptoms or biochemical abnormalities should prompt a careful search for metastatic disease. Metastases primarily involve liver, lung, and regional lymph nodes. Most metastatic recurrences appear within 1 year of tumor resection. Repeat surgical resection of metastatic lesions should be performed if possible and adjuvant therapy instituted. Radiation therapy has not been generally helpful. Antineoplastic agents such as cisplatin, doxorubicin and etoposide, ifosfamide and carboplatin, and 5-fluorouracil and leucovorin have had limited use in children, toxicity is high, and in adults with metastatic disease, progression-free survival is only a few months. Therapy with o,p′-DDD (mitotane), an adrenolytic agent, may relieve the symptoms of hypercortisolism or virilization in recurrent disease. In adults, treatment with mitotane plus local or regional treatment (surgery or radiotherapy) is associated with improved survival. Other agents that interfere with adrenal steroid synthesis, such as ketoconazole, aminoglutethimide, and metyrapone, may also relieve symptoms of steroid excess but do not improve survival.

A neoplasm of one adrenal gland may produce atrophy of the other because excessive production of cortisol by the tumor suppresses adrenocorticotropic hormone stimulation of the normal gland. Consequently, **adrenal insufficiency** may follow surgical removal of the tumor. This situation can be avoided by giving 10-25 mg of hydrocortisone every 6 hours, starting on the day of operation and gradually decreased postoperatively. Adequate quantities of water, sodium chloride, and glucose also must be provided.

617.2 Adrenal Incidentaloma

Perrin C. White

Adrenal masses are discovered with increasing frequency in patients undergoing abdominal imaging for reasons unrelated to the adrenal gland. There are no published data on the frequency of the occurrence of such tumors in childhood. They are likely to be infrequent, being found in approximately 7% of autopsies of persons older than age 70 years but in <1% of those younger than age 30 years. They are detected in 1–4% of abdominal CT examinations in adults.

The unexpected discovery of such a mass presents the clinician with a dilemma in terms of diagnostic steps to undertake and treatment interventions to recommend. The differential diagnosis of adrenal incidentaloma includes benign lesions such as cysts, hemorrhagic cysts, hematomas, and myelolipomas. These lesions can usually be identified on CT or MRI. If the nature of the lesion is not readily apparent, additional evaluation is required. Included in the differential diagnosis of lesions requiring additional evaluation are benign adenomas, pheochromocytomas, adrenocortical carcinoma, and metastasis from an extraadrenal primary carcinoma. Benign, hormonally inactive adrenocortical adenomas make up the majority of incidentalomas. Careful history, physical examination, and endocrine evaluation must be performed to seek evidence of autonomous cortisol, androgen, mineralocorticoid, or catecholamine secretion. Functional tumors require removal. If the adrenal mass is nonfunctional but is larger than 4-6 cm, recommendations are to proceed with surgical resection of the mass. Lesions of 3 cm or less should be followed clinically with periodic reimaging. Treatment must be individualized; nonsecreting adrenal incidentalomas may enlarge and become hyperfunctioning. Nuclear scan, and occasionally fine-needle aspiration, may be helpful in defining the mass.

617.3 Adrenal Calcification

Perrin C. White

Calcification within the adrenal glands may occur in a wide variety of situations, some serious and others of no obvious consequence. Adrenal calcifications are often detected as incidental findings in radiographic studies of the abdomen in infants and children. The physician may elicit a history of anoxia or trauma at birth. Hemorrhage into the adrenal gland at or immediately after birth is probably the most common factor that leads to subsequent calcification (see Fig. 615.1). Although it is advisable to assess the adrenocortical reserve of such patients, there is rarely any functional disorder.

Neuroblastomas, ganglioneuromas, adrenocortical carcinomas, pheochromocytomas, and cysts of the adrenal gland may be responsible for calcifications, particularly if hemorrhage has occurred within the tumor. Calcification in such lesions is almost always unilateral.

In the past, tuberculosis was a common cause of both calcification within the adrenals and Addison disease. Calcifications may also develop in the adrenal glands of children who recover from Waterhouse-Friderichsen syndrome; such patients are usually asymptomatic. Infants with Wolman disease, a rare lipid disorder caused by a deficiency of lysosomal acid lipase, have extensive bilateral calcifications of the adrenal glands (see Chapter 106.4).

Chapter 618

Virilizing and Feminizing Adrenal Tumors

Perrin C. White

Virilization is the most common presenting symptom in children with adrenocortical tumors (see Chapter 617), occurring in 50–80%. In males, the clinical picture is similar to that of simple virilizing congenital adrenal hyperplasia: accelerated growth velocity and muscle development, acne, penile enlargement, and the precocious development of pubic and axillary hair. In females, virilizing tumors of the adrenal gland cause masculinization of a previously normal female with clitoral enlargement, growth acceleration, acne, deepening of the voice, and premature pubic and axillary hair development.

Conversely, adrenal tumors can occasionally (<10%) secrete high levels of estrogens because of overexpression of CYP19 (aromatase). Gynecomastia in males or premature thelarche in females is often the initial manifestation. Growth and development may be otherwise normal, or concomitant virilization may occur.

In addition to virilization, 15–40% of children with adrenocortical tumors also have Cushing syndrome (see Chapter 619). Whereas isolated virilization occurs relatively frequently, children with adrenal tumors usually do not have Cushing syndrome alone.

LABORATORY FINDINGS

Serum levels of dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione are usually elevated, often markedly. Serum levels of testosterone are often increased, usually because of peripheral conversion of androstenedione, but infants with predominantly testosterone-secreting adenomas have been reported. Levels of estrone and estradiol are elevated in tumors from patients with feminizing signs. Urinary 17-ketosteroids (sex steroid metabolites) are also increased but are no longer routinely measured. Many adrenocortical tumors have a relative deficiency of 11β-hydroxylase activity and secrete increased amounts of deoxycorticosterone; these patients are hypertensive, and their tumors are often malignant.

DIFFERENTIAL DIAGNOSIS

For virilizing signs, the differential includes virilizing forms of adrenal hyperplasia (see Chapter 616) and factitious exposure to androgens, such as topical testosterone preparations. The differential diagnosis for adrenal tumors is discussed in Chapter 617.

TREATMENT

Functioning adrenocortical tumors should be removed surgically (see Chapter 617).

Chapter 619

Cushing Syndrome

Perrin C. White

Cushing syndrome is the result of abnormally high blood levels of cortisol or other glucocorticoids. This can be iatrogenic or the result of endogenous cortisol secretion, a result of either an adrenal tumor or of hypersecretion of corticotropin (adrenocorticotropic hormone [ACTH]) by the pituitary (Cushing disease), or by a tumor (Table 619.1).

Table 619.1 Etiologic Classification of Adrenocortical Hyperfunction

EXCESS ANDROGEN
Congenital adrenal hyperplasia
21-Hydroxylase (CYP21A2) deficiency
11β-Hydroxylase (CYP11B1) deficiency
3β-Hydroxysteroid dehydrogenase (HSD3B2) defect (deficiency or dysregulation)
Tumor
EXCESS CORTISOL (CUSHING SYNDROME)
Bilateral adrenal hyperplasia
Adenoma
Hypersecretion of corticotropin (Cushing disease)
Ectopic secretion of corticotropin
Exogenous corticotropin
Adrenocortical nodular dysplasia
Pigmented nodular adrenocortical disease (Carney complex)
Tumor
McCune-Albright syndrome
EXCESS MINERALOCORTICOID
Primary hyperaldosteronism
Aldosterone-secreting adenoma
Bilateral micronodular adrenocortical hyperplasia
Glucocorticoid-suppressible aldosteronism
Tumor
Deoxycorticosterone excess
Congenital adrenal hyperplasia
• 11β-Hydroxylase (CYP11B1)
• 17α-Hydroxylase (CYP17A1)
Tumor
Apparent mineralocorticoid excess (deficiency of 11β-hydroxysteroid dehydrogenase type 2 [HSD11B2])
EXCESS ESTROGEN
Tumor

ETIOLOGY

The most common cause of Cushing syndrome is prolonged exogenous administration of glucocorticoid hormones, especially at the high doses used to treat lymphoproliferative disorders. This rarely represents a diagnostic challenge, but management of hyperglycemia, hypertension, weight gain, linear growth retardation, and osteoporosis often complicates therapy with corticosteroids.

Endogenous Cushing syndrome is most often caused in infants by a functioning adrenocortical tumor (see Chapter 617). Patients with these tumors often exhibit signs of hypercortisolism along with signs of hypersecretion of other steroids such as androgens, estrogens, and aldosterone.

Although extremely rare in infants, the most common etiology of endogenous Cushing syndrome in children older than 7 years of age is **Cushing disease**, in which excessive ACTH secreted by a **pituitary adenoma** causes bilateral adrenal hyperplasia. Such adenomas are often too small to detect by imaging techniques and are termed **microadenomas**. They consist principally of chromophobe cells and frequently show positive immunostaining for ACTH and its precursor, proopiomelanocortin. Although most such tumors are sporadic, a small number occur in kindreds with **familial isolated pituitary adenoma syndrome**. This syndrome, which is caused by pathogenic variants in the *AIP* gene, accounts for perhaps 2% of pituitary adenomas; more commonly tumors with *AIP* variants secrete growth hormone or prolactin, and only rarely do they secrete ACTH. Similarly, multiple endocrine neoplasia type 1 (MEN1) patients who have pathogenic variants in the *MEN1* gene may develop pituitary tumors, but these are typically prolactinomas. Other genes have also been implicated (Fig. 619.1).

ACTH-dependent Cushing syndrome may also result from ectopic production of ACTH, although this is uncommon in children. Ectopic ACTH secretion in children is associated with islet cell carcinoma of the pancreas, neuroblastoma or ganglioneuroblastoma, hemangiopericytoma, Wilms tumor, and thymic carcinoid. Hypertension is more

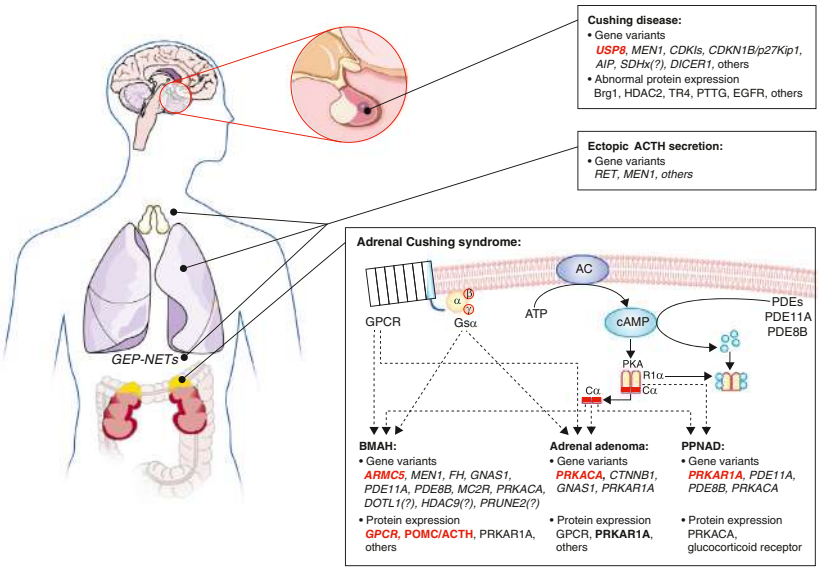

Fig. 619.1 Summary of genetic and molecular mechanisms implicated in Cushing syndrome. For each cause, the various pathogenic variants or abnormal protein expression believed to play a part in the pathophysiology is shown. The most frequent mechanisms are highlighted in red; the well-characterized mechanisms are highlighted in bold characters, and other potential mechanisms are in normal characters; a question mark shows an unconfirmed association or genetic predisposition. Please refer to the text for explanation of the various genetic defects under each diagnostic category. AC, Adenylate cyclase; ACTH, adrenocorticotropic hormone; BMAH, bilateral macronodular adrenal hyperplasia; Cα, catalytic subunit of PKA; GEP-NETs, gastroenteropancreatic neuroendocrine tumors; GPCR, G protein–coupled receptor; PDEs, phosphodiesterases; PKA, protein kinase A; PPNAD, primary pigmented nodular adrenocortical disease; R1α, type 1α regulatory subunit of PKA. *(From Lacroix A, Feelders RA, Stratakis CA, et al. Cushing's syndrome. Lancet. 2015;386:913–927. Fig. 1.)*

common in ectopic ACTH syndrome than in other forms of Cushing syndrome, because very high cortisol levels may overwhelm type 2 11β-hydroxysteroid dehydrogenase in the kidney (see Chapter 615) and thus have an enhanced mineralocorticoid (salt-retaining) effect.

Several syndromes are associated with the development of multiple autonomously hyperfunctioning nodules of adrenocortical tissue, rather than single adenomas or carcinomas (see Chapter 617). In many cases they are caused by pathogenic variants in genes in the cyclic adenosine monophosphate (cAMP)–mediated signaling pathway by which ACTH normally regulates cortisol secretion. **Primary pigmented nodular adrenocortical disease (PPNAD)** is a distinctive form of ACTH-independent Cushing syndrome. It may occur as an isolated event or, more commonly, as a familial disorder with other manifestations. The adrenal glands are small and have characteristic multiple small (<4 mm in diameter), pigmented (black) nodules containing large cells with cytoplasm and lipofuscin; there is cortical atrophy between the nodules. This adrenal disorder occurs as a component of **Carney complex**, an autosomal dominant disorder also consisting of centrofacial lentigines and blue nevi; cardiac and cutaneous myxomas; pituitary, thyroid, and testicular tumors; and pigmented melanotic schwannomas. Carney complex is inherited in an autosomal dominant manner, although sporadic cases occur. Genetic loci for Carney complex have been mapped to the gene for the type 1α regulatory subunit of protein kinase A *(PRKAR1A)* on chromosome 17q22-24 and less frequently to chromosome 2p16. Patients with Carney complex and *PRKAR1A* variants generally develop PPNAD as adults, and those with the disorder mapping to chromosome 2 (and most sporadic cases) develop PPNAD less frequently and later. Conversely, children presenting with PPNAD as an isolated finding rarely have pathogenic variants in *PRKAR1A,* or subsequently develop other manifestations of Carney complex. Some patients with isolated PPNAD have pathogenic variants in *PDE8B* or *PDE11A* encoding different phosphodiesterase isozymes. In contrast, activating *somatic* variants have been documented in the PRKACA catalytic subunit of protein kinase A in cortisol-secreting adenomas.

ACTH-independent Cushing syndrome with nodular hyperplasia and adenoma formation occurs rarely in cases of **McCune-Albright syndrome**, with symptoms beginning in infancy or childhood. McCune-Albright syndrome is caused by *somatic* variants of *GNAS* encoding the G protein, $G_s\alpha$, through which the ACTH receptor (MCR2) normally signals. When the variant is present in adrenal tissue, cortisol and cell division are stimulated independently of ACTH. Other tissues in which activating mutations may occur are bone (producing fibrous dysplasia), gonads, thyroid, and pituitary. Clinical manifestations depend on which tissues are affected.

The genes causing nodular adrenocortical hyperplasia that have been identified mainly produce overactivity of the ACTH signaling pathway either by constitutively activating $G_s\alpha$ (McCune-Albright syndrome), by reducing the breakdown of cAMP and thus increasing its intracellular levels (variants of *PDE8B* or *PDE11A*), by disrupting the regulation of the cAMP-dependent enzyme protein kinase A (PRKAR1A mutations), or via microduplications encompassing *PRKACA*. Additionally, *ARMC5,* a tumor-suppressor gene, is abnormal in approximately 40% of cases of primary bilateral macronodular adrenocortical hyperplasia. Adrenocortical lesions, including diffuse hyperplasia, nodular hyperplasia, adenoma, and rarely carcinoma, may occur as part of MEN1 syndrome (see Chapter 617), an autosomal dominant disorder in which there is homozygous inactivation of the menin (MEN1) tumor-suppressor gene on chromosome 11q13.

CLINICAL MANIFESTATIONS

Signs of Cushing syndrome have been recognized in infants younger than 1 year of age. The disorder appears to be more severe and the clinical findings more dramatic in infants than in older children. The face is rounded, with prominent cheeks and a flushed appearance (moon facies). Generalized obesity is common in younger children. In children with adrenal tumors, signs of abnormal masculinization occur frequently; accordingly, there may be hirsutism on the face and trunk, pubic hair, acne, deepening of the voice, and enlargement of the clitoris in females. Growth is impaired, with length falling below the third percentile, except when significant virilization produces normal or even accelerated growth. Hypertension is common and may occasionally lead to heart failure. An increased susceptibility to infection may also lead to sepsis.

In older children, in addition to obesity, short stature is a common presenting feature (Table 619.2). Gradual onset of obesity and deceleration or cessation of growth may be the only early manifestations. Older children most often have more severe obesity of the face and trunk compared with the extremities. However, obesity of the neck and upper back ("buffalo hump") is a nonspecific finding to which excessive importance should not be attached. Purplish striae on the hips, abdomen, and thighs are common. Pubertal development may be delayed, or amenorrhea may occur in females past menarche. Weakness, headache, and emotional lability may be prominent. Hypertension and hyperglycemia usually occur; hyperglycemia may progress to frank diabetes. Osteoporosis is common and may cause pathologic fractures.

Table 619.2	Presenting Signs and Symptoms of Cushing Syndrome in Children
Dermatologic	Facial plethora, acne, acanthosis nigricans, easy bruising, supratemporal and supraclavicular fat pads, moon facies, fungal infection, hirsutism, fine downy hair, violaceous striae (unusual in children <7 yr age)
Neurologic	Headaches
Cardiovascular	Hypertension, coagulopathy
Growth	Growth deceleration with concomitant weight gain, central obesity
Gonadal	Amenorrhea, virilization, gynecomastia
Other	Nephrolithiasis, bone fractures, impaired glucose tolerance, type 2 diabetes
Psychologic	Depression, anxiety, mood swings, irritability, fatigue

From Lodish MB, Keil MF, Stratakis CA. Cushing's syndrome in pediatrics: an update. *Endocrinol Metab Clin N Am.* 2018;47:451–462. Table 1.

LABORATORY FINDINGS

Cortisol levels in blood are normally highest at 8 AM and decrease to less than 50% of peak levels by midnight, except in infants and young children, in whom a diurnal rhythm is not always established. In patients with Cushing syndrome, this circadian rhythm is lost; *midnight cortisol levels >4.4 μg/dL strongly suggest the diagnosis*. It is difficult to obtain diurnal blood samples as part of an outpatient evaluation, but cortisol can be measured in *saliva samples*, which can be obtained at home at the appropriate times of day. Elevated nighttime salivary cortisol levels raise suspicion for Cushing syndrome.

Urinary excretion of free cortisol is increased. This is best measured in a 24-hour urine sample and is expressed as a ratio of micrograms of cortisol excreted per gram of creatinine. This ratio is independent of body size and completeness of the urine collection.

A single-dose dexamethasone suppression test is often helpful; a dose of 25-30 μg/kg (maximum: 2 mg) given at 11 PM results in a plasma cortisol level of less than 5 μg/dL at 8 AM the next morning in normal individuals but not in patients with Cushing syndrome. It is prudent to measure the dexamethasone level in the same blood sample to ensure the adequacy of dosing.

A glucose tolerance test is often abnormal but is of no diagnostic utility. Levels of serum electrolytes are usually normal, but potassium may be decreased, especially in patients with tumors that secrete ACTH ectopically.

After the diagnosis of Cushing syndrome has been established, it is necessary to determine whether it is caused by a pituitary adenoma, an ectopic ACTH-secreting tumor, or a cortisol-secreting adrenal tumor (Fig. 619.2). ACTH concentrations are usually suppressed in patients with cortisol-secreting tumors and are very high in patients with ectopic ACTH-secreting tumors, but may be normal in patients with ACTH-secreting pituitary adenomas. After an intravenous bolus of corticotropin-releasing hormone, patients with ACTH-dependent Cushing syndrome have an exaggerated ACTH and cortisol response, whereas those with adrenal tumors show no increase in ACTH and cortisol. The two-step dexamethasone suppression test consists of administration of dexamethasone, 30 and 120 μg/kg/24 hr in four divided doses, on consecutive days. In children with pituitary Cushing syndrome, the larger dose, but not the smaller dose, suppresses serum levels of cortisol. Typically, patients with ACTH-independent Cushing syndrome do not show suppressed cortisol levels with dexamethasone.

CT detects virtually all adrenal tumors larger than 1.5 cm in diameter. MRI may detect ACTH-secreting pituitary adenomas, but many are too small to be seen; the addition of gadolinium contrast increases the sensitivity of detection. Bilateral inferior petrosal blood sampling to measure concentrations of ACTH before and after corticotropin-releasing hormone administration may be required to localize the tumor when a pituitary adenoma is not visualized; this is not routinely available in many centers, and moreover may be of decreased specificity in children.

DIFFERENTIAL DIAGNOSIS

Cushing syndrome is frequently suspected in children with obesity, particularly when striae and hypertension are present. Children with simple obesity are usually tall, whereas those with Cushing syndrome are short or have a decelerating growth rate. Although urinary excretion of cortisol is often elevated in simple obesity, salivary nighttime levels of cortisol are usually normal, and cortisol secretion is normally suppressed by oral administration of low doses of dexamethasone.

Elevated levels of cortisol and ACTH without clinical evidence of Cushing syndrome occur in patients with generalized glucocorticoid resistance (see Chapter 615.4). Affected patients may be asymptomatic or exhibit hypertension, hypokalemia, and precocious pseudopuberty; these manifestations are caused by increased mineralocorticoid and adrenal androgen secretion in response to elevated ACTH levels. Mutations in the glucocorticoid receptor have been identified.

TREATMENT

Transsphenoidal pituitary microsurgery is the treatment of choice in *pituitary* Cushing disease in children. The overall success rate with follow-up of less than 10 years is 60–80%. Low postoperative serum or urinary cortisol concentrations predict long-term remission in most cases. Relapses are treated with reoperation or pituitary irradiation.

Cyproheptadine, a centrally acting serotonin antagonist that blocks ACTH release, has been used to treat Cushing disease in adults; remissions are usually not sustained after discontinuation of therapy. This agent is rarely used in children. Inhibitors of adrenal steroidogenesis (metyrapone, ketoconazole, aminoglutethimide, etomidate) have been used preoperatively to normalize circulating cortisol levels and reduce perioperative morbidity and mortality. Mifepristone, a glucocorticoid receptor antagonist, has been used in a limited number of cases. Pasireotide, a somatostatin analog, can inhibit ACTH secretion and is approved for use in adults with persistent disease after surgery or in whom surgery is contraindicated.

If a pituitary adenoma does not respond to treatment or if ACTH is secreted by an ectopic metastatic tumor, the adrenal glands may need to be removed. This can often be accomplished laparoscopically. Adrenalectomy may lead to increased ACTH secretion by an unresected pituitary adenoma, evidenced mainly by marked hyperpigmentation; this condition is termed **Nelson syndrome**, which occurs in ~25% of adults who have undergone adrenalectomy for Cushing syndrome.

Several drugs that inhibit adrenocortical function may be an alternative to adrenalectomy. FDA-approved agents include mitotane (which is toxic to adrenocortical cells) and osilodrostat (a cortisol synthesis inhibitor); levoketoconazole, a stereoisomer of ketoconazole, inhibits several steroidogenic enzymes and is in an advanced stage of development.

Management of patients undergoing adrenalectomy requires adequate preoperative and postoperative replacement therapy with a corticosteroid. Tumors that produce corticosteroids usually lead to atrophy of the normal adrenal tissue, and replacement with cortisol (10 mg/m^2/24 hr in three divided doses after the immediate postoperative period) is required until there is recovery of the hypothalamic-pituitary-adrenal axis. Postoperative complications may include sepsis, pancreatitis, thrombosis, poor wound healing, and sudden collapse, particularly in infants with Cushing syndrome. Substantial catch-up growth, pubertal progress, and increased bone density occur, but bone density remains abnormal and adult height is often compromised. The management of adrenocortical tumors is discussed in Chapter 617.

Chapter 620

Primary Aldosteronism

Perrin C. White

Primary aldosteronism encompasses disorders caused by excessive aldosterone secretion independent of the renin-angiotensin system. These disorders are characterized by hypertension, hypokalemia, and suppression of the renin-angiotensin system.

Aldosterone-secreting adenomas are unilateral and have been reported in children as young as 3.5 years of age. They are rarely malignant. Bilateral micronodular adrenocortical hyperplasia tends to occur in older ages. Primary aldosteronism caused by unilateral adrenal hyperplasia may also occur. Glucocorticoid-suppressible hyperaldosteronism is discussed in Chapter 616.8.

EPIDEMIOLOGY

These conditions are thought to be rare in children, but they may account for 5–10% of cases of hypertension in adults. Although usually sporadic, kindreds with several affected members have been reported. Genetic linkage to chromosome 7p22 was reported in some kindreds, but the involved gene has not yet been identified. Pathogenic variants in *KCNJ5* on chromosome 11q24 (encoding G protein–gated inward rectifier potassium channel 4) have been identified in several kindreds; these variants (*G151R* and *G151E*) altered channel selectivity, producing increased Na^+ conductance and membrane depolarization, which increase aldosterone production and proliferation of adrenal glomerulosa cells. Such variants have been identified in a subset of sporadic aldosterone-producing adenomas. Germline variants have also been reported in *CYP11B2* (encoding aldosterone synthase), *CLCN2* (encoding voltage-gated chloride channel ClC-2), and *CACNA1H* (encoding a subunit of the T-type voltage-gated calcium channel CaV3.2). Germline and somatic variants have also been reported in *CACNA1D* encoding a voltage-sensitive calcium channel and *somatic* variants in *ATP1A1* and *ATP2B3,* respectively, encoding sodium-potassium and calcium ATPases. Most aldosterone-producing adenomas have pathogenic variants that activate the Wnt/β-catenin signaling pathway, either in β-catenin *(CTNNB1)* itself, or in *APC,* which regulates this pathway.

CLINICAL MANIFESTATIONS

Some affected children have no symptoms, the diagnosis being established after incidental discovery of moderate hypertension. Others have severe hypertension (up to 240/150 mm Hg), with headache, dizziness, and visual disturbances. If present, chronic hypokalemia may lead to polyuria, nocturia, enuresis, and polydipsia. Muscle weakness and discomfort, tetany, intermittent paralysis, fatigue, and growth failure affect children with severe hypokalemia.

LABORATORY FINDINGS

Hypokalemia occurs frequently. Serum pH and carbon dioxide and sodium concentrations may be elevated and serum chloride and magnesium levels decreased. Serum levels of calcium are normal, even in children who manifest tetany. The urine is neutral or alkaline, and urinary potassium excretion is high. Plasma levels of aldosterone may be normal or elevated. Aldosterone concentrations in 24-hour urine collections are always increased. Plasma levels of renin are persistently low.

The diagnostic test of choice for primary aldosteronism is controversial. Both renin and aldosterone levels may vary by time of day, posture, and sodium intake, making it difficult to establish consistent reference ranges. It is desirable to establish a consistent sampling protocol, for example, at midmorning after the patient has been sitting for 15 minutes. If possible, antihypertensive drugs or other medications that can affect aldosterone or renin secretion should be avoided for several weeks before testing, including diuretics, β blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, clonidine, and nonsteroidal anti-inflammatory agents. Patients taking these agents may need to be changed to α-adrenergic blockers or calcium channel blockers that have smaller effects on the biochemical measurements. The ratio of plasma aldosterone concentration to renin activity is always high, and this represents a cost-effective screening test for primary aldosteronism. Aldosterone does not decrease with administration of saline solution or fludrocortisone, and renin does not respond to salt and fluid restriction. Urinary and plasma levels of 18-oxocortisol and 18-hydroxycortisol may be increased but not to the extent seen in glucocorticoid-suppressible hyperaldosteronism.

DIFFERENTIAL DIAGNOSIS

Primary aldosteronism should be distinguished from glucocorticoid-remediable aldosteronism (also termed **glucocorticoid-suppressible hyperaldosteronism**, see Chapter 616.8), which is specifically treated with glucocorticoids. An autosomal dominant pattern of inheritance should raise suspicion for the latter disorder. **Glucocorticoid-remediable aldosteronism** is diagnosed by dexamethasone suppression tests or by specific genetic testing.

Patients with primary aldosteronism should be evaluated by computed tomography (CT). It does not reliably distinguish aldosterone-producing adenomas, which tend to be small, from bilateral hyperplasia, but it can exclude the presence of large tumors that might otherwise raise concern for adrenocortical carcinomas. Adrenal venous sampling can accurately determine if excess aldosterone secretion is originating in one gland or both, but it is invasive and may not be available in all centers. Positron emission tomography with ^{11}C-metomidate is a non-invasive alternative.

TREATMENT

The treatment of an aldosterone-producing adenoma is laparoscopic adrenalectomy; successful enucleation of aldosterone-producing adenomas has also been reported. Hyperaldosteronism caused by bilateral adrenal hyperplasia is treated with the mineralocorticoid antagonist spironolactone (1-3 mg/kg/day to a maximum of 100 mg/day) or eplerenone (25-100 mg/day in 2 divided doses), often normalizing blood pressure and serum potassium levels. There is greater experience with spironolactone, but this agent has antiandrogenic properties that may be unacceptable in pubertal males. Eplerenone is a more specific antimineralocorticoid that is safe in children, but there is little specific experience with primary aldosteronism in the pediatric age-group. As an alternative, an epithelial sodium channel blocker, such as amiloride, may be used, with other antihypertensive agents added as necessary. In patients whose condition cannot be controlled medically, unilateral adrenalectomy may be considered.

Chapter 621

Pheochromocytoma

Perrin C. White

See also Chapter 555.4.

Pheochromocytomas are catecholamine-secreting tumors arising from chromaffin cells. The most common site of origin (approximately 90%) is the adrenal medulla; however, tumors may develop anywhere along the abdominal sympathetic chain and are likely to be located near the aorta at the level of the inferior mesenteric artery or at its bifurcation. They also appear in the periadrenal area, urinary bladder or ureteral walls, thoracic cavity, and cervical region. Ten percent occur in children, presenting most frequently between 6 and 14 years of age. Tumors vary from 1 to 10 cm in diameter; they are found more often on the right side than on the left. In more than 20% of affected children, the adrenal tumors are bilateral; in 30–40% of children, tumors are found in both adrenal and extraadrenal areas or only in an extraadrenal area.

Most pheochromocytomas are associated with germline pathogenic variants (see Table 555.2 in Chapter 555.4). They may be associated with genetic syndromes such as **von Hippel-Lindau disease, multiple endocrine neoplasia** (MEN) syndromes MEN2A and MEN2B, and less often, in association with **neurofibromatosis (type 1)** or **tuberous sclerosis**. The classic features of von Hippel-Landau syndrome, which occurs in 1 in 36,000 individuals, include retinal and central nervous system hemangioblastomas, renal clear cell carcinomas, and pheochromocytomas, but kindreds differ in their propensity to develop pheochromocytoma; in some kindreds, pheochromocytoma is the only tumor to develop. Germline variants in the *VHL* tumor-suppressor gene on chromosome 3p25-26 have been identified in patients with this syndrome. Variants of the *RET* protooncogene on chromosome 10q11.2 have been found in families with MEN2A and MEN2B. Patients with MEN2 are at risk of developing medullary thyroid carcinoma and parathyroid tumors; approximately 50% develop pheochromocytoma, with patients carrying variants at codon 634 of the *RET* gene being at particularly high risk. Variants are present in the *NF1* gene on chromosome 17q11.2 in neurofibromatosis type 1 patients (see Table 555.2 in Chapter 555.4).

Pheochromocytomas may occur in kindreds along with paragangliomas, particularly at sites in the head and neck. Such families typically carry pathogenic variants in *SDHB, SDHD,* and rarely the *SDHC* encoding subunits of the mitochondrial enzyme succinate dehydrogenase. Approximately 50% of tumors with *SDHB* variants are malignant. The *VHL* and the various *SDH* gene products participate in the *pseudohypoxia* signaling pathway (pseudohypoxia is a decrease in the ratio of the cytosolic oxidized to reduced forms of nicotinamide adenine dinucleotide [NAD (+)/NADH]) and thus represent a common pathogenetic pathway. In rare cases, individuals with germline variants in SDH genes develop pheochromocytomas and/or paragangliomas along with pituitary adenomas, which is termed the **3P association (3Pas)**.

Pheochromocytomas and paragangliomas can occur in association with **gastrointestinal stromal tumors** (GISTs; the association is termed the *Carney-Stratakis dyad*) and/or pulmonary chondromas (Carney-Stratakis triad) and adrenocortical tumors. These associations have heterogenous genetic etiologies but often involve variants in SDH genes.

CLINICAL MANIFESTATIONS

Pheochromocytomas detected by surveillance of patients who are known carriers of variants in tumor-suppressor genes may be asymptomatic. Particularly in adults, some are diagnosed on abdominal CT or MRI performed for another purpose (see Chapter 617). Otherwise, patients are detected owing to hypertension, which results from excessive secretion of metanephrines, epinephrine and norepinephrine. All

patients have hypertension at some point. Paroxysmal hypertension should particularly suggest pheochromocytoma as a diagnostic possibility, but in contrast to adults, the hypertension in children is more often sustained rather than paroxysmal. When there are paroxysms of hypertension, the attacks are usually infrequent at first, but become more frequent and eventually give way to a continuous hypertensive state. Between attacks of hypertension, the patient may be free of symptoms. During attacks, the patient complains of headache, palpitations, abdominal pain, and dizziness; pallor, vomiting, and sweating also occur. Seizures and other manifestations of hypertensive encephalopathy may occur. In severe cases, precordial pains radiate into the arms; pulmonary edema and cardiac and hepatic enlargement may develop. Symptoms may be exacerbated by exercise or with the use of nonprescription medications containing stimulants such as pseudoephedrine. Patients have a good appetite but because of the hypermetabolic state may not gain weight, and severe cachexia may develop. Polyuria and polydipsia can be sufficiently severe to suggest diabetes insipidus. Growth failure may be striking. The blood pressure may range from 180 to 260 mm Hg systolic and from 120 to 210 mm Hg diastolic, and the heart may be enlarged. Ophthalmoscopic examination may reveal papilledema, hemorrhages, exudate, and arterial constriction. The differential diagnosis is noted in Table 555.3.

LABORATORY FINDINGS

The urine may contain protein, a few casts, and occasionally glucose. Gross hematuria suggests that the tumor is in the bladder wall. Polycythemia is occasionally observed.

Pheochromocytomas produce norepinephrine and epinephrine. Normally, norepinephrine in plasma is derived from both the adrenal gland and adrenergic nerve endings, whereas epinephrine is derived primarily from the adrenal gland. In contrast to adults with pheochromocytoma in whom both norepinephrine and epinephrine are elevated, children with pheochromocytoma predominantly excrete norepinephrine in the urine (see Fig. 614.3 in Chapter 614). Daily urinary excretion of these compounds by unaffected children increases with age. Although urinary excretion of vanillylmandelic acid (3-methoxy-4-hydroxymandelic acid), the major metabolite of epinephrine and norepinephrine, is increased, vanilla-containing foods and fruits can produce falsely elevated levels of this compound, which therefore is no longer routinely measured.

Elevated levels of free catecholamines and metanephrines can also be detected in plasma. The consensus is to measure plasma free metanephrines and urinary fractionated metanephrines. The patient should be instructed to abstain from caffeinated drinks and to avoid acetaminophen, which can interfere with plasma normetanephrine immunoassays. If possible, the blood sample should be obtained from an indwelling intravenous catheter to avoid acute stress associated with venipuncture.

Most tumors in the area of the adrenal gland are readily localized by CT or MRI (Fig. 621.1), but extraadrenal tumors may be difficult to detect. ^{123}I or ^{131}I-metaiodobenzylguanidine (MIBG) is taken up by chromaffin tissue anywhere in the body and is useful for localizing small tumors. PET-CT with ^{18}F-fluorodeoxyglucose or ^{68}Ga-DOTA(0)-Tyr(3)-octreotate (a somatostatin receptor ligand) is highly sensitive and a more favored imaging approach (Fig. 621.2 and Fig. 555.2) for difficult-to-localize tumors. Venous catheterization with sampling of blood at different levels for catecholamine determinations is now only rarely necessary for localizing the tumor.

DIFFERENTIAL DIAGNOSIS

Various causes of hypertension in children must be considered, such as renal or renovascular disease; coarctation of the aorta; hyperthyroidism; Cushing syndrome; deficiencies of 11β-hydroxylase, 17α-hydroxylase, or 11β-hydroxysteroid dehydrogenase (type 2 isozyme); primary aldosteronism; adrenocortical tumors; and, rarely, essential hypertension (see Chapter 494). A nonfunctioning kidney may result from compression of a ureter or of a renal artery by a pheochromocytoma. Paroxysmal hypertension may be associated with porphyria or familial dysautonomia. Cerebral disorders and hyperthyroidism must also be considered in the differential diagnosis. Hypertension in patients with neurofibromatosis may be caused by renal vascular involvement or by concurrent pheochromocytoma.

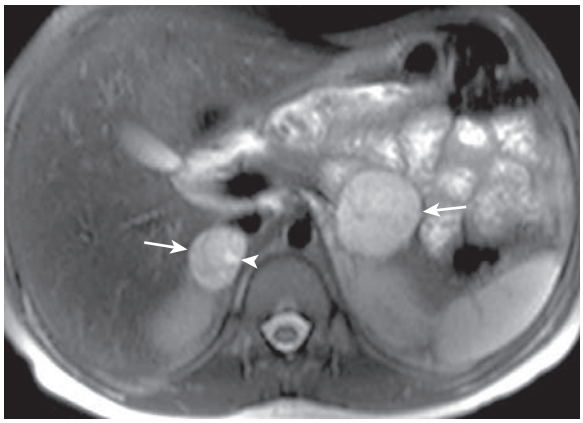

Fig. 621.1 Bilateral pheochromocytoma in an 11-yr-old child with von Hippel-Lindau disease and arterial hypertension. An axial fat-suppressed T2 weighted magnetic resonance image shows bilateral adrenal masses *(arrows)*, larger on the left. The masses are hyperintense with small cystic change on the right medially. *(From Navarro OM, Daneman A. Acquired conditions. In: Coley B, ed. Caffey's Pediatric Diagnostic Imaging, 12th ed. Philadelphia: Elsevier; 2013: Fig. 123.9.)*

Neuroblastoma, ganglioneuroblastoma, and ganglioneuroma frequently produce catecholamines, but urinary levels of most catecholamines are higher in patients with pheochromocytoma, although levels of dopamine and homovanillic acid are usually higher in neuroblastoma. Secreting neuroendocrine tumors often produce hypertension, excessive sweating, flushing, pallor, rash, polyuria, and polydipsia. Chronic secretory diarrhea may be associated with these tumors, particularly with ganglioneuroma.

TREATMENT

These tumors must be removed surgically, but careful preoperative, intraoperative, and postoperative management is essential. Manipulation and excision of these tumors result in marked increases in catecholamine secretion that increase blood pressure and heart rate. Therefore preoperative α- *and β-adrenergic blockade* are required. Whereas phenoxybenzamine has been most often used, it may not be covered by insurance, and selective α_1-blockers, such as doxazosin, as well as calcium channel blockers like amlodipine, have also been used. Because these tumors are often multiple in children, a thorough transabdominal exploration of all the usual sites offers the best opportunity to find them all. Appropriate choice of anesthesia and *expansion of blood volume with appropriate fluids before and during surgery* are critical to avoid a precipitous drop in blood pressure during operation or within 48 hours postoperatively. Surveillance must continue postoperatively.

Because bilateral and recurrent pheochromocytomas occur frequently, some have advocated for adrenal cortex–sparing surgery to reduce the probability of causing Addison disease. However, this approach increases the risk of tumor recurrence.

Although these tumors often appear malignant histologically, the only accurate indicators of malignancy are the presence of metastatic disease or local invasiveness that precludes complete resection, or both. Approximately 10% of all adrenal pheochromocytomas are malignant. Such tumors are rare in childhood; pediatric malignant pheochromocytomas occur more frequently in extraadrenal sites and are often associated with pathogenic variants in *SDHB* encoding a subunit of succinate dehydrogenase. Prolonged follow-up is indicated, particularly in patients with germline mutations in risk loci, because functioning tumors at other sites may be manifested many years after the initial operation. Examination of relatives of affected patients may reveal other individuals harboring unsuspected tumors that may be asymptomatic.

Fig. 621.2 Paraganglioma in a 30-yr-old woman who presented with refractory hypertension. **A,** Axial T2-weighted MRI shows homogeneously T2-hyperintense left periaortic mass just above the level of the aortic bifurcation (Zuckerkandl organ), illustrating the "light bulb" T2-bright appearance of pheochromocytomas and paragangliomas. **B,** Axial contrast-enhanced T1-weighted MRI demonstrates heterogeneous enhancement within the mass. **C,** ^{123}I-MIBG fused SPECT/CT axial image shows diffuse uptake within the tumor, compatible with paraganglioma. *(From Ho LM. Adrenal glands. In: Haaga JR, Boll DT, eds. CT and MRI of the Whole Body, 6th ed. Philadelphia: Elsevier; 2017: Fig. 53-18.)*

Section 5

Disorders of the Gonads

Chapter 622

Development and Function of the Gonads

Patricia A. Donohoue

GENETIC CONTROL OF EMBRYONIC GONADAL DIFFERENTIATION

Gonadal differentiation is a complex, multistep process that requires the sequential action and interaction of multiple gene products. Early in the first trimester, the undifferentiated, bipotential fetal gonad begins as a thickening of the urogenital ridge, near the developing kidney and adrenal cortex. At 6 weeks of gestation, the gonad contains germ cells, stromal cells that will become Leydig cells in the testes or theca, interstitial, or hilar cells in the ovaries, and supporting cells that will develop into Sertoli cells in the testes or granulosa cells in the ovaries. In males, the *SRY* gene (**s**ex-determining **r**egion on the **Y** chromosome) is transiently expressed, followed by a sequential upregulation of a number of testis-specific genes. In the absence of *SRY,* the bipotential gonad will be able to develop into an ovary. Ovarian development is also characterized by expression of ovary-specific genes during the same period. One such gene is *R-spondin1*. During the gestation period of 6-9 weeks, a number of genes are upregulated to the same degree in both the testis and the ovary, including *WNT4* and *CTNNB1*.

A chromosome complement of 46,XX is necessary for the development of normal ovaries. Both the long and short arms of the X chromosome contain genes for normal ovarian development. The DSS (**d**osage **s**ensitive/**s**ex reversal) locus associated with the *DAX1* (**D**SS **a**drenal hypoplasia on the **X** chromosome) gene, which is defective in 46,XY patients with X-linked congenital adrenal hypoplasia and hypogonadotropic hypogonadism, is a member of the nuclear receptor superfamily and acts as a repressor of male gene expression. The *DAX1* gene product acts by binding to a related nuclear receptor SF-1 (**s**teroidogenic **f**actor-1, also known as *NR5A1*). In vitro, the signaling gene *WNT4* stimulates expression of *DAX1,* resulting in the suppression of androgen synthesis in XX females. The WNTs are ligands that activate receptor-mediated signal transduction pathways and are involved in modulating gene expression as well as cell behavior, adhesion, and polarity. Once developed, the ovary requires FAX12 to preserve its differentiation and stability. A key to its role in humans was elucidated by a loss-of-function pathogenic variant of *WNT4* that was found in an 18-year-old 46,XX woman. She had an absence of müllerian-derived structures (uterus and fallopian tubes), unilateral renal agenesis, and clinical signs of androgen excess.

Pathogenic variants of the Wilms tumor 1 *(WT1)* gene may also affect sex differentiation. *WT1* pathogenic variants are associated with **Denys-Drash syndrome** (early-onset renal failure, abnormal external genitalia in genetic males, and Wilms tumor). Haploinsufficiency of a three–amino acid (KTS) form of *WT1* has been implicated in the gonadal dysgenesis of patients with **Fraser syndrome** (late-onset progressive glomerulopathy and 46,XY gonadal dysgenesis). Variants in the *FOXL2* and *SF-1* genes are associated with ovarian failure. Pathogenic variants of the *R-spondin1* gene has been described in individuals with 46,XX disorder of sex development (DSD). Other autosomal genes also play a role in normal ovarian organogenesis and testicular development. Several conditions of gonadal dysgenesis are associated with gross abnormalities of both autosomes and sex chromosomes. A deletion affecting the short arm of the X chromosome produces the typical somatic anomalies of Turner syndrome.

Development of the testis requires the short arm of the Y chromosome; this contains the *SRY* gene, which is required for testicular differentiation. During male meiosis, the Y chromosome must segregate from the X chromosome so that both X and Y chromosomes do not occur in the same spermatozoa. The major portion of the Y chromosome is composed of Y-specific sequences that do not pair with the X chromosome. However, a minor portion of the Y chromosome shares sequences with the X chromosome, and pairing does occur in this region. The genes and sequences in this area recombine between the sex chromosomes, behaving like autosomal genes. Therefore the term *pseudoautosomal region* is used to describe this portion of the chromosome, and the term indicates genetic behavior of these genes relative to pairing and recombinational events. The *SRY* gene is localized to the 35-kb portion proximal to the pseudoautosomal region of the Y chromosome. It contains a high-mobility group (HMG) nonhistone protein (HMG box), supporting SRY's role as a transcriptional regulator of other genes involved in sex differentiation. The gonadal ridge forms at around 33 days of gestation. SRY is detected at 41 days, peaks at 44 days when testis cords are first visible, and persists into adulthood.

Other genes that are found on autosomes are important in this process. *SOX9,* an *SRY*-related gene containing a region homologous with the HMG box 9 of *SRY,* is located on chromosome 17. Pathogenic variants of this gene result in **XY sex reversal** and **campomelic dysplasia**. *SF-1 (NR5A1)* on chromosome 9q33 is important

in adrenal and gonadal development, as well as the development of gonadotropin-releasing hormone–secreting neurons in the hypothalamus. *WTI,* especially the KST isoform on chromosome 11p13, is needed for early gonadal, adrenal, and renal development. Fibroblast growth factor-9, GATA-4, XH-2, and SOY9 are also important.

When genetic recombination events on sex chromosomes extend beyond the pseudoautosomal region, X- and Y-specific DNA may be transferred between the chromosomes. Such aberrant recombinations result in X chromosomes carrying *SRY,* resulting in **XX males**, or Y chromosomes that have lost *SRY,* resulting in **XY females**. SRY acts as a transcriptional regulator to increase cellular proliferation, attract interstitial cells from adjacent mesonephros into the genital ridge, and stimulate testicular Sertoli cell differentiation. Sertoli cells act as an organizer of steroidogenic and germ cell lines and produce **antimüllerian hormone** (AMH) that causes the female duct system to regress. Table 622.1 lists additional genes involved in sex development that, if abnormal, result in DSD.

Consensus statement on management of intersex disorders. International Consensus Conference on Intersex. Pediatrics. 2006;118:e488–e500; with additional data from Baxter RM, Arboleda VA, Lee H, et al. Exome sequencing for the diagnosis of 46,XY disorders of sex development. J Clin Endocrinol Metab. 2015;100:e333–e344; and Lourenco D, Brauner R, Rybczynska M, et al. Loss-of-function mutation in *GATA4* causes anomalies of human testicular development. PNAS. 2011;108:1597–1602.

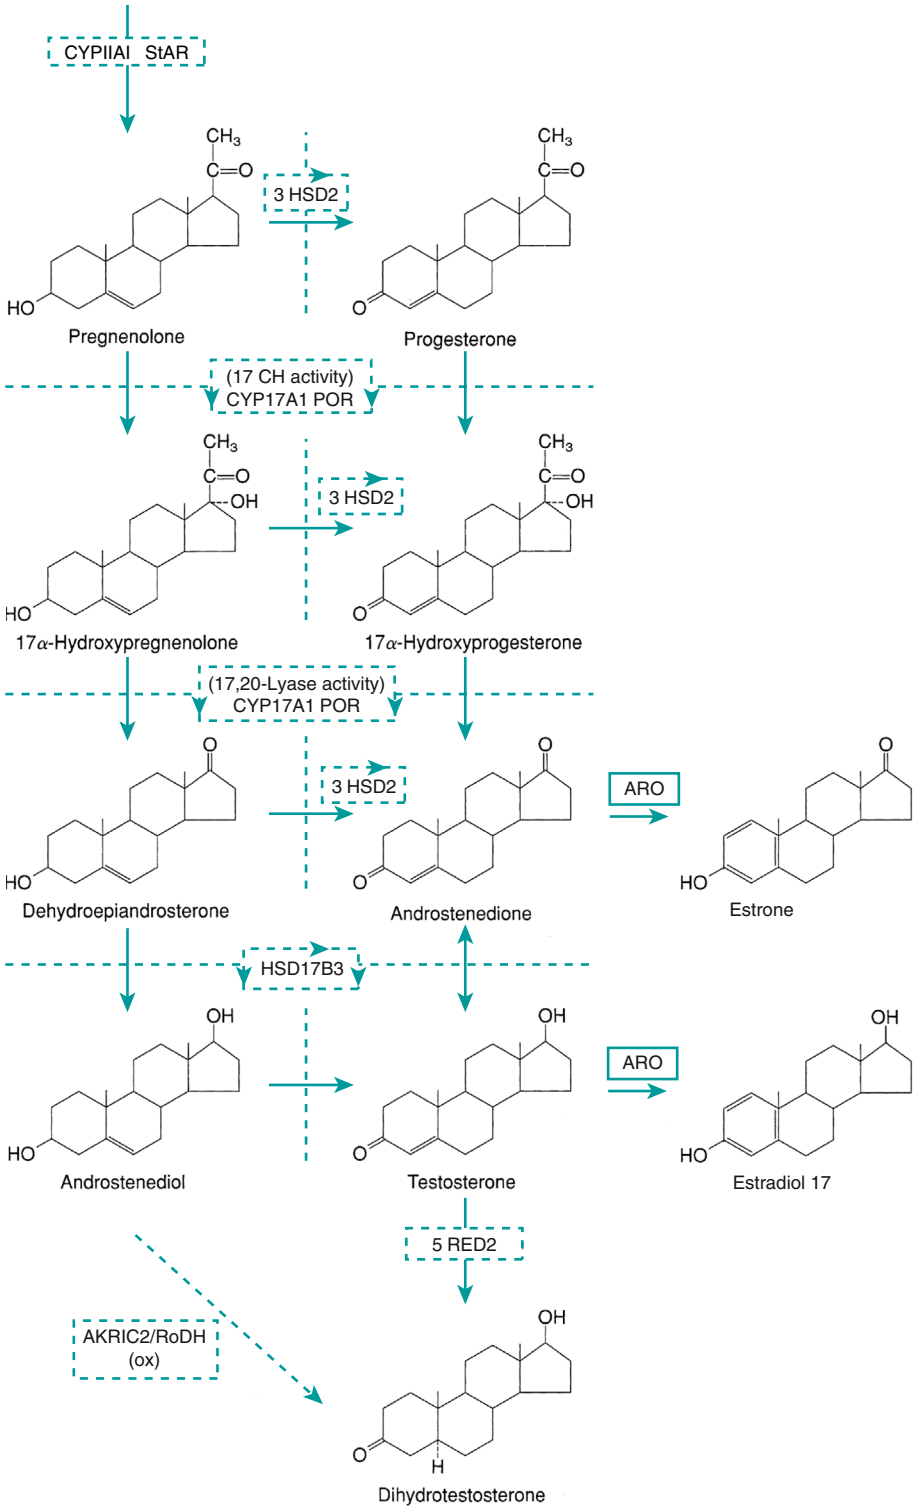

Fig. 622.1 Biosynthesis of sex steroids. *Dashed lines* indicate enzymatic defects associated with 46,XY disorders of sex development. 3β-HSD2, 3β-hydroxysteroid dehydrogenase type 2; 5RED2, 5α-reductase type 2; AKR1C2/RoDH (Ox), one of the enzymes in the alternative androgen biosynthetic pathway; ARO, aromatase; CYP17A1, the enzyme that catalyzes both 17α-hydroxylase (17-OH) and 17,20-lyase activities; HSD17B3, the enzyme that catalyzes the 17-ketoreductase reaction; POR, P450 oxidoreductase; StAR, steroidogenic acute regulatory protein.

Development of the ovary was once thought to be a passive process in the absence of SRY. Although the morphologic changes in the developing ovary are less marked than in the testis, sequentially expressed genes and pathways are required for complete ovarian development along with maintenance of ovarian integrity postnatally. One of these genes is *R-spondin1,* which if abnormal can result in testicular or ovotesticular development in 46,XX individuals. Some peptides in the Wnt-signaling pathway may antagonize testicular development, thus allowing for ovarian differentiation. This effect may be mediated by β-catenin signaling, which is required for suppressing testicular features. Once developed, the ovary requires FAX12 to preserve its differentiation and stability.

FUNCTION OF THE TESTES

Levels of placental chorionic gonadotropin peak at 8-12 weeks of gestation and stimulate the fetal Leydig cells to secrete testosterone, the main hormonal product of the testis (Fig. 622.1). By way of two different biosynthetic pathways, the more potent metabolite of testosterone, dihydrotestosterone (DHT), is produced. In the originally described

pathway, testosterone is converted by the enzyme 5α-reductase to DHT. In another pathway, DHT is produced from androstanediol. The early fetal period of DHT production and action is critical for normal and complete virilization of the XY fetus. Defects in this process lead to different forms of atypical male development (see Chapter 628.2). After virilization occurs, fetal levels of testosterone decrease but are maintained at lower levels in the latter half of pregnancy by luteinizing hormone (LH) secreted by the fetal pituitary; this LH-mediated testosterone secretion is required for continued penile growth and to some degree also for testicular descent.

As part of the normal transition from intrauterine to extrauterine life, perhaps related to the sudden withdrawal of maternal and placental hormones, newborns and young infants experience a transient surge of gonadotropins and sex steroids. This is the so-called **minipuberty**.

In males, LH and testosterone peak at 1-2 months of age and then decline to reach prepubertal levels by 4-6 months of age. Follicle-stimulating hormone (FSH), along with inhibin B, peak at 3 months and decline to prepubertal levels by 9 and 15 months, respectively. The LH rise is more dominant than that of FSH.

The neonatal surge may be important for postnatal maturation of the gonads, stabilization of male external genitalia, and perhaps also for gender identity and sexual behaviors. The postnatal surge in LH and testosterone is absent or blunted in infants with hypopituitarism, cryptorchidism, and complete androgen insensitivity syndrome. The development of nocturnal pulsatile secretion of LH marks the beginning of puberty.

Within specific target cells, 6–8% of testosterone is converted by 5α-reductase to DHT, the more potent androgen (see Fig. 622.1), and approximately 0.3% is acted on by aromatase to produce estradiol. Approximately half of circulating testosterone is bound to sex hormone–binding globulin and half to albumin; only 2% circulates in the free form. Plasma levels of sex hormone–binding globulin are low at birth, rise rapidly during the first 10 days of life, and then remain stable until the onset of puberty. Thyroid hormone may play a role in this physiologic increase because neonates with athyreosis (absence of the thyroid gland) have very low levels of sex hormone–binding globulin.

AMH (previously referred to as *müllerian inhibitory substance*), **inhibin**, and **activin** are members of the transforming growth factor-β (TGF-β) superfamily of growth factors. This group, which has more than 45 members, also includes bone morphogenetic proteins. Members of the TGF-β superfamily are involved in the regulation of developmental processes and multiple diverse human disease states, including chondrodysplasias and cancer.

AMH, a homodimeric glycoprotein hormone encoded by a gene on chromosome 19, is the earliest secreted product of the Sertoli cells of the fetal testis. Produced as a prohormone, its carboxyterminal fragment is cleaved to make it active. *AMH* transcription is initiated by *SOX9* acting through the HMG box, and its expression is upregulated by SF-1 binding to its promoter and further interacting with *SOX9, WT1,* and *GATA4.* AMH binds to two distinct serine/threonine receptors, each having a single transmembrane domain. The activated type 1 receptor signals to the SMAD family of intracellular mediators.

The gene for the AMH receptor (on chromosome 12) is expressed in Sertoli cells. In the female, it is expressed in fetal müllerian duct cells and in fetal and postnatal granulosa cells. During sex differentiation in males, AMH causes involution of the müllerian (paramesonephric) ducts, which are embryologic precursors of the cervix and uterus. It works in concert with SF-1 to cause involution of the fallopian tubes.

AMH is secreted in males by Sertoli cells during both fetal and postnatal life. In females, it is secreted by granulosa cells from 36 weeks of gestation to menopause but at lower levels. The serum concentration of AMH in males is highest at birth, whereas in females it is highest at puberty. After puberty, both sexes have similar serum concentrations of AMH. Its role in postnatal life is not yet fully characterized.

Inhibin is another glycoprotein hormone secreted by the Sertoli cells of the testes and granulosa and theca cells of the ovary. Inhibin A consists of an α-subunit disulfide linked to the β-A subunit, whereas inhibin B consists of the same α subunit linked to the β-B subunit. Activins are dimers of the B subunits, either homodimers (BA/BA, BB/BB) or heterodimers (BA/BB). Inhibins selectively inhibit, whereas activins stimulate pituitary FSH secretion. By means of immunoassays specific for inhibin A or B, it has been shown that inhibin A is absent in males and is present mostly in the luteal phase in women. Inhibin B is the principal form of inhibin in males and in females during the follicular phase. Inhibin B may be used as a marker of Sertoli cell function in males. FSH stimulates inhibin B secretion in females and males, but only in males is there also evidence for gonadotropin-independent regulation. Levels of inhibin B are potentially informative in children with various forms of gonadal and pubertal disorders. In males with delayed puberty, inhibin B may be a useful screening test to differentiate between constitutional delay of puberty and hypogonadotropic hypogonadism. In hypogonadotropic hypogonadism, the serum inhibin B level is very low to undetectable.

Like inhibin and activin, follistatin (a single-chain glycosylated protein) is produced by gonads and other tissues such as the hypothalamus, kidney, adrenal gland, and placenta. Follistatin inhibits FSH secretion principally by binding activins, thereby blocking the effects of activins at the level of both ovary and pituitary.

Many additional peptides act as mediators of the development and function of the testis. They include neurohormones such as growth hormone–releasing hormone, gonadotropin-releasing hormone, corticotropin-releasing hormone, oxytocin, arginine vasopressin, somatostatin, substance P, and neuropeptide Y; growth factors such as insulin-like growth factors (IGFs) and IGF-binding proteins, TGF-β, and fibroblast, platelet-derived, and nerve growth factors; vasoactive peptides; and immune-derived cytokines such as tumor necrosis factor and interleukins 1, 2, 4, and 6.

Clinical patterns of pubertal changes vary widely (see Chapter 599). In 95% of males, enlargement of the genitals begins between 9.5 and 13.5 years of age, reaching maturity at 13-17 years of age. In a minority of normal males, puberty begins after 15 years of age. In some males, pubertal development is completed in less than 2 years, but in others it may take longer than 4.5 years. Pubertal development and the adolescent growth spurt occur at an older age in males than in females by approximately 2 years.

The median age of sperm production (spermarche) is 14 years. This event occurs in midpuberty as judged by pubic hair, testis size, evidence of growth spurt, and testosterone levels. Nighttime levels of FSH are in the adult male range at the time of spermarche; the first conscious ejaculation occurs at about the same time.

FUNCTION OF THE OVARIES

In the normal female, the undifferentiated gonad can be identified histologically as an ovary by 10-11 weeks of gestation, after the upregulation of *R-spondin1*. Oocytes are present from the fourth month of gestation and reach a peak of 7 million by 5 months of gestation. For normal maintenance, oocytes need granulosa cells to form primordial follicles. Functional FSH (but not LH) receptors are present in oocytes of primary follicles during follicular development. Two normal X chromosomes are needed for maintenance of oocytes. In contrast to somatic cells, in which only one X chromosome is active, both X chromosomes are active in germ cells. At birth, the ovaries contain approximately 1 million active follicles, which decrease to 0.5 million by menarche. Thereafter, they decrease at a rate of 1,000/month and at an even higher rate after the age of 35 years.

The hormones of the fetal ovary are provided for the most part by the fetoplacental unit. As in males, peak gonadotropin secretion occurs in fetal life and then again at 2-3 months of life, with the lowest levels at about 6 years of age. In contrast to males, the FSH surge predominates over LH in females. FSH peaks around 3-6 months of age and declines by 12 months, but remains detectable for 24 months. Under LH influence, estradiol peaks at 2-6 months of age. The inhibin B response is variable, peaking between 2 and 12 months and remaining above prepubertal levels until 24 months.

In both infancy and childhood, gonadotropin levels are higher in females than in males.

The most important estrogens produced by the ovary are estradiol-17β (E_2) and estrone (E_1); estriol is a metabolic product of these two, and all three estrogens may be found in the urine of mature females. Estrogens also arise from androgens produced by the adrenal gland and both the female and male gonads (see Fig. 622.1). This conversion explains why in certain types of DSD in males, feminization occurs at puberty. In 17-ketosteroid reductase deficiency, for example, the enzymatic block results in markedly increased secretion of androstenedione, which is converted in the peripheral tissues to estradiol and estrone. These estrogens, in addition to those directly secreted by the testis, result in gynecomastia. Estradiol produced from testosterone in complete androgen insensitivity syndrome causes complete feminization in these XY individuals.

Estrogen regulates a host of functionally different activities in multiple tissues. There are at least two distinct estrogen receptors with different expression patterns. The ovary also synthesizes progesterone, the main progestational steroid; the adrenal cortex and testis also synthesize progesterone, where it is a precursor for other adrenal and testicular hormones.

A host of other hormones with autocrine, paracrine, and intracrine effects have been identified in the ovary. They include inhibins, activins, relaxin, and the growth factors IGF-1, TGF-α and TGF-β, and cytokines.

Plasma levels of estradiol increase slowly but steadily with advancing sexual maturation and correlate well with clinical evaluation of pubertal development, skeletal age, and rising levels of FSH. Levels of LH do not rise until secondary sexual characteristics are well developed. Estrogens, like androgens, inhibit secretion of both LH and FSH (negative feedback). In females, estrogens also provoke the surge of LH secretion that occurs in the midmenstrual cycle and stimulates ovulation. The capacity for this positive feedback is another maturational milestone of puberty.

The average age at menarche in American females is approximately 12.5-13 years, but the range of normal is wide, and 1–2% of normal females have not menstruated by 16 years of age. The age at onset of pubertal signs varies, with studies suggesting earlier ages than previously thought, especially in the US Black population (see Chapter 599). Menarche generally correlates closely with skeletal age. Maturation and closure of the epiphyses is estrogen-dependent, as demonstrated by a very tall 28-year-old, normally masculinized male with continued growth as a result of incomplete closure of the epiphyses, who had complete estrogen insensitivity caused by an estrogen receptor defect.

DIAGNOSTIC TESTING

In male infants, measurements of LH, FSH, and testosterone can detect pituitary and testicular defects. Leydig cell integrity in childhood can be determined by the testosterone response after human chorionic gonadotropin administration. One protocol is to inject 5,000 IU IM daily for 3 days; other protocols are available. The integrity and maturity of the hypothalamic-pituitary-gonadal axis in males and females can be assessed by measuring serial sex steroid, LH, and FSH levels after the subcutaneous administration of the gonadotropin-releasing hormone analog leuprolide. An ultrasensitive LH assay has been shown to differentiate between males with delayed puberty and those with complete, but not partial, hypogonadotropic hypogonadism.

The normal range for inhibin B levels has been established in infant males. Inhibin B may be a marker of spermatogenesis and also of tumors such as granulosa cell tumors. Inhibins may be involved in tumor suppression. Estrogen receptor assays may be clinically useful in the management of various ovarian cancers. AMH measurements are useful in the evaluation of children with nonpalpable gonads and DSD.

Chapter 623

Hypofunction of the Testes

Omar Ali and Patricia A. Donohoue

Testicular hypofunction during fetal life can be a component of some types of **disorders of sex development** (see Chapter 628.2) and may lead to varying degrees of ambiguous genitalia. After birth, neonates undergo *minipuberty* with relatively high levels of gonadotropins and sex steroids, but this phenomenon is transient, and its absence does not appear to lead to any obvious clinical findings. Because prepubertal children normally do not produce significant amounts of testosterone and are not yet producing sperm, there are no discernible effects of testicular hypofunction in this age-group. Testicular hypofunction from the age of puberty onward may lead to testosterone deficiency, infertility, or both. Such hypofunction may be primary in the testes **(primary hypogonadism)** or secondary to deficiency of pituitary gonadotropic hormones **(secondary hypogonadism)**. Insults to the testes (primary hypogonadism) tend to affect sperm counts more than testosterone secretion, as the seminiferous tubules take up much more of the testicular volume than Leydig cells do, so sperm production is usually affected more than testosterone production. On the other hand, hypogonadotropic hypogonadism tends to affect both testosterone and sperm production.

Both types of hypogonadism may be caused by inherited genetic defects or acquired causes, and in some cases the etiology may be unclear, but the level of the lesion (primary or secondary) is usually well defined; patients with primary hypogonadism have elevated levels of gonadotropins (hypergonadotropic); those with secondary hypogonadism have inappropriately low or absent levels (hypogonadotropic). Table 623.1 details the etiologic classification of male hypogonadism (see also Fig. 600.6).

623.1 Hypergonadotropic Hypogonadism in the Male (Primary Hypogonadism)

Omar Ali and Patricia A. Donohoue

Complete absence or severe dysfunction of the testes in the first trimester will lead to a lack of male sex differentiation and the fetus will have a female phenotype or pronounced ambiguous genitalia (see Chapter 628). If testicular function is present, sex differentiation is normally complete by the 14th week of intrauterine life. *Testicular dysfunction after this stage will lead to hypergonadotropic hypogonadism, and this can occur for a variety of reasons;* genetic or chromosomal anomalies may lead to testicular hypofunction that does not become apparent until the time of puberty, when these males may have delayed or incomplete pubertal development. In other cases, normally developed testes may be damaged by infarction, trauma, radiation, chemotherapy, infections, infiltration, or other causes after sexual differentiation has occurred. In some cases, genetic defects may predispose to atrophy or maldescent; torsion or infarction may lead to progressive testicular damage and atrophy after a period of normal development. If testicular compromise is global, both testosterone secretion and fertility (sperm production) are likely to be affected. Even when the primary defect is in testosterone production, low levels of intratesticular testosterone will frequently lead to infertility. The reverse is not necessarily true. Defects in sperm production and in the storage and transit of sperm may not be associated with low testosterone levels; infertility may thus be seen in patients with normal testosterone levels, normal libido, and normal secondary sexual characteristics.

Table 623.1 Etiologic Classification of Male Hypogonadism

HYPERGONADOTROPIC HYPOGONADISM (PRIMARY HYPOGONADISM; TESTES)
Congenital
Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) resistance
Pathogenic variants in steroid synthetic pathways
Gonadal dysgenesis
Klinefelter syndrome (47,XXY)
Noonan syndrome (RASopathy genes)
Cystic fibrosis (infertility)
Acquired
Cryptorchidism (some cases)
Vanishing testes
Chemotherapy
Testicular radiation
Infection (e.g., mumps)
Infarction (testicular torsion)
Trauma
HYPOGONADOTROPIC HYPOGONADISM (SECONDARY HYPOGONADISM; HYPOTHALAMIC-PITUITARY)
Congenital
Genetic defects causing Kallmann syndrome and/or normosmic hypogonadotropic hypogonadism (HH)
Other genetic disorders associated with HH: leptin gene, leptin receptor, DAX1 (dosage-sensitive/sex-reversal adrenal hypoplasia on the X chromosome), SF-1 (steroidogenic factor-1)
Inherited syndromes: Prader-Willi, Bardet-Biedl, Laurence-Moon-Biedl, Alström
Isolated HH at pituitary level (gonadotropin-releasing hormone receptor, FSH and LH β-subunit)
Multiple pituitary hormone deficiencies: septo-optic dysplasia (*HESX-1* in some cases) and other disorders of pituitary organogenesis (e.g., *PROP1, LHX3, LHX4, SOX-3*)
Idiopathic
Acquired
Anorexia nervosa
Drug use
Malnutrition
Chronic illness, especially Crohn disease
Hyperprolactinemia
Pituitary tumors
Pituitary infarction
Infiltrative disorders (e.g., histiocytosis, sarcoidosis)
Hemosiderosis and hemochromatosis
Cranial radiation

Various degrees of primary hypogonadism occur in a significant percentage of patients with chromosomal aberrations, as in **Klinefelter syndrome**, **males with more than one X chromosome**, and **XX males**. These chromosomal anomalies are also associated with other characteristic findings. Noonan syndrome is also associated with cryptorchidism and infertility, but other (nongonadal) features dominate its clinical picture (see Chapters 100 and 101).

CONGENITAL ANORCHIA OR TESTICULAR REGRESSION SYNDROME

Males in whom the external genitalia have developed normally (or nearly normally) and paramesonephric (müllerian) duct derivatives (uterus, fallopian tubes) are absent have had testicular function for at least some part of gestation. If their testes cannot be palpated at birth, they are said to have **cryptorchidism**. In most such cases, the testes are undescended or retractile, but in some cases no testes are found in any location, even after extensive investigation. This syndrome of absence of testes in a phenotypic male with a normal 46,XY karyotype (indicating that there was some period of testicular function in intrauterine life) is known as *vanishing testes, congenital anorchia,* or testicular regression syndrome.

Testicular regression syndrome is not uncommon. Cryptorchidism occurs in 1.5–9% of male births; in 10–20% of these cases, the testes are impalpable. Of children with impalpable testes, up to 50% may have no detectable testes after extensive investigation. Most cases appear to be sporadic and are thought to be the result of torsion or vascular accidents. The incompletely descended testis may be more prone to torsion, and this may be one of the causes of vanishing testes. Most cases are sporadic, but in a subset of patients, testicular regression syndrome occurs in monozygotic twins or in families with other affected individuals, suggesting a genetic etiology. Some cases are associated with micropenis, and in these cases the testicular loss probably occurred after the 14th week but well before the time of birth, or this may indicate a preexisting dysfunction of male hormonal development. Low levels of testosterone (<10 ng/dL) and markedly elevated levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are found in the early postnatal months; thereafter levels of gonadotropins tend to decrease even in agonadal children, rising to very high levels again as the pubertal years approach. Stimulation with human chorionic gonadotropin (hCG) fails to evoke an increase in the level of testosterone. *Serum levels of antimüllerian hormone (AMH) are undetectable or low.* All patients with undetectable testes should be tested for AMH and should undergo an hCG stimulation test. If the results indicate that no testicular tissue is present (absent AMH and no rise in testosterone after hCG stimulation), then the diagnosis of testicular regression syndrome is confirmed. If testosterone secretion is demonstrated, then imaging with abdominal magnetic resonance imaging (MRI) and/or surgical exploration is indicated. A small fibrotic nodule may be found at the end of the spermatic cord in many cases of testicular regression syndrome. There is no possibility of normal fertility in these patients.

Treatment of male hypogonadism (primary or secondary) is discussed in Chapter 623.2.

Chemotherapy and Radiation-Induced Hypogonadism

Testicular damage is a frequent consequence of chemotherapy and radiotherapy for cancer. The frequency and extent of damage depend on the agent used, total dose, duration of therapy, and posttherapy interval of observation. Another important variable is age at therapy; it has been suggested that prepubertal testes are less prone to damage than pubertal testes, though the evidence is not conclusive. Chemotherapy is most damaging if more than one agent is used, and alkylating agents and platinum-containing agents are the ones most likely to lead to testicular damage. Although many chemotherapeutic agents produce azoospermia and infertility, Leydig cell damage (leading to low testosterone levels) is less common. In many cases the damage is transient and sperm counts recover after 12-24 months. The use of alkylating agents such as cyclophosphamide in prepubertal children may not impair pubertal development, even though there may be biopsy evidence of germ cell damage. Cisplatin causes transient azoospermia or oligospermia at lower doses, whereas higher doses (400-600 mg/m^2) can cause permanent infertility. Interleukin 2 can depress Leydig cell function, whereas interferon-α does not seem to affect gonadal function. Both chemotherapy and radiotherapy are associated with an increase in the percentage of abnormal gametes, but data concerning the outcomes of pregnancies after such therapy have *not* shown any increase in genetically mediated birth defects, possibly because of selection bias against abnormal sperm.

Radiation damage is dose dependent. Temporary oligospermia can be seen with doses as low as 0.1 Gy, with permanent azoospermia seen with doses greater than 2 Gy. Recovery of spermatogenesis can be seen 5 years (or more) after irradiation, with higher doses leading to slower recovery. Leydig cells are more resistant to irradiation. Mild damage as determined by elevated LH levels can be seen with up to 6 Gy; doses greater than 30 Gy cause hypogonadism in most patients. Whenever possible, testes should be shielded from irradiation. Testicular function should be carefully evaluated in adolescents after multimodal treatment for cancer in childhood. Replacement therapy with testosterone and counseling concerning fertility may be indicated. The storage of sperm before chemotherapy or radiation treatment in pubertal

and postpubertal males is an option. Even in those cases where sperm counts are abnormal, recovery is possible, though the chances of recovery decline with increasing dose of radiation. If sperm counts remain low, fertility is still possible in some cases with testicular sperm extraction and intracytoplasmic sperm injection.

Sertoli Cell–Only Syndrome

Small testes and azoospermia are seen in patients with the extremely rare Sertoli cell–only syndrome (**SCO**, **germ cell aplasia**, or **Del Castillo syndrome**). These patients have no germ cells in the testes but usually have normal testosterone production and present as adults with infertility. Typically, patients have small testes and elevated FSH levels with normal LH and testosterone. They may have gynecomastia because of FSH stimulation of aromatase activity. Inhibin B levels may be decreased when compared with individuals with normal spermatogenesis. Most cases are sporadic and idiopathic, but large deletions involving the azoospermia factor (AZF) region of the Y chromosome (Yq11) may be found in some cases. Y chromosome microdeletions are also occasionally identified as a cause of SCO syndrome.

Other Causes of Testicular Hypofunction

Atrophy of the testes may follow damage to the vascular supply because of manipulation of the testes during surgical procedures for correction of cryptorchidism or because of bilateral torsion of the testes. **Cryptorchidism** is a common condition (found in 3% of male children at birth, decreasing to 1% by age 6 months), and guidelines stress the importance of treatment before age 12 months (or even earlier) to maximize future fertility. But a small percentage of cases will develop fertility issues even when surgical treatment is successful and is completed within the first year of life. These cases may represent intrauterine damage, surgical damage, or genetic defects in testicular development and are therefore included among the causes of testicular hypofunction.

Acute orchitis is common in pubertal or adult males with mumps and may lead to subfertility in ~10% of cases, though infertility is rare. Testosterone secretion usually remains normal. The incidence of mumps orchitis in postpubertal males has increased in some areas because of a decrease in measles, mumps, and rubella vaccination uptake. **Autoimmune polyendocrinopathy** may be associated with primary hypogonadism (associated with anti-P450scc antibodies), but this appears to be more common in females.

Testicular Dysgenesis Syndrome

The incidence of testicular cancer has increased in many developed societies, and the incidence of cryptorchidism, hypospadias, low sperm counts, and sperm abnormalities also appears to have increased in some, but not all, studies. It has been proposed that all these trends are linked by prenatal testicular dysgenesis. The hypothesis is that some degree of testicular dysgenesis develops in intrauterine life from genetic and environmental factors and is associated with an increased risk of cryptorchidism, hypospadias, hypofertility, and testicular cancer. The environmental influences that have been implicated in this syndrome include environmental chemicals that act as endocrine disruptors, such as bisphenol A and phthalates (components of many types of plastics), several pesticides, phytoestrogens or mycoestrogens, and other chemicals. The fact that these lesions can be reproduced in some animal models by environmental chemicals has led to efforts to remove these chemicals from products used by infants and pregnant mothers and from the environment in general. Nonetheless the evidence is only suggestive and not conclusive.

CLINICAL MANIFESTATIONS

Primary hypogonadism may be suspected at birth if the testes and penis are abnormally small. Normative data are available for different populations. The condition is often not noticed until puberty, when secondary sex characteristics fail to develop. Facial, pubic, and axillary hair are scant or absent; there is neither acne nor regression of scalp hair; and the voice remains high pitched. The penis and scrotum remain infantile and may be almost obscured by pubic fat; the testes are small or not palpable. Fat accumulates in the region of the hips and buttocks and sometimes in the breasts and on the abdomen. The epiphyses close later than normal; therefore the extremities are long. The span may be several inches longer than the height, and the distance from the symphysis pubis to the soles of the feet (lower segment) is much greater than that from the symphysis to the vertex (upper segment). The proportions of the body are described as **eunuchoid**. The ratio of the upper to lower segment is considerably less than 0.9. Many individuals with milder degrees of hypogonadism may be detected only by appropriate studies of the pituitary-gonadal axis. Examination of the testes should be performed routinely by the pediatrician; testicular volumes as determined by comparison with standard orchidometers or by measurement of linear dimensions should be recorded.

DIAGNOSIS

Levels of serum FSH and, to a lesser extent, of LH are elevated to greater than age-specific normal values in early infancy (when minipuberty normally occurs and the gonadotropins are normally disinhibited). This is followed by a time when even agonadal children may not exhibit significant elevation in gonadotropins, indicating that the gonadotropins are also suppressed at this stage by some mechanism independent of feedback inhibition by gonadal hormones. In the latter half of childhood and several years before the onset of puberty, this inhibition is released and gonadotropin levels again rise above age-based normal levels in subjects with primary hypogonadism. These elevated levels indicate that even in the prepubertal child there is an active hypothalamic-gonadal feedback relationship. After the age of 11 years, FSH and LH levels rise significantly, reaching the agonadal range. Measurements of random plasma testosterone levels in prepubertal males are not helpful because they are low in normal prepubertal children, rising during puberty to attain adult levels. During puberty, these levels, when measured in an early morning blood sample, correlate better with testicular size, stage of sexual maturity, and bone age than with chronological age. In patients with primary hypogonadism, testosterone levels remain low at all ages. There is an attenuated rise or no rise at all after administration of hCG, in contrast to normal males in whom hCG produces a significant rise in plasma testosterone at any stage of development.

AMH is secreted by the Sertoli cells, and this secretion is suppressed by testosterone. AMH levels are elevated in prepubertal males and suppressed at the onset of puberty. Males with primary hypogonadism continue to have elevated AMH levels in puberty. Detection of AMH may be used in the prepubertal years as an indicator of the presence of testicular tissue (e.g., in patients with bilateral cryptorchidism). Inhibin B is also secreted by the Sertoli cells, is present throughout childhood, and rises at the onset of puberty (more in males than in females). It may be used as another marker of the presence of testicular tissue in bilateral cryptorchidism and as a marker of spermatogenesis (e.g., in delayed puberty, cancer survivors, and patients with Noonan syndrome). Bone age x-rays are useful to document delayed bone age in patients with constitutional growth delay as well as primary hypogonadism.

NOONAN SYNDROME

The term *Noonan syndrome* has been applied to males and females with normal karyotypes who have certain phenotypic features that occur also in females with Turner syndrome (although the genetic causes are completely distinct) (see Chapter 101). Males with this syndrome frequently have cryptorchidism and small testes. Testosterone secretion may be low or normal, but spermatogenesis may be affected even in those with normal testosterone (and normal secondary sexual characteristics). Serum inhibin-B is a useful marker of Sertoli cell function in these patients. Puberty is delayed, and adult height is achieved by the end of the second decade; the syndrome is discussed in detail in Chapter 101. Patients with significant hypogonadism will need treatment as discussed in Chapter 623.2.

KLINEFELTER SYNDROME

See also Chapter 99.4.

Klinefelter syndrome is the most common sex chromosomal aneuploidy in males, with an incidence of 0.1–0.2% in the general population

(1 in 500-1,000) and rising to 4% among infertile males and 10–11% in those with oligospermia or azoospermia. Approximately 80% of them have a 47,XXY chromosome complement, whereas mosaics and higher degrees of poly-X are seen in the remaining 20%. Even with as many as four X chromosomes, the Y chromosome determines a male phenotype. The chromosomal aberration most often results from meiotic nondisjunction of an X chromosome during parental gametogenesis; the extra X chromosome is maternal in origin in 54% and paternal in origin in 46% of patients. A national study in Denmark revealed a prenatal prevalence of 213 per 100,000 male fetuses, but in adult men the prevalence was only 40 per 100,000, suggesting that 25% of adult males with Klinefelter syndrome were diagnosed. The incidence of Klinefelter syndrome increases with maternal age and possibly also with paternal age.

Clinical Manifestations

In patients who do not have a prenatal diagnosis, the diagnosis is rarely made before puberty because of the paucity or subtlety of clinical manifestations in childhood. Behavioral or psychiatric disorders may be apparent long before defects in sexual development. These children tend to have learning disabilities and deficits in executive function (concept formation, problem solving, task switching, and planning), and the condition should be considered in males with psychosocial, learning, or school adjustment problems. Affected children may be anxious, immature, or excessively shy and tend to have difficulty in social interactions throughout life. In a prospective study, a group of children with 47,XXY karyotypes identified at birth exhibited relatively mild deviations from normal during the first 5 years of life. None had major physical, intellectual, or emotional disabilities; some were inactive, with poorly organized motor function and mild delay in language acquisition. Problems often first become apparent after the child begins school. Full-scale IQ scores may be normal, with verbal IQ being somewhat decreased. Verbal cognitive defects and underachievement in reading, spelling, and mathematics are common. By late adolescence, many males with Klinefelter syndrome have generalized learning disabilities, most of which are language based. Despite these difficulties, most complete high school.

The patients tend to be tall and slim and have a specific tendency to have long legs (disproportionate to the arms and longer than those seen with other causes of hypogonadism), but body habitus can vary markedly. The testes tend to be small for age, but this sign may become apparent only after puberty, when normal testicular growth fails to occur. The phallus tends to be smaller than average, and cryptorchidism is more common than in the general population. Bone mineral density may be low in adults with Klinefelter syndrome, and this correlates with lower testosterone levels.

Pubertal development may be delayed, although some children undergo apparently normal or nearly normal virilization. Despite normal testosterone levels, serum LH and FSH concentrations and their responses to gonadotropin-releasing hormone (GnRH) stimulation are elevated starting at around 13 years of age. Approximately 50–80% of adults have **gynecomastia**; they have sparser facial hair. The most common testicular lesions are spermatogenic arrest and Sertoli cell predominance. The sperm have a high incidence of sex chromosomal aneuploidy. Azoospermia and infertility are usual, although rare instances of fertility are known. It is now clear that germ cell numbers and sperm counts are higher in early puberty and decline with age. Testicular sperm extraction followed by intracytoplasmic sperm injection can result in the birth of healthy infants, with success rates declining with increasing age. In nonmosaic Klinefelter patients, most testicular sperm (94%) have a normal pattern of sex chromosome segregation, indicating that meiotic checkpoints can remove most aneuploid cells. Antisperm antibodies have been detected in 25% of tested specimens.

There is an increased incidence in adulthood of central adiposity, metabolic syndrome, pulmonary disease, varicose veins, and cancer of the breast. Among 93 unselected **male breast cancer** patients, 7.5% were found to have Klinefelter syndrome. Mediastinal germ cell tumors have been reported; some of these tumors produce hCG and cause precocious puberty in young males. They may also be associated with leukemia, lymphoma, and other types of hematologic neoplasia. The highest cancer risk (relative risk: 2.7) occurs in the 15- to 30-year age-group. A large cohort study in Britain demonstrated an overall significantly increased standardized mortality ratio, with increases in deaths from diabetes, epilepsy, peripheral and intestinal vascular sufficiency, pulmonary embolism, and renal disease. Mortality from ischemic heart disease was decreased. In adults, structural brain abnormalities correlate with cognitive deficits.

Patients with Klinefelter syndrome also have an increased risk of *autoimmune disorders*. It seems that the presence of one or more X chromosomes changes the risk of autoimmune disorders, which are similar to those seen in XX females. These patients have an increased incidence of rheumatoid arthritis, Sjogren syndrome, systemic lupus erythematosus (SLE), and other autoimmune disorders.

In adults with XY/XXY mosaicism, the features of Klinefelter syndrome are decreased in severity and frequency. Children with mosaicism have a better prognosis for virilization, fertility, and psychosocial adjustment.

Klinefelter Variants and Other Poly-X Syndromes

When the number of X chromosomes exceeds two, the clinical manifestations, including intellectual disability and impairment of virilization, are more severe. Height decreases with increasing number of X chromosomes. The **XXYY** variant is the most common variant (1 in 18,000-40,000 male births). In most, intellectual disability occurs with IQ scores between 60 and 80, but 10% have IQs greater than 110. The XXYY male phenotype is not distinctively different from that of the XXY patient except that XXYY adults tend to be taller than the average XXY patient. The **49,XXXXY** variant is sufficiently distinctive to be detected in childhood. Its incidence is estimated to be 1 in 80,000-100,000 male births. The disorder arises from sequential nondisjunction in meiosis. Affected patients are severely cognitively impaired and have short necks and typical coarse facies. The eyes are wide set, with a mild upward slant of the fissures as well as epicanthus and strabismus; the nose is upturned, wide, and flat; also noted is a large open mouth and large malformed ears. The testes are small and may be undescended, the scrotum is hypoplastic, and the penis is very small. Defects suggestive of Down syndrome (short, incurved terminal fifth phalanges, single palmar creases, and hypotonia) and other skeletal abnormalities (including defects in the carrying angle of the elbows and restricted supination) are common. The most frequent radiographic abnormalities are radioulnar synostosis or dislocation, elongated radius, pseudoepiphyses, scoliosis or kyphosis, coxa valga, and retarded bone age. Most patients with such extensive changes have a 49,XXXXY chromosome karyotype; several mosaic patterns have also been observed: 48,XXXY/49,XXXXY; 48,XXXY/49,XXXXY/50,XXXXXY; and 48,XXXY/49,XXXXY/50,XXXXYY. Prenatal diagnosis of a 49,XXXXY infant has been reported. The fetus had intrauterine growth restriction, edema, and cystic hygroma colli.

The **48,XXXY** variant is relatively rare. The characteristic features are generally less severe than those of patients with 49,XXXXY and more severe than those of 47,XXY patients. Mild intellectual disability, delayed speech and motor development, and immature but passive and pleasant behavior are associated with this condition.

Very few patients have been described with 48,XYYY and 49,XXYYY karyotypes. Dysmorphic features and cognitive impairment are common to both.

Laboratory Findings

Most males with Klinefelter syndrome go through life undiagnosed. The chromosomes should be examined in all patients suspected of having Klinefelter syndrome, particularly those attending child guidance, psychiatric, and cognitive disability clinics. In infancy, inhibin B and AMH levels are normal but testosterone levels are lower than in controls. Before 10 years of age, males with 47,XXY Klinefelter syndrome have normal basal plasma levels of FSH and LH. Responses to gonadotropin-stimulating hormone and to hCG are normal. The testes show normal growth early in puberty, but by midpuberty the testicular growth stops, gonadotropins become elevated, and testosterone levels

are slightly low. Inhibin B levels are normal in early puberty, decrease in late puberty, and are low in adults with the syndrome. Elevated levels of estradiol, resulting in a high ratio of estradiol to testosterone, account for the development of gynecomastia during puberty. Sex hormone–binding globulin levels are elevated, further decreasing free testosterone levels. A long androgen receptor polyglutamine (CAG) repeat length is associated with the more severe phenotype, including gynecomastia, small testes, and short penile length.

Testicular biopsy before puberty may reveal only deficiency or absence of germinal cells. After puberty, the seminiferous tubular membranes are hyalinized and there is adenomatous clumping of Leydig cells. Sertoli cells predominate. Azoospermia is characteristic, and infertility is the rule.

Management

Males known to have Klinefelter syndrome should be monitored closely for speech, learning, and behavioral problems; they should be referred for early evaluation and treatment as needed. Testosterone, LH, and FSH levels should be checked at 11-12 years of age; replacement therapy with testosterone is recommended once FSH and LH begin to rise above normal. Fasting glucose, lipids, and hemoglobin A_{1C} should also be obtained, as these children are at risk for central adiposity and metabolic syndrome. A baseline dual-energy x-ray absorptiometry scan to assess bone density is also recommended by some authorities. Although testosterone treatment will normalize testosterone levels, stimulate the development of secondary sexual characteristics, increase bone and muscle mass, and improve body composition, it will *not* improve fertility (and will, in fact, suppress spermatogenesis). There is some evidence that it also improves mood and may have a positive effect on cognition and social functioning, but the findings are not conclusive at this time. Either long-acting testosterone injections or a daily application of testosterone gel may be used (testosterone patches have a high incidence of skin rash and are not frequently used in pediatrics). Testosterone enanthate or cypionate ester may be used in a starting dose of 25-50 mg injected intramuscularly or subcutaneously every 3-4 weeks, with 50-mg increments every 6-12 months until a maintenance dose for adults (200-250 mg every 3-4 weeks) is achieved. At that time, testosterone patches or testosterone gel may be substituted for the injections. Depending on patient and physician preference, transdermal testosterone may also be used as initial treatment instead of injections. For older males, larger initial doses and increments can achieve more rapid virilization. The various transdermal preparations differ somewhat, and standard references should be consulted for recommendations regarding dosage and mode of application.

Gynecomastia may be treated with aromatase inhibitors (which will also increase endogenous testosterone levels), but medical treatment is not always successful and plastic surgery may be needed. Fertility is usually not an issue in the pediatric age-group, but adults can father children using testicular sperm extraction followed by intracytoplasmic sperm injection. Because sperm counts decrease rapidly after the onset of puberty in children with Klinefelter syndrome, sperm banking during early puberty is an option that can be discussed with a fertility specialist. Sperm counts can be stimulated using hCG treatment before testicular sperm extraction. Therapy, counseling, and psychiatric services should be provided as needed for learning difficulties and psychosocial disabilities.

XX MALES

This disorder is thought to occur in 1 in 20,000 newborn males. Affected individuals have a male phenotype, small testes, a small phallus, and no evidence of ovarian or müllerian duct tissue. They therefore appear to be *distinct from* those with the **ovotesticular disorder of sexual development**. Undescended testes and hypospadias occur in a minority of patients. Infertility occurs in practically all cases, and the histologic features of the testes are essentially the same as in Klinefelter syndrome. Patients with the condition usually come to medical attention in adult life because of hypogonadism, gynecomastia, or infertility. Hypergonadotropic hypogonadism occurs secondary to testicular failure. A few cases have been diagnosed perinatally as a result of discrepancies between prenatal ultrasonography and karyotype findings.

In 90% of XX males with normal male external genitalia, one of the X chromosomes carries the *SRY* (sex-determining region on the Y chromosome) gene. The exchange from the Y to the X chromosome occurs during paternal meiosis, when the short arms of the Y and X chromosomes pair. XX males inherit one maternal X chromosome and one paternal X chromosome containing the translocated male-determining gene. A few cases of 46,XX males with 9P translocations have also been identified. Most XX males who are identified before puberty have hypospadias or a micropenis; this group of patients may lack Y-specific sequences, suggesting other mechanisms for virilization. Fluorescent in situ hybridization and primed in situ labeling have been used to identify small *SRY* DNA segments. Yp fragment abnormalities may result in sexually ambiguous phenotypes.

45,X MALES

In a few male patients recognized with a 45,X karyotype, Yp sequences are translocated to an autosomal chromosome. In one instance, the terminal short arm of the Y chromosome was translocated onto an X chromosome. In another, *SRY/autosomal* translocation was postulated. A male with the 45,X karyotype and Leri-Weill dyschondrosteosis, *SHOX* gene loss, and an SRY to Xp translocation has also been described.

47,XXX MALES

A Japanese male with poor pubic hair development, hypoplastic scrotal testes (4 mL), normal penis and normal height, gynecomastia, and severe cognitive impairment had 47,XXX karyotype caused by an abnormal X-Y interchange during paternal meiosis and X-X nondisjunction during maternal meiosis.

623.2 Hypogonadotropic Hypogonadism in the Male (Secondary Hypogonadism)

Omar Ali and Patricia A. Donohoue

In hypogonadotropic hypogonadism (HH), lack of gonadal function is secondary to deficiency of one or both gonadotropins: FSH or LH. The primary defect may lie either in the anterior pituitary or in the hypothalamus. Hypothalamic etiologies result in deficiency of GnRH. The testes are normal but remain in the prepubertal state because stimulation by gonadotropins is lacking. The disorder may be recognized in infancy but is much more commonly recognized because of marked pubertal delay. Rarely, patients with a milder inherited form of HH may go through puberty and may present with hypogonadism as adults.

HH may be genetic or acquired (Table 623.2). Several different genes can cause inherited forms of HH; the affected genes may be upstream of GnRH, at the level of GnRH receptors, or at the level of gonadotropin production. In addition, various genetic defects in transcription factors—such as POUF-1, LHX-3, LHX-4, and HESX-1—lead to defects in pituitary development and multiple pituitary hormone deficiencies, including deficiency of gonadotropins. Acquired pituitary gonadotropin deficiency may develop from various lesions in the hypothalamic-pituitary region (e.g., tumors, infiltrative disease, autoimmune disease, trauma, stroke).

ISOLATED GONADOTROPIN DEFICIENCY

Isolated gonadotropin deficiency in which other pituitary hormone levels are normal is more likely to be from defects in the secretion of GnRH from the hypothalamus rather than defects in gonadotropin synthesis in the pituitary. It affects approximately 1 in 10,000 males and 1 in 50,000 females and encompasses a heterogeneous group of entities. Many cases are associated with anosmia, and this combination of anosmia and HH defines **Kallmann syndrome**.

Table 623.2 Forms of Congenital Hypogonadotropic Hypogonadism and Differential Diagnosis

FORMS OF CHH
GnRH Deficiency and Defective Sense of Smell
Kallmann syndrome
Isolated GnRH Deficiency (Normal Sense of Smell)
Normosmic CHH
Complex Syndromes Including CHH or KS
Combined pituitary hormone deficiency
Septo-optic dysplasia
CHARGE syndrome
Adrenal hypoplasia congenita with HH
Waardenburg syndrome
Bardet-Biedl syndrome
Gordon Holmes syndrome
Others
DIFFERENTIAL DIAGNOSIS
Functional Causes
Malnutrition and/or malabsorption
Any chronic disease (e.g., IBD or asthma)
Celiac disease
Eating disorders
Excessive exercise
Systemic Causes
Hemochromatosis
Sarcoidosis
Histiocytosis
Thalassemia
Acquired Causes
Hyperprolactinemia
Pituitary adenomas and/or brain tumors
Rathke cleft cyst
Pituitary apoplexy
Radiation (brain or pituitary)
Medication induced (such as by steroids, opiates, or chemotherapy)

CHARGE, Coloboma, heart defects, atresia of choanae, retardation of growth and/or development, genital and/or urinary defects, ear anomalies or deafness; CHH, congenital hypogonadotropic hypogonadism; GnRH, gonadotropin-releasing hormone; HH, hypogonadotropic hypogonadism; IBD, inflammatory bowel disease; KS, Kallmann syndrome.

From Boehm U, Bouloux PM, Dattani MT, et al. European consensus statement on congenital hypogonadotropic hypogonadism—pathogenesis, diagnosis and treatment. Nat Rev. 2015;11:547–564. Box 2.

Kallmann syndrome is the most common form of HH and is genetically heterogeneous, with autosomal recessive, X-linked, and autosomal dominant forms of inheritance. Clinically it is characterized by its association with anosmia or hyposmia; 85% of cases appear to be autosomal and 15% are X-linked, but a specific genetic defect may not be identified in more than half of the cases of HH. There is a wide spectrum of severity and associated features in patients with Kallmann syndrome, and the same genetic pathogenic variants may be associated with different phenotypes, even within the same family. Some kindreds contain anosmic individuals *with or without* hypogonadism; others contain hypogonadal individuals who are anosmic. Cleft lip and palate, hypotelorism, median facial clefts, sensorineural hearing loss, unilateral renal aplasia, neurologic deficits, and other findings occur in some affected patients.

The **X-linked** form (*ANOS1*, formerly known as *KAL1*) is caused by variants of *ANOS1* at Xp22.3. This leads to failure of olfactory axons and GnRH-expressing neurons to migrate from their common origin in the olfactory placode to the brain. The *ANOS1* gene product anosmin-1, an extracellular 95-kDa matrix glycoprotein, facilitates neuronal growth and migration. The *ANOS1* gene is also expressed in various parts of the brain, facial mesenchyme, and mesonephros and metanephros, thus explaining some of the associated findings in patients with Kallmann syndrome, such as synkinesia (mirror movements), hearing loss, midfacial defects, and renal agenesis.

When Kallmann syndrome is caused by terminal or interstitial deletions of the Xp22.3 region, it may be associated with other contiguous gene syndromes, such as steroid sulfatase deficiency, chondrodysplasia punctata, X-linked ichthyosis, or ocular albinism.

The **autosomal dominant** form of Kallmann syndrome (sometimes referred to as *KAL2*) occurs in up to 10% of patients and is caused by a loss-of-function pathogenic variant in the fibroblast growth factor receptor 1 *(FGFR1)* gene. Cleft lip and palate are associated with this form, but not with the X-linked form. Oligodontia and hearing loss may occur with both KAL1 and KAL2.

A variety of other genes—including *SOX10, FGF8, PROK2/PROKR2, NELF, CHD7* (responsible for CHARGE [coloboma of the eye, heart anomaly, choanal atresia, retardation, and genital and ear anomalies] syndrome, which includes hypogonadism in its phenotype), *HS6ST1, WDR11,* and *SEMA3A*—are associated with defects in neuronal migration that can result in Kallmann syndrome.

Hypogonadotropic Hypogonadism Without Anosmia

A specific genetic defect is not found in most cases of *normosmic idiopathic hypogonadotropic hypogonadism (IHH)*, but the list of genes associated with this disorder is growing; pathogenic variants in *KISS1/KISS1R, TAC3/TACR3,* and *GNRH1/GNRHR* lead to abnormalities in the secretion and action of GnRH and are seen exclusively in patients with normosmic IHH. Variants in *FGFR1, FGF8, PROKR2, CHD7,* and *WDR11* more commonly present with anosmia/hyposmia (Kallmann syndrome) but are also associated with normosmic IHH in some cases. It appears that kisspeptin (the gene product of the *KISS1* gene) and its G protein–coupled receptor (GPCR54) play an important role in triggering puberty in humans and act downstream of the leptin receptor in this pathway. Rare cases of leptin deficiency and leptin receptor defects are also associated with HH. In addition, starvation and anorexia are associated with hypogonadism, most likely acting via the leptin pathway.

There are no known human variants of the *GnRH* gene, but several families with variants in the GnRH *receptor* have been described. These variants account for 2–14% of IHH without anosmia. The severity of the defect is variable, and many patients will respond to high-dose GnRH with increased gonadotropin secretion, indicating that the receptor defect is partial.

Variants in gonadotropin genes are extremely rare. Variants in the common α-subunit are not known in humans. Variants in the LH-β subunit have been described in a few individuals and may lead to low, absent, or elevated LH levels, depending on the variant. This leads to testosterone deficiency (diminished Leydig cell function), but because intratesticular testosterone is critical for spermatogenesis, this also leads to diminished sperm counts. Defects in the FSH-β subunit may be the cause of azoospermia in a few rare cases. Interestingly these patients may also have testosterone deficiency, indicating that Sertoli cells also play a role in supporting normal Leydig cell function.

Children with **X-linked adrenal hypoplasia congenita (AHC)** have associated HH because of impaired GnRH secretion. In these patients, there is a pathogenic variant of *DAX1* at Xp21.2-21.3. This region of the X chromosome includes genes for glycerol kinase, Duchenne muscular dystrophy, and ornithine transcarbamoyltransferase (OTC); these genes may be affected as part of a contiguous gene deletion syndrome that includes AHC, glycerol kinase deficiency, Duchenne muscular dystrophy, and OTC deficiency. Most males with *DAX1* variants develop HH in adolescence, although a patient with adult-onset adrenal insufficiency and partial HH and two females with HH and delayed puberty have also been described, the latter as part of extended families including males with classic HH. The *DAX1* gene defect is, however, rare in patients with delayed puberty or HH without at least a family history of adrenal failure (see Chapter 616).

It should be noted that genotype-phenotype correlations in IHH appear to be complex, and pedigrees with digenic or oligogenic inheritance have been described. The same genetic defect may be associated with Kallmann syndrome, normosmic IHH, additional birth defects,

delayed normal puberty, or an apparently normal phenotype. This variability has been observed more frequently in kindreds with pathogenic variants in *FGF8/FGFR1* and in *PROK2/PROKR2* ligand-receptor pairs and may result from other interacting genes, epigenetic effects, or environmental factors.

OTHER DISORDERS WITH HYPOGONADOTROPIC HYPOGONADISM

HH has been observed in a few patients with **polyglandular autoimmune syndrome**, in some with elevated melatonin levels, and in those with a variety of other syndromes, such as **Bardet-Biedl, Prader-Willi, multiple lentigines, and several ataxia syndromes**. In rare cases, HH is associated with complex chromosomal abnormalities.

HYPOGONADOTROPIC HYPOGONADISM ASSOCIATED WITH OTHER PITUITARY HORMONE DEFICIENCIES

Defects in pituitary transcription factors such as PROP-1, HESX-1, LHX-4, SOX-3, and LHX-3 lead to multiple pituitary deficiencies including HH. Most of these present with multiple pituitary hormone deficiency in infancy, but some cases (especially with *PROP-1* pathogenic variants) may present with hypogonadism or hypoadrenalism in adult life. Growth hormone is almost always affected in multiple pituitary hormone deficiency, but thyroid-stimulating hormone and adrenocorticotropic hormone may be spared in some cases. In patients with organic lesions in or near the pituitary, the gonadotropin deficiency is usually pituitary in origin.

DIAGNOSIS

Levels of gonadotropins and gonadal steroids are normally elevated for up to 6 months after birth (minipuberty); if the diagnosis of HH is suspected in early infancy, these levels will be found to be inappropriately low. By the second half of the first year of life, these normally decline to nearly undetectable levels and remain suppressed until late childhood. Routine laboratory tests cannot distinguish HH from normal suppression of gonadotropins in this age-group. At the normal age of puberty, these patients fail to show clinical signs of puberty or a normal increase in LH and FSH levels. *Children with constitutional delay of growth and puberty will have the same clinical picture and similar laboratory findings (these cases are far more common than true HH, especially in males), and their differentiation from patients with HH is extremely difficult.* Dynamic testing with GnRH or hCG may *not* be able to distinguish these groups in a reliable manner. A testosterone level greater than 50 ng/dL (1.7 nmol/L) generally indicates that normal puberty is likely, but a lower level does not reliably distinguish these groups. At least one study showed that an inhibin B level of <35 pg/mL in Tanner stage 1 and <65 pg/mL in Tanner stage 2 may be able to distinguish IHH from constitutional delay in males, but no single test will reliably distinguish these conditions in all patients.

Insulin-like growth factor-1, thyroid-stimulating hormone, free thyroxine, and morning cortisol levels should be checked to assess the status of other anterior pituitary hormones; dynamic testing for growth hormone deficiency and adrenal insufficiency may be necessary if these are abnormal or equivocal. HH is very likely if the patient has evidence of another pituitary deficiency, such as a deficiency of growth hormone, particularly if it is associated with adrenocorticotropic hormone deficiency. **Hyperprolactinemia** is a known cause of delayed puberty and should be excluded by determination of serum prolactin levels in all patients. The presence of *anosmia* usually indicates permanent gonadotropin deficiency, but occasional instances of markedly delayed puberty (18-20 years of age) have been observed in anosmic individuals. Although anosmia may be present in the family or in the patient from early childhood, its existence is rarely volunteered, and direct questioning is necessary in all patients with delayed puberty. Formal olfactometry, such as the University of Pennsylvania Smell Identification Test, is advisable to determine if partial degrees of hyposmia are present, because IHH patients display a broad spectrum of olfactory function.

In the absence of family history, it may not be possible to make the diagnosis of HH with certainty, but the diagnosis will become more and more likely as puberty is delayed further beyond the normal age. If pubertal delay persists beyond age 18 years with low 8 AM testosterone levels and inappropriately low gonadotropins (normal values are inappropriately low in this setting), then the patient can be presumptively diagnosed with HH. *An MRI of the brain is indicated* to look for tumors and other anomalies in the hypothalamic-pituitary region. Genetic testing for pituitary transcription factors and several of the genes involved in isolated HH is also available and should be performed when possible. A renal ultrasound is recommended in patients with Kallmann syndrome because of its association with unilateral renal agenesis. Some authorities also recommend obtaining a baseline bone-density evaluation.

TREATMENT

Constitutional delay of puberty should be ruled out before a diagnosis of HH is established and treatment is initiated. Testicular volume of less than 4 mL by 14 years of age occurs in approximately 3% of males, but most of these are cases of constitutional delay of puberty, and true HH is a rare condition. Although constitutional delay is a benign condition that will (by definition) resolve spontaneously, even relatively moderate delays in sexual development and growth may result in significant psychologic distress and require attention. Initially an explanation of the variations characteristics of puberty and reassurance suffice for the majority of males. If by 15 years of age no clinical evidence of puberty is apparent and the testosterone level is <50 ng/dL, a brief course of testosterone may be recommended. Various regimens are used, including testosterone enanthate or cypionate 100 mg intramuscularly once monthly for 4-6 months or 150 mg once monthly for 3 months. Some practitioners use oral oxandrolone in a dose of 1.25-2.5 mg daily for 6-12 months, which has the theoretical advantage that it is not aromatized and may have less effect on bone age advancement (though definitive evidence of advantage is lacking). Oral oxandrolone may cause hepatic dysfunction, and liver function tests should be monitored if it is used. Treatment is not necessary in all cases of constitutional delay, but if used it is usually followed by normal progression through puberty, and this may differentiate constitutional delay in puberty from isolated gonadotropin deficiency. The age of initiation of this treatment must be individualized.

If puberty fails to progress spontaneously after a short course of testosterone has been attempted, then HH becomes the likely diagnosis and necessitates continuous use of testosterone for normal pubertal development. At this point the patient should undergo an MRI scan and genetic testing to try to make a specific diagnosis. Once a diagnosis of HH has been made, treatment with testosterone will induce secondary sexual characteristics but will *not* stimulate testicular growth or spermatogenesis. Treatment with gonadotropins (either as a combination of hCG and human menopausal gonadotropins or as GnRH pulse therapy) will lead to testicular development, including spermatogenesis, but it is much more complex to manage, so in most cases testosterone treatment is still the best option. Either long-acting testosterone injections or a daily application of testosterone gel may be used (testosterone patches have a high incidence of skin rash and are infrequently used in pediatrics). Testosterone enanthate or cypionate ester may be used in a starting dose of 25-50 mg injected intramuscularly or subcutaneously every 3-4 weeks, with 50-mg increments every 6-9 months until a maintenance dose for adults (200-250 mg every 3-4 weeks) is achieved. At that time, testosterone patches or testosterone gel may be substituted for the injections. Depending on patient and physician preference, transdermal testosterone may also be used as initial treatment instead of injections. For older males, larger initial doses and increments can achieve more rapid virilization.

Treatment with gonadotropins is more physiologic but is expensive and complex, so it is less commonly used in adolescence. This treatment may be attempted in adult life when fertility is desired. The treatment schedule varies from 1,250 to 5,000 IU hCG in combination with 12.5-150 IU human menopausal gonadotropins 3 times per week intramuscularly. It may require up to 2 years of treatment to achieve

adequate spermatogenesis in adults. Recombinantly produced gonadotropins (LH and FSH) are also able to stimulate gonadal growth and function but are much more expensive. Treatment with GnRH (when available) is the most physiologically appropriate, but it requires the use of a subcutaneous infusion pump to deliver appropriately pulsed therapy because continuous exposure to GnRH will suppress gonadotropins rather than stimulate them. In some cases, patients with GnRH defects also have pituitary or testicular dysfunction (a dual defect) and may fail to respond adequately to GnRH or gonadotropin treatment. The rare patient with isolated LH deficiency can be treated effectively using hCG injections.

It has been found that up to 10% of patients diagnosed with HH (with or without anosmia) may exhibit spontaneous reversal of hypogonadism with sustained normal gonadal function after treatment has been discontinued; this may even occur in patients with known genetic variants in various genes, including *FGFR1, PROK2, GNRH, CHD7,* and *TAC/TACR3*. Such recovery is more likely in patients who show an increase in testicular volume during treatment or when treatment has been discontinued. A brief trial of interruption of treatment is justified in patients with idiopathic HH. However, the recovery of gonadal function may not be lifelong.

Chapter 624

Pseudoprecocity Resulting from Tumors of the Testes

Omar Ali and Patricia A. Donohoue

Testicular tumors are relatively rare tumors in childhood, accounting for only 2–4% of all childhood cancers. 35% of prepubertal tumors are malignant, but in pubertal children most tumors are malignant (98% of painless testicular masses in pubertal males are malignant). Testicular tumors are discussed further in Chapter 552. Tumors that cause masculinization or feminization are rare and are derived from Leydig cells (producing androgens) or Sertoli cells (producing feminization). In addition, *enlargement* of the testes can be seen in congenital adrenal hyperplasia (CAH, caused by adrenal rests), in fragile X syndrome, and in cases where one testis is lost and the other hypertrophies to compensate.

Leydig cell tumors of the testes are rare causes of precocious pseudopuberty (gonadotropin-independent puberty) and cause asymmetric enlargement of the testes. Leydig cells are sparse before puberty, and tumors derived from them are more common in the adult. However, rare cases do occur in children; the youngest reported case was in a 1-year-old male. Although up to 10% of adult tumors may be malignant, metastasizing malignant tumors have not been reported in children, and pediatric Leydig cell tumors are usually unilateral and benign. Some tumors may be the result of somatic activating pathogenic variants of the luteinizing hormone receptor.

The clinical manifestations are those of puberty in the male; onset usually occurs at 5-9 years of age. Unilateral pubarche caused by local hormone action has been described. Gynecomastia may occur. The tumor of the testis can usually be readily felt; the contralateral unaffected testis is normal in size for the age of the patient.

Plasma levels of testosterone are markedly elevated, and follicle-stimulating hormone and luteinizing hormone levels are suppressed. Ultrasonography may aid in the detection of small nonpalpable tumors. Fine-needle aspiration biopsy may help define the diagnosis.

Treatment consists of surgical removal of the affected testis. These tumors are generally resistant to chemotherapy. Progression of virilization ceases after removal of the tumor, and partial reversal of the signs of precocity may occur.

Testicular adrenal rests may develop into tumors that mimic Leydig cell tumors. **Testicular adrenal rest tumors (TARTs)** are usually bilateral and occur in children with inadequately controlled CAH, usually of the salt-losing variety, during adolescence or young adult life. The stimulus for the growth of the adrenal rests is inadequate corticosteroid suppressive therapy causing excess adrenocorticotropic hormone secretion; treatment with adequate doses may result in their regression if they have not become quite large. These tumors are histologically similar to primary Leydig cell tumors, but definite evidence of their origin may be achieved by demonstrating their 21-hydroxylase activity. Misdiagnosis of these tumors as primary Leydig cell tumors may lead to unnecessary orchiectomy and should be avoided. Treatment is frequently unsatisfactory; improving the control of CAH will lower adrenocorticotropic hormone (ACTH) levels and prevent further growth of TARTs but may not shrink existing masses. Surgical removal can relieve pain (and is indicated if severe pain is present) but will not necessarily restore fertility. Sperm banking is recommended in adults with TARTs because these treatment modalities may not reverse their effect on fertility.

Fragile X syndrome (see Chapter 59) is caused by the amplification of a polymorphic CGG repeat in the 5′ untranslated region of *FMRI* at Xp17.3. The gene encodes an RNA-binding protein that is highly expressed in the brain and the testis. In otherwise normal individuals, 6-50 CGG repeats are present in the gene; the presence of 50-200 repeats is associated with mild intellectual disability and other abnormalities, and the presence of more than 200 repeats (fragile X pathogenic variant) is associated with the classic fragile X syndrome. 50 to 200 repeats are present in 1 in 1,000 White males, and pathogenic variants are found in 1 in 4,000-8,000. A cardinal characteristic of the condition is testicular enlargement *(macroorchidism)*, reaching 40-50 mL after puberty. Although the condition has been recognized in a child as young as 5 months of age, affected males younger than 6 years of age rarely have testicular enlargement; by 8-10 years of age, most have testicular volumes greater than 3 mL. The testes are enlarged bilaterally, are not nodular, and are histologically normal. Results of hormonal studies are normal. Direct DNA analysis searching for CGG repeat sequences permits definitive diagnosis.

Large-cell calcifying Sertoli cell tumors of the testes (usually associated with **Carney complex**) and **sex cord tumors with annular tubules** (frequently associated with **Peutz-Jeghers syndrome**) are extremely rare Sertoli cell tumors that may be a cause of breast development in young males. These tumors often occur bilaterally, are multifocal, and are detectible by ultrasonography. Excessive production of aromatase (P450arom), the enzyme that converts testosterone to estradiol, causes feminization of these males. Because these tumors are usually benign, they may be left in place if they are not causing pain; the gynecomastia can be treated with aromatase inhibitors.

Other causes of testicular enlargement are also present. In males with unilateral cryptorchidism, the contralateral testis is approximately 25% larger than normal for age. Testicular enlargement has also been noted in males with Henoch-Schönlein purpura and lymphangiectasia. Epidermoid and dermoid cysts of the testes have been reported but are rare.

Chapter 625

Gynecomastia

Omar Ali and Patricia A. Donohoue

Gynecomastia, the proliferation of mammary glandular tissue in the male, is a common condition. True gynecomastia (the presence of glandular breast tissue) must be distinguished from pseudogynecomastia, which is the result of accumulation of adipose tissue in the area of the breast that is commonly seen in overweight males. True gynecomastia is characterized by the presence of a palpable fibroglandular mass at least 0.5 cm in diameter that is located concentrically beneath the nipple and areolar region.

PHYSIOLOGIC FORMS OF GYNECOMASTIA

Gynecomastia occurs in many newborn males as a result of normal stimulation by maternal estrogen; the effect usually disappears in a few weeks. It is then extremely rare in prepubertal males, in whom it should always be investigated to identify the cause, but it again becomes common during normal puberty.

Neonatal Gynecomastia

Transient gynecomastia occurs in 60–90% of male newborns secondary to exposure to estrogens during pregnancy. Breast development may be asymmetric, and galactorrhea is seen in approximately 5%. Most cases resolve within 4-8 weeks of birth, but a few can last as long as 12 months. No treatment is necessary.

Pubertal Gynecomastia

During early to mid-puberty, up to 70% of males develop various degrees of subareolar hyperplasia of the breasts. Incidence peaks at the same time as peak height velocity, which is around 14 years of age, at Tanner stage 3-4 and at a testicular volume of 5-10 mL. Physiologic pubertal gynecomastia may involve only one breast, and it is not unusual for both breasts to enlarge at disproportionate rates or at different times. Tenderness of the breast is common but transient. Spontaneous regression may occur within a few months; it rarely persists longer than 2 years. Significant psychosocial distress may be present, especially in obese males with relatively large breasts.

The cause is thought to be an imbalance between estrogen and androgen action at the level of breast tissue. Testing usually fails to reveal any significant difference in circulating estrogen and androgen levels between affected and unaffected males, but minor degrees of imbalance in free hormone levels may still be present. Other hormones, including leptin, insulin-like growth factor 1 (IGF-1), and luteinizing hormone, may directly stimulate breast development and may play a role in pubertal gynecomastia. Some cases may be caused by an increased sensitivity to estrogens and/or relative androgen resistance in the affected tissue. As androgen levels continue to rise in later puberty, *most cases resolve and no specific treatment is needed.*

Pathologic Gynecomastia

Monogenic forms of gynecomastia are extremely rare. Familial gynecomastia has occurred in several kindreds as an X-linked or autosomal dominant sex-limited trait. Some of these cases were found to be caused by constitutive activation of the P450 aromatase enzyme *(CYP19A1),* leading to increased peripheral conversion of C-19 steroids to estrogens (increased aromatization). A report of this syndrome in a father and his son and daughter suggests autosomal dominant inheritance.

Exogenous sources of estrogens are an important cause of gynecomastia in prepubertal children. Very small amounts of estrogens can cause gynecomastia in male children, and accidental exposure may occur by inhalation, percutaneous absorption, or ingestion. Common sources of estrogens include oral contraceptive pills and oral and transdermal estrogen preparations. Gynecomastia has been reported in workers involved in the manufacture of estrogens and even in the children of such workers. Gynecomastia can also occur secondary to exposure to medications that decrease the level of androgens (especially free androgens), increase estradiol, or displace androgens from breast androgen receptors. Spironolactone, alkylating agents, anabolic steroids, human chorionic gonadotropin, ketoconazole, cimetidine, and androgen inhibitors such as flutamide are all associated with the occurrence of gynecomastia. Antipsychotic medications may also cause gynecomastia by inducing hyperprolactinemia and hypogonadism. Weaker associations are seen with a large number of other medications and drugs, including opiates, alcohol, and marijuana, although the association with marijuana may not be as strong as previously thought. Lavender, tea tree oils, and excessive consumption of soy are also implicated as possible causes of prepubertal gynecomastia. An increased incidence of gynecomastia has also been reported in cancer survivors, in whom the mechanisms include the antiandrogenic or hypogonadotropic effects of cytotoxic drugs and radiotherapy.

Klinefelter syndrome and other causes of *male hypogonadism* are strongly associated with gynecomastia. Significant gynecomastia is seen in 50% of adolescents with Klinefelter syndrome; it is also seen in other conditions characterized by male undervirilization, including partial androgen insensitivity syndrome and 17-ketosteroid reductase deficiency. Gynecomastia has also been observed in children with congenital virilizing adrenal hyperplasia caused by 11β-hydroxylase deficiency and with Leydig and Sertoli cell tumors of the testis or with feminizing tumors of the adrenal gland. Patients with Klinefelter syndrome may also develop gynecomastia because of estrogen-secreting germ cell tumors of the mediastinum. The finding of such a tumor should prompt a karyotype; conversely, the finding of elevated β-human chorionic gonadotropin (HCG) in a patient with Klinefelter syndrome should lead to imaging of the mediastinum to look for a possible germ cell tumor there. The testes may not be enlarged in patients with Sertoli or Leydig cell tumors, and the tumor is frequently multifocal and bilateral. Excessive aromatase production and/or excessive estrogen production accounts for the gynecomastia. Feminizing Sertoli cell tumors are also a feature of Peutz-Jeghers syndrome and Carney complex. When gynecomastia is associated with galactorrhea, a prolactinoma should be considered. Hyperprolactinemia can also cause gynecomastia indirectly by inducing hypogonadism. Hyperthyroidism alters the ratio of androgen to estrogen by increasing bound androgen and decreasing the free testosterone; this may result in gynecomastia in up to 40% of cases. Gynecomastia is also seen in malnourished patients after restoration of normal nutrition (refeeding syndrome), in whom it may result from hepatic dysfunction or abnormal activation of the gonadotropin axis.

EVALUATION OF GYNECOMASTIA

In pubertal cases a detailed history and physical examination may be all that is needed to exclude rare pathologic causes. Historical evaluation should include family history of male relatives with gynecomastia, history of liver or renal disease, use of medications or drugs of abuse, and exposure to herbal and cosmetic products that may contain phytoestrogens. Physical examination should include special attention to the breasts (looking for overlying skin changes, fixation, local lymphadenopathy, and nipple discharge) as well as a testicular exam. No laboratory evaluation is indicated in routine cases with no other associated abnormality; however, all prepubertal cases and pubertal cases with suspicious features should be investigated. *Suspicious features include diameter >4 cm, rapid progression, persistence for more than 2 years, and persistence after age 17.*

Initial laboratory evaluation should include thyroid function tests (to rule out hyperthyroidism), testosterone, estradiol, HCG, luteinizing hormone, follicle-stimulating hormone, and prolactin levels. Because of circadian variation, these hormone levels should ideally be obtained in the morning. Liver and kidney function should also be evaluated. Most cases of hyperprolactinemia are associated with galactorrhea, but hyperprolactinemia can also cause gynecomastia without associated galactorrhea by suppressing gonadotropins and

inducing some degree of hypogonadism. A karyotype should be checked in all cases where history, examination, or laboratory tests suggest the possibility of Klinefelter syndrome. Gonadotropin levels can be a useful screen for Klinefelter syndrome and will be elevated in pubertal males with this condition. If they are elevated, a karyotype should be performed.

TREATMENT

Treatment in cases of benign pubertal gynecomastia usually consists of reassuring the boy and his family of the physiologic and transient nature of the phenomenon. When the enlargement is striking and persistent and causes serious emotional disturbance to the patient, specific treatment may be justified. Unfortunately, medical treatment is generally ineffective in long-standing cases. Early cases respond better to medical treatment, but it is then harder to justify, as most cases will resolve spontaneously. Agents that have been used for medical treatment include androgens, aromatase inhibitors, and estrogen antagonists. The effectiveness of synthetic androgens is variable and side effects are a concern, so these are rarely used in pediatrics. Aromatase inhibitors have a physiologic rationale, but placebo-controlled trials have been disappointing. Estrogen antagonists like tamoxifen and raloxifene are more effective, with raloxifene being the superior agent in at least one well-designed trial. If medical treatment is attempted, it should be in early cases (<12 months standing) using raloxifene (in a dose of 60 mg/day) or tamoxifen (10-20 mg/day) for 3-9 months, with the understanding that success rates are generally low in severe cases and that mild cases will likely resolve on their own without treatment.

In those cases where breast development is excessive (Tanner stages 3-5), causes significant psychologic distress, or fails to regress in 18-24 months, surgical removal of the enlarged breast tissue may be indicated, particularly in males who have completed or nearly completed pubertal development. Careful examination and laboratory testing to exclude nonphysiologic causes are advisable before proceeding to surgery.

Chapter 626

Hypofunction of the Ovaries

Alvina R. Kansra and Patricia A. Donohoue

Hypofunction of the ovaries can be either primary or central in etiology. It may be caused by congenital failure of development, postnatal injury (primary or hypergonadotropic hypogonadism), or lack of central stimulation by the pituitary and/or hypothalamus (secondary or tertiary hypogonadotropic hypogonadism). **Primary ovarian insufficiency** (hypergonadotropic hypogonadism), also termed *premature ovarian failure* (POF), is characterized by the arrest of normal ovarian function before 40 years of age. Certain genetic pathogenic variants have been identified that can result in primary ovarian insufficiency. Hypofunction of the ovaries because of a lack of central stimulation (hypogonadotropic hypogonadism) can be associated with other processes, such as multiple pituitary hormone deficiencies and some chronic diseases. Table 626.1 details the etiologic classification of ovarian hypofunction (see also Fig. 600.7).

626.1 Hypergonadotropic Hypogonadism in the Female (Primary Hypogonadism)

Alvina R. Kansra and Patricia A. Donohoue

A diagnosis of hypergonadotropic hypogonadism before puberty is difficult. Except in the case of Turner syndrome, most affected patients have no prepubertal clinical manifestations.

TURNER SYNDROME

The term *Ullrich-Turner syndrome* is frequently used in Europe but is infrequently used in the United States, where the condition is called just *Turner syndrome* (see Chapter 99.4). The syndrome is defined as the combination of the characteristic phenotypic features accompanied by a complete or partial absence of the second X chromosome with or without mosaicism.

Pathogenesis

Half the patients with Turner syndrome have a 45,X chromosomal complement. Approximately 15% of patients are mosaics for 45,X and a normal cell line (45,X/46,XX). Other mosaics with isochromosomes, 45,X/46,X,i(Xq); with rings, 45,X/46,X,r(X); or with fragments, 45,X/46fra, occur less often. Mosaicism is commonly detected when more than one tissue is examined. The single X chromosome is of maternal origin in nearly 80% of 45,X patients. The mechanism of chromosome loss is unknown, and the risk for the syndrome does not increase with maternal age. The genes involved in the Turner phenotype are X-linked genes that escape inactivation. A major locus involved in the control of linear growth has been mapped within the pseudoautosomal region of the X chromosome (PAR1). *SHOX,* a homeobox-containing gene of 170 kb of DNA within the PAR1, is thought to be important for controlling growth in children with Turner syndrome, with Leri-Weill syndrome, and, rarely, patients with idiopathic short stature. Genes for the control of normal ovarian function are postulated to be on Xp and perhaps two supergenes on Xq.

Turner syndrome occurs in approximately 1 in 1,500-2,500 liveborn females. The frequency of the 45,X karyotype at *conception* is approximately 3%. However, 99% of these are spontaneously aborted, accounting for 5–10% of all abortuses. Mosaicism (45,X/46,XX) occurs in a proportion higher than that seen with any other aneuploid state, but the mosaic Turner constitution is rare among the abortuses; these findings indicate preferential survival for mosaic forms.

The normal fetal ovary contains approximately 7 million oocytes, but these begin to disappear rapidly after the fifth month of gestation. At birth, there are only 2 million (1 million active follicles); by menarche, there are 400,000-500,000; and at menopause, 10,000 remain. In the absence of one X chromosome, this process is accelerated, and nearly all oocytes are gone by 2 years of age. In aborted 45,X fetuses, the number of primordial germ cells in the gonadal ridge appears to be normal, suggesting that the normal process of oocyte loss is accelerated in patients with Turner syndrome. Eventually, the ovaries are described as streaks and consist only of connective tissue, with very few germ cells present.

Clinical Manifestations

Many patients with Turner syndrome are recognizable at birth because of a characteristic edema of the dorsa of the hands and feet and loose skinfolds at the nape of the neck. Low birthweight and decreased birth length are common (see Chapter 99.4). Clinical manifestations in childhood include webbing of the neck, a low posterior hairline, small mandible, prominent ears, epicanthal folds, high arched palate, a broad chest presenting the illusion of widely spaced nipples, cubitus valgus, and hyperconvex fingernails. The diagnosis is often first suspected at puberty when breast development fails to occur.

Short stature, the cardinal finding in virtually all females with Turner syndrome, may be present with few other clinical manifestations. The linear growth deceleration begins in infancy and early childhood, gets progressively more pronounced in later childhood and adolescence,

Table 626.1 Etiologic Classification of Ovarian Hypofunction

HYPOGONADOTROPIC HYPOGONADISM

Hypothalamic

Genetic defects
- Kallmann syndrome: *KAL1, FGFR1, FGF8, PROK2, PROKR2, CHD7, WDR11, NELF, SEMA3A*
- Other gene defects: leptin, leptin receptor, KISS-1 (deficiency of kisspeptin), *DAX-1, TAC3* (deficiency of neurokinin B), *TACR3, SEMA7A*
- Inherited syndromes: Prader-Willi, Bardet-Biedl, and others
- Marked constitutional growth delay

Acquired defects (reversible)
- Anorexia nervosa
- Drug use
- Malnutrition
- Chronic illness, especially Crohn disease
- Hyperprolactinemia

Pituitary

Genetic defects
- Isolated gonadotropin deficiency (GnRH receptor, FSH, and LH β-subunit)
- Septo-optic dysplasia (*HESX-1* defect in some cases)
- Disorders of pituitary organogenesis (*PROP1, LHX3, LHX4, SOX-3*)

Acquired defects
- Hyperprolactinemia
- Pituitary tumors
- Pituitary infarction
- Infiltrative disorders (histiocytosis, sarcoidosis)
- Hemosiderosis and hemochromatosis
- Radiation

HYPERGONADOTROPIC HYPOGONADISM

Genetic
- Follicle-stimulating hormone and luteinizing hormone resistance
- Pathogenic variants in steroidogenic pathways
- 46,XX gonadal dysgenesis
- Turner syndrome and its variants
- Noonan syndrome (RASopathy genes)
- *SF-1* pathogenic variants
- Galactosemia
- Fragile X–associated disorders
- Bloom syndrome
- Werner syndrome
- Ataxia-telangiectasia
- Fanconi anemia

Acquired
- Chemotherapy
- Radiation
- Autoimmune ovarian failure from autoimmune polyendocrine syndromes 1 and 2

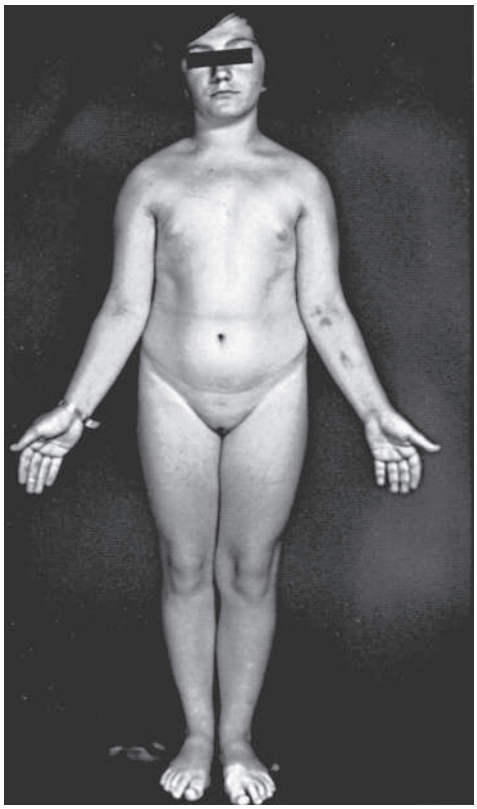

Fig. 626.1 Turner syndrome in a 15-yr-old female exhibiting failure of sexual maturation, short stature, cubitus valgus, and a goiter. There is no webbing of the neck. Karyotyping revealed 45,X/46,XX chromosome complement.

and results in significant adult short stature. Sexual maturation (breast development) fails to occur at the expected age; however, signs of adrenarche (pubic hair) are normally present. Among untreated patients with Turner syndrome, the mean adult height is 143-144 cm in the United States and most of Northern Europe, but 140 cm in Argentina and 147 cm in Scandinavia (Fig. 626.1). The height is well correlated with the midparental height (average of the parents' heights adjusted for child's sex). Specific growth curves for height have been developed for females with Turner syndrome.

Associated **cardiac defects** are common. In females with Turner syndrome, life-threatening consequences of X chromosome haploinsufficiency involve the cardiovascular system. There is a four- to fivefold increase in the rate of premature mortality secondary to congenital heart disease and premature coronary heart disease in adults with Turner syndrome. Clinically silent cardiac defects, mainly bicuspid aortic valve, are present in patients with Turner syndrome. Regardless of age, all patients with Turner syndrome need comprehensive cardiovascular evaluation by a cardiologist specializing in congenital heart disease at the time of diagnosis. Complete cardiologic evaluation, including echocardiography, reveals isolated nonstenotic bicuspid aortic valves in one third to half of the patients. In later life, bicuspid aortic valve disease can progress to dilation of the aortic root or aortic dissection. Less frequent defects include aortic coarctation (20%), aortic stenosis, mitral valve prolapse, and anomalous pulmonary venous drainage. In one study, 38% of patients with 45,X chromosomes had cardiovascular malformations compared with 11% of those with mosaic monosomy X; the most common were aortic valve abnormalities and aortic coarctation. Webbed neck in patients with or without recognized chromosome syndromes is associated with both flow-related and non–flow-related heart defects. Among patients with Turner syndrome, those with webbed necks have a much greater chance of having coarctation of the aorta than do those without webbed necks. Transthoracic echocardiogram in young females is adequate if cardiac anatomy is clearly seen; otherwise, magnetic resonance angiographic screening studies should be considered in asymptomatic individuals with Turner syndrome. During adolescence, and certainly before pregnancy (when possible) is contemplated, repeat cardiac evaluation should be considered even in those without prior findings of cardiac abnormalities. Blood pressure should be routinely monitored even in the absence of cardiac or renal lesions, especially in those with suggestions of aortic root dilation. Cardiac MRI is a valuable tool to detect and monitor aortic root dilation.

Renal ultrasound should be performed in all females with Turner syndrome at diagnosis. One fourth to one third of patients have **renal malformations** on ultrasonographic examination (50% of those with 45,X karyotypes). The more serious defects include pelvic kidney, horseshoe kidney, double collecting system, the complete absence of one kidney, and ureteropelvic junction obstruction. Some of the malformations may increase the risk of hypertension and urinary tract

infection. Idiopathic hypertension is also common. Females with Turner syndrome who had normal baseline renal ultrasound findings did not develop the renal disease during a follow-up period averaging 6 years.

When the ovaries are examined by ultrasonography, there are no age-related differences in detecting ovarian tissue; 27–46% of patients have detectable ovaries at various ages; 76% of those with X mosaicism and 26% of those with 45,X karyotypes have detectable ovaries.

Sexual maturation usually fails to occur, but 10–20% of females have spontaneous breast development, and a small percentage may have menstrual periods. Primary gonadal failure is associated with early onset of adrenarche (elevation in dehydroepiandrosterone sulfate) but delayed pubarche (pubic hair development). Spontaneous pregnancies have been reported in menstruating patients with Turner syndrome. Premature menopause, increased risk of miscarriage, and offspring with increased risk of trisomy 21 have been reported. A woman with a 45,X/46,X,r(X) karyotype treated with hormone replacement therapy had three pregnancies, resulting in a normal 46,XY male infant, a spontaneous abortion, and a healthy term female with Turner syndrome 45,X/46,Xr(X).

Antithyroid antibodies (thyroid peroxidase and/or thyroglobulin antibodies) occur in 30–50% of patients. The prevalence increases with advancing age. **Autoimmune thyroid disease**, with or without a goiter, occurs in 10–30% of patients. Age-dependent abnormalities in carbohydrate metabolism characterized by abnormal glucose tolerance and insulin resistance and, only rarely, frank type 2 diabetes occur in older patients with Turner syndrome. Impaired insulin secretion has been described in 45,X women. Cholesterol levels are elevated in adolescence, regardless of body mass index or karyotype.

Inflammatory bowel disease (both Crohn disease and ulcerative colitis), gastrointestinal bleeding because of abnormal mesenteric vasculature, and delayed gastric emptying time have all been reported. Screening for celiac disease is recommended because the risk of celiac disease is increased in Turner syndrome, with 4–6% of individuals affected. Although autoimmune diseases have been associated with Turner syndrome, the prevalence of type 1 diabetes with Turner syndrome is not very high.

Chronic liver disease may develop in adults with Turner syndrome. Its pathogenesis is poorly defined.

Sternal malformations can be detected by lateral chest radiography. An increased carrying angle at the elbow is usually not clinically significant. Scoliosis occurs in approximately 10% of adolescent females. Congenital hip dysplasia occurs more commonly than in the general population. Reported eye findings include anterior segment dysgenesis and keratoconus. Pigmented nevi become more prominent with age; melanocytic nevi are common. Essential hyperhidrosis, torus mandibularis, and alopecia areata occur rarely.

Recurrent bilateral otitis media develops in approximately 75% of patients. Sensorineural hearing deficits are common, and the frequency increases with age. Problems with gross and fine motor sensory integration, failure to walk before 15 months of age, and early language dysfunction often raise questions about developmental delay, but intelligence is normal in most patients. However, cognitive impairment does occur in patients with 45,X/46,X,r(X); the ring chromosome is unable to undergo inactivation and leads to two functional X chromosomes.

Special attention should be given to psychosocial development in females with Turner syndrome. In general, behavior is normal in females with Turner syndrome, but they are at an increased risk for social isolation, immaturity, and anxiety. Other conditions, such as dyslexia, nonverbal learning disability, and attention-deficit disorder, have been reported in females with Turner syndrome. In adults, deficits in perceptual spatial skills are more common than they are in the general population. Some unconfirmed data suggest the existence of an imprinted X-linked locus that affects cognitive function such as verbal and higher-order executive function skills. These functions are apparently better when the X is paternal in origin.

The prevalence of mosaicism depends in large part on the techniques used for studying chromosomal patterns. The use of fluorescent in situ hybridization and reverse transcription–polymerase chain reaction (PCR) has increased the reported prevalence of mosaic patterns to as high as 60–74%.

Mosaicism involving the Y chromosome occurs in 5%. A population study using PCR with five different primer sets found Y chromosome material in 12.2%. **Gonadoblastoma** among Y-positive patients occurred in 7–10%. Therefore the recommendation is that prophylactic gonadectomy be performed even in the absence of MRI or CT evidence of tumors. The recommended timing of this procedure is at the time of diagnosis, but this may need to be reevaluated in the future. The gonadoblastoma locus on the Y chromosome (GBY) maps close to the Y centromere. The presence of only the SRY (sex-determining region on the Y chromosome) locus is not sufficient to confer increased susceptibility for the development of gonadoblastoma. Routine PCR for Y chromosome detection for the purpose of assigning gonadoblastoma risk is not indicated. High-throughput quantitative genotyping may provide an effective and inexpensive method for the identification of X chromosome abnormalities and Y chromosome material identification.

In patients with 45,X/46,XX mosaicism, the clinical abnormalities are attenuated and fewer; short stature is as frequent as it is in the 45,X patient and may be the only manifestation of the condition other than ovarian failure (see Fig. 626.1).

Laboratory Findings

Chromosomal analysis must be considered routinely in females who have unexpected short stature based on parental heights. Turner syndrome is detected in ~5% of females referred to an endocrinology service because of short stature. Patients with a marker chromosome in some or all cells should be tested for DNA sequences at or near the centromere of the Y chromosome for GBY.

Ultrasonography of the heart, kidneys, and ovaries is indicated after the diagnosis is established. The most common skeletal abnormalities are shortening of the fourth metatarsal and metacarpal bones, epiphyseal dysgenesis in the joints of the knees and elbows, Madelung deformity, scoliosis, and, in older patients, inadequate osseous mineralization.

Plasma levels of gonadotropins, particularly follicle-stimulating hormone (FSH), are markedly elevated to greater than those of age-matched controls during infancy; at 2-3 years of age, a progressive decrease in levels occurs until they reach a nadir at 6-8 years of age, and by 10-11 years of age, they rise to adult agonadal levels.

Thyroid peroxidase antibodies should be checked to detect autoimmune thyroiditis if the thyroid-stimulating hormone (TSH) level is abnormal. Annual or biannual TSH levels are recommended. Females with Turner syndrome should be screened for celiac disease by measuring tissue transglutaminase immunoglobulin A antibodies. Initial testing should be done around age 4 years and repeated every 2-5 years. Extensive studies have failed to establish that growth hormone deficiency plays a primary role in the pathogenesis of the growth disorder. Defects in normal secretory patterns of growth hormone are seen in adolescents because of a lack of gonadal steroids, but not in younger females with Turner syndrome.

Treatment

Treatment with recombinant human growth hormone increases height velocity and ultimate stature in most, but not all, children with Turner syndrome. Many females achieve heights of greater than 150 cm with early initiation of treatment. In one clinical trial, 99 patients with Turner syndrome who started receiving growth hormone at a mean age of 10.9 years at doses between 0.27 and 0.36 mg/kg/wk achieved a mean height of 149 cm, with nearly one third reaching heights greater than 152.4 cm (60 in). In the Netherlands, higher doses of growth hormone (up to 0.63 mg/kg/wk in the third year of treatment) resulted in 85% of the subjects reaching adult heights in the normal range for the Dutch reference population. Growth hormone treatment should be initiated in early childhood and/or when there is evidence of height velocity attenuation on specific Turner syndrome growth curves. Growth hormone therapy does not significantly aggravate carbohydrate tolerance and does not result in marked adverse events in patients with Turner syndrome. Serum levels of insulin-like growth factor 1 should be monitored if the patient is receiving high doses of growth hormone. If the insulin-like growth

factor 1 levels are significantly elevated, the dose of growth hormone may need to be reduced. Treatment with growth hormone can cause excessive growth of the hands and feet in some females with Turner syndrome.

Oxandrolone has also been used to treat the short stature associated with Turner syndrome, either alone or in combination with growth hormone. This nonaromatizable synthetic anabolic steroid has weak androgenic effects, and patients should be monitored for signs of pubarche and hepatotoxicity. The latter is rare.

Replacement therapy with estrogens is indicated, but there is variation among pediatric endocrinologists about the optimal age at which to initiate treatment. The psychologic preparedness of the patient to accept therapy must be considered. The improved growth achieved by females treated with growth hormone in childhood permits initiation of estrogen replacement at 12-13 years. Delaying estrogen therapy to optimize height potential until 15 years of age, as previously recommended, seems unwarranted. This change to starting earlier estrogen therapy was considered because of the psychologic importance of age-appropriate pubertal maturation. In addition, delaying estrogen therapy could be deleterious for bone health and potentially other aspects of the child's health. Low-dose estrogen replacement at 12 years of age permits a normal pace of puberty without interfering with the positive effect of growth hormone on the final adult height. Estrogen therapy improves verbal and nonverbal memory in females with Turner syndrome. In young women with age-appropriate pubertal development who achieve normal height, health-related quality-of-life questionnaires have yielded normal results.

Many forms of estrogen are available. Oral estrogens had been mostly used in the past. Transdermal patches are increasing in popularity. This is because transdermal patches bypass the first-pass hepatic metabolism, requiring only a small amount of estrogen to attain adequate function. Many treatment protocols have been developed, and several are as follows. For oral preparations, a conjugated estrogen (Premarin), 0.15-0.625 mg daily, or micronized estradiol (Estrace), 0.5 mg given daily for 3-6 months, is usually effective in inducing puberty. The recommendations for transdermal patch therapy are 6.25 μg daily, gradually increased over 2 years to the adult dose of 100-200 μg daily. The estrogen may be cycled (taken on days 1-23) or not. A progestin (Provera) is added (taken on days 10-23) in a dose of 5-10 mg daily. In the week after the progestin, withdrawal bleeding usually occurs. Combination oral contraceptive pills may also be used for hormone replacement therapy.

Prenatal chromosome analysis for advanced maternal age has revealed a frequency of 45,X/46,XX that is 10 times higher than when diagnosed postnatally. Most of these patients have no clinical manifestations of Turner syndrome, and levels of gonadotropins are normal. Awareness of this mild phenotype is important in counseling patients.

Psychosocial support for these females is an integral component of treatment. A comprehensive psychologic education evaluation is recommended either at the time of Turner syndrome diagnosis, depending on the patient's age, when any of the components of behavior or cognition become obvious, or immediately preceding school entry. In addition to the healthcare team, the Turner Syndrome Society, which has local chapters in the United States and similar groups in Canada and other countries, provides a valuable support system for these patients and their families.

Successful pregnancies have been carried to term using ovum donation and in vitro fertilization. Adolescents with few signs of spontaneous puberty may have ovaries with follicles. There remains a future possibility of using cryopreserved ovarian tissue with immature oocytes before the regression of the ovaries for future pregnancies. In adult women with Turner syndrome, there seems to be a high prevalence of undiagnosed bone mineral density, lipid, and thyroid abnormalities. Glucose intolerance diminished first-phase insulin response, elevated blood pressure, and lowered fat-free mass are common. Glucose tolerance worsens, but fat-free mass and blood pressure and general physical fitness improve with sex hormone replacement. The neurocognitive profile of adult women is unaffected by estrogen status.

XX GONADAL DYSGENESIS

Some phenotypically and genetically normal females have gonadal lesions identical to those in 45,X patients but without somatic features of Turner syndrome; their condition is termed **pure gonadal dysgenesis** or pure **ovarian dysgenesis**.

The disorder is rarely recognized in prepubertal children because the external genitals are normal, no other abnormalities are visible, and growth is normal. At pubertal age, sexual maturation fails to take place. Plasma gonadotropin levels are elevated. Delay of epiphyseal fusion may result in a *eunuchoid* habitus. Pelvic ultrasonography reveals streak ovaries.

Affected siblings, parental consanguinity, and failure to uncover mosaicism suggest female-limited autosomal recessive inheritance. The disorder appears to be especially frequent in Finland (1 in 8,300 liveborn females). In this population, several pathogenic variants in the FSH receptor gene (on chromosome 2p) are demonstrated as the cause of the condition. In contrast, FSH receptor gene variants are not detected in Mexican women with 46,XX gonadal dysgenesis. In some patients, XX gonadal dysgenesis has been associated with sensorineural deafness (**Perrault syndrome**). A patient with this condition and concomitant growth hormone deficiency and virilization has also been reported. There may be distinct genetic forms of this disorder. **Müllerian agenesis**, or **Mayer-Rokitansky-Küster-Hauser** syndrome, which is second to gonadal dysgenesis as the most common cause of primary amenorrhea, occurring in 1 in 4,000-5,000 females, has been reported in association with 46,XX gonadal dysgenesis in a 17-year-old adolescent with primary amenorrhea and lack of breast development. One case of dysgerminoma with syncytiotrophoblastic giant cells was reported. An 18-year-old woman with primary amenorrhea and an absence of müllerian-derived structures, unilateral renal agenesis, and clinical signs of androgen excess—a phenotype resembling Mayer-Rokitansky-Küster-Hauser syndrome—was found to have a loss-of-function variant in *WNT4*. Treatment consists of estrogen replacement therapy.

45,X/46,XY GONADAL DYSGENESIS

45,X/46,XY gonadal dysgenesis, also called **mixed gonadal dysgenesis**, has extreme postnatal phenotypic variability that may extend from a Turner-like syndrome to a male phenotype with a penile urethra; it is possible to delineate three major clinical phenotypes. Short stature is a major finding in all affected children. Ninety percent of prenatally diagnosed cases have a normal male phenotype.

Some patients have no evidence of virilization; they have a female phenotype and often have the somatic signs of Turner syndrome. The condition is discovered prepubertally when chromosomal studies are made in short females or later when chromosomal studies are made because of failure of sexual maturation. Fallopian tubes and uterus are present. The gonads consist of intraabdominal undifferentiated streaks; chromosomal study of the streak often reveals an XY cell line. The streak gonad differs somewhat from that in females with Turner syndrome; in addition to wavy connective tissue, there are often tubular or cordlike structures, occasional clumps of granulosa cells, and, frequently, mesonephric or hilar cells.

Some children have mild virilization manifested only by prepubertal clitoromegaly. Normal müllerian structures are present, but at puberty virilization occurs. These patients usually have an intraabdominal testis, a contralateral streak gonad, and bilateral fallopian tubes.

Many 45,X/46,XY children present with frank ambiguity of the genitals in infancy (Fig. 626.2). A testis and vas deferens are found on one side in the labioscrotal fold, and a streak gonad is identified on the contralateral side. Despite the presence of a testis, fallopian tubes are often present bilaterally. An infantile or rudimentary uterus is often present.

Other genotypes and phenotypes have been described in mixed gonadal dysgenesis. Approximately 25% of 200 analyzed patients have a dicentric Y chromosome (45,X/46,X,dic Y). In some patients the Y chromosome may be represented by only a fragment (45,X/45,X +fra); application of Y-specific probes can establish the origin of the fragment. It is unclear why the same genotype (45,X/46,XY) can result in

Fig. 626.2 A 45,X/46XY neonate with sex chromosome disorder of sex development was noted at birth to have male-appearing external genitalia with a phallus measured at 2.5 × 1.2 cm and penoscrotal hypospadias. The left gonad was palpable in an incompletely fused scrotum, whereas the right gonad was not palpable. Gonadal biopsy revealed a testis on the left side and streak gonad on the right. The diagnosis was mixed gonadal dysgenesis. *(From Remeithi SA, Wherret DK. Disorders of sexual development. In: Martin RJ, Fanaroff AA, Walsh MC, eds. Fanaroff and Martin's Neonatal-Perinatal Medicine, 10th ed. Philadelphia: Elsevier; 2015: Fig. 98–13)*

diverse phenotypes. Pathogenic variants in *SRY* have been described in some patients.

Children with a female phenotype present no problem in gender of rearing. Patients who are only slightly virilized are usually assigned a female gender of rearing before a diagnosis is established. Patients with ambiguity of the genitals are often clinically indistinguishable from patients with various types of 46,XY disorders of sex development (46,XY DSD). In some instances, there may need to be careful consideration regarding gender of rearing. Factors that may influence this decision include short stature, the need for surgical genital reconstruction, the presence of müllerian structures, and the need for gonadectomy because of predisposition of the gonad to the development of malignancy. In some patients followed to adulthood, the putative normal testis proves to be dysgenetic with eventual loss of Leydig and Sertoli cell function (see Chapter 623). In an analysis of 22 patients with mixed gonadal dysgenesis, no significant associations or correlations were found between internal and external phenotypes or endocrine function and gonadal morphologic features. The appearance of the external genitalia determined the gender of rearing. In 11 patients, basal and human chorionic gonadotropin–stimulated testosterone levels were lower than in control subjects.

Gonadal tumors, usually **gonadoblastomas**, occur in approximately 25% of these children. A gonadoblastoma locus has been localized to a region near the centromere of the Y chromosome (GBY). These germ cell tumors are preceded by the changes of carcinoma in situ. Accordingly, both gonads should be removed in all patients reared as females, and the undifferentiated gonad should be removed in the patients reared as males.

There is no correlation among the proportion of 45,X/46,XY cell lines in either blood or fibroblasts with the phenotype. In the past, all patients came to clinical attention because of their abnormal phenotypes. However, 45,X/46,XY mosaicism is found in approximately 7% of fetuses, with true chromosome mosaicism encountered prenatally. Of 76 infants with 45,X/46,XY mosaicism diagnosed prenatally, 72 had a normal male phenotype, 1 had a female phenotype, and only 3 males had hypospadias. Of 12 males whose gonads were examined, only 3 were abnormal. These data must be considered when counseling a family in which a 45,X/46,XY infant is discovered prenatally.

XXX, XXXX, AND XXXXX FEMALES

XXX Females

The 47,XXX (trisomy) chromosomal constitution is the most frequent extra X chromosome abnormality in females, occurring in almost 1 in 1,000 liveborn females. In 68%, this condition is caused by maternal meiotic nondisjunction, but paternal sex chromosome errors cause most 45,X and half of 47,XXY constitutions. The phenotype is that of a normal female; affected infants and children are not recognized based on the genital appearance.

Sexual development and menarche are normal. Most pregnancies have resulted in normal infants. By 2 years of age, delays in speech and language become evident, and some see a lack of coordination, poor academic performance, and immature behavior. These females tend to be tall, manifest behavior disorders, and often require special education classes. Using high-resolution MRI, 47,XXX subjects have lower amygdala volumes than euploid controls; 47,XXY subjects had even lower amygdala volumes. In a review of 155 females, 62% were physically normal. There is marked variability within the syndrome, and a small proportion of affected females are well coordinated, socially outgoing, and academically superior.

XXXX and XXXXX Females

The great majority of females with these rare karyotypes have intellectual disabilities. Commonly associated defects are epicanthal folds, hypertelorism, clinodactyly, transverse palmar creases, radioulnar synostosis, and congenital heart disease. Sexual maturation is often incomplete and may not occur at all. Nevertheless, three women with tetra-X syndrome gave birth, but no pregnancies were reported in 49,XXXXX women. Most 48,XXXX women tend to be tall, with an average height of 169 cm, whereas short stature is a common feature of the 49,XXXXX phenotype.

NOONAN SYNDROME

Females with Noonan syndrome show certain anomalies also seen in females with 45,X Turner syndrome, but they have normal 46,XX chromosomes (see Chapter 101.1). The most common abnormalities are the same as those described for males with Noonan syndrome (see Chapter 623). Short stature is one of the cardinal signs of this syndrome. The phenotype differs from Turner syndrome in several respects. Cognitive impairment is often present, the cardiac defect is most often pulmonary valvular stenosis or an atrial septal defect rather than an aortic defect, normal sexual maturation usually occurs but is delayed by 2 years on average, and POF has been reported. The FDA approves growth hormone therapy for use in Noonan syndrome patients with short stature.

OTHER OVARIAN DEFECTS

Some young women with no chromosomal abnormalities are found to have streak gonads that may contain only occasional or no germ cells. Gonadotropins are increased. Cytotoxic drugs, especially alkylating agents such as cyclophosphamide and busulfan, procarbazine, etoposide, and exposure of the ovaries to irradiation for the treatment of malignancy are frequent causes of ovarian failure. Young women with Hodgkin disease demonstrate that combination chemotherapy and pelvic irradiation may be more deleterious than either therapy alone. Teenagers are more likely than older women to retain or recover ovarian function after irradiation or combined chemotherapy; normal pregnancies have occurred after such treatment. Treatment regimens may result in some ovarian damage in most females treated for cancer. The median lethal dose for the human oocyte is estimated to be approximately 4 Gy; doses as low as 6 Gy have produced primary amenorrhea. Ovarian transposition before abdominal and pelvic irradiation

in childhood can preserve ovarian function by decreasing the ovarian exposure to less than 4-7 Gy.

Autoimmune ovarian failure occurs in 60% of children older than 13 years of age with type I autoimmune polyendocrinopathy (Addison disease, hypoparathyroidism, mucocutaneous candidiasis). This condition, also known as *polyglandular autoimmune disease type 1,* is rare worldwide but not in Finland, where, as a result of a founder gene effect, it occurs in 1 in 25,000 people. Affected females may not develop sexually; secondary amenorrhea may occur in young women. The ovaries may have lymphocytic infiltration or appear simply as streaks. Most affected patients have circulating steroid cell antibodies and autoantibodies to 21-hydroxylase. Among patients with polyglandular autoimmune syndromes, 5% have hypogonadism.

The condition also occurs in young women as an isolated event or in association with other autoimmune disorders, leading to secondary amenorrhea (POF). It occurs in 0.2–0.9% of women younger than 40 years of age. POF is a heterogeneous disorder with many causes: chromosomal, genetic, enzymatic, infectious, and iatrogenic. When associated with autoimmune adrenal disease, steroid cell autoantibodies are usually present. These antibodies react with P450scc, 17α-OH, or 21-OH enzymes. Steroid cell autoantibodies are rarely found when associated with an entire host of endocrine and nonendocrine autoimmune diseases and not adrenal autoimmunity. A second autoimmune disorder, often subclinical, is found in 10–39% of adult patients with POF, including autoimmune thyroid disease, type 1 diabetes, systemic lupus erythematosus (SLE), inflammatory bowel disease, immune thrombocytopenia or hemolytic anemia, celiac disease, myasthenia gravis, and rheumatoid arthritis. One 17-year-old with idiopathic thrombocytopenic purpura and 47,XXX chromosomes had autoimmune POF. Patients with POF do not have the neurocognitive defects found in Turner syndrome patients.

Galactosemia, particularly the classical form of the disease, usually results in ovarian damage, beginning during intrauterine life. Levels of FSH and luteinizing hormone (LH) are elevated early in life. Ovarian damage may be caused by deficient uridine diphosphate-galactose (see Chapter 107.2). **Denys-Drash syndrome** caused by a *WT1* pathogenic variant can result in ovarian dysgenesis.

Ataxia-telangiectasia may be associated with ovarian hypoplasia and elevated gonadotropins; the cause is unknown. Gonadoblastomas and dysgerminomas have occurred in a few females.

Hypergonadotropic hypogonadism occurs as a result of resistance of the ovary to both endogenous and exogenous gonadotropins **(Savage syndrome)**. This condition also occurs in women with POF. Antiovarian antibodies or FSH receptor abnormalities may cause this condition. The FSH receptor gene variants have been reported as an autosomal recessive condition (see Chapter 622). A few females with 46,XX chromosomes presenting in primary amenorrhea with elevated gonadotropin levels were found to have inactivating variants of the LH receptor gene. This suggests that LH action is needed for normal follicular development and ovulation. Other genetic defects associated with ovarian failure include pathogenic variants in *SF-1, FOXL2, GNAS, CYP17,* and *CYP19.*

626.2 Hypogonadotropic Hypogonadism in the Female (Secondary Hypogonadism)

Alvina R. Kansra and Patricia A. Donohoue

Hypofunction of the ovaries can result from failure to secrete normal pulses of the gonadotropins LH and FSH. Hypogonadotropic hypogonadism (HH) may occur if the hypothalamic-pituitary-gonadal axis is interrupted either at the hypothalamic or pituitary level. The mechanisms that result in HH include failure of the hypothalamic LH–releasing hormone (also known as *gonadotropin-releasing hormone*) pulse generator or inability of the pituitary to respond with secretion of LH and FSH. It is often difficult to distinguish between marked constitutional delay and HH.

HYPOPITUITARISM

Hypogonadotropic hypogonadism is most commonly seen with multiple pituitary hormone deficiencies resulting from malformations (e.g., septo-optic dysplasia, other midline defects), pituitary transcription factor defects such as in PROP-1, or lesions of the pituitary that are acquired postnatally. Familial isolated gonadotropin deficiency associated with anosmia (Kallmann syndrome) may occur in females. Many other genetic causes for HH have been identified. A gene important in LH-releasing hormone secretion is named *KISS* (encoding the protein kisspeptin), which is suggested to play a significant role in the development of the LH-releasing hormone–secreting cells. Another set of genes implicated in HH are the genes for neurokinin B *(TAC3)* and its receptor *(TAC3R).*

In children with idiopathic hypopituitarism, the defect is usually found in the hypothalamus. In these patients, administration of gonadotropin-releasing hormone results in increased plasma levels of FSH and LH, establishing the integrity of the pituitary gland.

Hypogonadotropic hypogonadism is less common than hypergonadotropic hypogonadism. Ovarian function may be abnormal when associated with LH excess, a condition known as *polycystic ovarian syndrome* (polycystic ovary syndrome; see Chapter 589).

Isolated Deficiency of Gonadotropins

This heterogeneous group of disorders is evaluated more fully with the use of the gonadotropin-releasing hormone analog stimulation test rather than a single measurement of gonadotropin levels. In most children the pituitary gland is normal, and the defect causing gonadotropin deficiency resides in the hypothalamus. Patients with **hyperprolactinemia**, most often caused by a pituitary prolactin-secreting adenoma, often have suppression of gonadotropin secretion. If breast development has occurred, then galactorrhea and amenorrhea are frequently seen.

Several sporadic instances of anosmia with hypogonadotropic hypogonadism have been reported. **Anosmic** hypogonadal females have also been reported in kindreds with Kallmann syndrome, but hypogonadism more frequently affects the males in these families. Pathogenic variants in the gene for the β-subunit of FSH and LH have been reported.

Some autosomal recessive disorders, such as Laurence-Moon-Biedl, multiple lentigines, and Carpenter syndromes, appear in some instances to include gonadotropic hormone deficiency. Patients with Prader-Willi syndrome usually have some degree of HH. Females with severe thalassemia may have gonadotropin deficiency from pituitary damage caused by chronic iron overload secondary to multiple transfusions. Anorexia nervosa frequently results in HH. The rare patients described with leptin deficiency or leptin receptor defects have failure of pubertal maturation because of gonadotropin deficiency.

DIAGNOSIS

The diagnosis may be apparent in patients with other deficiencies of pituitary tropic hormones, but, as in males, it is difficult to differentiate isolated hypogonadotropic hypogonadism from physiologic delay of puberty. Repeated measurements of FSH and LH, particularly during sleep, may reveal the rising levels that herald the onset of puberty. Stimulation testing with gonadotropin-releasing hormone analog may help to establish the diagnosis. Morbidity for both men and women with hypogonadism includes infertility and an increased risk of osteoporosis.

Chapter 627

Pseudoprecocity Resulting from Lesions of the Ovary

Alvina R. Kansra and Patricia A. Donohoue

Females with signs of early puberty may, in rare circumstances, have ovarian tumors or cysts that secrete estrogenic, androgenic, or both types of hormones. In these patients, the sex steroid production is not mediated by pituitary gonadotropin secretion; they produce pseudoprecocity.

Ovarian tumors are rare in the pediatric population, occurring at a rate of fewer than 3 in 100,000. Most ovarian masses are benign, but 10–30% may be malignant. If they occur before 8 years of age, they may cause signs of puberty. Ovarian malignancies, the most common genital neoplasms in adolescence, account for only 1% of childhood cancers. More than 60% are germ cell tumors, which are dysgerminomas that can secrete tumor markers and sex hormones (see Chapter 552). Five to 10% of germ cell tumors occur in phenotypic females, with abnormal gonads associated with the presence of a Y chromosome. The next most common are epithelial cell tumors (20%), and nearly 10% are sex cord/stromal tumors (granulosa, Sertoli cell, and mesenchymal tumors). Multiple tumor markers can be seen in ovarian tumors, including α-fetoprotein, human chorionic gonadotropin, carcinoembryonic antigen, oncoproteins, p105, p53, *KRAS* pathogenic variants, cyclin D_1, epidermal growth factor–related proteins and receptors, cathepsin B, and others. Variable levels of inhibin-activin subunit gene expression have been detected in ovarian tumors.

Functioning lesions of the ovary consist of benign cysts or malignant tumors. The majority synthesize estrogens; a few synthesize androgens. The most common estrogen-producing ovarian tumor causing precocious puberty is the granulosa cell tumor. Other tumors that can cause precocious puberty are thecomas, luteomas, mixed types, theca-lutein, follicular cysts, and other ovarian tumors (i.e., teratoma, choriocarcinoma, and dysgerminoma).

ESTROGENIC LESIONS OF THE OVARY

These lesions cause **isosexual** precocious sexual development but account for only a small percentage of all cases of precocity. Benign ovarian follicular cysts are the most common tumors associated with isosexual precocious puberty in females; they may rarely be gonadotropin dependent. Gonadotropin-independent follicular cysts that produce estrogen are often associated with **McCune-Albright syndrome**.

Juvenile Granulosa Cell Tumor

In childhood, the most common neoplasm of the ovary with estrogenic manifestations is the granulosa cell tumor, although it makes up only 1–10% of all ovarian tumors. These tumors have distinctive histologic features that differ from those encountered in older females (adult granulosa cell tumor). The cells have high mitotic activity, follicles are often irregular, Call-Exner bodies are rare, and luteinization is frequent. The tumor may be solid or cystic or both. It usually is benign. This tumor has been associated with multiple enchondromas **(Ollier disease)** and with multiple subcutaneous hemangiomas **(Maffucci syndrome)**.

Clinical Manifestations and Diagnosis

The juvenile granulosa cell tumor has been observed in newborns and may manifest with sexual precocity at 2 years of age or younger; about half these tumors occurred before 10 years of age. The mean age at diagnosis is 7.5 years. The tumors are almost always unilateral. The breasts become enlarged, rounded, and firm, and the nipples prominent. The external genitals resemble those of a normal girl at puberty, and the uterus is enlarged. A white vaginal discharge is followed by irregular or cyclic menstruation. However, ovulation does not occur. The presenting manifestation may be abdominal pain or swelling. Pubic hair is usually absent unless there is mild virilization.

A mass is readily palpable in the lower portion of the abdomen in most children by the time sexual precocity is evident. However, the tumor may be small and escape detection even on careful rectal and abdominal examination; ultrasonography may detect the tumors, but CT or MRI scans are most sensitive. Most tumors are diagnosed at very early stages of malignancy.

Plasma estradiol levels are markedly elevated. Plasma levels of gonadotropins are suppressed and do not respond to gonadotropin-releasing hormone analog stimulation. Levels of antimüllerian hormone, inhibin B, and α-fetoprotein may be elevated. Activating pathogenic variants of $G_S\alpha$ are seen in 30%, and GATA-4 expression is retained in the more aggressive tumors, whereas antimüllerian hormone levels are inversely proportional to tumor size. Bone age is moderately advanced. Several case reports showing the association of 45,X/46,XY karyotype and ambiguous genitalia with ovarian granulosa tumor have been published.

Treatment and Prognosis

The tumor should be removed as soon as the diagnosis is established. Prognosis is excellent because less than 5% of these tumors in children are malignant. However, advanced-stage tumors behave aggressively and require difficult decisions regarding surgical approaches and the use of irradiation and chemotherapy. In adults with granulosa cell tumors, p53 expression is associated with unfavorable prognosis. Vaginal bleeding immediately after removal of the tumor is common. Signs of precocious puberty abate and may disappear within a few months after the operation. The secretion of estrogens returns to normal.

Sex cord tumor with annular tubules is a distinctive tumor, thought to arise from granulosa cells, that occurs primarily in patients with **Peutz-Jeghers syndrome**. These tumors are multifocal, bilateral, and usually benign. The presence of calcifications aids ultrasonographic detection. Increased aromatase production by these tumors results in gonadotropin-independent precocious puberty. Inhibin A and B levels are elevated and decrease after tumor removal. In one study, 9 of 13 sex cord/stromal tumors exhibited follicle-stimulating hormone receptor pathogenic variants, suggesting a role for such mutation in the development of these tumors.

Chorioepithelioma has been reported only rarely. This highly malignant tumor is thought to arise from a preexisting teratoma. The usually unilateral tumor produces large amounts of human chorionic gonadotropin, which stimulates the contralateral ovary to secrete estrogen. Elevated levels of human chorionic gonadotropin are diagnostic.

Follicular Cyst

Small ovarian cysts (<0.7 cm in diameter) are common in prepubertal children. At puberty and in females with true isosexual precocious puberty, larger cysts (1-6 cm) are often seen; these are secondary to stimulation by gonadotropins. Similar larger cysts occur occasionally in young females with precocious puberty in the absence of luteinizing hormone and follicle-stimulating hormone. Surgical removal or spontaneous involution of these cysts results in regression of pubertal changes. The mechanism of production of these autonomously functioning cysts is unknown. Such cysts may form only once, or they may disappear and recur, resulting in waxing and waning of the signs of precocious puberty. They may be unilateral or bilateral. The sexual precocity that occurs in young females

with **McCune-Albright syndrome** is usually associated with autonomous follicular cysts caused by somatic-activating pathogenic variants of the $G_S\alpha$-protein occurring early in development (see Chapter 600.6). Gonadotropins are suppressed, and estradiol levels are often markedly elevated, but they may fluctuate widely and even temporarily may return to normal. Gonadotropin-releasing hormone analog stimulation fails to evoke an increase in gonadotropins. Ultrasonography is the method of choice for the detection and monitoring of such cysts. Aromatase inhibitors are shown to be the mainstay of therapy in females with McCune-Albright syndrome and persistent estradiol elevation. Estrogen receptor blockers have also been used. A short period of observation to ascertain the lack of spontaneous resolution is advisable before cyst aspiration or cystectomy is considered. Cystic neoplasms must be considered in the differential diagnosis.

ANDROGENIC LESIONS OF THE OVARY

Virilizing ovarian tumors are rare at all ages but particularly so in prepubertal females. **Arrhenoblastoma** has been reported as early as 14 days of age, but few cases have been reported in females younger than 16 years of age.

The **gonadoblastoma** occurs exclusively in dysgenetic gonads, particularly in phenotypic females who have a Y chromosome or a Y fragment in their genotype (46,XY; 45,X/46,XY; 45,X/46,X-fra). There is a gonadoblastoma locus on the Y chromosome (GBY). The tumors may be bilateral. Virilization occurs with some, but not all, tumors. The clinical features are the same as those seen in patients with virilizing adrenal tumors and include accelerated growth, acne, clitoral enlargement, and growth of sexual hair. A palpable, abdominal mass is found in about 50% of patients. Plasma levels of testosterone and androstenedione are elevated, and gonadotropins are suppressed. Ultrasonography, CT, and MRI usually localize the lesion. The dysgenetic gonad of phenotypic females with a Y chromosome or fragment of Y chromosome containing GBY should be removed prophylactically. *When a unilateral tumor is removed, the contralateral dysgenetic gonad should also be removed.* Association of gonadoblastoma and WAGR (Wilms tumor, aniridia, genitourinary anomalies, mental retardation) syndrome is also reported. In an immunohistochemical study of two gonadoblastomas, expressions of *WT1, p53,* and *MIS*, as well as inhibin, were all demonstrated.

Virilizing manifestations occur occasionally in females with **juvenile granulosa cell tumors**. Adrenal rests and hilum cell tumors rarely lead to virilization. Activating pathogenic variants of G protein genes have been described in ovarian (and testicular) tumors. $G_S\alpha$ variants, usually seen in gonadal tumors associated with **McCune-Albright syndrome**, were also noted in four of six Leydig cell tumors (three ovarian, one testicular). Two granulosa cell tumors and 1 thecoma of 10 ovarian tumors studied were found to have *GIP-2* variants.

Sertoli-Leydig cell tumors, rare sex cord/stromal neoplasms, constitute less than 1% of ovarian tumors. The average age at diagnosis is 25 years; less than 5% of these tumors occur before puberty. α-Fetoprotein levels may be mildly elevated. In one 12-month-old with Sertoli-Leydig cell tumor presenting with isosexual precocity, the only detectable tumor marker was the serum inhibin level, with elevations in both A and B subunits. Five-year survival rates are 70–90%.

Of 102 consecutive patients who underwent surgery because of ovarian masses over a 15-year period, the presenting symptoms were acute abdominal pain in 56% and abdominal or pelvic mass in 22%. Of nine children whose cause for surgery was presumed malignancy, three had dysgerminomas, two had teratomas, two had juvenile granulosa cell tumors, one had a Sertoli-Leydig cell tumor, and one had a yolk sac tumor.

Chapter 628

Disorders of Sex Development

Patricia A. Donohoue

SEX DIFFERENTIATION

See also Chapter 622.

Differentiation and development of the gonads and genitalia are largely complete in the first half of gestation. In normal differentiation, the final form of all sexual structures is consistent with normal sex chromosomes (either XX or XY). A 46,XX complement of chromosomes, as well a genetic factors such as DAX1 (dosage-sensitive/sex-reversal adrenal hypoplasia on the X chromosome), the signaling molecule WNT-4, and R-Spondin1, are among the many needed for the development of normal ovaries. Development of the male phenotype is potentially more complex. It requires a Y chromosome and, specifically, an intact *SRY* (sex-determining region on the Y chromosome) gene, which, in association with genes such as *SOX9, SF-1* (steroidogenic factor-1), *WT1* (Wilms tumor 1), and others (see Chapter 622), directs the undifferentiated gonad to become a testis. Aberrant recombinations may result in X chromosomes carrying *SRY,* resulting in XX males, or Y chromosomes that have lost *SRY,* resulting in XY females.

Antimüllerian hormone (AMH) causes the müllerian (paramesonephric) ducts to regress; in its absence, they persist as the uterus, fallopian tubes, cervix, and upper vagina. AMH activation in the testes probably requires the *SF-1* gene. By about 8 weeks of gestation, the Leydig cells of the testis begin to produce testosterone. During this critical period of male differentiation, testosterone secretion is stimulated by placental human chorionic gonadotropin (hCG), which peaks at 8-12 weeks. In the latter half of pregnancy, lower levels of testosterone are maintained by luteinizing hormone (LH) secreted by the fetal pituitary. Testosterone produced locally initiates development of the ipsilateral wolffian (mesonephric) duct into the epididymis, vas deferens, and seminal vesicle. Complete development of the external genitalia also requires dihydrotestosterone (DHT), the more active metabolite of testosterone. DHT is produced largely from circulating testosterone and is necessary to fuse the genital folds to form the penis and scrotum. DHT is produced from testosterone via the action of the enzyme 5α-reductase. DHT is also produced through an alternative biosynthetic pathway from androstanediol, and this pathway must be intact for normal and complete prenatal virilization to occur. Figure 628.1 illustrates the production of steroid hormones in various glands and the integrated pathways to the synthesis of DHT. A functional androgen receptor, produced by an X-linked gene, is required for testosterone and DHT to induce these androgen effects.

In the XX fetus with normal long and short arms of the X chromosome, the bipotential gonad develops into an ovary by about the 10th to 11th week. This occurs only in the absence of SRY, testosterone, and AMH and requires a normal gene in the dosage-sensitive/sex-reversal locus *DAX1,* the WNT-4 molecule, and R-Spondin1. A female external phenotype develops in the absence of fetal gonads. However, the male phenotype development requires androgen production and action. Estrogen is unnecessary for normal prenatal sexual differentiation, as demonstrated by 46,XX patients with aromatase deficiency.

Chromosomal aberrations may result in ambiguity of the external genitalia. Conditions of aberrant sex differentiation may also occur with the XX or XY genotype. The appropriate term for what was previously called *intersex* is **disorders of sex development (DSD)**. This term defines a condition "in which development of chromosomal, gonadal, or anatomic sex is atypical." It is increasingly preferable to use the term *atypical genitalia* rather than *ambiguous genitalia.* Tables 628.1 and 628.2 compare previous

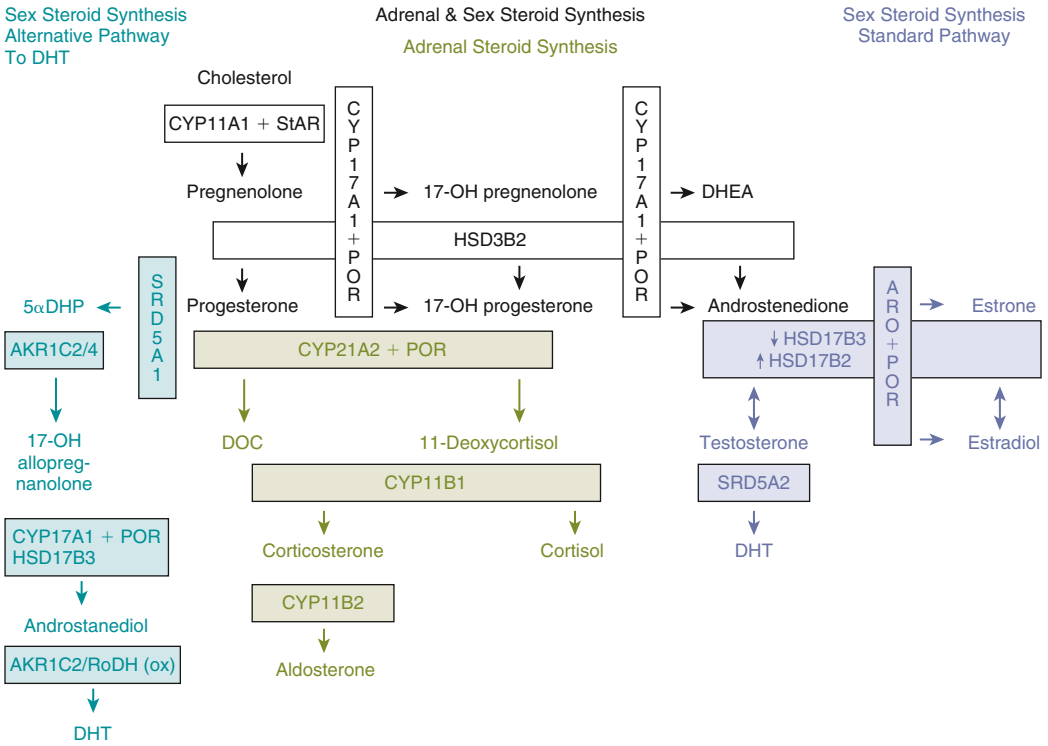

Fig. 628.1 Steroidogenic pathways enzyme names and activities. CYP11A1: cholesterol side-chain cleavage. Enzyme activities include 20-hydroxylase, 22-hydroxylase, and 20,22-lyase. CYP17A1: activities include 17α-hydroxylase and 17,20-lyase. 3βHSD2 (HSD3B2): activities include 3β-hydroxysteroid dehydrogenase (type 2) and D5D4-isomerase. CYP21A2: activity is 21-hydroxylase. CYP11B1: activity is 11β-hydroxylase. CYP11B2: activities include 18-hydroxylase (CMOI) and 18-dehydrogenase (CMOII). SRD5A1: activity is 5α-reductase type 1. SRD5A2: activity is 5α-reductase type 2. HSD17B2: activity is 17β-hydroxysteroid dehydrogenase type 2. HSD17B3: activity is 17β-hydroxysteroid dehydrogenase type 3. AKR1C2/4: activities are 3α-reductase types 1 and 3. AKR1C2/RoDH (ox): activities are 3α-reductase and 3-hydroxyepimerase. terms with their revised etiologic classification nomenclature. Table 622.1 in Chapter 622 lists some of the many genes that may be abnormal in various forms of DSD. Gender fluidity (nonconformity) has become a socially and, in New York State, legally accepted concept and is often expressed by self-identified people as intersex. New York State has an intersex category on its birth certificate. Partial androgen insensitivity, 5α-reductase deficiency, and mixed gonadal dysgenesis are often associated with gender dissatisfaction, and an intersex designation may help with future self-identification once the child is mature.

The definition of atypical or ambiguous genitalia, in a broad sense, is any case in which the external genitalia do not appear completely male or completely female. Although there are standards for genital size dimensions, variations in size of these structures do not always constitute ambiguity.

Development of the external genitalia begins with the potential to be either male or female (Fig. 628.2). Virilization of a female, the most common form of DSD, results in varying phenotypes (Fig. 628.3) that develop from the basic bipotential genital appearances of the embryo (see Fig. 628.2).

DIAGNOSTIC APPROACH TO THE PATIENT WITH ATYPICAL OR AMBIGUOUS GENITALIA

The appearance of the external genitalia is rarely diagnostic of a particular disorder and thus does not often allow distinction among the various forms of DSD. The most common forms of 46,XX DSD are *virilizing forms of congenital adrenal hyperplasia*. It is important to note that in 46,XY DSD, the specific diagnosis is not found in up to 50% of cases; partial androgen insensitivity syndrome (PAIS) and

46,XX DSD
Androgen Exposure
Fetal/fetoplacental source
21-Hydroxylase (P450c21 or CYP21) deficiency
11β-Hydroxylase (P450c11 or CYP11B1) deficiency
3β-Hydroxysteroid dehydrogenase II (3β-HSD II) deficiency
Cytochrome P450 oxidoreductase (POR deficiency)
Aromatase (P450arom or CYP19) deficiency
Glucocorticoid receptor gene pathogenic variant
Maternal source
Virilizing ovarian tumor
Virilizing adrenal tumor
Androgenic drugs
Disorder of Ovarian Development
XX gonadal dysgenesis
Testicular DSD (SRY+, SOX9 duplication)
Undetermined Origin
Associated with genitourinary and gastrointestinal tract defects
46,XY DSD
Defects in Testicular Development
Denys-Drash syndrome (pathogenic variant in *WT1*)
WAGR syndrome (Wilms tumor, aniridia, genitourinary malformation, retardation)
Deletion of 11p13
Campomelic syndrome (autosomal gene at 17q24.3-q25.1) and SOX9 pathogenic variant
XY pure gonadal dysgenesis (Swyer syndrome)
Pathogenic variant in SRY
XY gonadal agenesis
Unknown cause
Deficiency of Testicular Hormones
Leydig cell aplasia
Pathogenic variant in LH receptor
Lipoid adrenal hyperplasia (P450scc or CYP11A1) deficiency; pathogenic variant in StAR (steroidogenic acute regulatory protein)
3β-HSD II deficiency
17-Hydroxylase/17,20-lyase (P450c17 or CYP17) deficiency
Persistent müllerian duct syndrome because of antimüllerian hormone gene variants or receptor defects for antimüllerian hormone
Defect in Androgen Action
Dihydrotestosterone deficiency because of 5α-reductase II pathogenic variants or AKR1C2/AKR1C4 variants
Androgen receptor defects:
Complete androgen insensitivity syndrome
Partial androgen insensitivity syndrome (Reifenstein and other syndromes)
Smith-Lemli-Opitz syndrome (defect in conversion of 7-dehydrocholesterol to cholesterol, DHCR7)
OVOTESTICULAR DSD
XX
XY
XX/XY chimeras
SEX CHROMOSOME DSD
45,X (Turner syndrome and variants)
47,XXY (Klinefelter syndrome and variants)

Data from Lee PA, Houk CP, Ahmed SF, et al. Consensus statement on management of intersex disorders. *Pediatrics.* 2006;118:e488–e500.

pure gonadal dysgenesis are common identifiable etiologies in XY DSD. At one center with a large experience, the etiologies of DSD in 250 patients older than 25 years were compiled. The six most common diagnoses accounted for 50% of the cases. These included virilizing congenital adrenal hyperplasia (14%), androgen insensitivity syndrome (AIS; 10%), mixed gonadal dysgenesis (8%), clitoral/labial anomalies (7%), hypogonadotropic hypogonadism (6%), and 46,XY small-for-gestational-age males with hypospadias (6%). Potential diagnostic clues are noted in Tables 628.3 and 628.4.

The potential of not finding a diagnosis in patients with DSD and the resulting lack of specific management emphasizes the need for thorough diagnostic evaluations. These include biochemical characterization of possible steroidogenic enzymatic defects in each patient with genital ambiguity. The parents need counseling about the potentially complex nature of the baby's condition and guidance as to how to deal with their well-meaning but curious friends and family members. The evaluation and management should be carried out by a multidisciplinary team of experts that includes pediatric endocrinology, pediatric surgery/urology, pediatric radiology, newborn medicine, genetics, and psychology. Once the sex of rearing has been agreed on by the family and team, treatment can be organized. Genetic counseling should be offered when the specific diagnosis is established.

After a complete history and physical exam, the common diagnostic approach includes multiple steps, described in the following outline. These steps are usually performed simultaneously rather than waiting for results of one test before performing another, because of the sensitive and sometimes urgent nature of the condition. Careful attention to the presence of physical features other than the genitalia is crucial to determine if a diagnosis of a particular multisystem syndrome is possible (see Chapters 628.1, 628.2, and 628.3). Table 628.5 summarizes many of the features of commonly encountered causes of DSD. Exome sequencing or molecular testing using specific DSD DNA panels are quite useful in the diagnostic evaluation, especially in 46,XY DSD, and may become first-line diagnostic tests.

Diagnostic tests include the following:

1. Blood karyotype, with rapid determination of sex chromosomes (in many centers this is available within 24-48 hours)
2. Other blood tests
   a. Screen for congenital adrenal hyperplasia: cortisol biosynthetic precursors and adrenal androgens (particularly 17-hydroxyprogesterone and androstenedione for 21-hydroxylase deficiency, the most common form). In the United States, all 50 states have a newborn screen for 21-hydroxylase deficiency.
   b. Screen for androgen biosynthetic defects with serum levels of androgens and their precursors.
   c. Assess for gonadal response to gonadotropin stimulation to screen for the presence and function of testicular gonadal tissue: obtain serum levels of testosterone and DHT before and after IM injections of hCG.
   d. Molecular genetic analyses for SRY, other Y-specific loci, and when needed, other single-gene defects associated with DSD.
   e. Gonadotropin (LH and follicle-stimulating hormone [FSH]) levels.
3. The internal anatomy of patients with ambiguous genitalia can be defined with one or more of the following studies:
   a. Voiding cystourethrogram
   b. Endoscopic examination of the genitourinary tract
   c. Pelvic ultrasound; renal and adrenal ultrasound
   d. Pelvic MRI
   e. Exploratory laparoscopy to locate and characterize/biopsy the gonads

628.1 46,XX DSD

Patricia A. Donohoue

The genotype is XX and the gonads are ovaries, but the external genitalia are virilized. There is no significant prenatal AMH production because the gonads are ovaries. Thus the uterus, fallopian tubes, and cervix develop. The varieties and causes of this condition are relatively few. Most instances result from exposure of the female fetus to excessive *exogenous* or *endogenous* androgens during intrauterine life. The changes consist principally of virilization of the external genitalia (clitoral hypertrophy and labioscrotal fusion).

CONGENITAL ADRENAL HYPERPLASIA

See Chapter 616.1.

POR, P450 oxidoreductase; AMH, anti-Mullerian hormone; CAH, congenital adrenal hyperplasia.
Modified from Rodriguez-Buritica D. Overview of genetics of disorders of sexual development. Curr Opin Pediatr. 2015;27:675–684. Table 1.

This is the most common cause of atypical genitalia and of 46,XX DSD. Females with the 21-hydroxylase and 11-hydroxylase defects are the most highly virilized, although minimal virilization also occurs with the type II 3β-hydroxysteroid dehydrogenase defect (see Fig. 628.3). Female patients with salt-losing congenital adrenal hyperplasia (CAH) caused by 21-hydroxylase deficiency tend to have more virilization than do patients with the non–salt-losing form. Masculinization may be so complete that a penile urethra results, and the patient may appear to be a male with bilateral cryptorchidism.

AROMATASE DEFICIENCY

In 46,XX females, the rare condition of aromatase deficiency during fetal life leads to 46,XX DSD and results in hypergonadotropic hypogonadism at puberty because of ovarian failure to synthesize estrogen.

Examples of this condition include two 46,XX infants who had enlargement of the clitoris and posterior labial fusion at birth. In one instance, maternal serum and urinary levels of estrogen were very low and serum levels of androgens were high. Cord serum levels of estrogen were also extremely low, and levels of androgen were elevated. The second patient also had virilization of unknown cause since birth, but the aromatase deficiency was not diagnosed until 14 years of age, when she had further virilization and failed to go into puberty. At that time, she had elevated levels of gonadotropins and androgens but low estrogen levels, and ultrasonography revealed large ovarian cysts bilaterally. These patients demonstrate the important role of aromatase in the conversion of androgens to estrogens. Additional female and male patients with aromatase deficiency as a consequence of pathogenic variants in the *aromatase gene (CYP19)* are known. Two siblings with this gene defect were described, both of whom had tall stature because of a lack of estrogen-mediated epiphyseal fusion. The 28-year-old XX proband was 177.6 cm tall (+2.5 SD) after having received hormonal replacement therapy. Her 24-year-old brother was 204 cm tall (+3.7 SD) and had a bone age of 14 years. Low-dose estradiol replacement, carefully adjusted to maintain normal age-appropriate levels, may be indicated for affected females, even prepubertally.

CORTISOL RESISTANCE CAUSED BY A GLUCOCORTICOID RECEPTOR GENE PATHOGENIC VARIANT

A 9-year-old female with 46,XX DSD, thought to be caused by 21-hydroxylase deficiency (CAH) since the age of 5 years, had elevated cortisol levels both at baseline and after dexamethasone, hypertension, and hypokalemia, suggestive of the diagnosis of generalized glucocorticoid resistance. A novel homozygous variant in exon 5 of the glucocorticoid receptor was demonstrated. In this Brazilian family, the condition was autosomal recessive. Virilization occurs because of excess adrenocorticotropic hormone (ACTH) stimulation of adrenal steroid production because the glucocorticoid receptor defect is also present in the pituitary gland, which senses inadequate cortisol effect to provide negative feedback.

P450 Oxidoreductase Deficiency

Cytochrome P450 oxidoreductase (POR), encoded by a gene on 7q11.2, is a cofactor required for normal enzymatic activity of the microsomal 21- and 17-hydroxylases. POR deficiency thus causes partial combined P450C17 and P450C21 steroidogenic defects. Females are born with ambiguous genitalia, but as opposed to classic CAH, the virilization does not progress postnatally and androgen levels are normal or low. Males may be born undervirilized. Both may exhibit bony abnormalities seen in **Antley-Bixler syndrome**. Conversely, in a series of Antley-Bixler syndrome patients, those with ambiguous genitalia and disordered steroidogenesis had cytochrome POR deficiency. Those without genital ambiguity with normal steroidogenesis had *FGFR2* pathogenic variants. The cardinal features of Antley-Bixler syndrome include craniosynostosis, severe midface hypoplasia, proptosis, choanal atresia/stenosis, frontal bossing, dysplastic ears, depressed nasal bridge, radiohumeral synostosis, long bone fractures and femoral bowing, and urogenital abnormalities.

VIRILIZING MATERNAL TUMORS

Rarely, the female fetus has been virilized by a *maternal* androgen-producing tumor. In a few cases, the lesion was a benign adrenal adenoma, but all others were ovarian tumors, particularly androblastomas, luteomas, and Krukenberg tumors (Table 628.6). **Maternal virilization** may be manifested by enlargement of her clitoris, acne, deepening of the voice, decreased lactation, hirsutism, and elevated levels of androgens. In the infant, there is enlargement of the clitoris of varying degrees, often with labial fusion. Mothers of children with unexplained 46,XX DSDs should undergo physical examination and measurements of their own levels of plasma testosterone, dehydroepiandrosterone (DHEA) sulfate, and androstenedione.

EXPOSURE TO ANDROGENIC DRUGS BY WOMEN DURING PREGNANCY

Testosterone and 17-methyltestosterone have been reported to cause 46,XX DSDs in some instances (see Table 628.6). The greatest number of cases has resulted from the use of certain progestational compounds

Table 628.5 Atypical Genitalia: Steps in Establishing the Diagnosis

for the treatment of threatened abortion. These progestins have since been replaced by nonvirilizing ones.

Infants with virilization and 46,XX chromosomes and caudal anomalies have been reported for whom no virilizing agent could be identified. In such instances, the disorder is usually associated with other congenital defects, particularly of the urinary and gastrointestinal tracts. Y-specific DNA sequences, including *SRY*, are absent. In one case, a scrotal raphe and elevated testosterone levels were found, but the cause remains unknown.

SF-1 Pathogenic Variants

In a worldwide study of patients with **46,XX ovotesticular DSD**, a specific variant in *SF-1* was identified: p.Arg92Trp. Functional studies showed that the variant probably interfered with inhibition of testicular development. In one family with a maternally transmitted variant, the mother had early menopause. Multiple other *SF-1* variants have been reported to cause isolated ovarian insufficiency, some associated with 46,XY DSDs in their offspring.

46,XX Testicular DSD

In this condition, also known as **XX male**, the gonads are testicular and virilization is typically incomplete. Infertility and/or gonadal failure may develop after childhood. Many cases are caused by translocation of *SRY* sequences onto one of the X chromosomes, often paired with duplication of *SOX-9*. The appropriate sex of rearing may be difficult to determine.

46,XX Gonadal Dysgenesis

These females typically present at puberty with normal female genitalia and lack of breast development and hypergonadotropic hypogonadism. Normal müllerian structures are present, but ovaries are absent or streaked.

Undetermined/Unknown

Rarely, 46,XX DSDs can be associated with other congenital anomalies, especially those of the GU or GI tract, and are thus multifactorial in

origin. These include cloacal exstrophy and **MURCS association** (müllerian hypoplasia, renal agenesis, and cervicothoracic somite abnormalities). Isolated deficiency of müllerian development is known as **Meyer-Rokitansky-Küster-Hauser syndrome**.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

628.2 46,XY DSD

Patricia A. Donohoue

In this condition the genotype is XY but the external genitalia are either not completely virilized, are ambiguous (atypical), or are completely female. When gonads can be found, they typically contain *testicular* elements; their development ranges from rudimentary to normal. Because the process of normal virilization in the fetus is so complex, it is not surprising that there are many varieties and causes of 46,XY DSD. The etiology is not identified in up to 50% of cases.

DEFECTS IN TESTICULAR DIFFERENTIATION

The first step in male differentiation is conversion of the bipotential gonad into a testis. In the XY fetus, if there is a deletion of the short arm of the Y chromosome or of the *SRY* gene, male differentiation does not occur. The phenotype is female; müllerian (paramesonephric) ducts are well developed because of the absence of AMH, and gonads consist of undifferentiated streaks. By contrast, even extreme deletions of the long arm of the Y chromosome (Yq−) have been found in normally developed males, most of whom are azoospermic and have short stature. This indicates that the long arm of the Y chromosome normally has genes that prevent these manifestations. In many syndromes in which the testes fail to differentiate, Y chromosomes are morphologically normal on karyotyping.

Wilms Tumor-Suppressor Gene Pathogenic Variants: Denys-Drash, Frasier, and WAGR Syndromes

Denys-Drash syndrome: The constellation of nephropathy with atypical (ambiguous) genitalia and bilateral Wilms tumor is the major phenotype of this syndrome. Most reported cases have been 46,XY. Müllerian ducts are often present, indicating a global deficiency of fetal testicular function. Patients with a 46,XX karyotype have normal external genitalia. The onset of proteinuria in infancy progresses to nephrotic syndrome and end-stage renal failure by 3 years of age, with focal or diffuse mesangial sclerosis being the most consistent histopathologic finding. Wilms tumor usually develops in children younger than 2 years of age and is frequently bilateral. Gonadoblastomas have also been reported.

Several pathogenic variants in *WT1,* located on chromosome 11p13, have been found. *WT1* functions as a tumor suppressor gene and a transcription factor and is expressed in the genital ridge and fetal gonads. Nearly all reported variants are near or within the zinc finger–coding region. One report found a zinc finger domain variant in the *WT1* alleles of a patient with no GU abnormalities, suggesting that some cases of sporadic Wilms tumor may carry the *WT1* pathogenic variant.

Frasier syndrome: Different pathogenic variants in *WT1,* constitutional heterozygote variants at intron 9, have been described in Frasier syndrome, a condition of nonspecific focal and segmental glomerulosclerosis, 46,XY gonadal dysgenesis, and frequent gonadoblastoma, but *without* Wilms tumor.

WAGR syndrome: This acronym refers to a contiguous gene syndrome consisting of Wilms tumor, aniridia, GU malformations, and retardation (WAGR). These children have a deletion of one copy of chromosome 11p13, which may be visible on karyotype analysis. The deleted region encompasses the aniridia gene *(PAX6)* and the Wilms tumor suppressor gene *(WT1).* Only the 46,XY patients have genital abnormalities, ranging from cryptorchidism to severe deficiency of virilization. Gonadoblastomas have developed in the dysgenetic gonads. Wilms tumor usually occurs by 2 years of age. Some cases also had unexplained obesity, raising the question of an obesity-associated gene in this region of chromosome 11 and naming the syndrome *WAGRO.*

Campomelic Syndrome

See Chapter 735.

This form of **short-limbed skeletal dysplasia** is characterized by anterior bowing of the femur and tibia, small, bladeless scapulae, small thoracic cavities, and 11 pairs of ribs, along with malformations of other organs. It is usually lethal in early infancy. Approximately 75% of reported 46,XY patients exhibit a completely **female phenotype**; the external and internal genitalia are female. Some 46,XY patients have ambiguous genitalia. The gonads appear to be ovaries but histologically may contain elements of both ovaries and testes.

The gene responsible for the condition is *SOX9* and is on 17q24-q25. This gene is structurally related to *SRY* and directly regulates development of the type II collagen gene *(COL2A1)*. The same variants may result in different gonadal phenotypes. Gonadoblastoma was reported in a patient with this condition. The inheritance is autosomal dominant.

SF-1 (Also Known as *Ad4BP* and *NR5A1*) Defects and 46,XY DSD

Adrenal insufficiency and 46,XY gonadal dysgenesis have been described in patients with pathogenic variants in *SF-1*. In some of these patients, if the mother shares the *SF-1* variant, she has premature ovarian insufficiency. *SF-1*–related 46,XY DSD may also occur in the absence of adrenal insufficiency and may resemble PAIS.

46,XY sex reversal has also been described in patients with deletions of parts of autosomal loci on chromosomes 2q, 9p, and 10q.

XY Pure Gonadal Dysgenesis (Swyer Syndrome)

The designation *pure* distinguishes this condition from forms of gonadal dysgenesis that are of chromosomal origin and associated with somatic anomalies. Affected patients have normal stature and a female phenotype, including vagina, uterus, and fallopian tubes, but at pubertal age, breast development and menarche fail to occur. None of the other phenotypic features associated with 45,X (Turner syndrome) are present. Patients present at puberty with hypergonadotropic primary amenorrhea. Familial cases suggest an X-linked or a sex-limited dominant autosomal transmission. Most of the patients examined have had pathogenic variants in *SRY*. The gonads consist of almost totally undifferentiated streaks despite the presence of a cytogenetically normal Y chromosome. The primitive gonad cannot accomplish any testicular function, including suppression of müllerian (paramesonephric) ducts. There may be hilar cells in the gonad capable of producing some androgens; accordingly, some virilization, such as clitoral enlargement, may occur at the age of puberty. The streak gonads may undergo neoplastic changes, such as gonadoblastomas and dysgerminomas, and should be removed as soon as the diagnosis is established, regardless of the age of the patient.

Pure gonadal dysgenesis also occurs in XX individuals.

XY Gonadal Agenesis Syndrome (Embryonic Testicular Regression Syndrome)

In this rare syndrome, the external genitalia are slightly ambiguous but more nearly female. Hypoplasia of the labia; some degree of labioscrotal fusion; a small, clitoris-like phallus; and a perineal urethral opening are present. No uterus, no gonadal tissue, and usually no vagina can be found. At the age of puberty, no sexual development occurs and gonadotropin levels are elevated. Most children have been reared as females. In several patients with XY gonadal agenesis in whom no gonads could be found on exploration, significant rises in testosterone followed stimulation with hCG, indicating

Leydig cell function somewhere. Siblings with the disorder are known.

It is presumed that testicular tissue was active long enough during fetal life for AMH to inhibit development of müllerian ducts but not long enough for testosterone production to result in virilization. In one patient, no deletion of the Y chromosome was found by means of Y-specific DNA probes. Testicular degeneration seems to occur between the 8th and 12th fetal week. Regression of the testis before the 8th week of gestation results in Swyer syndrome; between the 14th and 20th weeks of gestation, it results in the rudimentary testis syndrome; and after the 20th week, it results in anorchia.

In **bilateral anorchia**, sometimes referred to as *vanishing testes syndrome,* testes are absent, but the male phenotype is complete; it is presumed that tissue with fetal testicular function was active during the critical period of genital differentiation but that sometime later it was damaged. Bilateral anorchia in identical twins and unilateral anorchia in identical twins and in siblings suggest a genetic predisposition. Coexistence of anorchia and gonadal agenesis syndrome in a sibship is evidence for a relationship between the disorders. A retrospective review of urologic explorations revealed absent testes in 21% of 691 testes. Of those, 73% had blind-ending cord structures with the suggested site of the vanishing testes being the inguinal canal (59%), abdomen (21%), superficial inguinal ring (18%), and scrotum (2%). It was suggested that the presence of cord structures on laparoscopy should prompt inguinal exploration because viable testicular tissue was found in four of these children.

DEFICIENCY OF TESTICULAR HORMONE PRODUCTION

Several genetic defects have been delineated in the enzymatic synthesis of testosterone by the fetal testis, and a defect in Leydig cell differentiation has been described. These defects produce 46,XY males with inadequate masculinization. Because levels of testosterone are normally low before puberty, an hCG stimulation test may be needed in children to assess the ability of the testes to synthesize testosterone.

Leydig Cell Aplasia

Patients with aplasia or hypoplasia of the Leydig cells usually have female phenotypes, but there may be mild virilization. Testes, epididymis, and vas deferens are present; the uterus and fallopian tubes are absent because of normal production of AMH. There is no breast development at puberty, but pubic hair development may be normal because of the production of adrenal androgens. Plasma levels of testosterone are low and do not respond to hCG; LH levels are elevated. The Leydig cells of the testes are absent or markedly deficient. The defect may involve a lack of functional receptors for LH. In children, hCG stimulation is necessary to differentiate the condition from the AISs. There is male-limited autosomal recessive inheritance. The human LH/chorionic gonadotropin (CG) receptor is a member of the G-protein–coupled superfamily of receptors that contains seven transmembrane domains. Several inactivating pathogenic variants of the LH/CG receptor have been described in males with hypogonadism suspected of having Leydig cell hypoplasia or aplasia.

High serum LH and low FSH were noted in one male with hypogonadism owing to a pathogenic variant in the gene for the β-subunit of FSH (see Table 622.1).

Lipoid Adrenal Hyperplasia

See Chapter 616.

This is the most severe form of CAH; enlarged adrenal glands result from accumulation of cholesterol and cholesterol esters. The rate-limiting process in steroidogenesis is the transport of free cholesterol through the cytosol to the inner mitochondrial membrane, where the P450 side-chain cleavage enzyme (P450scc; CYP11A1) acts. Cholesterol transport into mitochondria is mediated by the steroidogenic acute regulatory protein (StAR). StAR is a 30-kDa protein essential for steroidogenesis and is encoded by a gene on chromosome 8p11.2. The mitochondrial content of StAR increases between 1 and 5 hours after ACTH stimulation, long after the acute ACTH-induced increase in steroidogenesis. This has led some to suggest that extramitochondrial StAR might also be involved in the acute response to ACTH. Most patients with lipoid CAH have pathogenic variants in the gene encoding *StAR,* and a few have variants in *CYP11A1*.

All serum steroid levels are low or undetectable, whereas ACTH and plasma renin levels are quite elevated. The phenotype is female in both genetic females and males. Genetic males have no müllerian structures because the testes can produce normal AMH but no steroid hormones. These children present with acute adrenal crisis and salt wasting in infancy. Most patients are 46,XY. In a few patients, ovarian steroidogenesis is present at puberty.

The regulatory role of StAR-independent steroidogenesis is illustrated by 46,XX 4-month-old twins with lipoid adrenal hyperplasia. One died at 15 months because of cardiac complications related to coarctation of the aorta. The adrenal glands had characteristic lipid deposits. The surviving twin had spontaneous puberty with feminization at 11.5 years and menarche at 13.8 years. When restudied at the age of 15 years, a homozygous frameshift-inactivating variant in *StAR* was discovered. This supports the hypothesis that StAR-independent steroidogenesis was able to proceed until enough intracellular lipid accumulated to damage steroidogenic activity. Partial defects in only partially virilized males and delayed onset of salt wasting have been described. Complete *CYP11A1* defects may be incompatible with life because only this enzyme can convert cholesterol to pregnenolone, which then becomes progesterone, a hormone essential for the maintenance of normal mammalian pregnancy. Heterozygous variants in *CYP11A1* were described in a 4-year-old with 46,XY sex reversal and late-onset form of lipoid adrenal hyperplasia. At 6-7 weeks of gestation, when maternal corpus luteum progesterone synthesis stops, the placenta, which does not express StAR, produces progesterone by StAR-independent steroidogenesis using the CYP11A1 enzyme system.

3β-Hydroxysteroid Dehydrogenase Deficiency

Males with this form of CAH (see Chapter 616) have various degrees of hypospadias, with or without bifid scrotum and cryptorchidism, and, rarely, a complete female phenotype. Affected infants usually develop salt-losing manifestations shortly after birth. Incomplete defects, occasionally seen in males with premature pubarche, as well as late-onset nonclassic forms, have been reported. These children have pathogenic variants of the gene for type II 3β-hydroxysteroid enzyme, resulting in impairment of steroidogenesis in the adrenals and gonads; the impairment may be unequal between adrenals and gonads. Normal pubertal changes in some males could be explained by the normally present type I 3β-hydroxysteroid dehydrogenase present in many peripheral tissues. Infertility is frequent. There is no correlation between degree of salt wasting and degree of phenotypic abnormality.

Deficiency of 17-Hydroxylase/17,20-Lyase

A single enzyme (CYP17A1) encoded by a single gene on chromosome 10q24.3 has both 17-hydroxylase and 17,20-lyase activities in adrenal and gonadal tissues (see Chapter 616). Many different pathogenic gene variants have been reported. Genetic males usually have a complete female phenotype or, less often, various degrees of undervirilization, from labioscrotal fusion to perineal hypospadias and cryptorchidism. Pubertal development fails to occur in both genetic sexes.

In the classical disorder, there is decreased synthesis of cortisol by the adrenals and of sex steroids by the adrenals and gonads. Levels of the steroid precursor with mineralocorticoid activity, deoxycorticosterone and corticosterone, are markedly increased and lead to the hypertension and hypokalemia characteristic of this form of 46,XY

DSD. Although levels of cortisol are low, the elevated ACTH and corticosterone levels prevent symptomatic cortisol deficiency. The renin-aldosterone axis is suppressed because of the strong mineralocorticoid effect of elevated deoxycorticosterone. Virilization does not occur at puberty; levels of testosterone are low and those of gonadotropins are increased. Because fetal production of AMH is normal, no müllerian duct remnants are present. In XY phenotypic females, gonadectomy and replacement therapy with hydrocortisone and sex steroids are indicated.

The defect follows autosomal recessive inheritance. Affected XX females are usually not detected until young adult life, when they fail to experience normal pubertal changes and are found to have hypertension and hypokalemia. This condition should be suspected in patients presenting with primary amenorrhea and hypertension whose chromosomal complement is either 46,XX or 46,XY.

Some patients originally described as having isolated 17,20 lyase deficiency were subsequently shown to have a defect in the production of DHT because of deficiency of enzymes in the alternative pathway of DHT synthesis.

Deficiency of 17-Ketosteroid Reductase

This enzyme, also called *17β-hydroxysteroid dehydrogenase,* catalyzes the final step in testosterone biosynthesis. It is necessary to convert androstenedione to testosterone, DHEA to androstenediol, and estrone to estradiol. Deficiency of 17-ketosteroid reductase in the fetal testis causes the male fetus to have complete or near-complete female phenotype. Müllerian ducts are absent, and a shallow vagina is present. The diagnosis is based on the ratio of androstenedione to testosterone. In prepubertal children, stimulation with hCG may be necessary to make the diagnosis.

The defect is inherited in an autosomal recessive fashion. At least four different types of 17β-hydroxysteroid dehydrogenase are recognized, each coded by genes on different chromosomes. Type III is the enzyme responsible for testicular production of testosterone. This defect is more common in a highly inbred Arab population in Gaza than it is in other populations. The gene for the disorder is at 9q22 and is expressed only in the testes, where it converts androstenedione to testosterone. Most patients are diagnosed at puberty because of virilization and the failure to menstruate. Testosterone levels at puberty may approach normal, presumably as a result of peripheral conversion of androstenedione to testosterone; at this time, some patients may spontaneously adopt a male gender role.

Type I 17β-hydroxysteroid dehydrogenase, encoded by a gene on chromosome 17q21, converts estrone to estradiol and is found in the placenta, ovary, testis, liver, prostate, adipose tissue, and endometrium. Type II, whose gene is on chromosome 16q24, reverses the reactions of types I and III (converting testosterone to androstenedione and estrone to estradiol, respectively). Type IV is similar in action to type II. A late-onset form of 17-ketosteroid reductase deficiency presents as gynecomastia in young adult males.

Persistent Müllerian Duct Syndrome

In this disorder, there is persistence of müllerian (paramesonephric) duct derivatives in otherwise completely virilized males. Cases have been reported in siblings and identical twins. Cryptorchidism is present in 80% of affected males, and during surgery for this or inguinal hernia, the condition is discovered when a fallopian tube and uterus are found. The degree of müllerian development is variable and may be asymmetric. Testicular function is normal in most, but testicular degeneration has been reported. Some affected males acquire testicular tumors after puberty. In a study of 38 families, 16 families had defects in the AMH gene, located on the short arm of chromosome 19. Affected patients had low AMH levels. In 16 families with high AMH levels, the defect was in the AMH type II receptor gene, with 10 of 16 having identical 27-bp deletions on exon 10 in at least one allele.

Fig. 628.4 5α-Reductase deficiency. *(From Wales JKH, Wit JM, Rogol AD. Pediatric Endocrinology and Growth, 2nd ed. Philadelphia: Saunders, 2003: p. 165.)*

Treatment consists of removal of as many of the müllerian structures as possible without causing damage to the testis, epididymis, or vas deferens.

DEFECTS IN ANDROGEN ACTION

Dihydrotestosterone Deficiency

Decreased production of DHT in utero results in marked ambiguity of external genitalia of affected males. Biosynthesis and peripheral action of testosterone are normal.

The phenotype commonly associated with this condition results in males who have a small phallus, bifid scrotum, urogenital sinus with perineal hypospadias, and a blind vaginal pouch (Fig. 628.4). Testes are in the inguinal canals or labioscrotal folds and are normal histologically. There are no müllerian structures. Wolffian (mesonephric) structures—the vas deferens, epididymis, and seminal vesicles—are present. Most affected patients have been identified initially as females but at puberty, *virilization occurs;* the phallus enlarges, the testes descend and grow normally, and spermatogenesis occurs. There is no gynecomastia. Beard growth is scanty, acne is absent, the prostate is small, and recession of the temporal hairline fails to occur. Virilization of the wolffian duct is caused by the action of testosterone itself, although masculinization of the urogenital sinus and external genitals depends on the action of DHT during the critical period of fetal masculinization. Growth of facial hair and of the prostate also appears to be DHT dependent.

The adult height reached is close to that of the father and other male siblings. There is significant phenotypic heterogeneity. This has led to a classification of such patients into five types of **steroid 5α-reductase deficiency (SRD)**.

Several different gene defects of *SRD5A2* (the 5α-reductase type 2 gene leading to SRD) have been identified, located on the short arm of chromosome 2, in patients from throughout the world. Familial clusters have been reported from the Dominican Republic, Turkey, Papua New Guinea, Brazil, Mexico, and the Middle East. There is no reliable correlation between genotype and phenotype.

The disorder is inherited as an autosomal recessive trait but is limited to males; normal homozygous females with normal fertility indicate that in females DHT has no clinically significant role in sexual differentiation or in ovarian function later in life. The clinical diagnosis

should be made as early as possible in infancy. It is important to distinguish this from PAIS because patients with PAIS are far less sensitive to androgen than are patients with SRD. The biochemical diagnosis of SRD is based on finding normal serum testosterone levels, normal or low DHT levels with markedly increased basal and especially hCG-stimulated testosterone:DHT ratios (>17), and high ratios of urinary etiocholanolone to androsterone. Children with androgen insensitivity have normal hepatic 5α reduction and thus a normal ratio of tetrahydrocortisol to 5α-tetrahydrocortisol, as opposed to those with SRD.

It is important to note that many, but not all, children with SRD reared as females in childhood have changed to a male role around the time of puberty. It appears that exposures to testosterone in utero, neonatally, and at puberty have variable contributions to the formation of male gender identity. Infants with this condition should be reared as males whenever practical. Treatment of male infants with DHT results in phallic enlargement.

Another cause of DHT deficiency is a block in an alternative pathway of DHT synthesis. Patients previously thought to have 46,XY DSD because of isolated 17,20-lyase deficiency have subsequently been characterized as having pathogenic variants in *AKR1C2* (3α-reductase type 3) or both *AKR1C2* and *AKR1C4* (3α-reductase type 4) (see Fig. 628.1). These findings showed that both the classical and alternative pathways to DHT must be intact for normal prenatal virilization.

Androgen Insensitivity Syndromes

The AISs are the most common forms of male DSDs, occurring with an estimated frequency of 1/20,000 genetic males. This group of heterogeneous X-linked recessive disorders is caused by more than 150 different pathogenic variants in the androgen receptor gene, located on Xq11-12: single point variants result in amino acid substitutions or premature stop codons, frameshift and premature terminations, gene deletions, and splice-site variants.

Clinical Manifestations

The clinical spectrum of patients with AISs, all of whom have a 46,XY chromosomal complement, range from phenotypic females (in *complete* AIS), to males with various forms of ambiguous genitalia and undervirilization (*partial* AIS, or clinical syndromes such as **Reifenstein syndrome**), to phenotypically normal-appearing males with infertility. In addition to normal 46,XY chromosomes, the presence of testes and normal or elevated testosterone and LH levels are common to all such children (Figs. 628.5 and 628.6).

In **complete androgen insensitivity syndrome (CAIS)**, an extreme form of failure of virilization, genetic males appear female at birth and are invariably reared accordingly. The external genitalia are female. The vagina ends blindly in a pouch, and the uterus is absent because of the normal production and effect of AMH by the testes. In ~30% of patients, unilateral or bilateral fallopian tube remnants are found. The testes are usually intraabdominal but may descend into the inguinal canal; they consist largely of seminiferous tubules. At puberty, there is normal development of breasts and the habitus is female, but menstruation does not occur and sexual hair is absent. Adult heights are commensurate with those of normal males despite profound congenital deficiency of androgenic effects.

The testes of affected adult patients produce normal male levels of testosterone, which are converted to normal levels of DHT. Failure of normal male differentiation during fetal life reflects a defective response to androgens at that time. The absence of androgenic effects is caused by a striking resistance to the action of endogenous or exogenous testosterone at the cellular level.

Prepubertal phenotypic females with this disorder are often detected when inguinal masses prove to be testes or when a testis is unexpectedly found during herniorrhaphy. Approximately 1–2% of females with an inguinal hernia prove to have this disorder. In infants, elevated LH levels should suggest the diagnosis. In older children and adults, amenorrhea is the usual presenting symptom. In prepubertal children, the condition must be differentiated from other types of XY undervirilized males in which there is complete feminization. These include XY gonadal dysgenesis **(Swyer syndrome)**, true agonadism, Leydig cell aplasia including LH receptor defects, and 17-ketosteroid reductase deficiency. All these conditions, unlike CAIS, are characterized by low

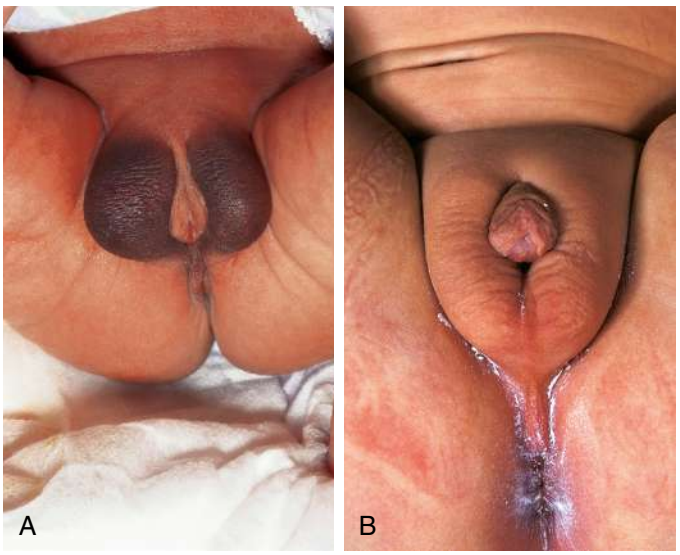

Fig. 628.5 A, Partial androgen insensitivity with descended testes in bifid labioscrotal folds. levels of testosterone as neonates and during adult life and by failure to respond to hCG during the prepubertal years.

Although patients with CAIS have unambiguously female external genitals at birth, those with **PAIS** have a wide variety of phenotypic presentations, ranging from **perineoscrotal hypospadias**, bifid scrotum, and cryptorchidism to extreme undervirilization appearing as clitoromegaly and labial fusion. Some forms of PAIS are known as specific syndromes. Patients with **Reifenstein syndrome** have incomplete virilization characterized by hypogonadism, severe hypospadias, and gynecomastia (see Fig. 628.6). **Gilbert-Dreyfus** and **Lubs syndromes** are also classified as PAISs. In all cases, abnormalities in the androgen receptor gene have been identified. Table 628.7 lists other causes of a PAIS-like syndrome.

Diagnosis

The diagnosis of patients with PAIS may be particularly difficult in infancy. The postnatal surge in testosterone and LH is diminished in those with CAIS but not in those with PAIS. In some, especially those sufficiently virilized in infancy, the diagnosis is not suspected until puberty, when there is inadequate virilization with lack of facial hair or voice change and the appearance of gynecomastia. Azoospermia and infertility are common. Androgen receptor defects are recognized in adults who have a small phallus and testes and infertility. A single–amino acid substitution in the androgen receptor was reported in a large Chinese family in whom some affected members were fertile whereas others had gynecomastia and/or hypospadias.

Treatment and Prognosis

In patients with CAIS whose sexual orientation is unambiguously female, the testes should be removed because they have malignant potential. Historically, they were removed as soon as they were discovered. However, there is a trend to allow the testes to remain because they are the source of estradiol (through conversion from testosterone), and this results in normally timed puberty with the individual's endogenous hormones. Careful monitoring for testicular masses should be performed, and removal of the testes is advised in early adulthood. Laparoscopic removal of Y chromosome–bearing gonads has been performed in patients with AIS and in those with gonadal dysgenesis. In ~30% of patients, malignant tumors, usually seminomas, develop by 50 years of age. Several teenage females developed seminomas. Replacement therapy with estrogens is indicated at the age of puberty in those whose testes were removed in childhood.

Normal breasts develop in affected females who have not had their testes removed by the age of puberty. The absence of androgenic activity in addition to the production of estradiol contributes to the feminization of these women.

The psychosexual and surgical management of patients with PAIS is extremely complex and depends in large part on the presenting phenotype. Osteopenia is recognized as a late feature of AIS.

Molecular analyses have suggested that phenotype may depend in part on somatic mosaicism of the androgen receptor gene. The presence of mosaicism shifts the phenotype to a higher degree of virilization than expected from the genotype of the mutant allele alone.

Genetic counseling is difficult in families with androgen receptor gene variants. In addition to lack of genotype-phenotype correlations, there is a high rate (27%) of de novo pathogenic variants in families.

Sex hormone–binding globulin reduction after exogenous androgen administration (stanozolol) correlates with the severity of the receptor defect and may become a useful clinical tool. Successful therapy with supplemental androgens has been reported in patients with PAIS and various variants of the androgen receptor in the DNA-binding domain and the ligand-binding domain.

Pathogenic variants in androgen receptors are also reported in patients with **spinal and bulbar muscular atrophy** in whom clinical manifestations including testicular atrophy, infertility, gynecomastia, and elevated LH, FSH, and estradiol levels usually manifest between the third and fifth decades of life.

UNDETERMINED CAUSES

Other XY undervirilized males display great variability of the external and internal genitalia and various degrees of phallic and müllerian development. The testes may be histologically normal or rudimentary, or there may only be one. No recognized cause is identified in up to 50% of children with 46,XY DSDs. Some ambiguity of the genitalia is associated with a wide variety of chromosomal aberrations, which must always be considered in the differential diagnosis, the most common being 45,X/46,XY syndrome (see Chapter 626.1). It may be necessary to karyotype several tissues to establish mosaicism. Other complex genetic syndromes, many resulting from single-gene variants, are associated with varying degrees of ambiguity of the genitalia, particularly in the male. These entities must be identified by the associated extragenital malformations.

Smith-Lemli-Opitz syndrome is an autosomal recessive disorder caused by pathogenic variants in the sterol Δ7-reductase gene located on chromosome 11q12-q13. It is characterized by prenatal and postnatal growth restriction, microcephaly, ptosis, anteverted nares, broad alveolar ridges, syndactyly of the second to third toes, and severe cognitive impairment (see Chapter 106.3). Its incidence is 1 in 20,000-30,000 live births in populations of Northern and Central European origin; 70% are male. Genotypic males usually have genital ambiguity and, occasionally, partial sex reversal with female genital ambiguity or complete sex reversal with female external genitalia. Müllerian duct derivatives are usually absent. Affected 46,XX patients have normal genitalia. Two types of Smith-Lemli-Opitz syndrome have been recognized: the **classical form (type I)** described earlier and the acrodysgenital syndrome, which is usually lethal within 1 year and is associated with severe malformations, postaxial polydactyly, and extremely abnormal external genitalia **(type II)**. Pyloric stenosis is associated with Smith-Lemli-Opitz syndrome type I and Hirschsprung disease with type II. Cleft palate, skeletal abnormalities, and one case of a lipoma of the pituitary gland have been seen in **type II** cases. Some authors believe in a spectrum of disease severity rather than in the previous classification. Low plasma cholesterol with elevated 7-dehydrocholesterol, its precursor, are found in types I and II, and the levels do not correlate with severity. Maternal apolipoprotein E values do seem to correlate with severity. The most common prenatal expression of Smith-Lemli-Opitz syndrome is intrauterine growth retardation (see Chapter 106.3 for treatment).

46,XY DSD subjects also have been described in siblings with α-thalassemia/mental retardation syndrome.

628.3 Ovotesticular DSD

Patricia A. Donohoue

In ovotesticular DSD, both ovarian and testicular tissues are present, either in the same or in opposite gonads. Affected patients have ambiguous genitalia, varying from normal female genitalia with only slight enlargement of the clitoris to almost normal male external genitalia (see Fig. 628.3A).

Approximately 70% of all patients have a 46,XX karyotype. Ninety-seven percent of affected patients of African descent are 46,XX. Less than 10% of persons with ovotesticular DSD are 46,XY. Approximately 20% have 46,XX/46,XY mosaicism. Half of these are derived from more than one zygote and are chimeras (chi 46,XX/46,XY). The presence of paternal and both maternal alleles for some blood groups is demonstrated. An ovotesticular DSD chimera, 46,XX/46,XY, was reported as resulting from embryo amalgamation after in vitro fertilization. Each embryo was derived from an independent, separately fertilized ovum.

Examination of 46,XX ovotesticular DSD patients with Y-specific probes has detected less than 10% with a portion of the Y chromosome, including the *SRY* gene. Ovotesticular DSD is usually sporadic, but several siblings have been reported. The cause of many cases of ovotesticular DSD is unknown.

The most frequently encountered gonad in ovotesticular DSD is an ovotestis, which may be bilateral. If unilateral, the contralateral gonad is usually an ovary but may be a testis. The ovarian tissue is normal, but the testicular tissue is dysgenetic. The presence and function of testicular tissue can be determined by measuring basal and hCG-stimulated testosterone levels along with AMH levels. Patients who are highly virilized and have had adequate testicular function with no uterus are usually reared as males. If a uterus exists, virilization is often mild and testicular function minimal; assignment of female sex may be indicated. Selective removal of gonadal tissue inconsistent with sex of rearing may be indicated. In a few families, 46,XY ovotesticular DSD subjects and 46,XX males have been described in the same sibship.

Defects in R-Spondin1, encoded by the *RSPO1* gene, have been described in 46,XX ovotesticular DSD. Defects in SF-1 have been described in both XX and XY ovotesticular DSD.

Pregnancies with living offspring have been reported in 46,XX ovotesticular DSD individuals reared as females, but very few males with ovotesticular DSD have fathered children. Approximately 5% of patients will develop gonadoblastomas, dysgerminomas, or seminomas.

DIAGNOSIS AND MANAGEMENT OF DISORDERS OF SEX DEVELOPMENT

In the neonate, ambiguity of the genitals requires immediate attention to decide on the sex of rearing as early in life as possible. The family of the infant needs to be informed of the child's condition as early, completely, compassionately, and honestly as possible. Caution must be used to avoid feelings of guilt, shame, and discomfort. Guidance needs to be provided to alleviate both short-term and long-term concerns and to allow the child to grow up in a completely supportive environment. The initial care is best provided by a team of professionals that includes neonatologists and pediatric specialists, endocrinologists, radiologists, surgeons/urologists, psychologists, and geneticists, all of whom remain focused foremost on the needs of the child. Management of the potential psychologic upheaval that these disorders can generate in the child or the family is of paramount importance and requires physicians and other healthcare professionals with sensitivity, training, and experience in this field.

While awaiting the results of chromosomal analysis, pelvic ultrasonography is indicated to determine the presence of a uterus and ovaries. Presence of a uterus and absence of palpable gonads usually suggest a virilized XX female; however, as described previously, these structures may also be found in 46,XY DSD. A search for the source of virilization should be undertaken; this includes studies of adrenal hormones to rule out varieties of congenital adrenal hyperplasia, and studies of androgens and estrogens occasionally may be necessary to rule out aromatase deficiency. Virilized XX females are generally (but not always) reared as females even when highly virilized.

The absence of a uterus, with or without palpable gonads, often indicates an undervirilized male and an XY karyotype. Measurements of levels of gonadotropins, testosterone, AMH, and DHT are necessary to determine whether testicular production of androgen is present and is normal. Undervirilized males who are totally feminized may be reared as females. Certain significantly feminized infants, such as those with 5α-reductase deficiency, may be reared as males because these children virilize normally at puberty. Sixty percent of individuals with 5α-reductase deficiency assigned as female in infancy live as males as adults. An infant with a comparable degree of feminization resulting from an androgen receptor defect, such as CAIS, may be successfully reared as a female.

When receptor disorders are suspected in the XY male with a small phallus (micropenis), a course of three monthly IM injections of testosterone enanthate (25-50 mg) may assist in the differential diagnosis of androgen insensitivity and in the treatment of the small phallus.

In some mammals, the female exposed to androgens prenatally or in early postnatal life exhibits nontraditional sexual behavior in adult life. Most, but not all, females who have undergone fetal masculinization from CAH or from maternal progestin therapy have female sexual identity, although during childhood they may appear to prefer male playmates and activities over female playmates and feminine play with dolls in mothering roles.

In the past it was thought that surgical treatment of ambiguous genitalia to create a female appearance, particularly when a vagina is present, was more successful than construction of male genitalia. Considerable controversy exists regarding these decisions. Sexual functioning is to a large extent more dependent on neurohormonal and behavioral factors than the physical appearance and functionality of the genitalia. Similarly, controversy exists regarding the timing of the performance of invasive and definitive procedures, such as surgery. Whenever possible without endangering the physical or psychologic health of the child, an expert multidisciplinary team should consider deferring elective surgical repairs and gonadectomies until the child can participate in the informed consent for the procedure. One study of children (59 males and 18 females) with gender dysphoria but without documentation of genomic or enzymologic abnormalities indicated that most of these children no longer have gender dysphoria after completion of puberty. Among those who do, homosexuality and bisexuality are the most frequent diagnoses.

For patients with DSD who have Y-chromosome material and intraabdominal gonads, gonadectomy is generally recommended because of the risk of gonadal tumors, many of which are malignant.

The pediatrician, pediatric endocrinologist, and psychologist, along with the appropriate additional specialists, should provide ongoing compassionate, supportive care to the patient and the patient's family throughout childhood, adolescence, and adulthood. Support groups are available for families and patients with many of the conditions discussed.

Section 6

Diabetes Mellitus in Children

Chapter 629

Diabetes Mellitus

629.1 Classification of Diabetes Mellitus

David R. Weber

Diabetes mellitus (DM) is a common chronic metabolic disease characterized by hyperglycemia as a cardinal biochemical feature. The major forms of diabetes are differentiated by insulin deficiency versus insulin resistance: **type 1 diabetes mellitus (T1DM)** results from deficiency of insulin secretion because of pancreatic β-cell damage; **type 2 diabetes mellitus (T2DM)** is a consequence of insulin resistance occurring at the level of skeletal muscle, liver, and adipose tissue, with various degrees of β-cell impairment. T1DM is the most common endocrine metabolic disorder of childhood and adolescence, with important consequences for physical and emotional development. Individuals with T1DM confront serious lifestyle alterations, including an absolute daily requirement for exogenous insulin, the need to monitor their own glucose level, and the need to pay attention to dietary intake. Morbidity and mortality stem from a constant potential for acute metabolic derangements and from long-term complications. Potential acute complications include the development of hypoglycemia related to insulin excess or hyperglycemic ketoacidosis from insulin deficiency. Long-term complications typically manifest in adulthood and are related to the adverse effects of chronic hyperglycemia and associated metabolic abnormalities on tissues and organ systems. This can result in microvascular diseases such as retinopathy, nephropathy, and neuropathy and macrovascular complications such as ischemic heart disease and arterial obstruction with gangrene of the extremities.

DM is not a single entity, but rather a heterogeneous group of disorders in which there are distinct genetic patterns and other etiologic and pathophysiologic mechanisms that lead to impairment of glucose tolerance through deficient insulin production or action. The American Diabetes Association (ADA) has proposed a diabetes classification system that includes four categories: type 1 diabetes, type 2 diabetes, other specific types, and gestational diabetes. An expanded list of diabetes etiologies is provided in Table 629.1. The current criteria for the diagnosis of diabetes are provided in Table 629.2. A thorough clinical history and physical exam are often sufficient to determine the etiology; however, in some cases additional testing may be required.

TYPE 1 DIABETES MELLITUS

Formerly called *insulin-dependent diabetes mellitus* (IDDM) or *juvenile diabetes,* T1DM is characterized by low or absent levels of endogenously produced insulin and by dependence on exogenous insulin to prevent development of ketoacidosis, an acute life-threatening complication of T1DM. The natural history includes four distinct stages: (1) preclinical β-cell autoimmunity with progressive defect of insulin secretion, (2) onset of clinical diabetes, (3) transient remission honeymoon period, and (4) established diabetes during which there may occur acute and/or chronic complications and decreased life expectancy. The onset occurs predominantly in childhood, with a median age of 7-15 years, but it may present at any age. The incidence of T1DM varies markedly across the world but has increased in nearly all parts of the world over recent decades (Fig. 629.1). Both genetic susceptibility and environmental factors contribute to the pathogenesis. Susceptibility to T1DM is genetically controlled by alleles of the major histocompatibility complex (MHC) class II genes expressing human leukocyte antigens (HLAs). Autoantibodies to β-cell antigens, including islet cell cytoplasm (ICA), insulin autoantibody (IAA), glutamic acid decarboxylase (GAD), islet antigen 2 (IA-2A, formerly ICA512), and zinc transporter 8 (ZnT8A), are detected in serum from affected subjects. These can be detected months to years before the clinical onset of T1DM. In some children and adolescents with apparent T1DM, the β-cell destruction is not immune mediated. This subtype of diabetes occurs in patients of African or Asian origin and is distinct from known causes of β-cell destruction such as drugs or chemicals, viruses, mitochondrial gene defects, pancreatectomy, and ionizing radiation. These individuals may have ketoacidosis, but they have extensive periods of remission with variable insulin deficiency, similar to patients with T2DM. Patients with T1DM require lifelong treatment with insulin.

TYPE 2 DIABETES MELLITUS

Formerly known as *adult-onset diabetes mellitus* or *non–insulin-dependent diabetes mellitus,* T2DM develops because of insulin resistance and progressive non-autoimmune β-cell failure. There is a strong heritable component to T2DM, although the genetic basis remains poorly understood. Population-based studies have linked T2DM risk with polymorphisms in a large number of genes related to insulin secretion, insulin action, energy expenditure, and birthweight; however, the collective contribution of these variants to overall T2DM risk remains low at <20%. Although T2DM has long been the most prevalent form of diabetes in adults, the rise in childhood obesity over the past few decades has led to a markedly increased incidence of this disease in children and adolescents. Pediatric T2DM accounts for most of the new cases of diabetes in high-risk populations such as obese adolescents of Black or Hispanic population ancestry (see Chapter 65). *Childhood-onset T2DM differs from adult disease in that it is associated with a more rapid decline in β-cell function and the earlier development of T2DM-related complications.*

The presentation of T2DM is typically more insidious than that with T1DM. In contrast to patients with T1DM, who are usually ill at the time of diagnosis and whose presentation rarely spans more than a few weeks, children with T2DM often seek medical care because of excessive weight gain and fatigue as a result of insulin resistance and/or the incidental finding of glycosuria during routine physical examination. A history of polyuria and polydipsia is not always a cardinal clinical feature in these patients. **Acanthosis nigricans** (dark pigmentation of skin creases in the nape of the neck especially), a sign of insulin resistance, is present in the majority of patients with T2DM and is accompanied by a relative hyperinsulinemia at the time of the diagnosis. However, as the disease progresses, β-cell function becomes increasingly impaired such that children with advanced T2DM often present in diabetic ketoacidosis (DKA).

Healthy lifestyle interventions and treatment with metformin remain the cornerstones of T2DM treatment in children and adolescents. Liraglutide (a glucagon-like peptide-1 receptor agonist) is approved in children ≥10 years and may have an additional benefit of slowing weight gain. Insulin therapy is required for patients who present with severe hyperglycemia and for those patients in whom hyperglycemia worsens in spite of lifestyle modification and noninsulin pharmacologic management.

OTHER SPECIFIC TYPES OF DIABETES

Monogenic Diabetes

The term *monogenic diabetes* is used to refer to a heterogeneous group of single-gene disorders resulting in impaired insulin secretion. This category encompasses **maturity-onset diabetes of the young (MODY)** and **transient and permanent neonatal diabetes (TND or PND)**. Characteristics of monogenic diabetes can include age of onset before 6 months (for TND or PND), development of hyperglycemia before 25 years of age, and strong family history of diabetes. Monogenic etiologies are estimated to comprise anywhere from 1% to 10% of all diabetes cases, with the uncertainty related to the clinical difficulty in differentiating these cases from T1DM and T2DM. Monogenic forms of diabetes may present with hyperglycemia, and consequent polyuria and polydipsia, or may be diagnosed simply by routine screening. Extrapancreatic manifestations vary by genetic defect (see Table 629.1 and Chapter 629.4) and can include hepatic, renal, and central nervous system (CNS) manifestations. Treatment is guided by genetic diagnosis and clinical course, with

Table 629.1 Etiologic Classifications of Diabetes Mellitus

I. TYPE 1 DIABETES (B-CELL DESTRUCTION ULTIMATELY LEADING TO COMPLETE INSULIN DEFICIENCY)
- *A. Immune Mediated*
- *B. Idiopathic*

II. TYPE 2 DIABETES (VARIABLE COMBINATIONS OF INSULIN RESISTANCE AND INSULIN DEFICIENCY)
- *A. Typical*
- *B. Atypical*

III. OTHER SPECIFIC TYPES
- *A. Genetic Defects Of β-Cell Function (Monogenic Diabetes)*
  1. Neonatal diabetes
     a. Pathogenic variants leading to transient neonatal diabetes (*KCNJ11, ABCC8, 6q24 overexpression, INS, ZFP57, SLC2A2 HNF1β*)
     b. Pathogenic variants leading to permanent neonatal diabetes (*KCNJ11, ABCC8, INS, GATA6, EIF2AK3, GCK, PTF1A, FOXP3, GLIS3, PDX1, SLC2A2, SLC19A2, GATA4, NEUROD1, NEUROG3, NKX2-2, RFX5, IER3IP1, MNX1*)
  2. MODY (maturity-onset diabetes of the young) syndromes
     a. MODY 1 chromosome 20, *HNF4α*
     b. MODY 2 chromosome 7, *GCK*
     c. MODY 3 chromosome 12q24.2, *HNF1α, TCF-1*
     d. MODY 4 chromosome 13q12.1, *IPF-1 (PDX1)*
     e. MODY 5 chromosome 17, *HNF1β, TCF-2*
     f. MODY 6 chromosome 2q32, *NEUROD1*
     g. MODY 7 chromosome 2p25, *KLF11*
     h. MODY 8 chromosome 9q34, *CEL*
     i. MODY 9 chromosome 7q32, *PAX4*
     j. MODY 10 chromosome 11p15.5, *INS*
     k. MODY 11 chromosome 8p23, *BLK*
     l. MODY 12 chromosome 11p15, *ABCC8*
     m. MODY 13 chromosome 11p15, *KCNJ11*
     n. MODY 14 chromosome 3p14, *APPL1*
  3. Mitochondrial DNA pathogenic variants (includes one form of Wolfram syndrome, Pearson syndrome, Kearns-Sayre, and maternally inherited diabetes and deafness)
  4. Wolfram syndrome—DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, deafness):
     a. WFS1-Wolframin—chromosome 4p
     b. Wolfram locus 2—chromosome 4q22-24
     c. Wolfram mitochondrial
  5. Thiamine-responsive megaloblastic anemia and diabetes
- *B. Genetic Defects of Insulin Action*
  1. Type A insulin resistance
  2. Donohue syndrome
  3. Rabson-Mendenhall syndrome
  4. Lipoatrophic diabetes syndromes
- *C. Other Genetic Syndromes Associated With Diabetes (Insulin Resistance Or Deficiency)*
  1. Down syndrome
  2. Turner syndrome
  3. Klinefelter syndrome
  4. Prader-Willi syndrome
  5. Bardet-Biedl syndrome
  6. Alström syndrome
  7. Werner syndrome
  8. Friedreich ataxia
- *D. Other Autoimmune Syndromes Associated With Diabetes*
  1. IPEX (immunodysfunction, polyendocrinopathy, enteropathy, X-linked)
  2. Autoimmune polyendocrinopathy syndromes (APS)
     a. APS-1 (APCED)
     b. APS-2
  3. Stiff person syndrome
  4. Anti-insulin receptor antibodies
- *E. Drug Or Chemical Induced*
  1. Antirejection—cyclosporine, sirolimus
  2. Glucocorticoids (with impaired insulin secretion; e.g., cystic fibrosis)
  3. l-Asparaginase
  4. β-Adrenergic blockers
  5. Vacor (rodenticide)
  6. Phenytoin (Dilantin)
  7. α-Interferon
  8. Diazoxide
  9. Nicotinic acid
  10. Pentamidine
  11. Immune checkpoint inhibitors (immune mediated)
- *F. Diseases of Exocrine Pancreas*
  1. Cystic fibrosis
  2. Trauma/pancreatectomy
  3. Pancreatitis/ionizing radiation
  4. Hemochromatosis
  5. Fibrocalculous pancreatopathy
- *G. Infections*
  1. Congenital rubella
  2. Cytomegalovirus
  3. Hemolytic-uremic syndrome
- *H. Endocrinopathies Associated With Diabetes*
  1. Cushing (hypercortisolism)
  2. Acromegaly (growth hormone excess)
  3. Pheochromocytoma
  4. Glucagonoma
  5. Somatostatinoma
  6. Aldosteronoma

IV. GESTATIONAL DIABETES

Modified from Sperling MA, Tamborlane WV, Battelino T, et al. Diabetes mellitus. In: Sperling MA. *Pediatric Endocrinology*, 4th ed. Philadelphia: Elsevier; 2014: Box 19-1.

some forms being responsive to oral sulfonylureas and others requiring insulin replacement. *Children diagnosed with diabetes before 6 months of age should have genetic testing for TND/PND, and older individuals with diabetes not characteristic of T1DM or T2DM in the setting of a family history of diabetes should have genetic testing for monogenic forms of diabetes.* A comparison of the four types of diabetes is noted in Table 629.3.

OTHER ETIOLOGIES OF DIABETES

Examples include diabetes secondary to exocrine pancreatic diseases (cystic fibrosis), other endocrine diseases (Cushing syndrome), infection, and ingestion of certain drugs or poisons (the rodenticide Vacor). In organ transplantation survivors, there is a linkage between cyclosporine and tacrolimus and post-transplantation DM, ascribed to a number of mechanisms. Certain genetic syndromes, including those with abnormalities of the insulin receptor or the immune system, are also included in this category.

PREDIABETES

The term *prediabetes* is used to identify individuals with abnormalities in blood glucose homeostasis who are at increased risk for the development of diabetes (see Table 629.2). Prediabetes is defined by **impaired fasting glucose** (IFG, fasting glucose 100-125 mg/dL

Table 629.2 Diagnostic Criteria for Dysglycemia and Diabetes Mellitus

DYSGLYCEMIA	DIABETES MELLITUS
IMPAIRED FASTING GLUCOSE	
Fasting (at least 8 hr) plasma glucose 100-125 mg/dL (5.6-7.0 mmol/L)	Fasting (at least 8 hr) plasma glucose ≥126 mg/dL (7.0 mmol/L) *Or*
IMPAIRED GLUCOSE TOLERANCE	
2-hr plasma glucose during OGTT ≥140 mg/dL (7.8 mmol/L), but <200 mg/dL (11.1 mmol/L)	2-hr plasma glucose during OGTT ≥200 mg/dL (11.1 mmol/L) *Or*
PREDIABETES	
Hemoglobin A_{1c} 5.7–6.4% (39-47 mmol/mol)	Hemoglobin A_{1c} ≥6.5% (48 mmol/mol) *Or* Symptoms* of diabetes mellitus plus random or casual plasma glucose ≥200 mg/dL (11.1 mmol/L)†

*Symptoms include polyuria, polydipsia, and unexplained weight loss with glucosuria and ketonuria.
†Results should be confirmed by repeat testing if in absence of unequivocal hyperglycemia.
OGTT, Oral glucose tolerance test.

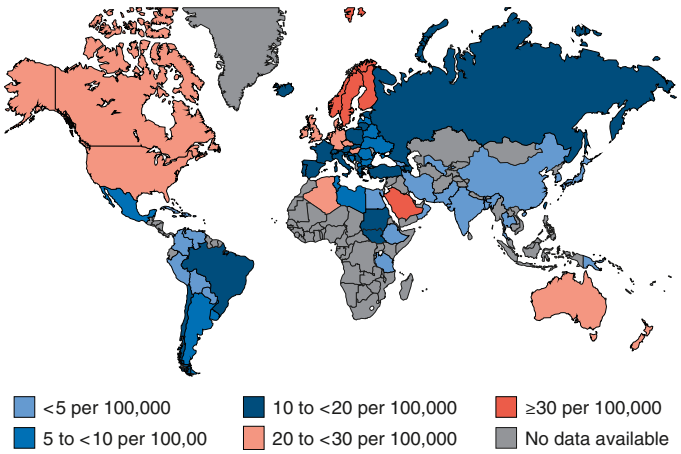

Fig. 629.1 Map of age-sex standardized incidence rates (per 100,000) from publications of type 1 diabetes in children age under 15 yr. *(From Patterson CC, Karuranga S, Salpea P, et al. Worldwide estimates of incidence, prevalence and mortality of type 1 diabetes in children and adolescents: results from the International Diabetes Federation Diabetes Atlas, 9th edition. Diabetes Res Clin Pract. 2019;157:107842. Fig 1.)*

[5.6-6.9 mmol/L]), **impaired glucose tolerance** (IGT, 2 hours postprandial glucose 140-199 mg/dL [7.8-11 mmol/L]), or hemoglobin A_{1c} (HbA_{1c}) values of 5.7–6.4% (39-47 mmol/mol). A fasting glucose concentration of 99 mg/dL (5.5 mmol/L) is the upper limit of normal. This choice is near the level above which acute-phase insulin secretion is lost in response to intravenous administration of glucose and is associated with a progressively greater risk of the development of microvascular and macrovascular complications. Many individuals with IFG are euglycemic in their daily lives and may have normal or nearly normal HbA_{1c} levels. Individuals with IFG often manifest hyperglycemia only when challenged with the oral glucose load used in the standardized oral glucose tolerance test (OGTT).

Prediabetes is not a clinical entity, but rather a risk factor for future diabetes and cardiovascular disease. This may be observed as an intermediate stage in any of the disease processes listed in Table 629.1. Prediabetes is often associated with **insulin resistance syndrome** (also known as **metabolic syndrome**), which consists of insulin resistance, compensatory hyperinsulinemia to maintain glucose homeostasis, obesity (especially abdominal or visceral obesity), dyslipidemia of the high-triglyceride or low- or high-density lipoprotein type, or both in addition to hypertension. Insulin resistance is directly involved in the pathogenesis of T2DM.

629.2 Type 1 Diabetes Mellitus (Immune Mediated)

David R. Weber

EPIDEMIOLOGY

T1DM accounts for approximately 10% of all cases of diabetes in all ages, affecting up to 2 million people in the United States and more than 15 million people in the world; approximately 15,000 youths are diagnosed with T1DM each year. Although T1DM accounts for most cases of diabetes in childhood, it is not limited to this age-group; new cases continue to present in adult life, and up to 50% of individuals with T1DM present as adults. The incidence of T1DM is highly variable among different racial and ethnic groups (see Fig. 629.1). The overall age-adjusted incidence of T1DM varies from <5 in 100,000 per year in parts of Asia, Africa, and South America to more than 30 in 100,000 per year in Northern Europe. The incidence of T1DM is increasing in most (but not all) populations, and this increase appears to be most marked in populations where the incidence of autoimmune diseases was historically low. Data from Western European diabetes centers suggest that the annual rate of increase in T1DM incidence is 2–5%, whereas some Central and Eastern European countries demonstrate an even more rapid increase—up to 9%. Data from the United States have shown that the incidence of T1DM in children increased by 1.9% per year from 2002 to 2015 from 19.5/100,000 to 22.3/100,000. Steeper increases in annual incidence were seen in people of Asian/Pacific Islander (4.4%), Hispanic (4%), and Black (2.7%) versus those of White (0.7%) racial/ethnic background.

Females and males are almost equally affected, with a modest male preponderance in some populations (Western European/United States and a female preponderance in others (Japanese); there is no apparent correlation with socioeconomic status. Peaks of presentation occur in two age-groups: at 5-7 years of age and at the time of puberty. The first peak may correspond to the time of increased exposure to infectious agents coincident with the beginning of school; the second peak may correspond to the pubertal growth spurt induced by gonadal steroids and the increased pubertal growth hormone secretion (which antagonizes insulin). The understanding of the cause of diabetes or of its increased incidence remains elusive. A growing number of cases are presenting between 1 and 2 years of age, especially in high-risk groups; the average age of presentation is older in low-risk populations. Low-risk groups that migrate to a high-risk country seem to acquire the increased risk of that country. There can be marked differences in incidence rates in various ethnic groups within the same country; incidence rates (per 100,000) in the 10- to 14-year-old age-group in the United States range from a low of 7.1 in Native Americans to 17.6 in Hispanics, 19.2 in Black Americans, and 32.9 in Whites.

GENETICS

There is a clear familial clustering of T1DM, with prevalence in siblings approaching 8%, whereas the prevalence in the general population in the United States is only 0.4%. Risk of T1DM is also increased when a parent has T1DM, and this risk differs between the two parents; the risk is 3–4% if the mother is affected but 5–6% when the father is affected. In monozygotic twins, the concordance rate ranges from 30% to 65%, whereas dizygotic twins have a concordance rate of 6–10%.

Table 629.3 Key Features of Diabetes in Pediatric Patients

	TYPE 1 DIABETES	TYPE 2 DIABETES	MONOGENIC DIABETES (MATURITY-ONSET DIABETES IN THE YOUNG)	NEONATAL DIABETES
Age at diagnosis	6 mo-18 yr	Puberty; rarely younger than 10 yr	Younger than 25 yr	Younger than 6 mo
Causes and genetic factors	Autoimmune; genetic predisposition (HLA and other genes)	Obesity; genetic and ethnic predisposition	Autosomal dominant; *HNF1A, HNF4A, GCK, HNF1B* (see Table 629.1)	*KCNJ11, ABCC8, INS* (see Table 629.1)
Associated features	Lean or mildly overweight at diagnosis, often with weight loss; thyroid autoimmunity; celiac disease	Obesity; acanthosis nigricans; polycystic ovarian syndrome; hypertension; hyperlipidemia; fatty liver disease; family history	Lean or weight loss at diagnosis; *GCK* variants are asymptomatic	Failure to thrive
Diabetic ketoacidosis at presentation	Yes; about 25%	Yes; 5–20%	No	Yes; frequency not described
Treatment	Insulin	Lifestyle modification; metformin; liraglutide; insulin; bariatric surgery	Sulfonylurea; no treatment for *GCK* variants	Sulfonylurea for *KCJN11* and *ABCC8* variants; insulin for other variants

Adapted from Cameron FJ, Wherrett DK. Care of diabetes in children and adolescents: controversies, changes, and consensus. Lancet. 2015;385:2096–2104. Table 1.

Because the concordance rate of dizygotic twins is higher than the sibling risk, factors other than the shared genotypes (e.g., the shared intrauterine environment) may play a role in increasing the risk in dizygotic twins. Furthermore, the genetic susceptibility for T1DM in the parents of an affected child is estimated at 3%. It should be kept in mind that although there is a large genetic component in T1DM, 85% of newly diagnosed patients with T1DM do not have an affected family member.

Monogenic Type 1 Diabetes Mellitus

Classic single-gene defects are an extremely rare cause of autoimmune-mediated T1DM. **IPEX (immune dysfunction, polyendocrinopathy, enteropathy, X-linked) syndrome** is caused by pathogenic variants in *FOXP3* and other genes. The *FOXP3* is a gene involved in immune system responses. A member of the FOX protein family, *FOXP3* appears to function as the master regulator in the development and function of regulatory T cells. These variants lead to the lack of a major population of regulatory T lymphocytes, with resulting overwhelming autoimmunity and development of diabetes (as early as 2 days of age) in approximately 80% of the children with this disorder.

Wolfram syndrome (DIDMOD: diabetes insipidus, diabetes mellitus, optic atrophy, deafness) is an autosomal recessive disease caused predominantly by pathogenic variants in *WFS1* and is a progressive neurodegenerative disease. Case definition requires the presence of T1DM and optic atrophy. This syndrome may be present in ~5% of patients with T1DM.

Autoimmune polyendocrinopathy syndrome type 1 (APS-1) is caused by pathogenic variants in *AIRE* leading to abnormalities in expression of peripheral antigens within the thymus and/or abnormalities of negative selection in the thymus. This results in widespread autoimmunity. Approximately 18% of children with this syndrome develop T1DM.

Genes Altering the Risk of Autoimmune Type 1 Diabetes Mellitus

The risk of developing T1DM is modified by the influence of several risk loci. The genomic region with by far the greatest contribution to the risk of T1DM is the MHC on chromosome 6p21. Outside of the MHC, genome-wide association studies have identified T1DM to be associated with at least 100 different single-nucleotide polymorphisms, from which about 50 genes have emerged as potentially causal. Notable high-risk loci include *INS*, *PTPN22*, *IL2RA*, *CTLA4*, *IFIH1*, *ERBB3*, and *BAD*. The contribution of each non-MHC locus to T1DM risk is small, making individual variants less useful for predicting the genetic risk of T1DM in a patient. The known functions of these genes suggest the primary etiologic pathways of diabetes, namely, HLA class II and class I molecules binding, T- and β-cell activation, innate pathogen viral responses, chemokine and cytokine signaling, and T-regulatory and antigen-presenting cell functions.

Major Histocompatibility Complex/Human Leukocyte Antigen–Encoded Susceptibility to Type 1 Diabetes Mellitus

The MHC is a large genomic region that contains a number of genes related to immune system function in humans. These genes are further divided into HLA classes I, II, III, and IV. Class II genes are the ones most strongly associated with risk of T1DM, but some of the risk associated with various HLA types is a result of variation in genes in HLA classes other than class II. Overall, genetic variation in the HLA region can explain 40–50% of the genetic risk of T1DM.

Some of the known associations include the HLA DR3/4-DQ2/8 genotype; compared to a population prevalence of T1DM of approximately 1 in 300, DR3/4-DQ2/8 newborns from the general population have a 1 in 20 genetic risk. This risk of development of T1DM is even higher when the high-risk HLA haplotypes are shared with a sibling or parent with T1DM. If one sibling has T1DM and shares the same high-risk DR3/4-DQ2/8 haplotype with another sibling, the risk of autoimmunity in the other sibling is 50%. Moreover, this risk approaches 80% when siblings share both HLA haplotypes identical by descent. This is known as the *relative paradox* and points to the existence of other shared genetic risk factors (most likely in the extended HLA haplotype).

With advances in genotyping, further discrimination is possible and we can identify more specific risk ratios for specific haplotypes. For example, the DRB1*0401-DQA1*0301g-DQB1*0302 haplotype has an odds ratio (OR) of 8.39, whereas the DRB1*0401-DQA1*0301g-DQB1*0301 haplotype has an OR of 0.35, implicating the DQB1*0302 allele as a critical susceptibility allele. There are some dramatically protective DR-DQ haplotypes (e.g., DRB1*1501-DQA1*0102-DQB1*0602 [OR = 0.03], DRB1*1401-DQA1*0101-DQB1*0503 [OR = 0.02], and DRB1*0701-DQA1*0201-DQB1*0303 [OR = 0.02]). The DR2 haplotype (DRB1*1501-DQA1*0102-DQB1*0602) is dominantly protective and is present in 20% of the general population but is seen in only 1% of patients with T1DM.

Role of Aspartate at Position 57 in DQB1

DQB1*0302 (high risk for diabetes) differs from DQB1*0301 (protective against diabetes) only at position 57, where it lacks an aspartic acid

residue. The DQB1*0201 allele (increased risk for diabetes) also lacks aspartic acid at position 57, and it has been proposed that the presence of aspartate at this position alters the protein-recognition and protein-binding characteristics of this molecule. Although the absence of aspartate at this position appears to be important in most studies on White individuals, it does not have the same role in Korean and Japanese populations. Moreover, certain low-risk DQB1 genotypes also lack aspartic acid at position 57, including DQB1*0302/DQB1*0201 (DR7) and DQB1*0201 (DR3)/DQB1*0201 (DR7). Thus the presence of aspartate at this position is usually, but not always, protective in White populations but not necessarily in other populations.

Role of Human Leukocyte Antigen Class I

Although the alleles of class II HLA genes appear to have the strongest associations with diabetes, recent genotyping studies and analyses of pooled data have identified associations with other elements in the HLA complex, especially HLA-A and HLA-B. The most significant association is with HLA-B39, which confers high risk for T1DM in three different populations, makes up the majority of the signal from HLA-B, and is associated with a lower age of onset of the disease.

Non-MHC/HLA Genes Associated with T1DM Risk

The second locus found to be associated with risk of T1DM was localized to a region upstream of the *INS*. Susceptibility in this region has been primarily mapped to a variable number of tandem repeats approximately 500 base pairs (bp) upstream of the insulin gene. This highly polymorphic region consists of anywhere from 30 to several hundred repeats of a 14- to 15-bp unit sequence (ACAGGGGTCTGGGG). The high-risk allele has been found to be associated with lower insulin and messenger RNA (mRNA) production in the thymus, suggesting a possible mechanism for decreased immune tolerance to insulin. A number of candidate genes linked to T1DM susceptibility have also been associated with increased risk of *other* autoimmune disease. These include the genes *PTPN22, IL2RA, CTLA4,* and *IFIH1,* which are involved in immune system regulation. Others, such as *ERBB3* and *BAD,* are thought to be associated with cell apoptosis.

ENVIRONMENTAL FACTORS

That ~45–70% of monozygotic twins are discordant for T1DM, the variation seen in urban and rural areas populated by the same ethnic group, the change in incidence that occurs with migration, the increase in incidence that has been seen in almost all populations in the last few decades, and the occurrence of seasonality all provide evidence that environmental factors also play a significant role in the causation of T1DM.

Viral Infections

It is possible that various viruses play a role in the pathogenesis of T1DM, but no single virus, and no single pathogenic mechanism, stands out in the environmental etiology of T1DM. Instead, a variety of viruses and mechanisms may contribute to the development of diabetes in genetically susceptible hosts. Invoked mechanisms involve direct infection of β cells by viruses resulting in lysis and release of self-antigens, direct viral infection of antigen-presenting cells causing increased expression of cytokines, and molecular mimicry, which is the notion that viral antigens exhibit homology to self-epitopes.

The clearest evidence of a role for viral infection in human T1DM is seen in congenital rubella syndrome. Prenatal infection with rubella is associated with β-cell autoimmunity in up to 70%, with development of T1DM in up to 40% of infected children. The time lag between infection and development of diabetes may be as large as 20 years. T1DM after congenital rubella is more likely in patients who carry the higher-risk genotypes. Interestingly, there appears to be no increase in risk of diabetes when rubella infection develops after birth or when live-virus rubella immunization is used.

Studies have shown an increase in evidence of enteroviral infection in patients with T1DM and an increased prevalence of enteroviral RNA in prenatal blood samples from children who subsequently develop T1DM. It has been reported that mumps infection leads to the development of β-cell autoimmunity with high frequency and to T1DM in some cases. Although mumps may play a role in some cases, the fact that T1DM incidence has increased steadily in several countries after universal mumps vaccination was introduced and that the incidence is extremely low in several populations where mumps is still prevalent indicates that mumps alone is not a major causal factor in diabetes.

The Hygiene Hypothesis: Possible Protective Role of Infections

Although some viral infections may increase the risk of T1DM, infectious agents may also play a protective role against diabetes. The hygiene hypothesis states that T1DM risk is increased in industrialized countries, where the observation that there are fewer infections implies that the immune system is less well trained for its main task, namely host defense. Some call this theory the *microbial deprivation hypothesis*. The hygiene hypothesis states that lack of exposure to childhood infections may increase an individual's chances of developing autoimmune diseases, including T1DM. Rates of T1DM and other autoimmune disorders are generally lower in underdeveloped nations with a high prevalence of childhood infections and tend to increase as these countries become more developed. The incidence of T1DM differs almost sixfold between Russian Karelia and Finland, even though both are populated by genetically related populations and are adjacent to each other and at the same latitude. The incidence of autoimmunity in the two populations varies inversely with immunoglobulin (Ig) E antibody levels, and IgE is involved in the response to parasitic infestation. All these observations suggest that decreased exposure to certain parasites and other microbes in early childhood may lead to an increased risk of autoimmunity in later life, including autoimmune diabetes. Nonetheless, retrospective case-control studies have been equivocal at best, and direct evidence of protection by childhood infections is still lacking.

Gastrointestinal Microbiome

There is emerging evidence that the intestinal microbiome is altered in T1DM; however, a cause-and-effect relationship has yet to be established. Human studies have found that the intestinal microbiome in T1DM has decreased diversity of microbial species and contains fewer butyrate-producing organisms compared to healthy controls. Butyrate is a short-chain fatty acid that is thought to be antiinflammatory and may have a role in protecting the intestinal epithelium, either directly or indirectly, through an effect to increase mucin production. Theoretically, a disruption in epithelial integrity (the so-called *leaky gut*) could trigger inflammation and an enhanced autoimmune response because of increased entry of pathogenic or dietary antigens into the bloodstream. Early, small-scale prospective studies in infants and children at high risk for T1DM have shown an imbalance favoring species including *Bacteroides dorei* and *Bacteroides vulgatus* among individuals who went on to develop T1DM autoantibodies or disease compared with those who did not. A larger study across six different study sites in The Environmental Determinants of Diabetes in the Young (TEDDY) study identified significant geographic differences in fecal microbiome composition, highlighting the challenges in this field of study.

Diet

Dietary exposure may modify T1DM risk; a definitive link between any single dietary exposure and T1DM development has not been found. The majority of interventional studies have not shown an effect of delayed gluten exposure or the use of hydrolyzed formula to reduce the risk for development of T1DM autoantibodies of disease. A meta-analysis of both interventional and observational studies concluded that there was no association between early exposure of gluten or milk protein and risk of T1DM. Some, but not all, studies have suggested that breastfeeding lowers the risk of T1DM. The potential mechanism for a protective effect of breast milk is not well understood but could be related to a beneficial effect of breast milk on the infant immune system or an indirect effect such as reduced exposure to other dietary antigens early in life. Timing of solid food introduction may modify T1DM risk, as seen in a report from the Diabetes Autoimmunity Study in the

Young (DAISY), which found that both early (before 4 months of age) and late (after 6 months of age) introduction of solid foods predicted development of T1DM.

Other dietary factors that have been suggested at various times as playing a role in T1DM risk include omega-3 fatty acids, vitamin D, ascorbic acid, zinc, and vitamin E. Vitamin D is biologically plausible (it has a role in immune regulation), and deficiency is more common in northern countries like Finland where T1DM incidence is highest; however, most observational studies have failed to find associations between vitamin D level or supplementation and T1DM risk. Interventional studies to assess the effect of vitamin D supplementation on T1DM risk are lacking.

PATHOGENESIS AND NATURAL HISTORY OF TYPE 1 DIABETES MELLITUS

In T1DM, a genetically susceptible host develops autoimmunity against the host's own β cells. What triggers this autoimmune response is complex and multifactorial. In some (but not all) patients, this immune-mediated process results in progressive destruction of β cells until a critical mass of β cells is lost and insulin deficiency develops. Insulin deficiency, in turn, leads to the onset of clinical signs and symptoms of T1DM. At the time of diagnosis, if viable β cells are still present and produce some insulin, there may be a partial remission of the disease (**honeymoon period**), but over time, more β-cell mass is destroyed, despite any regeneration and/or persistence of β cells, and the patient becomes totally dependent on exogenous insulin for survival (Fig. 629.2). Over time, some of these patients develop secondary complications of diabetes that appear, in part, to be related to how well-controlled the diabetes has been. The natural history of T1DM involves some or all of the following stages, with two distinct identifiable stages before onset of symptoms:

1. Persistence of one or more islet autoantibodies with normoglycemia and presymptomatic; can last years to decades (onset of autoimmune islet disease AID])
2. β-cell autoimmunity with dysglycemia and presymptomatic; shorter
3. Onset of symptomatic disease; usually quite brief, weeks, rarely months
4. Transient remission, usually within weeks of onset, may last 6-12 months ("honeymoon")
5. Established disease, lifelong
6. Development of complications, quite variable

Initiation of Autoimmunity

Genetic susceptibility to T1DM is determined by several genes, with the largest contribution coming from variants in the HLA system. Nonetheless even with the highest-risk haplotypes, most carriers will not develop T1DM. In monozygotic twins, the concordance of the development of T1DM is reported to be 30–65%. The observed rise in incidence of T1DM, and particularly so in younger children with an essentially genetically stable patient population, implies that something has accordingly changed in the environment. A number of factors, including maternal and intrauterine environmental influences, route of neonatal delivery, foods and diet in infancy, viral infections, lack of exposure to certain infections and antibiotic use, host microbiome, and even psychologic stress, are implicated in the pathogenesis of T1DM, but their exact role and the mechanism by which they trigger or aggravate autoimmunity remain uncertain. What is clear is that markers of autoimmunity are much more prevalent than clinical T1DM, indicating that initiation of autoimmunity is a necessary, but not a sufficient, condition for T1DM. Although no conclusive triggering factor has been identified, it seems that in most cases of T1DM that are diagnosed in childhood, the onset of autoimmunity occurs very early in life. In most children diagnosed before age 10 years, the first signs of autoimmunity appear before age 2 years. Development of autoimmunity is associated with the appearance of several autoantibodies. IAAs are usually the first to appear in young children, followed by GAD, and later by IA-2 and ZnT8 antibodies. The earliest antibodies are predominantly of the IgG_1 subclass. Not only is there spreading of autoimmunity to more antigens (IAA, GAD, IA-2A, ZnT8) but there is also epitope spreading within one antigen. Initial GAD antibodies tend to be against the middle region or the carboxyl-terminal region, whereas amino terminal antibodies usually appear later and are less common in children.

Preclinical Autoimmunity with Progressive Loss of β-Cell Function

In nearly all patients, the appearance of autoimmunity is followed by progressive or eventual destruction of β cells (Figs. 629.3 and 629.4).

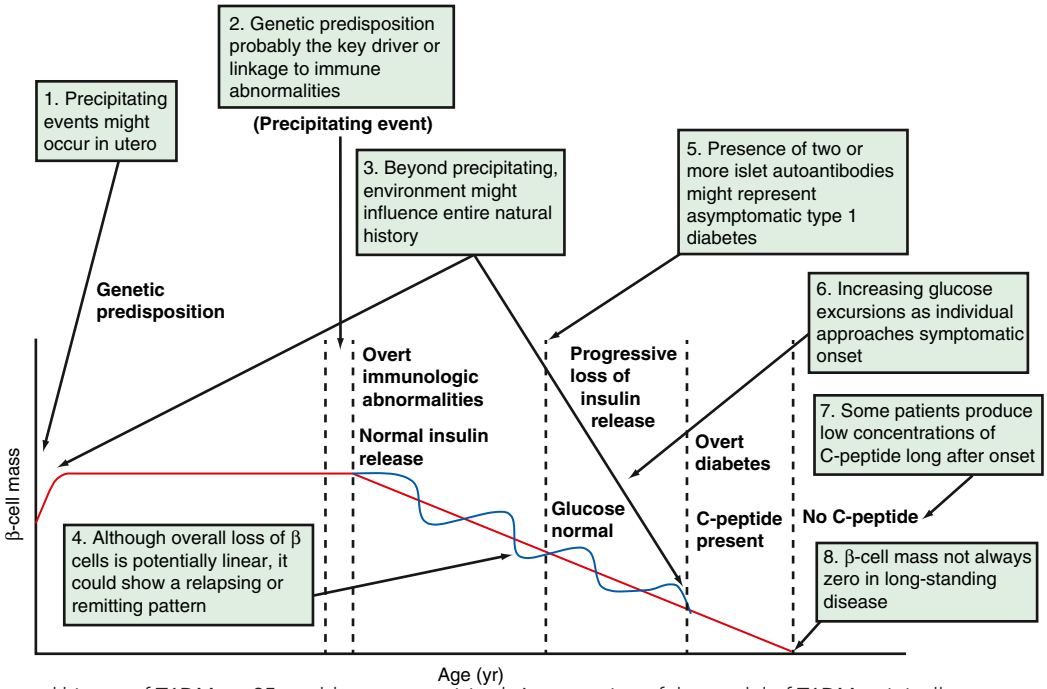

Fig. 629.2 The natural history of T1DM—a 25-yr-old concept revisited. A re-creation of the model of T1DM, originally proposed in 1986, is shown in *black*. Additions and conjectures based on recent knowledge gains are shown in *green boxes*. *(From Atkinson MA, Eisenbarth GS, Michels AW. Type 1 diabetes. Lancet. 2014;383:69–78. Fig. 4.)*

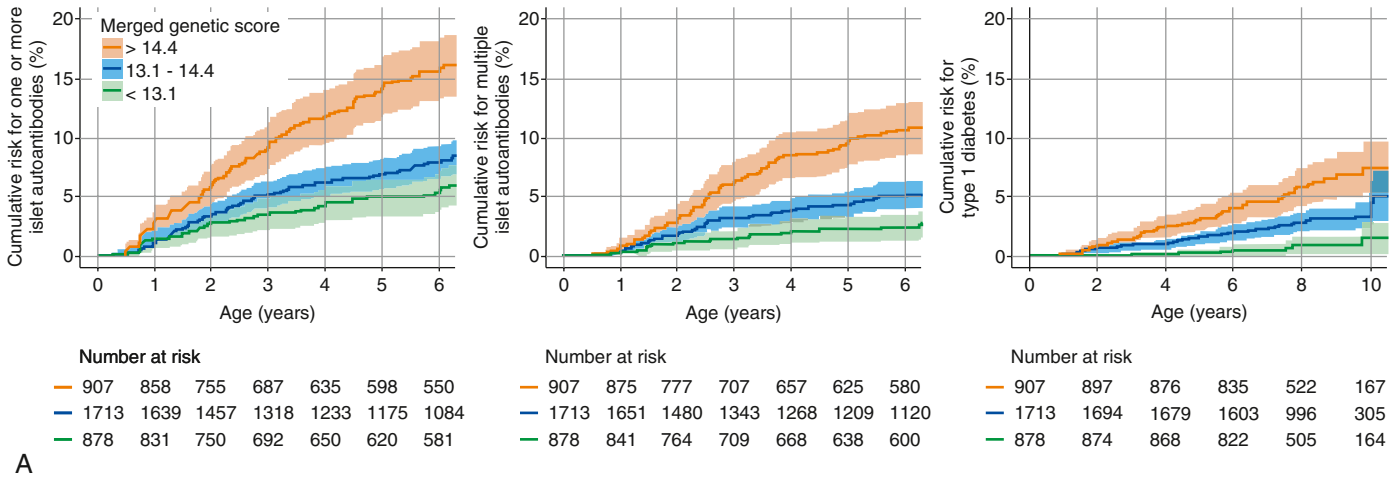

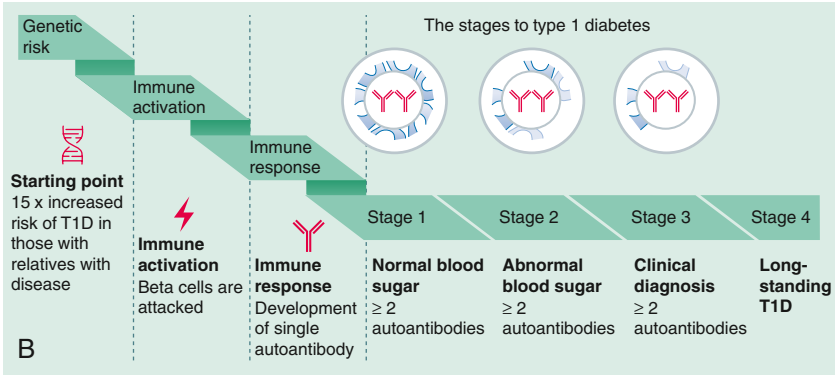

Fig. 629.3 Contributing factors and disease progression in type 1 diabetes. **A,** Cumulative risks of one or more islet autoantibodies, multiple islet autoantibodies, and type 1 diabetes development in TEDDY children with the HLA DR3/DR4-DQ8 or DR4-DQ8/DR4-DQ8 genotype stratified by their merged score. The cumulative risk of developing one or more islet autoantibodies *(left graph)*, multiple islet autoantibodies *(middle graph)*, and type 1 diabetes (*right graph, y* axis) is shown relative to age in yr (*x* axis) and was calculated using the Kaplan ± Meier method. Curves are shown for children with genetic scores in the upper *(orange line)*, lower *(green line)*, and two middle *(blue line)* quartiles. The shaded areas represent the 95% confidence interval of the cumulative risk. The numbers at risk indicate the number of children included in the analysis at each age. **B,** Type 1 diabetes progression and stages of type 1 diabetes. Stage 1 is the start of type 1 diabetes, marked by individuals having two or more diabetes-related autoantibodies and normal blood sugar concentrations. In stage 2, individuals have dysglycemia without symptoms. Stage 3 is the time of clinical diagnosis. T1D, type 1 diabetes. *(**A** from Bonifacio E, Beyerlein A, Hippich M, et al. Genetic scores to stratify risk of developing multiple islet autoantibodies and type 1 diabetes: A prospective study in children. PLoS Med. 2018;15:e1002548. Fig. 4; **B** from Greenbaum CJ, Speake C, Krischer J, et al. Strength in numbers: opportunities for enhancing the development of effective treatments for type 1 diabetes—the TrialNet experience. Diabetes. 2018;67:1216–1225.)*

Antibodies are a marker for the presence of autoimmunity, but the actual damage to the β cells is primarily T-cell mediated (see Fig. 629.4). Histologic analysis of the pancreas from patients with recent-onset T1DM reveals insulitis, with an infiltration of the islets of Langerhans by mononuclear cells, including T and B lymphocytes, monocytes/macrophages, and natural killer cells. The process in human T1DM is not necessarily linear, and there may be an undulating downhill course, with remissions and relapses, in the development of T1DM.

Role of Autoantibodies

Even though T1DM does not occur as a direct consequence of autoantibody formation, the risk of developing clinical disease increases dramatically with an increase in the number of antibodies; only 15% of children with one antibody will progress to diabetes in 10 years, but this risk increases to 70% when two antibodies are present and 90% when three are present. The risk of progression also varies with the intensity of the antibody response, and those with higher antibody titers are more likely to progress to clinical disease. Another factor that appears to influence progression of β-cell damage is the age at which autoimmunity develops; children in whom IAAs appeared within the first 2 years of life rapidly developed anti–islet cell antibodies and progressed to diabetes more frequently than children in whom the first antibodies appeared between ages 5 and 8 years.

Role of Genetics in Disease Progression

In a large study of *healthy* children, the appearance of single antibodies is relatively common and usually transient and does not correlate with the presence of high-risk HLA alleles; those carrying high-risk HLA alleles are more likely to develop multiple antibodies and progress to disease. Similarly, the appearance of antibodies is more likely to predict diabetes in those with a family history of diabetes versus those with no family history of T1DM. Environmental factors may induce transient autoimmunity in many children, but those with genetic susceptibility are more likely to see progression of autoimmunity and eventual development of diabetes.

Role of Environmental Factors

Environmental factors may also act as accelerators of T1DM after the initial appearance of autoimmunity. This is evident from the fact that the incidence of T1DM can vary several-fold between populations that have the same prevalence of autoimmunity. The incidence of T1DM in Finland is almost fourfold higher than in Lithuania, but the incidence of autoimmunity is similar in both countries.

The fact that all children with evidence of autoimmunity and of autoreactive T cells do not progress to diabetes indicates that there are checkpoints at which the autoimmune process can be halted or reversed before it progresses to full-blown diabetes.

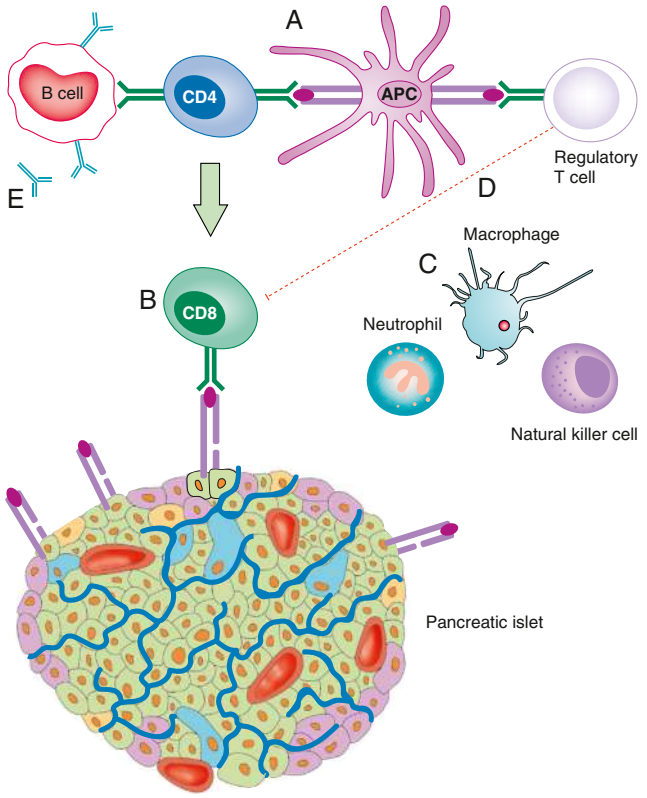

Fig. 629.4 The immunopathogenesis of type 1 diabetes. The development of type 1 diabetes is thought to be initiated by the presentation of β-cell peptides by antigen-presenting cells *(APCs)*. APCs bearing these autoantigens migrate to the pancreatic lymph nodes, where they interact with autoreactive $CD4^+$ T lymphocytes, which in turn mediate the activation of autoreactive $CD8^+$ T cells *(A)*. These activated $CD8^+$ T cells return to the islet and lyse β cells expressing immunogenic self-antigens on major histocompatibility complex class I surface molecules *(B)*. β-Cell destruction is further exacerbated by the release of proinflammatory cytokines and reactive oxygen species from innate immune cells (macrophages, natural killer cells, and neutrophils) *(C)*. This entire process is amplified by defects in regulatory T lymphocytes, which do not effectively suppress autoimmunity *(D)*. Activated T cells within the pancreatic lymph node also stimulate B lymphocytes to produce autoantibodies against β-cell proteins. These autoantibodies can be measured in circulation and are considered a defining biomarker of type 1 diabetes *(E)*. *(From DiMeglio LA, Evans-Molina C, Oram RA. Type 1 diabetes. Lancet. 2018;391:2449–2458. Fig. 3.)*

Onset of Clinical Disease

Patients with progressive β-cell destruction will eventually present with clinical T1DM. It was thought that 90% of the total β-cell mass is destroyed by the time clinical disease develops, but other studies have revealed that this is not always the case. It appears that β-cell destruction is more rapid and more complete in younger children, whereas in older children and adults, the proportion of surviving β cells is greater (10–20% in autopsy specimens), and some β cells (about 1% of the normal mass) survive up to 30 years after the onset of diabetes. Because autopsies are usually done only on patients who died of DKA, these figures may underestimate the actual β-cell mass present at diagnosis. Functional studies indicate that up to 40% of the insulin secretory capacity may be preserved in adults at the time of presentation of T1DM. Ultrasensitive assays indicate that C-peptide production is measurable decades after the onset of T1DM. The fact that newly diagnosed diabetic individuals may still have a significant surviving β-cell mass is important because it raises the possibility of *secondary* prevention of T1DM. Similarly, the existence of viable β cells years or decades after initial presentation indicates that even patients with long-standing diabetes may be able to exhibit some recovery of β-cell function if the autoimmune destructive process could be halted and if islet cell regeneration could occur.

PREDICTION

Autoimmunity precedes clinical T1DM, and indicators of autoimmune responses may be useful markers for disease prediction. Individuals at risk for T1DM can be identified by a combination of genetic, immunologic, and metabolic markers. The most informative genetic locus, HLA class II, confers about half of the total genetic risk but has a low positive predictive value (PPV) when used in the general population. Autoantibodies provide a practical readout of β-cell autoimmunity, are easily sampled in venous blood, and have become the mainstay of T1DM prediction efforts. By comparison, and even though T lymphocytes mediate β-cell destruction, T cells are rare in blood, and assays of their function have been difficult to standardize and validate. In the first-degree relatives of patients with T1DM, the number of positive autoantibodies can help estimate the risk of developing T1DM: low risk (single autoantibodies: PPV of 2–6%), moderate risk (2 autoantibodies: PPV of 21–40%), and high risk (>2 autoantibodies: PPV of 59–80%) over a 5-year period. In children carrying the T1DM highest-risk genotype (HLA-DQB1*0201-DQA1*05/DQB1*0302-DQA1*03), insulitis is almost 10 times more frequent (PPV 21%) than in children with other genotypes (PPV 2.2%). But although autoantibodies are useful for the prediction of T1DM in the relatives of patients with T1DM, outside of that obvious population, the screening of the general population would be required to identify healthy subjects at risk of T1DM. Indeed, ~90% of individuals with new-onset T1DM have no family background of T1DM. Screening the general population is difficult to justify, in part, because the observed autoantibody prevalence greatly exceeds the low disease prevalence in nonrelatives, leading to high false-positive rates.

PREVENTION

Strategies for the prevention of T1DM are focused primarily on slowing progression of β-cell loss after the onset of autoimmune islet disease through targeted immunosuppression of autoreactive regulatory T cells. Numerous compounds are under investigation for this purpose, including agents that could modulate regulatory T cells via stimulating interleukin (IL)-2, tumor necrosis factor (TNF)-α signaling, or CTLA signaling and by inhibiting IL-17 or T-cell receptor (TCR) signaling. Teplizumab, a humanized anti-CD3 monoclonal antibody that inhibits TCR signaling, has been shown to delay the onset of clinical diabetes in high-risk children and young adults. It is approved for use in the United States for patients 8 years and older with stage 2 T1DM, defined by at least two positive pancreatic islet cell autoantibodies and dysglycemia without hyperglycemia.

PATHOPHYSIOLOGY OF T1DM

Insulin performs a critical role in the storage and retrieval of cellular fuel. Its secretion in response to feeding is exquisitely modulated by the interplay of neural, hormonal, and substrate-related mechanisms to permit controlled disposition of ingested foodstuff as energy for immediate or future use. Insulin levels must be lowered to then mobilize stored energy during the fasted state. Thus in normal metabolism, there are regular swings between the postprandial, high-insulin anabolic state and the fasted, low-insulin catabolic state that affect liver, muscle, and adipose tissue (Table 629.4). T1DM is a progressive low-insulin catabolic state in which feeding does not reverse, but rather exaggerates, these catabolic processes. With moderate insulinopenia, glucose use by muscle and fat decreases and postprandial hyperglycemia appears. At even lower insulin levels, the liver produces excessive glucose via glycogenolysis and gluconeogenesis, and fasting hyperglycemia begins. Hyperglycemia produces an osmotic diuresis (glycosuria) when the renal threshold is exceeded (180 mg/dL; 10 mmol/L). The resulting loss of calories and electrolytes, as well as the worsening dehydration, produces a physiologic stress with hypersecretion of stress hormones (epinephrine, cortisol, growth hormone, and glucagon). These hormones, in turn, contribute to the metabolic decompensation by further impairing insulin secretion (epinephrine), by antagonizing its action (epinephrine, cortisol, growth hormone), and by promoting

Table 629.4 Influence of Feeding (High Insulin) or of Fasting (Low Insulin) on Some Metabolic Processes in Liver, Muscle, and Adipose Tissue*

	HIGH PLASMA INSULIN (POSTPRANDIAL STATE)	LOW PLASMA INSULIN (FASTED STATE)
Liver	Glucose uptake	Glucose production
	Glycogen synthesis	Glycogenolysis
	Absence of gluconeogenesis	Gluconeogenesis
	Lipogenesis	Absence of lipogenesis
	Absence of ketogenesis	Ketogenesis
Muscle	Glucose uptake	Absence of glucose uptake
	Glucose oxidation	Fatty acid and ketone oxidation
	Glycogen synthesis	Glycogenolysis
	Protein synthesis	Proteolysis and amino acid release
Adipose tissue	Glucose uptake	Absence of glucose uptake
	Lipid synthesis	Lipolysis and fatty acid release
	Triglyceride uptake	Absence of triglyceride uptake

*Insulin is considered to be the major factor governing these metabolic processes. Diabetes mellitus may be viewed as a permanent low-insulin state that, if untreated, results in exaggerated fasting.

glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis (glucagon, epinephrine, growth hormone, and cortisol) while decreasing glucose use and glucose clearance (epinephrine, growth hormone, cortisol).

The combination of insulin deficiency and elevated plasma values of the counterregulatory hormones is also responsible for accelerated lipolysis and impaired lipid synthesis, with resulting increased plasma concentrations of total lipids, cholesterol, triglycerides, and free fatty acids. The hormonal interplay of insulin deficiency and glucagon excess shunts the free fatty acids into ketone body formation; the supranormal rate of formation of these ketone bodies, principally β-hydroxybutyrate and acetoacetate, exceeds the capacity for peripheral use and renal excretion. Accumulation of these keto acids results in metabolic acidosis (DKA) and compensatory rapid, deep, nondyspneic breathing to excrete excess CO_2 (Kussmaul respiration). Acetone, formed by nonenzymatic conversion of acetoacetate, is responsible for the characteristic fruity odor of the breath. Ketones are excreted in the urine in association with cations and thus further increase losses of water and electrolyte and bicarbonate regenerating ability. With progressive dehydration, acidosis, hyperosmolality, and diminished cerebral oxygen use, consciousness becomes impaired, and the patient ultimately becomes comatose.

CLINICAL MANIFESTATIONS

The classic clinical manifestations of new-onset diabetes in children reflect the hyperglycemic and catabolic physiologic state and include polyuria, polydipsia, polyphagia, and weight loss. Other common symptoms include fatigue, weakness, and a general feeling of malaise. Patients presenting with more advanced disease will exhibit signs of **DKA**, including dehydration, nausea, vomiting, lethargy, altered mental status, and in extreme cases, coma. If the diagnosis is not recognized, the progression of symptoms follows a predictable course from early intermittent polyuria, to sustained polyuria and weight loss, followed by development of DKA. In most cases, this initial progression occurs over a period of weeks rather than months.

Initially, when only insulin reserve is limited, occasional asymptomatic postprandial hyperglycemia occurs. When insulin secretory capacity declines, blood glucose levels begin to rise. When the blood glucose increases above the renal threshold, intermittent polyuria and/or nocturia begins. With further β-cell loss, chronic hyperglycemia causes a more persistent diuresis, which often includes nocturnal enuresis in younger children. Female patients may develop vulvovaginal candidiasis from the chronic glycosuria. Eventually, daily losses of water and glucose may be as high as 5 L and 250 g, respectively, representing 1,000 calories, or 50%, of the average daily caloric intake. These losses trigger compensatory polydipsia and polyphagia; however, progressive dehydration and weight loss will inevitably ensue unless treatment is initiated.

When the disease continues to progress, ketoacids begin to accumulate. At this stage in the disease, rapid clinical deterioration is possible. Ketoacids produce abdominal pain, anorexia, nausea, and emesis and thereby impede the patient's ability to maintain sufficient oral replacement of urinary water losses. Dehydration accelerates, as manifested by weakness, orthostasis, and further weight loss. As in any hyperosmotic state, the degree of dehydration may be clinically underestimated because intravascular volume is conserved at the expense of intracellular volume. Signs and symptoms of advanced ketoacidosis include Kussmaul respirations (deep, heavy, nonlabored, rapid breathing), fruity breath odor (acetone), prolonged corrected Q-T interval, diminished neurocognitive function, and coma. Approximately 20–40% of children with new-onset diabetes progress to DKA before diagnosis; data from the United States suggest that the prevalence of DKA at onset of T1DM is increasing.

Clinical progression typically happens more quickly in younger children, owing to either more aggressive autoimmune destruction of β-cells and/or to lower β-cell mass. Disease onset in infancy is associated with a greater likelihood of DKA at presentation. Weight loss in younger children and individuals with more rapidly progressive disease will be composed mostly of acute fluid loss, whereas weight loss in adolescents and individuals with slowly progressive disease will also include significant fat and lean mass deficits as a result of prolonged starvation. In any child, the progression of symptoms may be accelerated by the stress of an intercurrent illness or trauma, when counterregulatory (stress) hormones counter the limited insulin secretory capacity.

DIAGNOSIS

The diagnosis of T1DM is usually straightforward (see Table 629.2). Although most symptoms are nonspecific, the most important clue is an inappropriate polyuria in any child with signs of dehydration and poor weight gain. Hyperglycemia can be identified quickly from capillary blood by use of a glucometer; glycosuria and ketonuria can readily be determined by urine dipstick. Nonfasting blood glucose greater than 200 mg/dL (11.1 mmol/L) with typical symptoms is diagnostic with or without ketonuria. In the obese child, T2DM must be considered (see Chapter 629.3). Once hyperglycemia is confirmed, it is prudent to determine whether DKA is present (especially if ketonuria is found) by checking a venous blood sample for bicarbonate and pH and also to evaluate for electrolyte abnormalities—even if signs of dehydration are minimal. A baseline HbA_{1c} will be confirmatory and allows an estimate of the duration of hyperglycemia and provides an initial value by which to compare the effectiveness of subsequent therapy. Falsely low HbA_{1c} levels are noted in hemolytic anemias (sickle cell anemia, others), pure red cell aplasia, blood transfusions, and anemias associated with hemorrhage, cirrhosis, myelodysplasias, or renal disease treated with erythropoietin.

Testing for autoimmunity (T1DM autoantibodies) (see Chapter 629.1) should be considered in cases where the differentiation between T1DM and T2DM is not apparent and in cases where there is a strong family history suggestive of monogenic and syndromic diabetes. The presence of other autoimmune diseases associated with T1DM should be sought at or shortly after diagnosis, including celiac disease (by tissue transglutaminase immunoglobulin A [IgA] and total IgA) and autoimmune hypothyroidism (by thyroid-stimulating hormone [TSH] and free or total thyroxine). Because significant physiologic perturbations can affect thyroid and celiac screening tests, individuals with

only mild abnormalities should have tests repeated *after* several weeks before instituting therapy. In addition, because there is an increased risk of cardiovascular disease associated with diabetes, it is also recommended to obtain a fasting lipid profile in children ≥10 years of age once glucose control has been established.

Rarely, a child has transient hyperglycemia with glycosuria while under substantial physical stress or illness. This usually resolves permanently during recovery from the stressors. **Stress-produced hyperglycemia** can reflect a limited insulin reserve temporarily revealed by elevated counterregulatory hormones. A child with temporary hyperglycemia should therefore be monitored for the development of symptoms of persistent hyperglycemia and be tested with an HbA_{1c} if such symptoms occur. Formal testing in a child who remains clinically asymptomatic is not necessary.

Routine screening procedures, such as postprandial determinations of blood glucose or screening OGTTs, have yielded low detection rates in healthy, asymptomatic children, even among those considered at risk, such as siblings of diabetic children. Accordingly, such screening procedures are not recommended in children.

TREATMENT

Therapy is tailored to the degree of insulinopenia at presentation. Most children with new-onset T1DM have mild to moderate symptoms, have minimal dehydration with no history of emesis, and have not progressed to ketoacidosis. They can be started on subcutaneous insulin therapy directly. About 20–40% of children with new-onset diabetes present in DKA, which can be arbitrarily classified as mild, moderate, or severe (Table 629.5), and the range of symptoms depends on the degree of ketoacidosis. Cardinal biochemical abnormalities include elevations in blood and urine ketones, an increased anion gap, a decreased serum bicarbonate (or total CO_2) and pH, and an elevated effective serum osmolality. Hyponatremia is commonly present with hyperglycemia and is the result of an osmotic dilution as water shifts into the extracellular fluid. Potassium and phosphate depletion is common after prolonged polyuria but may be masked by acidosis, which leads to extracellular shifting of these ions.

Treatment of Diabetic Ketoacidosis

Severe insulinopenia (or lack of effective insulin action) results in a physiologic cascade of events in three general pathways:

1. Excessive glucose production coupled with reduced glucose use raises serum glucose. This triggers an osmotic diuresis, with urinary loss of fluid and electrolytes, dehydration, and activation of the renin-angiotensin-aldosterone axis with accelerated potassium loss. When glucose elevation and dehydration are severe and persist for several hours, the risk of cerebral edema increases.
2. Increased catabolic processes result in cellular losses of sodium, potassium, and phosphate.
3. Increased release of free fatty acids from peripheral fat stores supplies substrate for hepatic ketoacid production. When ketoacids accumulate, buffer systems are depleted, and a metabolic acidosis ensues.

Therapy must address both the initiating event in this cascade (insulinopenia) and the subsequent physiologic disruptions.

Reversal of DKA is associated with inherent risks that include hypoglycemia, hypokalemia, and cerebral edema. Any protocol must be used with caution and close monitoring of the patient. Adjustments based on sound medical judgment may be necessary for any given level of DKA (Figs. 629.5 and 629.6).

Dehydration and Hyperglycemia

Judicious fluid resuscitation is the first step in the medical management of DKA. Correction of fluid deficits must be tempered by the potential risk of cerebral edema. It is prudent to approach any child in any hyperosmotic state with cautious rehydration. The effective serum osmolality ($E_{osm} = 2 \times [Na_{uncorrected}] + [glucose]$) is an accurate index of tonicity of the body fluids, reflecting intracellular and extracellular hydration better than measured plasma osmolality. It is calculated with sodium and glucose in mmol/L. This value is usually elevated at the beginning of therapy and should steadily normalize. A rapid decline, or a slow decline to a subnormal range, may indicate an excess of free water entering the vascular space and an increasing risk of cerebral edema. Therefore patients should not be allowed oral fluids until rehydration is well underway and significant electrolyte shifts are no longer likely. Limited ice chips may be given as a minimal oral intake. All fluid intake and output should be closely monitored.

Calculation of fluid deficits using clinical signs is difficult in children with DKA because intravascular volume is better maintained in the hypertonic state. For any degree of tachycardia, delayed capillary refill, decreased skin temperature, or orthostatic blood pressure change, the child with DKA will be more dehydrated than the child with a normotonic fluid deficit. Typically, an initial intravenous bolus of 10-20 mL/kg of glucose-free isotonic sodium salt solution such as Ringer lactate or 0.9% sodium chloride is given over 1 to 2 hours. Further fluid boluses should be given only for hemodynamically unstable patients. This bolus is given as isotonic saline because the patient is inevitably hypertonic, keeping most of the initial infusion in the intravascular space. Subsequent fluid replacement then consists of 0.45% or 0.9% sodium chloride infused at a rate calculated to replace the fluid deficit (after subtracting initial fluid bolus) over 24-48 hours plus maintenance. The fluid deficit can be calculated empirically if a recent weight is available, estimated at 5–10% of body weight based upon clinical severity, or by assuming a standard water deficit (85 mL/kg). Practically, this is generally equivalent to a rate of ~1.5 times maintenance, which can be substituted for simplicity in most situations.

The optimal fluid protocol to prevent CNS complications (cerebral edema) of DKA remains uncertain. When children with DKA were randomly assigned to one of four treatment arms consisting of fast or slow fluid deficit repletion of 0.9% or 0.45% sodium chloride, there were no differences in short- or long-term neurocognitive outcomes among any of the treatment arms. In general, after reestablishing the intravascular volume and avoiding rapid declines of blood glucose levels and hyponatremia, fluid replacement rates or fluid composition may subsequently be administered per protocol (see Fig. 629.5). *It is possible that cerebral injury preceded therapy and is the result of DKA and not rates or composition of IV fluids.*

Insulin must be given to promote movement of glucose into cells, to subdue hepatic glucose production, and to halt the movement of fatty acids from the periphery to the liver. An initial IV insulin bolus does not speed recovery and may increase the risk of hypokalemia and hypoglycemia. *Therefore insulin infusion is typically begun without an insulin bolus at*

Table 629.5 Classification of Diabetic Ketoacidosis

	NORMAL	MILD	MODERATE	SEVERE*
HCO_2 (mEq/L, venous)†	20-28	16-20	10-15	<10
pH (venous)†	7.35-7.45	7.25-7.35	7.15-7.25	<7.15
Clinical	No change	Oriented, alert but fatigued	Kussmaul respirations; oriented but sleepy; arousable	Kussmaul or depressed respirations; sleepy to depressed sensorium to coma

*Severe hypernatremia (corrected Na >150 mEq/L) would also be classified as severe diabetic ketoacidosis.
†HCO_2 and pH measurement are method dependent; normal ranges may vary.

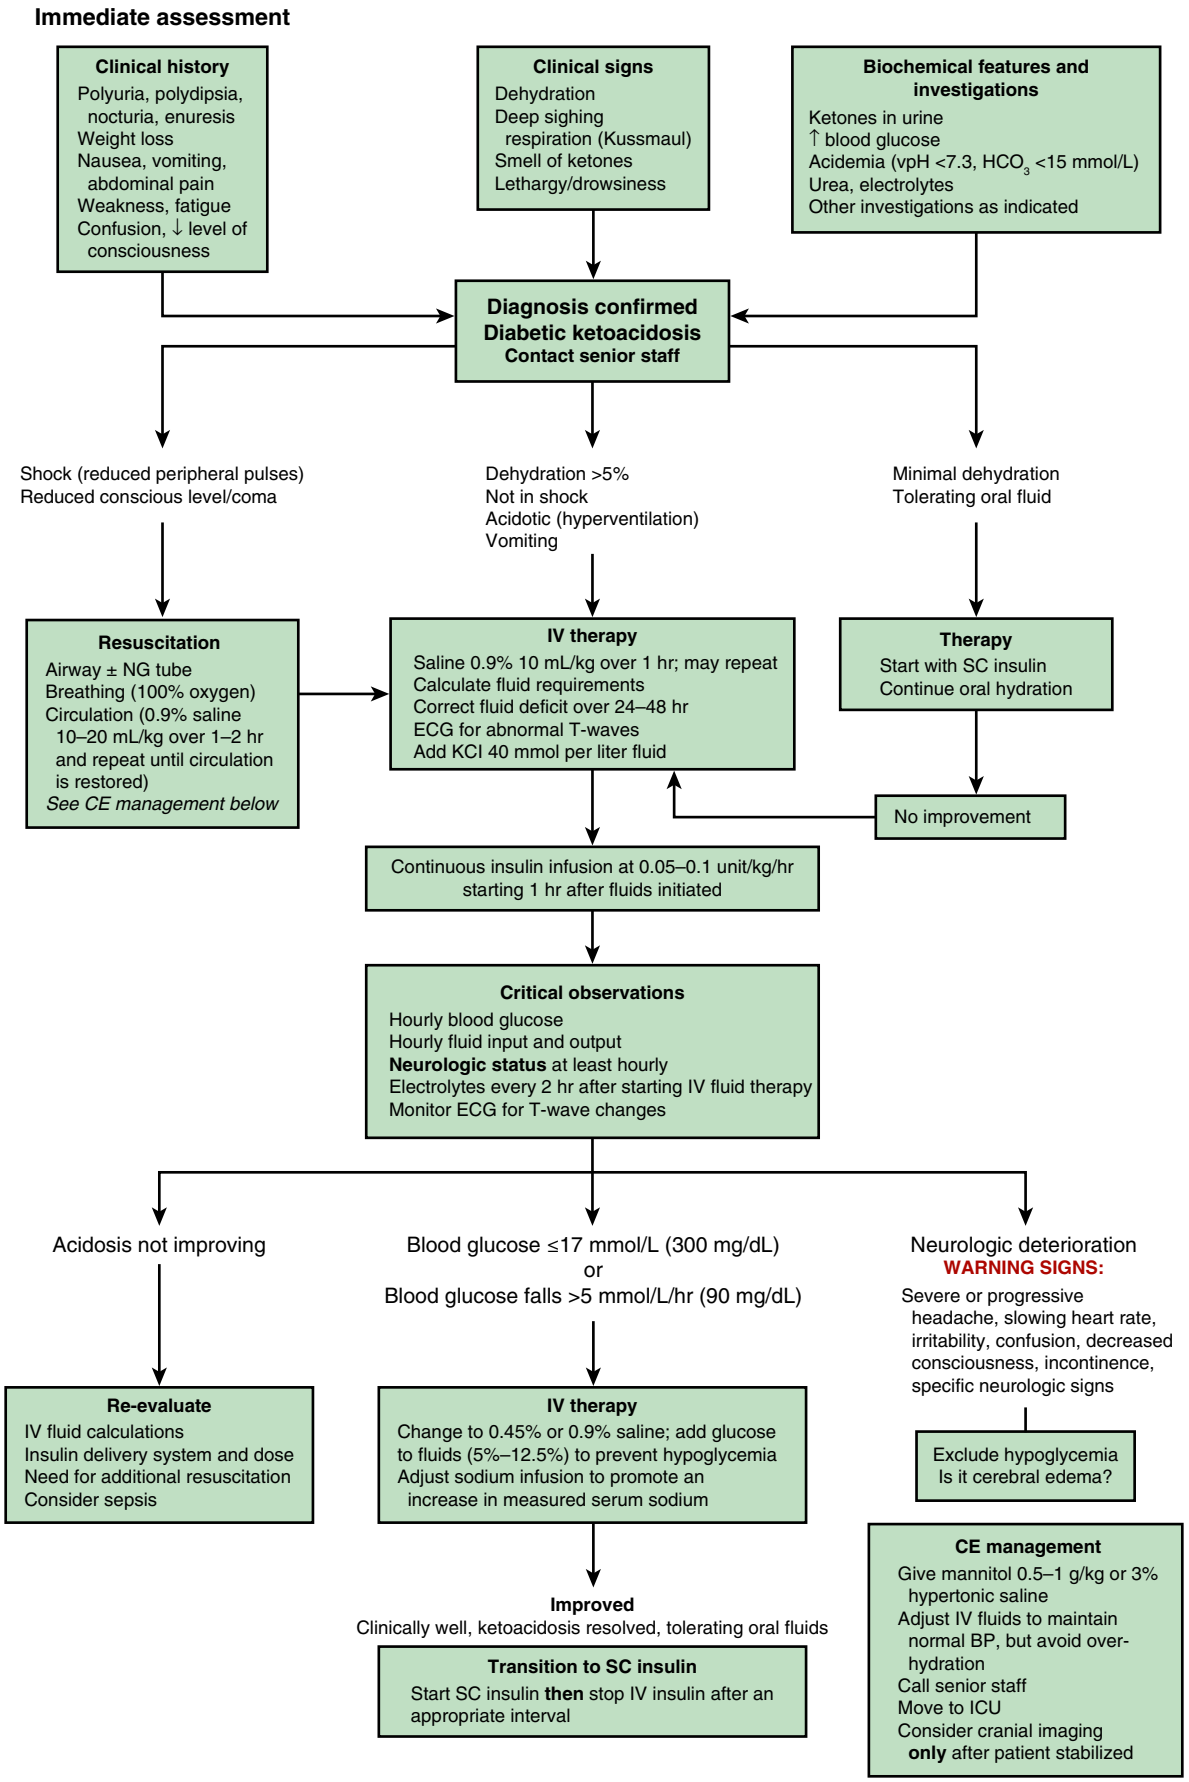

Fig. 629.5 Algorithm for the management of diabetic ketoacidosis. CE, cerebral edema; ECG, electrocardiogram; KCl, potassium chloride; SC, subcutaneous. *(Adapted from Pinhas-Hamiel O, Sperling M. Diabetic ketoacidosis. In: Hochberg Z, ed. Practical Algorithms in Pediatric Endocrinology. 3rd ed. Basel, Switzerland: Karger; 2017:112–113.)*

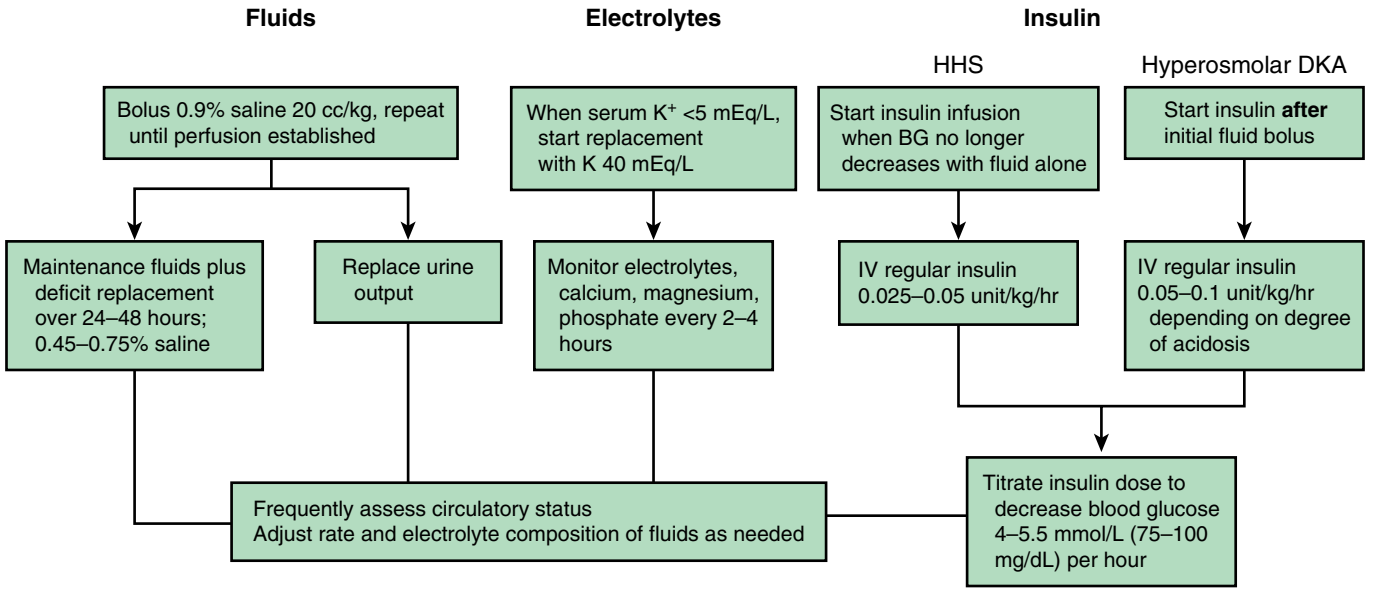

Fig. 629.6 Algorithm for the treatment of hyperglycemic hyperosmolar syndromes (HHS). BG, blood glucose. *(From Zeitler P, Haqq A, Rosenbloom A, Glaser N. Hyperglycemic hyperosmolar syndrome in children: pathophysiological considerations and suggested guidelines for treatment. J Pediatr. 2011;158(1):9–14, 14.e1–2.)*

a rate of 0.05 to 0.1 units/kg/hr after initial fluid resuscitation is complete. This approximates maximal insulin output in normal subjects during an OGTT. Rehydration alone also lowers glucose levels by improving renal perfusion and enhancing renal excretion. The combination of these therapies usually causes a rapid initial decline in serum glucose levels. Persistent decreases in serum glucose of >100 mg/dL/hr may increase the risk of cerebral edema; therefore careful monitoring of serum glucose and adjustment of the dextrose concentration of the IV fluids is essential. The dextrose concentration of the IV fluids should be 5% (D5) once serum glucose falls below ~300 mg/dL and 10% once glucose is below 200 mg/dL. The use of a two-bag system is the preferred approach for managing the dextrose concentrations of the infused IV fluid during DKA. A two-bag system consists of two IV bags of identical electrolyte concentrations, where one bag contains 0% dextrose and the other contains 10% dextrose. The fluids are administered via a Y-site and can be easily titrated to infuse fluids ranging from 0% to 10% dextrose.

Once the blood glucose level decreases below ~180 mg/dL (10 mmol/L), the osmotic diuresis stops and rehydration accelerates without further increase in the infusion rate. Repair of hyperglycemia occurs well before correction of acidosis. Therefore insulin is still needed to control fatty acid release and ketosis after normal glucose levels are reached. If serum glucose levels fall below 100 mg/dL despite an infusion of D10-containing IV fluids, the glucose infusion rate can be increased by increasing dextrose to 12.5% or by increasing the infusion rate. Alternatively, the IV insulin rate can be decreased if ketosis continues to improve.

The initial serum sodium is usually normal or low because of the osmolar dilution caused by hyperglycemia and the effect of an elevated sodium-free lipid fraction. An estimate of the reconstituted, or "true," serum sodium for any given glucose level above 100 mg/dL (5.6 mmol/L) is calculated as follows:

$$\left[Na^+\right] + \left(\begin{array}{l}1.6\,\text{mEq/L}\,Na^+ \text{ for every } 100\,\text{mg/dL glucose in}\\ \text{excess of } 100\end{array}\right)$$

or

$$\left[Na^+\right] + \left(\frac{1.6\,\text{mEq}}{\begin{array}{l}\text{L}Na^+ \text{ for every } 5.6\,\text{mmol}\\ \text{L glucose}\end{array}} \text{ in excess of } 5.6\right)$$

The sodium should *increase* by approximately 1.6 mmol/L for each 100 mg/dL *decline* in the glucose. The corrected sodium is usually normal or slightly elevated and indicates moderate hypernatremic dehydration. If the corrected value is greater than 150 mmol/L, severe hypernatremic dehydration may be present and may require *slower* fluid replacement. The sodium should steadily increase with therapy. *Declining sodium may indicate excessive free water accumulation and increased risk of cerebral edema.*

Both the metabolic shift to a catabolic predominance and the acidosis move potassium and phosphate from the cell to the serum. The osmotic diuresis, the kaliuretic effect of the hyperaldosteronism, and the ketonuria then accelerate renal losses of potassium and phosphate. Sodium is also lost with the diuresis, but free water losses are greater than isotonic losses. With prolonged illness and severe DKA, total body losses can approach 10-13 mEq/kg of sodium, 5-6 mEq/kg of potassium, and 4-5 mEq/kg of phosphate. These losses continue for several hours during therapy until the catabolic state is reversed and the diuresis is controlled. For example, 50% of infused sodium may be lost in the urine during IV therapy. Even though the sodium deficit may be repaired within 24 hours, intracellular potassium and phosphate may not be completely restored for several days.

Although patients with DKA have a total body potassium deficit, the initial serum level is often normal or elevated. This is caused by the movement of potassium from the intracellular space to the serum, both as part of the ketoacid buffering process and as part of the catabolic shift. These effects are reversed with therapy, and potassium returns to the cell. Improved hydration increases renal blood flow, allowing for increased excretion of potassium in the elevated aldosterone state. The net effect is often a dramatic decline in serum potassium levels, especially in severe DKA. This can precipitate changes in cardiac conductivity, flattening of T waves, and prolongation of the QRS complex and can cause skeletal muscle weakness or ileus. The risk of myocardial dysfunction is increased with shock and acidosis. Potassium levels must be closely followed and electrocardiographic monitoring continued until DKA is substantially resolved. Potassium should be added to the IV fluids once serum potassium declines below 5.5 mEq/L and titrated. A 1:1 mixture of potassium chloride (or acetate) and potassium phosphate is typically used. Rarely, the IV insulin must be temporarily held if serum potassium levels drop below 3 mEq/L. It is unclear whether phosphate deficits contribute to symptoms of DKA such as generalized muscle weakness. In pediatric patients, a deficit has not been shown to compromise oxygen delivery via a deficiency of 2,3-diphosphoglycerate. In most cases, the inclusion of potassium phosphate as outlined earlier will be sufficient; however, additional IV supplementation with potassium phosphate can be used if needed.

Pancreatitis (usually mild) is occasionally seen with DKA, especially if prolonged abdominal distress is present; serum amylase and lipase may be elevated. If the serum lipase is not elevated, the amylase is likely nonspecific or salivary in origin. Serum creatinine adjusted for age may be falsely elevated owing to interference by ketones in the autoanalyzer methodology. An initial elevated value rarely indicates renal failure and should be rechecked when the child is less ketonemic. Blood urea nitrogen may be elevated with prerenal azotemia and should be rechecked as the child is rehydrated. Mildly elevated creatinine or blood urea nitrogen is not a reason to withhold potassium therapy if good urinary output is present.

Ketoacid Accumulation

Low insulin infusion rates (0.02-0.05 units/kg/hr) are usually sufficient to stop peripheral release of fatty acids, thereby eliminating the flow of substrate for ketogenesis. Ketogenesis continues until fatty acid substrates already in the liver are depleted, but this production declines much more quickly without new substrate inflow. Bicarbonate buffers, regenerated by the distal renal tubule and by metabolism of ketone bodies, steadily repair the acidosis once ketoacid production is controlled. *Bicarbonate therapy may increase the risk of hypokalemia and cerebral edema; it should be considered only in rare situations with severe acidosis unresponsive to standard DKA management.*

There should be a steady increase in pH and serum bicarbonate as therapy progresses. Kussmaul respirations should abate and abdominal pain resolve. Persistent acidosis may indicate inadequate insulin or fluid therapy, infection, or rarely lactic acidosis. Urine ketones may be positive after ketoacidosis has resolved because the nitroprusside reaction routinely used to measure urine ketones by dipstick measures only acetoacetate. During DKA, most excess ketones are β-hydroxybutyrate, which increases the normal ratio to acetoacetate from 3:1 to as high as 8:1. With resolution of the acidosis, β-hydroxybutyrate converts to acetoacetate, which is excreted into the urine and detected by the dipstick test. Therefore persistent ketonuria may not accurately reflect the degree of clinical improvement and should not be relied on as an indicator of therapeutic failure. β-Hydroxybutyrate can be measured from serum and even by bedside capillary ketometer and is used in some protocols to monitor the resolution of DKA and help determine when to transition from IV to subcutaneous insulin administration.

All patients with known diabetes presenting in DKA should be checked for precipitating events (infection, poor compliance, trauma) that may have triggered the metabolic decompensation.

Diabetic Ketoacidosis Protocol

See Figure 629.5.

Even though DKA can be of variable severity, a common approach to all cases simplifies the therapeutic regimen and can be safely used for most children. Fluids are best calculated based on weight, not body surface area (m^2), because heights are rarely available for the acutely critically ill child. Children with milder DKA recover in 10-20 hours (and need less total IV fluid before switching to oral intake), whereas those with more severe DKA may require up to 36 hours with this protocol. Any child can be transitioned to oral intake and subcutaneous insulin when DKA has resolved (total CO_2 >15 mEq/L; pH >7.30; sodium is stable between 135 and 145 mEq/L; anion gap closed; no emesis). A dose of long-acting insulin is given (or continuous subcutaneous infusion is started via pump) and the insulin drip is discontinued approximately 30 minutes later. Typically, transition is timed to occur around mealtime so that short-acting insulin can be given as well. Frequent (every 2-3 hours) short-acting insulin bolusing may need to be given until ketosis resolves.

A flow sheet is mandatory for accurate monitoring of changes in acidosis, electrolytes, fluid balance, and clinical status, especially if the patient is transferred from the emergency department to an inpatient setting with new caretakers. This flow sheet is best implemented by a central computer system, which allows for rapid update and wide availability of results, as well as rule-driven highlighting of critical values. A paper flow sheet suffices if it stays with the patient, is kept current, and is reviewed frequently by the physician. Any flow sheet should include columns for serial electrolytes, pH, glucose, and fluid balance. Blood glucose should be tested every hour and electrolytes should be tested every 1-2 hours for children with severe DKA and every 3-4 hours for those with mild to moderate DKA.

Cerebral Edema

Cerebral edema is an important cause of morbidity and mortality in children and adolescents with T1DM. Despite the clinical significance of this complication, its etiology remains incompletely understood. A case control study of DKA suggested that baseline acidosis and abnormalities of sodium, potassium, and blood urea nitrogen concentrations were important predictors of risk of cerebral edema. Early bolus administration of insulin and high volumes of fluid were also identified as risk factors. The incidence of cerebral edema in children with DKA has not changed over the past 15-20 years, despite the widespread introduction of gradual rehydration protocols during this interval. Radiographic imaging is frequently unhelpful in making the diagnosis of cerebral edema. Consequently, each patient must be closely monitored (see Fig. 629.5). For all but the mildest cases, this includes frequent neurologic checks for any signs of increasing intracranial pressure, such as a change of consciousness, depressed respiration, worsening headache, bradycardia, apnea, pupillary changes, papilledema, ptosis, posturing, and seizures. In the event of the development of cerebral edema, immediate interventions should include elevation of the head of the bed, reduction in IV fluid rate, and administration of mannitol (typically 1 g/kg infused intravenously over 20 minutes). Children with moderate to severe DKA have a higher overall risk of cerebral edema and should be treated in a hospital environment where appropriate monitoring can occur.

Nonketotic Hyperosmolar Coma

This syndrome is characterized by severe hyperglycemia (blood glucose >800 mg/dL; 44 mmol/L), absence of or only slight ketosis, nonketotic acidosis, severe dehydration, depressed sensorium or frank coma, and various neurologic signs that may include grand mal seizures, hyperthermia, hemiparesis, and positive Babinski signs. Respirations are usually shallow, but coexistent metabolic (lactic) acidosis may be manifested by Kussmaul breathing. Serum osmolarity is commonly 350 mOsm/kg or greater. This condition is uncommon in children, although it may be increasing in frequency with the rise in the incidence of T2DM. Among adults, mortality rates are high, possibly in part because of delays in recognition and institution of appropriate therapy. In children, there has been a high incidence of preexisting neurologic injury. Profound hyperglycemia may develop over a period of days, and initially, the obligatory osmotic polyuria and dehydration may be partially compensated for by increasing fluid intake. In some cases, consumption of excessive sugar-sweetened beverages may further exacerbate hyperglycemia. With progression of disease, thirst becomes impaired, possibly because of alteration of the hypothalamic thirst center by hyperosmolarity and, in some instances, because of a preexisting defect in the hypothalamic osmoregulating mechanism.

The low production of ketones is attributed mainly to the hyperosmolarity, which in vitro blunts the lipolytic effect of epinephrine and the antilipolytic effect of residual insulin; blunting of lipolysis by the therapeutic use of β-adrenergic blockers may contribute to the syndrome. Depression of consciousness is closely correlated with the degree of hyperosmolarity in this condition and in DKA. Hemoconcentration may also predispose to cerebral arterial and venous thromboses before therapy is initiated.

Treatment of nonketotic hyperosmolar coma is directed at rapid repletion of the vascular volume deficit with normal saline and very slow correction of the hyperosmolar state (see Fig. 629.6). The fluid deficit should be estimated at 12–15% of body weight. Additional normal saline boluses may be required to reduce tachycardia and poor perfusion. One-half isotonic saline (0.45% NaCl; may use normal saline) is administered at a rate estimated to replace 50% of the volume deficit in the first 12 hours, and the remainder is administered during the ensuing 24 hours. The rate of infusion and the saline concentration are titrated to result in a slow decline of serum osmolality. When

the blood glucose concentration approaches 300 mg/dL, the hydrating fluid should be changed to 5% dextrose in 0.45% NaCl. Approximately 20 mEq/L of potassium chloride should be added to each of these fluids to prevent hypokalemia. Serum potassium and plasma glucose concentrations should be monitored at 2-hour intervals for the first 12 hours and at 4-hour intervals for the next 24 hours to permit appropriate adjustments of administered potassium and insulin.

Insulin can be given by continuous intravenous infusion only after serum glucose levels no longer decline with fluid administration. The IV insulin should be initiated at a low dose of 0.025-0.05 units/kg/hr and titrated to achieve a slow decline in serum glucose of 50-75 mg/dL/hr (2.8-4.2 mmol/L/hr). The presence of ketosis or more severe acidosis may necessitate earlier insulin initiation.

INITIATION OF SUBCUTANEOUS INSULIN THERAPY

Excellent diabetes control involves many goals: to maintain blood glucose and HbA_{1c} levels as close to normal without causing hypoglycemia, to eliminate polyuria and nocturia, to prevent ketoacidosis, to permit normal growth and development, and to avoid development of diabetes-related complications—all while minimizing the impact on lifestyle. The specific components of therapy include initiation and adjustment of insulin, extensive teaching of the child and caretakers, and reestablishment of the life routines. Each aspect should be addressed early in the overall care.

Insulin Therapy

Insulin therapy is initiated at the time of diagnosis for all patients with T1DM. The starting dose may range from 0.4 to 1.2 units/kg/day and is calculated based on a number of factors, including age, pubertal stage, and presence or absence of DKA. Typically, prepubertal children presenting without DKA can be started on a dose of 0.4-0.6 units/kg/day. Overweight pubertal adolescents presenting with DKA may need up to 1-1.2 units/kg/day. Insulin requirements in infancy vary tremendously, from <0.2 units/kg/day to >1 unit/kg day. Table 629.6 shows typical starting ranges for total daily insulin dose (units/kg/day) in children.

The precise optimal insulin dose can only be determined empirically, after beginning with the previously mentioned starting doses, with frequent self-monitored blood glucose levels and insulin adjustment by the diabetes team. Many children with new-onset diabetes have some residual β-cell function (the honeymoon period), which is associated with reduced exogenous insulin needs shortly after starting treatment. Residual β-cell function usually fades within a few months and is reflected as a steady increase in insulin requirements and wider glucose excursions.

The initial insulin schedule should be directed toward the optimal degree of glucose control in an attempt to duplicate the activity of the β cell. There are inherent limits to our ability to mimic the β cell. Exogenous insulin does not have a first pass to the liver, whereas 50% of pancreatic portal insulin is taken up by the liver, a key organ for the disposal of glucose. Absorption of an exogenous dose continues despite hypoglycemia, whereas endogenous insulin secretion ceases and serum levels quickly lower with a normally rapid clearance. The absorption rate from an injection varies by injection site and patient activity level, whereas endogenous insulin is secreted directly into the portal circulation. Despite these fundamental physiologic differences, acceptable glucose control can be obtained with insulin analogs used in a **basal-bolus regimen**. Basal-bolus regimens can be accomplished with multiple daily injections (MDIs), where a slow-onset, long-duration background insulin is given once or twice daily for between-meal glucose control (basal) and a rapid-onset insulin is given with meals to provide carbohydrate coverage and correct hyperglycemia. Alternatively, an **insulin pump** can be used, where a rapid-onset insulin is used to provide both basal (via continuous infusion) and bolus (at mealtimes and as needed for hyperglycemia) coverage. The doses of short-acting insulin include two components: **carbohydrate ratio** (typically expressed as 1 unit of insulin for a set number of grams of carbohydrates) and **insulin sensitivity factor** (ISF), also referred to as the *correction factor,* and typically expressed as 1 unit of insulin will decrease blood sugar by a set number of mg/dL to achieve a target blood glucose level). Target blood glucose levels should be individualized according to factors including age, duration of diabetes, history of hypoglycemia, time of day, and physical activity, but will generally range between 90 and 180 mg/dL. Formulas for calculating the basal dose, carbohydrate ratio, and ISF from the total daily insulin dose are provided in Table 629.6

Table 629.6 Approach to Calculating Initial Subcutaneous Insulin Doses at Diagnosis of Type 1 Diabetes (or Type 2 Diabetes Requiring Intensive Insulin Therapy) for Patients Starting on a Basal-Bolus Regimen

CALCULATE *TOTAL DAILY DOSE* (TDD) OF INSULIN*	
Minimum starting dose:	0.2 units/kg/day
Add to the minimum dose as follows:	
- Initial blood glucose >200 mg/dL	+ 0.2 units/kg/day
- Ketosis at presentation	+ 0.2 units/kg/day
- Acidosis (by pH or serum bicarbonate)	+ 0.2 units/kg/day
- Puberty (Tanner stage 2 or greater)†	+ 0.2 units/kg/day
CALCULATE DOSES OF *BASAL* AND *BOLUS* INSULIN‡	
Basal dose (long-acting insulin)	x = 50% of TDD (x = daily dose of basal insulin, typically given as one dose before bedtime)
Carbohydrate coverage (short-acting insulin)	y = 450 / TDD (1 unit of insulin for every "y" grams of carbohydrates consumed at snacks/meals)
Insulin sensitivity factor (short-acting insulin)	z = 1800 / TDD (1 unit of insulin will lower blood glucose by "z" mg/dL)

*Patients with obesity or severe insulin resistance may require an additional 0.2 units/kg/day (or more) of insulin.

†For example, a prepubertal child presenting with hyperglycemia only with a blood glucose of 325 mg/dL would be started on a TDD of insulin of 0.4 units/kg/day, whereas a pubertal adolescent presenting in DKA would be started on 1 units/kg/day.

‡Other equations for calculating basal and bolus insulin doses have been proposed and can be found in the literature. All equations provide only an estimate of insulin requirements. All patients need frequent monitoring of blood glucose after initiation of insulin, and most will require dose adjustments.

All preanalog insulins form hexamers, which must dissociate into monomers subcutaneously before being absorbed into the circulation. Thus a detectable effect for **regular insulin** is delayed by 30-60 minutes after injection. This, in turn, requires delaying the meal 30-60 minutes after the injection for optimal effect—a delay rarely attained in a busy child's life. Regular insulin has a wide peak and a long tail for bolus insulin. This profile limits postprandial glucose control, produces prolonged peaks with excessive hypoglycemic effects between meals, and increases the risk of nighttime hypoglycemia. **Neutral protamine Hagedorn** (**NPH**, also known as *insulin isophane*) is an intermediate-acting insulin with inherent limitations as a basal insulin because it does not achieve a peakless background insulin level. This produces a significant hypoglycemic effect during the midrange of the duration. Thus it is often difficult to predict its interaction with fast-acting insulins. When regular insulin is combined with NPH, the composite insulin profile poorly mimics normal endogenous insulin secretion. Lente and ultralente insulins were other intermediate-acting insulins that have since been discontinued.

Lispro, **aspart**, and **glulisine insulin** are rapid-onset analogs that are absorbed much more quickly because they do not form hexamers. They provide discrete pulses, with onset of action in as little as 10 minutes, with little, if any, overlap and short tail effect. This allows better control of postmeal glucose increase and reduces between-meal or nighttime hypoglycemia. Other ultra-fast-acting insulin analogs are being developed that promise even faster onset of action, a feature that

may make these insulins especially useful in insulin pumps and closed-loop systems.

The **long-acting analogs glargine**, **detemir**, and **degludec** are designed to provide longer duration of action, ranging from ~20 hours (glargine) to ~40 hours (degludec). Glargine forms a precipitate after subcutaneous injection, detemir binds to circulating albumin, and degludec forms dihexamers—all of which lead to stabilization of the hexameric structure, slower disassociation into insulin monomers, and prolonged duration of action. The result is a flatter 24-hour profile, making it easier to predict the combined effect of a rapid bolus (lispro, aspart, or glulisine) on top of the basal insulin and thereby create a more physiologic pattern of insulin effect. Postprandial glucose elevations are better controlled, and between-meal and nighttime hypoglycemia are reduced. An illustration of the insulin effect profiles of the currently available short- and long-acting insulins is provided in Figures 629.7 and 629.8.

At diagnosis, the basal dose of long-acting insulin is typically calculated to provide around 50% of the total daily dose, with the remainder provided with bolus doses of short-acting insulin at mealtimes (calculations used to determine insulin doses are provided in Table 629.6). Over time the ratio of basal to bolus will typically shift downward and will be affected by the magnitude of carbohydrate intake (especially during adolescence). Some infants and toddlers may do well with a higher percentage of their daily insulin provided as basal. There is considerable individual variability in the duration of action of long-acting insulins, and some younger children and obese adolescents will require twice-daily dosing of glargine. Both long- and short-acting insulins are available for administration via multidose insulin pens, which are generally easier to use compared with a traditional syringe and vial approach.

Some families may be unable to administer four daily injections. In these cases, a compromise may be needed. A three-injection regimen combining NPH with a rapid analog bolus at breakfast, a rapid-acting analog bolus at supper, and glargine at bedtime may provide fair glucose control and eliminate the need for an injection at school. Further compromise to a two-injection regimen may occasionally be needed and frequently involves use of premixed insulin preparations that include both rapid- and intermediate-acting insulins (e.g., 70/30). For this regimen, 70% of the total daily dose (TDD) is typically provided with breakfast and 30% of TDD with dinner. An illustration of commonly used insulin regimens is shown in Figure 629.8.

Insulin Pump Therapy

Continuous subcutaneous insulin infusion (CSII) via battery-powered pumps provides a closer approximation of normal plasma insulin profiles and increased flexibility regarding timing of meals and snacks compared with conventional insulin injection regimens. Insulin pump models can be programmed with a patient's personal insulin dose algorithms, including the ISF and carbohydrate ratios for premeal glucose levels. At mealtimes, the patient enters the blood glucose level (or it is automatically transmitted from a linked glucometer) and the carbohydrate content of the meal, and the pump computer will calculate the proper insulin bolus dose. Although CSII frequently improves metabolic control, this may not always be the case. The degree of glycemic control is mainly dependent on how closely patients adhere to the principles of diabetes self-care, regardless of the type of intensive insulin regimen. One benefit of pump therapy may be a reduction in severe hypoglycemia and associated seizures. Randomized trials comparing multiple daily insulin regimens using glargine insulin and CSII in children with T1DM demonstrate similar metabolic control and frequency of hypoglycemic events. Most patients will initiate therapy with insulin pens; timing of transition to an insulin pump can be individualized per patient preference as soon as 6-12 months after diagnosis.

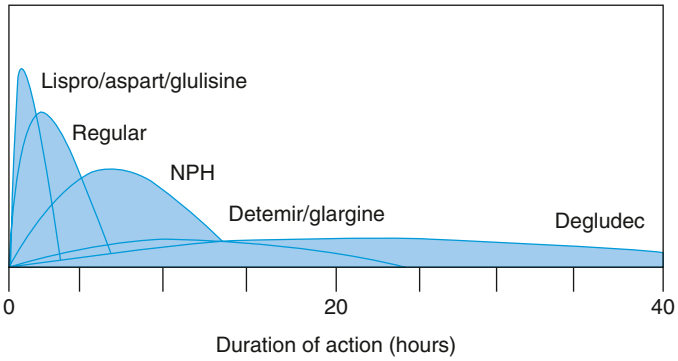

Fig. 629.7 Approximate insulin effect profiles. The following relative peak effect and duration units are used: lispro/aspart/glulisine, peak 20 for 4 hr; regular, peak 15 for 7 hr; neutral protamine Hagedorn *(NPH)* peak 12 for 12 hr; detemir/glargine, peak 5 for 20-24 hr; degludec peak 5 for 42 hr.

Continuous Glucose Monitoring Systems

Continuous glucose monitoring systems (CGMs) consist of a subcutaneous glucose sensor that continuously measures interstitial fluid glucose levels and a receiver to collect and display glucose data. CGMs reduce, but do not eliminate, the need for finger stick blood glucose checking, as calibrations with capillary blood glucose readings are required at least every 12 hours. CGMs report blood glucose levels to the patient/caregiver in real time and can be integrated with smartphones/watches for remote monitoring. To avoid hypoglycemia, the CGM system sounds an alarm once a critical low blood sugar threshold is reached. Additional alerts can be set to notify users of hyperglycemia or rapid rates of change in glucose levels. Short-term studies indicate clinical benefits of these devices as compared to conventional methods of blood glucose monitoring when used by motivated and well-informed patients. CGMs also allow for the determination of **time in range**, where the amount of time in and out of the target glycemic range *(defined by international consensus as glucose between 70 and 180 mg/dL)* can be determined and tracked. Glycemic control has been traditionally monitored by HbA_{1c}, which provides an estimate of average blood glucose over the prior 2 to 3 months. Time in range allows for a more granular assessment of glucose excursions within and between days and may prove to be a more clinically significant metric of diabetes control. A limitation of CGM-only systems is that they require the user to respond to the alert, interpret the data, and intervene to prevent hypoglycemic or hyperglycemic episodes. This limitation is mitigated when the CGM is combined with an insulin pump in a closed-loop system.

Closed-Loop Systems

A closed-loop system allows for direct communication between the continuous glucose sensor and insulin pump for automatic adjustment of insulin infusion rates in response to glucose levels (Fig. 629.9). A fully closed-loop system would be completely independent of the user and theoretically could improve glycemic control through the early identification and response to glucose perturbation and by minimizing the opportunity for human error in insulin dosing. Both single-hormone (insulin only) and bihormone (insulin and glucagon) systems are undergoing clinical investigation.

Several hybrid closed-loop systems with integrated insulin pumps and continuous glucose sensors have gained regulatory approval and entered clinical practice. There is emerging evidence from short-term clinical trials that the use of hybrid closed-loop systems can improve time in range and reduce hyperglycemia and hypoglycemia compared to sensor-augmented systems. Current issues hampering full implementation of this technology include limitations in the accuracy and precision of interstitial fluid glucose sensing, the need for short-acting insulins with more rapid onset of action, and complexity of day-to-day use.

Adjunct Pharmacotherapy

Pramlintide acetate, a synthetic injectable analog of amylin, may be of therapeutic value combined with insulin therapy. However, it has not

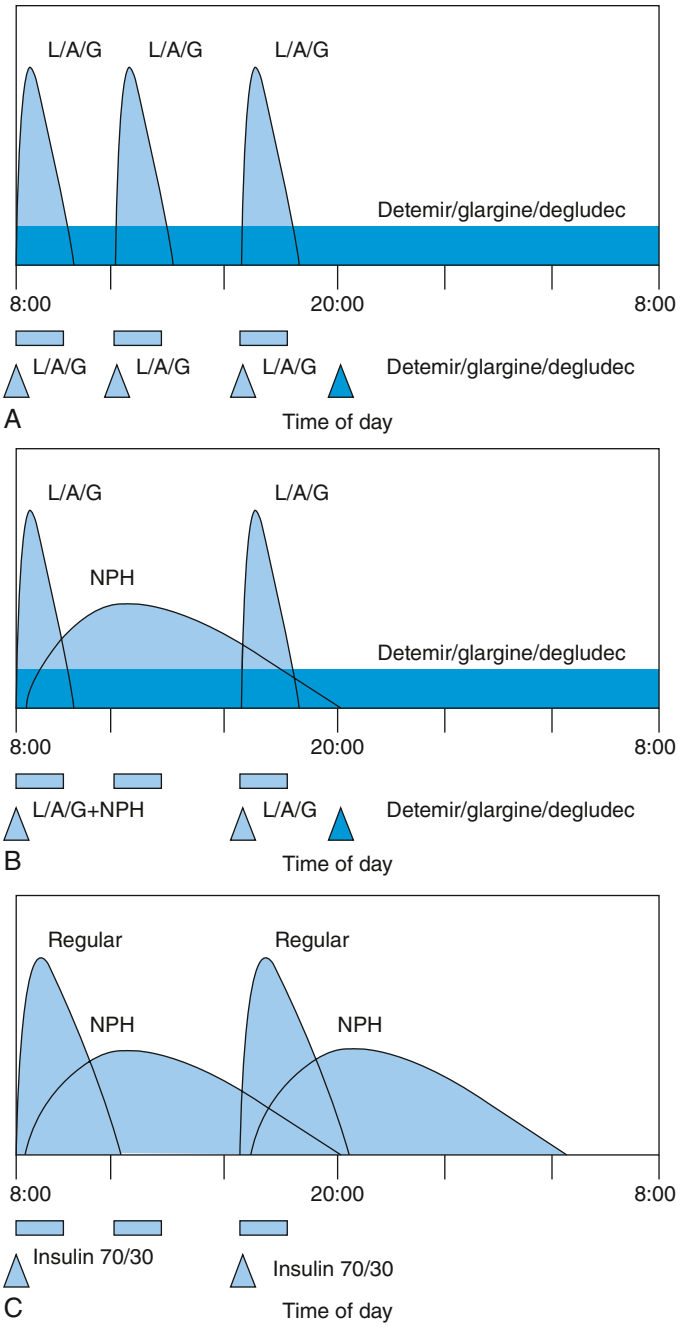

Fig. 629.8 Approximate composite insulin effect profiles of various insulin dosing strategies. Meals are shown as *rectangles* below the time axis. Injections are shown as labeled *triangles;* L/A/G, lispro, aspart, glulisine. All profiles are idealized using average absorption and clearance rates. In typical clinical situations, these profiles vary among patients. A given patient has varying rates of absorption depending on the injection site, physical activity, and other variables. **A,** Basal-bolus regimen: A short-acting insulin (Lantus/aspart/glulisine) is injected before meals, and a long-acting basal insulin (glargine/detemir/degludec) is injected at bedtime. Additional short-acting insulin is given to cover between-meal snacks as needed (not shown). For patients on insulin pumps, the composite insulin profile is similar; however, the basal insulin coverage is provided by a continuous infusion of short-acting insulin. **B,** Thrice-daily injection regimen: A short-acting insulin (Lantus/aspart/glulisine) and neutral protamine Hagedorn *(NPH)* are injected with breakfast (the two types of insulin can be drawn up into one syringe for administration with a single injection), a short-acting insulin is injected with dinner, and a long-acting basal insulin (glargine/detemir/degludec) is injected at bedtime. Because NPH is not a peakless insulin, this regimen is associated with greater risk of hypoglycemia compared with the basal-bolus regimen show in Figure 629.6A but does offer the advantage of eliminating the need for an injection at lunchtime. **C,** Twice-daily injection regimen: The use of a premixed insulin containing a short- and an intermediate-acting insulin that is given twice daily is sometimes necessary for families who are unable to manage more complex dosing regimens. Insulin 70/30 is one such product that combines regular and NPH insulins. This produces the least physiologic profile, with large excesses before lunch and during the early night, combined with poor coverage before supper and breakfast.

gained widespread use. Metformin, an oral antihyperglycemic commonly used to treat T2DM, is sometimes used clinically as an adjunct therapy in T1DM patients with evidence of significant insulin resistance (i.e., obesity, insulin requirements >1.2 units/kg/day, acanthosis nigricans on exam). A clinical trial investigating the addition of metformin in overweight adolescents with T1DM did not find a sustained effect of metformin to lower HbA_{1c} but did show a reduction in daily insulin dose and body mass index (BMI). Reports from observational studies are likewise mixed. These agents would typically not be started at diagnosis of T1DM.

Basic and Advanced Diabetes Education

Therapy consists not only of initiation and adjustment of insulin dose but also of education of the patient and family. Teaching is most efficiently provided by experienced diabetes educators and dietitians. In the acute phase, the family must learn the basics, which includes monitoring the child's blood glucose and urine and/or blood ketones, preparing and injecting the correct insulin dose subcutaneously at the proper time, recognizing and treating low blood glucose reactions, and having a basic meal plan. Most families are trying to adjust psychologically to the new diagnosis of diabetes in their child and thus have a limited ability to retain new information. Written materials covering these basic topics help the family during the first few days.

Children and their families are also required to complete advanced self-management classes to facilitate implementation of flexible insulin management. These educational classes will help patients and their families acquire skills for managing diabetes during athletic activities and sick days. Likewise, further patient and caregiver education with a diabetes educator familiar with diabetes technology is imperative when adding a CGM or transitioning to an insulin pump.

Nutritional Management

Nutrition plays an essential role in the management of patients with T1DM. This is of critical importance during childhood and adolescence, when appropriate energy intake is required to meet the needs for energy expenditure, growth, and pubertal development. There are no special nutritional requirements for the diabetic child other than those for optimal growth and development. Nutritional requirements for the child are outlined on the basis of age, sex, weight, activity, and food preferences. Cultural ethnic considerations must also be integrated into the nutrition plan.

Total recommended caloric intake is based on size or surface area and can be obtained from standard tables (Tables 629.7 and 629.8). The caloric mixture should comprise approximately 55% carbohydrate, 30% fat, and 15% protein, but must be individualized to meet specific patient needs. Approximately 70% of the carbohydrate content should be derived from complex carbohydrates such as starch; intake of sucrose and highly refined sugars should be limited. Complex carbohydrates require prolonged digestion and absorption and thereby raise plasma glucose levels slowly, whereas glucose from refined sugars, including carbonated beverages, is rapidly absorbed and may cause wide swings in the metabolic pattern. The consumption of sugar-sweetened beverages, including soda and juice, should be discouraged. Priority should be given to total calories and total carbohydrates consumed rather than the source. Carbohydrate counting has become a mainstay in the nutrition education and management of patients with T1DM. Patients and their families are provided with information regarding the carbohydrate contents of different foods and food label reading. This allows patients to adjust their insulin dosage to their mealtime carbohydrate

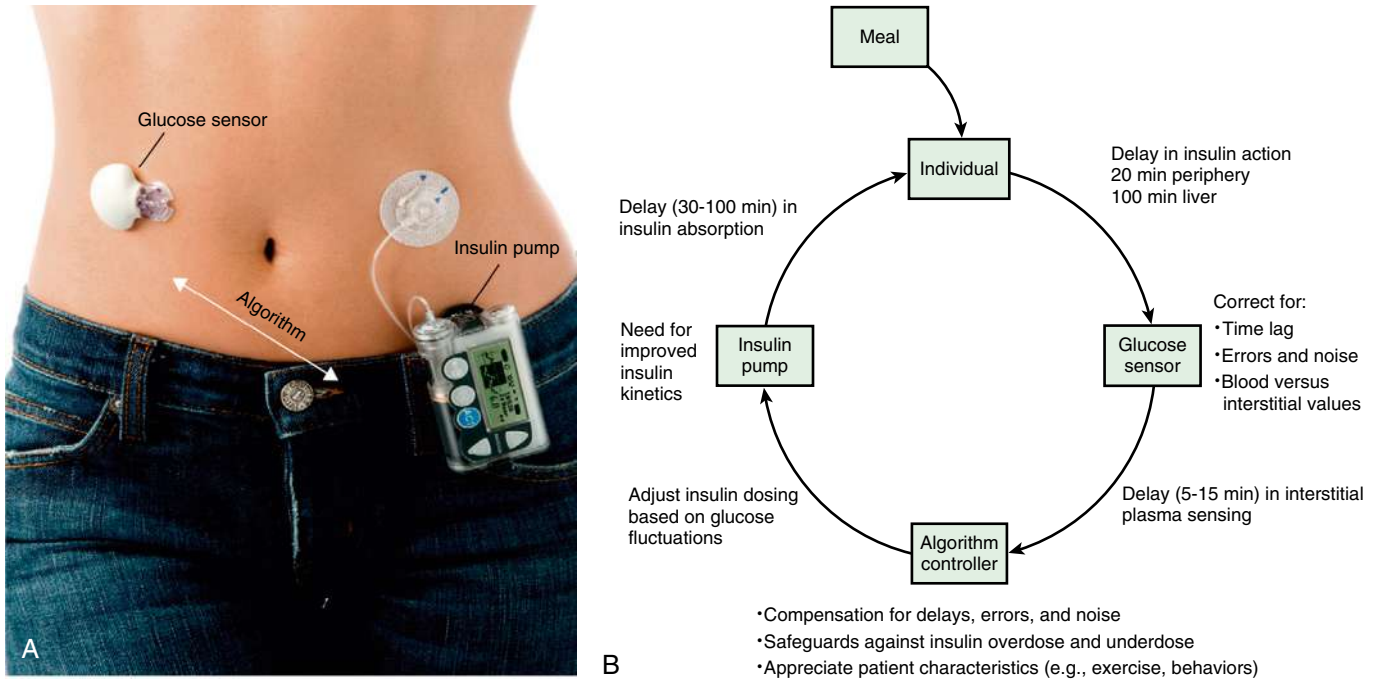

Fig. 629.9 Closed-loop system for T1DM (artificial pancreas). **A,** Prototype of a closed-loop system. **B,** Components of a closed-loop system. Three potential delays in the system include glucose sensing in interstitial fluid, insulin absorption (depends on use of rapid vs regular insulin), and insulin action in peripheral tissues and liver. *(From Atkinson MA, Eisenbarth GS, Michels AW. Type 1 diabetes. Lancet. 2014;383:69–78. Fig. 5.)*

Table 629.7 Calorie Needs for Children and Young Adults

AGE	KCAL REQUIRED/KG BODY WEIGHT*
CHILDREN	
0-12 mo	120
1-10 yr	100-75
YOUNG WOMEN	
11-15 yr	35
≥16 yr	30
YOUNG MEN	
11-15 yr	80-55 (65)
16-20 yr	
Average activity	40
Very physically active	50
Sedentary	30

*Gradual decline in calories per unit weight as age increases.
Numbers in parentheses are means.
From *Nutrition Guide for Professionals. Diabetes education and meal planning.* Alexandria, VA, and Chicago, IL: The American Diabetes Association and The American Dietetic Association, 1988.

intake. The use of carbohydrate counting and insulin-to-carbohydrate ratios as a part of an MDI regimen allows for less rigid meal planning. Flexibility in the use of insulin in relation to carbohydrate content of food improves the quality of life.

Diets with high fiber content are useful in improving control of blood glucose. Daily recommended fiber intake can be determined using the equation:

$$\text{Age in years} + 5 = \text{grams of fiber per day}$$

Moderate amounts of sucrose consumed with fiber-rich foods such as whole-grain bread may have no more glycemic effect than their low-fiber, sugar-free equivalents. Saturated fat intake may increase in patients with T1DM who reduce carbohydrate consumption to avoid taking insulin doses by ingesting carbohydrate-free foods. Total energy from fat should not exceed 35%, and education should be provided such that <10% of total energy should come from saturated and trans fats. Dietary fats derived from animal sources should be reduced and replaced by polyunsaturated fats from vegetable sources. Substituting vegetable oil for animal oils or butter in cooking and lean cuts of meat, poultry, and fish for fatty meats can help to achieve these goals. The intake of cholesterol is also reduced by these measures. These simple measures may reduce serum low-density lipoprotein cholesterol, a predisposing factor to atherosclerotic disease. Table 629.8 summarizes typical nutritional guidelines for T1DM.

Each child and family can and should select a diet based on personal taste with the help of the physician or dietitian (or both). Emphasis should be placed on lifestyle changes to promote adherence to a healthy, balanced diet on a daily basis. Occasional excesses (treats) are permissible but should be limited just as for any child without diabetes. Adjustments in meal planning must constantly be made to meet the needs and the desires of each child. A consistent eating pattern with appropriate supplements for exercise, the pubertal growth spurt, and pregnancy in an adolescent with diabetes is important for metabolic control.

Monitoring

Success in the daily management of the child with diabetes can be measured by the competence acquired by the family, and subsequently by the child, in assuming responsibility for daily self-care. Their initial and ongoing instruction in conjunction with their supervised experience can lead to a sense of confidence in adjusting an insulin dosage for dietary deviations, for unusual physical activity, and for some intercurrent illnesses. Such acceptance of responsibility should make them relatively independent of the physician for their ordinary care. The physician must maintain ongoing interested supervision and shared responsibility with the family and the child.

Self-monitoring of blood glucose is an essential component of managing diabetes. Effective monitoring often also includes other factors that influence blood glucose such as insulin dose, physical activity,

Table 629.8 Summary of Nutrition Guidelines for Children and/or Adolescents with Type 1 Diabetes Mellitus

NUTRITION CARE PLAN		
Promotes optimal compliance.		
Incorporates goals of management: normal growth and development, control of blood glucose, maintenance of optimal nutritional status, and prevention of complications. Uses staged approach.		
NUTRITION RECOMMENDATIONS AND DISTRIBUTION		
NUTRIENT	% OF CALORIES	RECOMMENDED DAILY INTAKE
Carbohydrate	Will vary	High fiber, especially soluble fiber; optimal amount unknown
Fiber		>20 g/day
Protein	12–20	
Fat	<30	
Saturated	<10	
Polyunsaturated	6–8	
Monounsaturated	Remainder of fat allowance	
Cholesterol		300 mg
Sodium		Avoid excessive; limit to 3,000-4,000 mg if hypertensive
ADDITIONAL RECOMMENDATIONS		
Energy: If using measured diet, reevaluate prescribed energy level at least every 3 mo.		
Protein: High-protein intakes may contribute to diabetic nephropathy. Low intakes may reverse preclinical nephropathy. Therefore 12–20% of energy is recommended; lower end of range is preferred. In guiding toward the end of the range, a staged approach is useful.		
Alcohol: Safe use of moderate alcohol consumption should be taught as routine anticipatory guidance as early as junior high school.		
Snacks: Snacks vary according to individual needs (generally three snacks per day for children; midafternoon and bedtime snacks for junior high children or teens).		
Alternative sweeteners: Use of a variety of sweeteners is suggested.		
Educational techniques: No single technique is superior. Choice of educational method used should be based on patient needs. Knowledge of variety of techniques is important. Follow-up education and support are required.		
Eating disorders: Best treatment is prevention. Unexplained poor control or severe hypoglycemia may indicate a potential eating disorder.		
Exercise: Education is vital to prevent delayed or immediate hypoglycemia and to prevent worsened hyperglycemia and ketosis.		

From Connell JE, Thomas-Doberson D. Nutritional management of children and adolescents with insulin-dependent diabetes mellitus: a review by the Diabetes Care and Education Dietetic Practice Group. J Am Diet Assoc. 1991;91:1556.

dietary changes, hypoglycemia, and illness. A record of these items may be valuable in interpreting the self-monitoring of blood glucose, prescribing appropriate adjustments in insulin doses, and teaching the family. If there are discrepancies in the self-monitoring of blood glucose and other measures of glycemic control (such as the HbA_{1c}), the clinician should attempt to clarify the situation in a manner that does not undermine their mutual confidence.

Daily blood glucose monitoring is accomplished using blood test strips or a CGM. Test strips are impregnated with glucose oxidase that permit blood glucose measurement from a drop of blood. A portable calibrated reflectance meter can approximate the blood glucose concentration accurately. Glucometers contain a memory chip enabling recall of each measurement and the ability to calculate measurement average over a given interval and display the pattern on a computer screen. Such information is a useful educational tool for verifying degree of control and modifying recommended regimens. A small, spring-loaded device that automates capillary bloodletting (lancing device) in a relatively painless fashion is commercially available. Parents and patients should be taught to use these devices and measure blood glucose at least 4 times daily—before breakfast, lunch, and supper and at bedtime. When insulin therapy is initiated and when adjustments are made that may affect the overnight glucose levels, self-monitoring of blood glucose should also be performed at midnight and 3 AM to detect nocturnal hypoglycemia. Standard blood glucose targets are 90-130 mg/dL before meals and 90-150 mg/dL before bedtime; however, glycemic goals must be individualized to the patient based on age, hypoglycemia risk, and other factors.

Glucose measurements that are consistently at or outside these limits, in the absence of an identifiable cause such as exercise or dietary indiscretion, are an indication for a change in the insulin dose. If the fasting blood glucose is high, the evening dose of long-acting insulin (or the early morning/overnight basal rate for insulin pump users) is increased by 10–20% and/or additional fast-acting insulin coverage for a bedtime snack may be considered. If the noon glucose level exceeds set limits, the morning fast-acting insulin-to-carbohydrate ratio is increased by 10–20%. If the presupper glucose is high, the noon fast-acting insulin-to-carbohydrate ratio is increased by 10–20%. If the prebedtime glucose is high, the presupper fast-acting insulin-to-carbohydrate ratio is increased by 10–15%. The ISF can be increased by 10–20% if it is found that insulin corrections given for hyperglycemia do not normalize glucose levels as expected. Similarly, reductions in the insulin type and dose should be made if the corresponding blood glucose measurements are consistently below desirable limits.

A minimum of four daily blood glucose measurements (or CGM use) should be performed. However, some children and adolescents may need to have more frequent blood glucose monitoring based on their level of physical activity and history of frequent hypoglycemic reactions. Families should be encouraged to become sufficiently knowledgeable about managing diabetes.

The FDA has approved the use of CGMs to replace finger stick blood glucose checking for the monitoring and treatment of diabetes in children 2 years of age and older. CGMs are minimally invasive and entail the placement of a small, subcutaneous catheter that can be easily worn by adults and children. The system provides information that allows the patient and healthcare team to adjust the insulin regimen and the nutrition plan to improve glycemic control. CGMs can be helpful in detecting asymptomatic nocturnal hypoglycemia and in lowering HbA_{1c} values without increasing the risk for severe hypoglycemia. Although there are potential pitfalls in CGM use, including suboptimal compliance, human error, incorrect technique, and sensor

failure, the implementation of CGMs in ambulatory diabetes practice allows the clinician to diagnose abnormal glycemic patterns in a more precise manner. In many cases, CGMs are now factory calibrated and nearly eliminate the need for finger sticks. For these reasons, CGMs are increasingly replacing finger stick blood testing as the primary means of glucose monitoring in many patients with T1DM.

Glycosylated Hemoglobin (HbA_{1c})

A reliable index of long-term glycemic control is provided by measurement of glycosylated hemoglobin. HbA_{1c} represents the fraction of hemoglobin to which glucose has been nonenzymatically attached in the bloodstream. The formation of glycosylated hemoglobin is a slow reaction that is dependent on the prevailing concentration of blood glucose; it continues irreversibly throughout the red blood cell's life span of approximately 120 days. The higher the blood glucose concentration and the longer the red blood cell's exposure to it, the higher the fraction of glycosylated hemoglobin, which is expressed as a percentage of total hemoglobin. Because a blood sample at any given time contains a mixture of red blood cells of varying ages, exposed for varying times to varying blood glucose concentrations, an HbA_{1c} measurement reflects the average blood glucose concentration from the preceding 2-3 months. For some patients, it may be helpful to translate HbA_{1c} into estimated average glucose (eAG) using the following equation:

$$eAG = 28.7 * HbA_{1c} - 46.7$$

When measured by standardized methods to remove labile forms, HbA_{1c} is not influenced by an isolated episode of hyperglycemia.

HbA_{1c} measurements should be obtained three to four times a year to obtain a profile of long-term glycemic control. The lower the HbA_{1c} level, the more likely it is that microvascular complications such as retinopathy and nephropathy will be less severe, delayed in appearance, or even avoided altogether. Depending on the method used for determination, HbA_{1c} values may be spuriously elevated in thalassemia (or other conditions with elevated hemoglobin F) and spuriously lower in sickle cell disease (or other conditions with high red blood cell turnover). Fructosamine can be used instead of HbA_{1c} in these patients. Although values of HbA_{1c} may vary according to the method used for measurement, in individuals without diabetes, the HbA_{1c} is usually less than 6%. The HbA_{1c} target should be individualized, but the general recommendation of the ADA and the International Society for Pediatric and Adolescent Diabetes is that children, adolescents, and young adults with T1DM should aim to achieve an HbA_{1c} of <7%.

Exercise

Regular, daily exercise with the goal of 60 minutes of moderate- to vigorous-intensity aerobic activity daily, with vigorous muscle-strengthening and bone-strengthening activities at least 3 days per week is recommended for all children with T1D. A potential complication of exercise in patients with diabetes is the development of hypoglycemia during or within the hours after exercise. Patients and families should be educated on the risk of hypoglycemia and taught strategies to ameliorate this risk, including frequent glucose monitoring before, during, and after exercise; modifying diet and insulin doses around times of exercise; and ensuring access to fast-acting carbohydrates during exercise to treat hypoglycemia should it develop. Regular exercise also improves glucoregulation by increasing glucose use by muscles and increasing the insulin receptor number. In patients who are in poor metabolic control, vigorous exercise may precipitate ketoacidosis because of the exercise-induced increase in the counterregulatory hormones.

Benefits of Improved Glycemic Control

The Diabetes Control and Complications Trial (DCCT) established conclusively the association between higher glucose levels and long-term microvascular complications. Intensive management produced dramatic reductions of retinopathy, nephropathy, and neuropathy by 47–76%. The data from the adolescent cohort demonstrated the same degree of improvement and the same relationship between the outcome measures of microvascular complications.

The beneficial effect of intensified treatment was determined by the degree of blood glucose normalization independently of the type of intensified treatment used. Frequent blood glucose monitoring was considered an important factor in achieving better glycemic control for the intensively treated adolescents and adults. Patients who were intensively treated had individualized glucose targets, frequent adjustments based on ongoing capillary blood glucose monitoring, and a team approach that focused on the person with diabetes as the prime initiator of ambulatory care. Care was constantly adjusted toward reaching normal or near-normal glycemic goals while avoiding or minimizing severe episodes of hypoglycemia. Teaching emphasized a preventive approach to blood glucose fluctuations with constant readjustment to counterbalance any high or low blood glucose readings. Target blood glucose goals were adjusted upward if hypoglycemia could not be prevented.

Total duration of diabetes contributes to development and severity of complications. Nonetheless, many professionals have concerns about applying the results of the DCCT to preschool-age children, who often have hypoglycemia unawareness with unique safety issues, and to prepubertal school-age children, who were not included in the DCCT. The follow-up study to the DCCT, called Epidemiology of Diabetes Interventions and Complications (EDIC), assessed the incidence and predictors of cardiovascular disease events such as heart attack, stroke, or needed heart surgery, as well as diabetic complications related to the eye, kidney, and nerves. The EDIC demonstrated that intensive blood glucose control reduced the risk of any cardiovascular disease event by 42%. In addition, intensive therapy reduced the risk of nonfatal heart attack, stroke, or death from cardiovascular causes by 57%.

Hypoglycemic Reactions

Hypoglycemia is the major limitation to tight control of glucose levels. Once injected, insulin absorption and action are independent of the glucose level, thus creating a unique risk of hypoglycemia from an unbalanced insulin effect. Insulin analogs may help reduce, but cannot eliminate, this risk. Most children with T1DM can expect mild hypoglycemia each week, moderate hypoglycemia a few times each year, and severe hypoglycemia every few years. These episodes are usually not predictable, although exercise, delayed meals or snacks, and wide swings in glucose levels increase the risk. Infants and toddlers are at higher risk for hypoglycemia because they have more variable meals and activity levels, are unable to recognize early signs of hypoglycemia, and are limited in their ability to seek a source of oral glucose to reverse the hypoglycemia. The very young have an increased risk of permanently reduced cognitive function as a long-term sequela of severe hypoglycemia. For these reasons, a more relaxed degree of glucose control may be tolerated in infants and young children.

Hypoglycemia can occur at any time of the day or night. Early symptoms and signs (mild hypoglycemia) may occur with a sudden decrease in blood glucose to levels that do not meet standard criteria for hypoglycemia in children without diabetes. The child may show pallor, sweating, apprehension or fussiness, hunger, tremor, and tachycardia, all as a result of the surge in catecholamines as the body attempts to counter the excessive insulin effect. Behavioral changes such as tearfulness, irritability, and aggression are more prevalent in children. As glucose levels decline further, cerebral glucopenia occurs with drowsiness, personality changes, mental confusion, and impaired judgment (moderate hypoglycemia), progressing to inability to seek help and seizures or coma (severe hypoglycemia). Prolonged severe hypoglycemia can result in a depressed sensorium or strokelike focal motor deficits that persist after the hypoglycemia has resolved. Although permanent sequelae are rare, severe hypoglycemia is frightening for the child and family and can result in significant reluctance to attempt even moderate glycemic control afterward.

Important counterregulatory hormones in children include growth hormone, cortisol, epinephrine, and glucagon. The latter two seem more critical in the older child. Many older patients with long-standing T1DM lose their ability to secrete glucagon in response to hypoglycemia. In the young adult, epinephrine deficiency may also develop as part of a general autonomic neuropathy. This substantially increases the

risk of hypoglycemia because the early warning signals of a declining glucose level are as a result of catecholamine release. Recurrent hypoglycemic episodes associated with tight metabolic control may aggravate partial counterregulatory deficiencies, producing a syndrome of hypoglycemia unawareness and reduced ability to restore euglycemia (hypoglycemia-associated autonomic failure). Avoidance of hypoglycemia allows some recovery from this unawareness syndrome.

The most important factors in the management of hypoglycemia are an understanding by the patient and family of the symptoms and signs of the reaction and an anticipation of known precipitating factors such as gym or sports activities. Tighter glucose control increases the risk. Families should be taught to look for typical hypoglycemic scenarios or patterns in the home blood glucose log, so that they may adjust the insulin dose and avert predictable episodes. A source of emergency glucose should be available at all times and places, including at school and during visits to friends. If possible, it is important to document the hypoglycemia before treating, because some symptoms may not always be from hypoglycemia. Any child suspected of having a moderate to severe hypoglycemic episode should be treated before testing. It is important not to give too much glucose in response to hypoglycemia; 15 g should be given as juice or a sugar-containing beverage or candy, and the blood glucose checked 15-20 minutes later.

Patients, parents, and teachers should also be instructed in the administration of **glucagon** when the child cannot take glucose orally. Glucagon is available for intramuscular or subcutaneous injection and as a nasal powder. A glucagon kit should be kept at home and school. The intramuscular dose of glucagon is 0.5 mg if the child weighs less than 20 kg and 1.0 mg if more than 20 kg; the subcutaneous dose (via prefilled device) is 0.5 mg if less than 45 kg and 1.0 mg if more than 45 kg; the intranasal dose is 3 mg. Glucagon produces a brief release of glucose from the liver. Glucagon often causes emesis, which precludes giving oral supplementation if the blood glucose declines after the glucagon effects have waned. Caretakers must then be prepared to take the child to the hospital for IV glucose administration, if necessary. Mini-dose glucagon (10 μg/yr of age up to a maximum of 150 μg subcutaneously) is effective in treating hypoglycemia in children with blood glucose less than 60 mg/dL who fail to respond to oral glucose and remain symptomatic. Glucagon is reconstituted as per standard instructions, then drawn up for subcutaneous injection using a standard insulin syringe, whereby 1 unit is the equivalent of 10 mcg of glucagon.

Dawn Phenomenon and Somogyi Phenomenon

There are several reasons that blood glucose levels increase in the early morning hours before breakfast. The most common is a simple decline in insulin levels. This usually results in routinely elevated morning glucose. The **dawn phenomenon** is thought to be mainly caused by overnight growth hormone secretion and increased insulin clearance. It is a normal physiologic process seen in most adolescents without diabetes, who compensate with more insulin output. A child with T1DM cannot compensate. The dawn phenomenon is usually recurrent and modestly elevates most morning glucose levels. Rarely, high morning glucose is caused by the **Somogyi phenomenon**, a theoretical rebound from late-night or early-morning hypoglycemia thought to be from an exaggerated counterregulatory response. It is unlikely to be a common cause, in that most children remain hypoglycemic (do not rebound) once nighttime glucose levels decline. CGMs may help clarify a child's ambiguously elevated morning glucose levels.

Behavioral/Psychologic Aspects and Eating Disorders

Diabetes in a child affects the lifestyle and interpersonal relationships of the entire family. Feelings of anxiety and guilt are common in parents. Similar feelings, coupled with denial and rejection, are equally common in children, particularly during the rebellious teenage years. Family conflict has been associated with poor treatment adherence and poor metabolic control among youths with T1DM. On the other hand, it has been shown that shared responsibility is consistently associated with better psychologic health, good self-care behavior, and good metabolic control, whereas responsibility assumed by either the child or parent alone does not have outcomes that are equally successful. In some cases, links of shared responsibility to health outcomes were stronger among older adolescents. However, no specific personality disorder or psychopathology is characteristic of diabetes; similar feelings are observed in families with children who have other chronic diseases.

COGNITIVE FUNCTION

There is evidence that children with T1DM are at higher risk of developing small differences in cognitive abilities compared to healthy age-matched peers. Evidence suggests that early-onset diabetes (younger than 7 years) is associated with cognitive difficulties compared to late-onset diabetes and healthy controls. The cognitive difficulties observed were primarily learning and memory skills (both verbal and visual) and attention/executive function skills. It is likely that the impact of diabetes on pediatric cognition appears shortly after diagnosis. Indeed, it has been observed that early-onset diabetes and longer duration of diabetes in some children with diabetes adversely affect their school performance and educational achievements.

COPING STYLES

Children and adolescents with T1DM are faced with a complex set of developmental changes and shifting burdens of the disease. Adjustment problems might affect psychologic well-being and the course of the disease by affecting self-management and leading to poor metabolic control. Coping styles refer to typical habitual preferences for ways of approaching problems and might be regarded as strategies that people generally use to cope across a wide range of stressors. Problem-focused coping refers to efforts directed toward rational management of a problem, and it is aimed at changing the situation causing distress. On the other hand, emotion-focused coping implies efforts to reduce emotional distress caused by the stressful event and to manage or regulate emotions that might accompany or result from the stressor. In adolescents with diabetes, avoidance coping and venting emotions have been found to predict poor illness-specific self-care behavior and poor metabolic control. Patients who use more mature defenses and exhibit greater adaptive capacity are more likely to adhere to their regimen. Coping strategies seem to be age dependent, with adolescents using more avoidance coping than younger children with diabetes.

NONADHERENCE

Family conflict, anger, sadness, or denial and feelings of anxiety or loss of control find expression in nonadherence to instructions regarding nutritional and insulin therapy and in noncompliance with self-monitoring. When adolescents externalize behavior problems, such behaviors interfere with adherence and may result in deterioration of glycemic control. Such externalizing behaviors are common, whereas repeated omission of insulin resulting in ketoacidosis in the same individual is less common, and episodes of deliberate overdosage with insulin resulting in hypoglycemia are even less prevalent. They may, however, be pleas for psychologic help or be manipulative attempts to escape an environment perceived as undesirable or intolerable; occasionally, they may be manifestations of suicidal intent. Frequent admissions to the hospital for ketoacidosis or hypoglycemia should arouse suspicion of an underlying emotional conflict. Overprotectiveness on the part of parents is common and often is not in the best interest of the adolescent patient. Feelings of being different or of being alone, or both, are common and must be acknowledged. Tailoring the insulin administration and the timing of meals and blood sugar tests may support individual lifestyle choices. Aggregating what they know about diabetes, families and patients worry about the risk of complications from diabetes and about the decreased life span. Unfortunately, misinformation abounds about the risks of the development of diabetes in siblings or offspring and of pregnancy in young diabetic women. Even appropriate information may cause further anxiety.

All of these issues must be spoken about at the outset, and many of these problems can be averted through continued empathic counseling based on correct information, focusing on normality and on planning to be a productive member of society. Recognizing the potential

impact of these problems and that feelings of isolation and frustration tend to be lessened by the sharing of common problems, peer discussion groups have been organized in many locales. Summer camps for diabetic children afford an excellent opportunity for learning and sharing under expert supervision. Education about the pathophysiology of diabetes, insulin dose, technique of administration, nutrition, exercise, and hypoglycemic reactions can be reinforced by medical and paramedical personnel. The presence of numerous peers with similar problems offers new insights to the diabetic child. Residential treatment for children and adolescents with difficult-to-manage T1DM is rarely available.

ANXIETY AND DEPRESSION

It has been shown that there are significant correlations between poor metabolic control and depressive symptoms, a high level of anxiety, or a previous psychiatric diagnosis. In a similar way, poor metabolic control is related to higher levels of personal, social, school maladjustment, or family environment dissatisfaction. It is estimated that 20–26% of adolescent patients may develop major depressive disorder. The prevalence of depression is twofold greater than controls in children with diabetes and threefold greater in adolescents. Additionally, the prevalence of psychopathology is greater in people with diabetes. The course characteristics of depression in young diabetic subjects and psychiatric control subjects appear to be similar. However, eventual propensity of diabetic youths for more protracted depressions is greater. There is also a higher risk of recurrence among young diabetic females. On balance, anxiety and depression play an important and complex role in T1DM; their relationship to metabolic control does not yet appear clear. Therefore the healthcare providers managing a child or adolescent with diabetes should be aware of their pivotal role as counselor and advisor and should closely monitor the mental health of patients with diabetes. Accordingly, the recommendation is screening for anxiety and/or depression in subjects exhibiting symptoms, using a validated screening tool, followed by the appropriate referral to mental health providers when warranted.

FEAR OF SELF-INJECTING AND SELF-TESTING

Extreme fear of self-injecting insulin *(injection phobia)* is likely to compromise glycemic control and emotional well-being. Likewise, fear of finger pricks of CGM and pump site insertions can be a source of distress and may seriously hamper self-management. Children and adolescents may either omit insulin dosing or refuse to rotate their injection sites because repeated injection in the same site is associated with less pain sensation. Failure to rotate injection sites results in subcutaneous scar formation **(lipohypertrophy)**. Insulin injection into the lipohypertrophic skin is usually associated with poor insulin absorption, consequent frustration with lack of expected glucose control, and/or insulin leakage with resultant suboptimal glycemic control. Children and adolescents with injection phobia and fear of self-testing can be counseled by a trained behavioral therapist and benefit from such techniques as desensitization and biofeedback to attenuate pain sensation and psychologic distress associated with these procedures.

EATING DISORDERS

Treatment of T1DM involves constant monitoring of food intake. In addition, improved glycemic control is sometimes associated with increased weight gain. These factors, along with individual, familial, and socioeconomic factors, can lead to an increased incidence of both nonspecific and specific eating disorders, which can disrupt glycemic control and increase the risk of long-term complications. Eating disorders and subthreshold eating disorders are almost twice as common in adolescent females with T1DM as in their nondiabetic peers. There is less information regarding the prevalence of eating disorders among male adolescents with T1DM. The prevalence of eating disorders identified in females with T1DM has ranged from 9% to 32% in different studies. Other studies have found that approximately 11% of T1DM adolescent females take less insulin than prescribed to lose weight. Among adolescent females with T1DM and an eating disorder, the misuse of insulin to lose weight is not uncommon.

When behavioral/psychologic problems and/or eating disorders are assumed to be responsible for poor adherence with the medical regimen, referral for psychologic evaluation and management is indicated. Behavioral therapists and psychologists usually form part of the pediatric diabetes team in most centers and can help assess and manage emotional and behavioral disorders in diabetic children. Evaluation of nurse-delivered motivational enhancement with and without cognitive-behavioral therapy in adults revealed that combined therapy resulted in modest improvement in glycemic control. However, motivational enhancement therapy alone did not improve glycemic control. Whereas in some studies the effect of therapist-delivered motivational enhancement therapy on glycemic control in adolescents with T1DM lasted only as long as intensive individualized counseling continued, in other studies, motivational interviewing was shown to be an effective method of facilitating changes in a teenager's behavior with T1DM, with corresponding improvement in glycemic control.

Management During Infections

Although infections are no more common in diabetic children than in nondiabetic ones, they can disrupt glucose control and may precipitate DKA. In addition, the child with diabetes is at increased risk of dehydration if hyperglycemia causes an osmotic diuresis or if ketosis causes emesis. Counterregulatory hormones associated with stress blunt insulin action and elevate glucose levels. If anorexia occurs from ketosis, lack of caloric intake increases the risk of hypoglycemia. Although children younger than 3 years of age tend to become hypoglycemic and older children tend toward hyperglycemia, the overall effect is unpredictable. Therefore frequent blood glucose monitoring, monitoring of urine and/or blood ketones, and adjustment of insulin doses are essential elements of **sick day guidelines** (Table 629.9).

The overall goals are to maintain hydration, control glucose levels, and avoid ketoacidosis. This can usually be done at home if proper sick day guidelines are followed and with telephone contact with healthcare providers. The development of ketones in a patient on insulin pump therapy may be a sign of infusion failure and the infusion set should be changed. The family should seek advice if home treatment does not

Table 629.9 Guidelines for Sick Day Management

	GLUCOSE TESTING AND EXTRA RAPID-ACTING INSULIN		
URINE KETONE STATUS	**INSULIN**	**CORRECTION DOSES***	**COMMENT**
Negative or small†	q2h	q2h for glucose >250 mg/dL	Check ketones every other void
Moderate to large‡	q1h	q1h for glucose >250 mg/dL	Check ketones each void; go to hospital if emesis occurs

*Give insulin based on individualized dosing schedule. Also give usual dose for carbohydrate intake if glucose >150 mg/dL.
†For home serum ketones <1.5 mmol/L per commercial kit.
‡For home serum ketones >1.5 mmol/L.
Basal insulin: glargine or detemir basal insulin should be given at the usual dose and time. NPH and lente should be reduced by half if blood glucose <150 mg/dL and the oral intake is limited.
Oral fluids: sugar-free if blood glucose >250 mg/dL (14 mmol/L); sugar-containing if blood glucose <250 mg/dL.
Call physician or nurse if blood glucose remains elevated after three extra doses, if blood glucose remains <70 mg/dL and child cannot take oral supplement, if dehydration occurs.

control ketosis, hyperglycemia, or hypoglycemia or if the child shows signs of dehydration or has persistent vomiting. A child with significant ketosis and emesis should be seen in the emergency department for a general examination, to evaluate hydration, and to determine whether ketoacidosis is present by checking serum electrolytes, glucose, pH, and total CO_2. A child whose blood glucose declines to less than 50-60 mg/dL (2.8-3.3 mmol/L) and who cannot maintain oral intake may need IV glucose, especially if further insulin is needed to control ketosis.

Management During Surgery

Surgery can disrupt glucose control in the same way as intercurrent infections can. Stress hormones associated with the underlying condition and with the surgery itself cause insulin resistance. This increases glucose levels, exacerbates fluid losses, and may initiate DKA. On the other hand, caloric intake is usually restricted, which decreases glucose levels. The net effect is as difficult to predict as during an infection. Vigilant monitoring and frequent insulin adjustments are required to maintain euglycemia and avoid ketosis.

For most elective and other smaller surgical procedures, patients can simply be continued on their typical home basal regimens. This includes injection of the usual dose of long-acting insulin at the usual time for patients on shots. Patients on pumps can simply wear the pump during the surgery, if approved by hospital policy. Blood sugar should be monitored hourly during the procedure and perioperatively; hyperglycemia can be corrected using the standard home ISF, and IV dextrose can be provided as needed for hypoglycemia. For major procedures, trauma, or situations where a prolonged period of decreased oral intake is expected postoperatively, it is advisable to manage insulin requirements with an IV insulin drip (Table 629.10). IV insulin is typically started at a dose of 0.03 units/kg/hr for patients who are euglycemic at the time of surgery. Serum glucose levels should be followed every hour operatively and perioperatively, and the insulin dose and/or the dextrose concentration of the IV fluids can be adjusted as needed. In patients who are found to be hyperglycemic preoperatively (serum glucose >250 mg/dL), it is advisable to check for ketones before starting surgery. If significant ketosis is identified, surgery should be delayed (if possible) until the ketosis can be treated and resolved. Postoperatively, the patient should not be discharged until blood glucose levels are stable and oral intake is tolerated.

LONG-TERM COMPLICATIONS: RELATION TO GLYCEMIC CONTROL

Complications of DM include microvascular complications, such as retinopathy and nephropathy; macrovascular complications, including coronary artery disease, cerebrovascular disease, and peripheral vascular disease; peripheral and autonomic neuropathies; and diabetic osteopathy manifesting as increased risk for osteoporosis and fracture.

Diabetic Retinopathy

Diabetic retinopathy is the leading cause of blindness in the United States in adults age 20-65 years. The risk of diabetic retinopathy after 15 years' duration of diabetes is 98% for individuals with T1DM and 78% for those with T2DM. Rates for diabetic retinopathy range from close to 15% to up to 30%. Lens opacities (caused by glycation of tissue proteins and activation of the polyol pathway) are present in at least 5% of those younger than age 19 years. Metabolic control has an impact on the development of this complication, as prevalence rates are substantially higher with increased duration of diabetes and higher HbA_{1c}, hypertension, and high cholesterol levels. Independent of duration, the prevalence of diabetic retinopathy is higher in T1DM. Genetic factors may have a role, because only 50% of patients develop proliferative retinopathy. The earliest clinically apparent manifestations of diabetic retinopathy are classified as nonproliferative or background diabetic retinopathy—microaneurysms, dot and blot hemorrhages, hard and soft exudates, venous dilation and beading, and intraretinal microvascular abnormalities. These changes do not impair vision. The more severe form is proliferative diabetic retinopathy, which manifests by neovascularization, fibrous proliferation, and preretinal and vitreous hemorrhages. Proliferative retinopathy, if not treated, is relentlessly progressive and impairs vision, leading to blindness. The mainstay of treatment is panretinal laser photocoagulation. In advanced diabetic eye disease—manifested by severe vitreous hemorrhage or fibrosis, often with retinal detachment—vitrectomy is an important therapeutic modality. Eventually, the eye disease becomes quiescent, a stage termed *involutional retinopathy.* A separate subtype of retinopathy is diabetic maculopathy, which is manifested by severe macular edema impairing central vision. Focal laser photocoagulation may be effective in treating diabetic maculopathy.

Diabetic patients should have an initial dilated and comprehensive examination by an ophthalmologist shortly after the diagnosis of diabetes is made in patients with T2DM and within 3-5 years after the onset of T1DM (but not before age 10 years). Any patients with visual symptoms or abnormalities should be referred for ophthalmologic evaluation. Subsequent evaluations for both T1DM and T2DM patients should be repeated every 1-2 years as recommended by an eye care professional experienced in the diagnosis and management of diabetic retinopathy (Table 629.11).

Diabetic Nephropathy

Diabetic nephropathy is the leading known cause of end-stage renal disease (ESRD) in the United States. Most ESRD from diabetic nephropathy is preventable. Diabetic nephropathy affects 20–30% of patients with T1DM and 15–20% of T2DM patients 20 years after onset. The mean 5-year life expectancy for patients with diabetes-related ESRD is less than 20%. The increased mortality risk in long-term T1DM may be the result of nephropathy, which may account for approximately 50% of deaths. The risk of nephropathy increases with the duration of diabetes (up until 25-30 years' duration, after which this complication rarely begins), degree of metabolic control, and genetic predisposition to essential hypertension. Only 30–40% of patients affected by T1DM eventually experience ESRD. The glycation of tissue proteins results in glomerular basement membrane thickening. The course of diabetic nephropathy is slow. An increased urinary albumin excretion rate of 30-300 mg/24 hr (20-200 μg/min)—**microalbuminuria**—can be detected and constitutes an early stage of nephropathy from intermittent to persistent (incipient), which is commonly associated with glomerular hyperfiltration and blood pressure elevation. As nephropathy evolves to an early overt stage with proteinuria (albumin excretion rate >300 mg/24 hr or >200 μg/min), it is accompanied by hypertension. Advanced-stage nephropathy is defined by a progressive decline in renal function (declining glomerular filtration rate and elevation of serum blood urea and creatinine), progressive proteinuria, and hypertension. Progression to ESRD is recognized by the appearance of uremia, nephrotic syndrome, and the need for renal replacement (transplantation or dialysis).

Screening for diabetic nephropathy is a routine aspect of diabetes care. The ADA recommends yearly screening for individuals with T2DM and yearly screening for those with T1DM after 5 years' duration of disease with a random spot urine sample for albumin-to-creatinine ratio. Abnormal results should be confirmed by two

Table 629.10 Guidelines for Intravenous Insulin Coverage During Surgery

BLOOD GLUCOSE LEVEL (mg/dL)	INSULIN INFUSION (units/kg/hr)	BLOOD GLUCOSE MONITORING
<120	0.00	1 hr
121-200	0.03	2 hr
200-300	0.06	2 hr
300-400	0.08	1 hr*
400	0.10	1 hr*

*Check urine ketones.
An infusion of 5% glucose and 0.45% saline solution with 20 mEq/L of potassium acetate is given at 1.5 times the maintenance rate.

Table 629.11 Screening Guidelines

	INITIAL TESTING	FREQUENCY	TEST
Thyroid disease	At diagnosis	Every 1-2 yr or sooner if symptoms	TSH, thyroid antibodies
Celiac	At diagnosis	Within 2 yr and again at 5 yr or sooner if symptoms	IgA and TTG
Hypertension	At diagnosis	Each visit	Elevated BP based on ≥90th% for age, sex, height on three separate occasions
Dyslipidemia	≥10 yr of age at diagnosis once glucose control established	If abnormal annually; every 5 yr if initially normal	Goal LDL-C <100 mg/dL
Nephropathy	At puberty or age ≥10 yr whichever comes first, if T1DM ≥5 yr	Annually	Albuminuria; urine albumin-to-creatinine ratio
Retinopathy	T1DM ≥3-5 yr when ≥10 yr or puberty, whichever comes first	Annually	Dilated eye exam
Neuropathy	At puberty or ≥10 year, whichever earlier if T1DM >5 yr	Annually	Foot exam

BP, Blood pressure; IgA, immunoglobulin A; LDL, low density lipoprotein; TSH, thyroid-stimulating hormone; TTG, tissue transglutaminase.

additional specimens on separate days because of the high variability of albumin excretion in patients with diabetes. Short-term hyperglycemia, strenuous exercise, urinary tract infections, marked hypertension, heart failure, and acute febrile illness can cause transient elevation in urinary albumin excretion. There is marked day-to-day variability in albumin excretion, so at least two of three collections done in a 3- to 6-month period should show elevated levels before microalbuminuria is diagnosed and treatment is started. Once albuminuria is diagnosed, a number of factors attenuate the effect of hyperfiltration on kidneys: (1) meticulous control of hyperglycemia, (2) aggressive control of systemic blood pressure, (3) selective control of arteriolar dilation by use of angiotensin-converting enzyme inhibitors (thus decreasing transglomerular capillary pressure), and (4) dietary protein restriction (because high protein intake increases the renal perfusion rate). Tight glycemic control will delay the progression of microalbuminuria and slow the progression of diabetic nephropathy.

DIABETIC NEUROPATHY

Both the peripheral and autonomic nervous systems can be involved; diabetic neuropathy can develop in both children and adolescents. The etiology of diabetic neuropathy remains incompletely understood, and the impact of hyperglycemia on its development remains uncertain. Observational studies done in the years before the era of intensive insulin therapy for T1DM reported a higher incidence of neuropathy compared with more recent studies. However, several studies have found that the development of preclinical and symptomatic peripheral diabetic neuropathy in childhood is not strongly associated with either glycemic control or duration of disease. The polyol pathway, nonenzymatic glycation, and/or disturbances of myoinositol metabolism, affecting one or more cell types in the multicellular constituents of the peripheral nerve, have been hypothesized to have an inciting role. Other factors, such as possible direct neurotrophic effects of insulin, insulin-related growth factors, nitric oxide, and stress proteins, may also contribute to the development of neuropathy. Using quantitative sensory testing, abnormal cutaneous thermal perception is a common finding in both upper and lower limbs in neurologically asymptomatic young diabetic patients. Heat-induced pain threshold in the hand is correlated with the duration of the diabetes. There is no correlation between quantitative sensory testing scores and metabolic control. Subclinical motor nerve impairment as manifested by reduced sensory nerve conduction velocity and sensory nerve action potential amplitude have been detected in as many as 10–58% of children with diabetes. An early sign of autonomic neuropathy, such as decreased heart rate variability, may present in adolescents with a history of long-standing disease and poor metabolic control. A number of therapeutic strategies have been attempted with variable results. These treatment modalities include (1) improvement in metabolic control, (2) use of aldose reductase inhibitors to reduce by-products of the polyol pathway, (3) use of α-lipoic acid (an antioxidant) that enhances tissue nitric oxide and its metabolites, (4) use of anticonvulsants (e.g., lorazepam, valproate, gabapentin, carbamazepine, pregabalin, phenytoin, tiagabine, and topiramate) for treatment of neuropathic pain, and (5) use of antidepressants (amitriptyline, imipramine, and selective serotonin reuptake inhibitors). Additional medications include antiarrhythmics such as lidocaine, topical analgesics, and nonsteroidal antiinflammatory drugs.

Skeletal Effects of Type 1 Diabetes Mellitus

The skeleton is adversely affected by diabetes, with T1DM patients at greater risk for skeletal complications than those with T2DM. T1DM is associated with an increased risk of fracture that first becomes evident in childhood and persists across the entire life span. This includes a dramatically increased hip fracture risk in adults, ranging from two- to sevenfold higher than patients without diabetes, depending on the population studied. Most, but not all, studies have shown T1DM to be associated with low bone mineral density. This differs from T2DM, where bone density is normal or even above average because of increased mechanical loading in association with obesity. The deficits in bone density do not appear to be sufficient to explain the degree of increased fracture risk, leading to the hypothesis that bone quality may be impaired as well. The mechanism(s) underlying diabetic-related osteopathy is poorly understood and presumed to be multifactorial. Most, but not all, studies show an association between poor glycemic control and adverse skeletal outcomes, suggesting a role for hyperglycemia and/or insulin deficiency. Chronic exposure to hyperglycemia may weaken bone strength through the accumulation of advanced glycation end products (AGEs) in bone. Other factors hypothesized to impair bone health in diabetes include chronic inflammation, abnormalities in the growth hormone-insulin-like growth factor 1 (IGF-1) axis, and abnormalities in bone mineral metabolism including excess urinary calcium loss. There are no standard guidelines for bone health screening in children. Assessment of bone density by dual-energy x-ray absorptiometry (DXA) and markers of bone mineral metabolism is recommended in adults with fracture history and other risk factors for osteoporosis. Dietary education should reinforce the importance of meeting the recommended daily allowance (RDA) for calcium and vitamin D intake from diet and supplements.

Other Complications

Mauriac syndrome is a rare complication related to chronic underinsulinization that is characterized by growth failure and hepatomegaly

caused by excess glycogen accumulation in the liver. It has become much less common since longer-acting insulins have become available. Clinical features of Mauriac syndrome include moon face, protuberant abdomen, proximal muscle wasting, and enlarged liver from fat and glycogen infiltration.

The syndrome of **limited joint mobility** is frequently associated with the early development of diabetic microvascular complications, such as retinopathy and nephropathy, which may appear before 18 years of age. The prevalence of limited joint mobility has significantly decreased, which is attributed to the improved overall metabolic control of children and adolescents with T1DM.

PROGNOSIS

T1DM is a serious, chronic disease. It has been estimated that the average life span of individuals with diabetes is approximately 10 years shorter than that of people without diabetes, but with improved care, that figure is lessening consistently. Although most children with T1DM eventually attain a height within the normal adult range, puberty may be delayed, and the final height may be less than the genetic potential. From studies in identical twins, it is apparent that despite seemingly satisfactory control, the affected twin manifests delayed puberty and a substantial reduction in height when the onset of disease occurs before puberty. These observations indicate that, in the past, conventional criteria for judging control were inadequate and that adequate control of T1DM was almost never achieved by routine means.

The changing pattern of metabolic control is having a profound influence on reducing the incidence and the severity of certain complications. For example, after 20 years of diabetes, there was a decline in the incidence of nephropathy in T1DM in Sweden among children whose disease was diagnosed in 1971–1775 compared with in the preceding decade. In addition, in most patients with microalbuminuria in whom it was possible to obtain good glycemic control, microalbuminuria disappeared. This improved prognosis is directly related to metabolic control.

PANCREAS AND ISLET TRANSPLANTATION AND REGENERATION

In an attempt to cure T1DM, transplantation of a segment of the pancreas or of isolated islets has been performed in adults. These procedures are both technically demanding and associated with the risks of disease recurrence and complications of rejection or its treatment by immunosuppression. Long-term complications of immunosuppression include the development of malignancy. Some antirejection drugs, notably cyclosporine and tacrolimus, are toxic to the islets of Langerhans, impairing insulin secretion and even causing diabetes. Hence, segmental pancreas transplantation is generally only performed in association with transplantation of a kidney for a patient with ESRD caused by diabetic nephropathy in which the immunosuppressive regimen is indicated for the renal transplantation. Several thousand such transplants have been performed in adults. With experience and better immunosuppressive agents, functional survival of the pancreatic graft may be achieved for up to several years, during which time patients may be in metabolic control with no or minimal exogenous insulin and reversal of some of the microvascular complications. However, because children and adolescents with DM are not likely to have ESRD from their diabetes, pancreas transplantation as a primary treatment in children cannot be recommended.

Islet cell transplantation is challenging because of limited survival of the transplanted cells and because of rejection. An islet transplantation strategy (Edmonton protocol) infused isolated pancreatic islets into the portal vein of adults with T1DM, along with immunosuppressive medications that had lower side effect profiles than other drugs. Although lasting insulin independence was initially low, engraftment and insulin independence have improved over the last decade, and over a thousand patients have undergone the procedure. There has been improved islet engraftment using improved induction and maintenance immunosuppression. Still, in 5-year follow-up studies, only ~10% maintain insulin independence, with an average duration of insulin independence of ~15 months. Long-term challenges remain the toxicity of immunosuppression, the limited procurement of viable tissue, and funding and limitations of engraftment itself.

629.3 Type 2 Diabetes Mellitus

David R. Weber

Formerly known as *non–insulin-dependent diabetes* or *adult-onset diabetes,* T2DM is a heterogeneous disorder, characterized by peripheral insulin resistance and failure of the β cell to keep up with increasing insulin demand. Patients with T2DM have relative rather than absolute insulin deficiency. Generally, they are not ketosis prone, but ketoacidosis is the initial presentation in 5–10% of affected subjects (Table 629.12).

NATURAL HISTORY

T2DM is a heterogenous, polygenic disease aggravated by environmental factors, including low physical activity and excessive caloric intake. Most patients are obese, although the disease can occasionally be seen in normal-weight individuals. People of Asian ancestry appear to be at risk for T2DM at lower degrees of total adiposity. Obesity, in particular central obesity, is associated with the development of insulin resistance (Fig. 629.10). In addition, patients who are at risk for developing T2DM exhibit decreased glucose-induced insulin secretion. Obesity does not lead to the same degree of insulin resistance in all individuals, and even those who develop insulin resistance do not necessarily exhibit impaired β-cell function. Thus many obese individuals have some degree of insulin resistance but compensate for it by increasing insulin secretion.

Those individuals who are unable to adequately compensate for insulin resistance by increasing insulin secretion develop IGT and IFG, usually, although not always, in that order. Hepatic insulin resistance leads to excessive hepatic glucose output (failure of insulin to suppress hepatic glucose output), and skeletal muscle insulin resistance leads to decreased glucose uptake in a major site of glucose disposal. Over time hyperglycemia worsens, a phenomenon that has been attributed to the deleterious effect of chronic hyperglycemia (glucotoxicity) or chronic hyperlipidemia (lipotoxicity) on β-cell function and is often accompanied by increased triglyceride content and decreased insulin gene expression.

At some point, blood glucose elevation meets the criteria for a diagnosis of T2DM (see Table 629.2), but most patients with T2DM remain asymptomatic for months to years after this point because hyperglycemia is moderate and symptoms are not as dramatic as the polyuria and weight loss at presentation of T1DM. Weight gain may even continue. The prolonged hyperglycemia may be accompanied by the development of microvascular and macrovascular complications. Among the differences between T2DM in children and adults is a faster decline in β-cell function and insulin secretion, as well as faster development of diabetes complications in children.

In T2DM, insulin deficiency is rarely absolute, so patients usually do not need insulin to survive, at least early in the disease course. However, in some cases, the degree of hyperglycemia is such that exogenous insulin therapy is needed. DKA is uncommon in patients with T2DM but does occur and appears to be more common in children than in adults. Although it is generally believed that autoimmune destruction of pancreatic β-cells does not occur in T2DM, autoimmune markers of T1DM—namely, GAD, ICA512, and IAA—may be positive in ~30% of the cases of adolescent T2DM. The presence of these autoimmune markers does not rule out T2DM in children and adolescents. At the same time, because of the general increase in obesity, the presence of obesity does not preclude the diagnosis of T1DM. Although most newly diagnosed children and adolescents can be confidently assigned a diagnosis of T1DM or T2DM, a few exhibit features of both types and are difficult to classify.

EPIDEMIOLOGY

The prevalence of T2DM in children (10-19 years) has risen dramatically from 34 cases per 100,000 youth in 2001 to 67 cases per 100,000

Table 629.12 Characteristics at Presentation for Type 1, Type 2, and Monogenic Diabetes

	TYPE 1 DIABETES	TYPE 2 DIABETES	MATURITY-ONSET DIABETES OF THE YOUNG
Age of onset during childhood and adolescence	Any	Rarely before puberty	Any
Weight status	Any	Rarely with normal weight	Any
Symptomatic (polyuria, polydipsia, weight loss)	Nearly universal	Two thirds	Common
Duration of symptoms before presentation	<1 mo	Frequently >1 mo	Any
Diabetic ketoacidosis at presentation	Common	Rare (6–11%)	—
Family history of diabetes before age 40	Uncommon	Strong family history for type 2 diabetes	Very strong family history, classically in three generations
Acanthosis nigricans	Rare	Common (86%)	—
Ethnicity	Any	Predominantly Black or minority ethnicity	Any
Diabetes-associated antibodies (IA2, glutamate decarboxylase, insulin)	Positive in majority	Negative (<10%)	Negative (<1%)
Pathogenic variants in *HNF1A, GCK,* or *HNF4A*	Negative	Negative	Nearly universal
Complications at presentation	Very rare	Common	Rare

IA2, Tyrosine phosphatase-related islet antigen 2.
From Viner R, White B, Christie D. Type 2 diabetes in adolescents: a severe phenotype posing major clinical challenges and public health burden. Lancet. 2017;389:2252–2260.

in 2017. Certain ethnic groups appear to be at higher risk; for example, Native Americans, Hispanic Americans, and Black Americans (in that order) have higher incidence rates than White Americans (Fig. 629.11). Although most children presenting with diabetes have T1DM, the percentage of children presenting with T2DM is increasing and represents up to 50% of the newly diagnosed children in some centers.

GENETICS

T2DM has a strong genetic component; concordance rates among identical twins are in the 40–80% range, but there is not a simple mendelian pattern. Twinning itself increases the risk of T2DM (because of intrauterine growth restriction), and this may distort estimates of genetic risk. Monozygotic twins have a lifetime concordance of T2DM of around 70%, indicating that shared environmental factors (including the prenatal environment) may have a role in the development of T2DM; dizygotic twins have a lifetime concordance of around 20–30%. The genetic basis for T2DM is complex and incompletely defined; no single identified defect predominates. Genome-wide association studies have identified certain genetic polymorphisms that are associated with increased T2DM risk in most populations studied; the most consistently identified are variants of *TCF7L2,* which may have a role in β-cell function. Other identified risk alleles include variants in *PPARG* and *KCNJ11-ABCC8.* These variants only explain a small portion (probably less than 20%) of the population risk of diabetes, and in many cases the mechanism by which these polymorphisms confer risk of T2DM is not clear.

EPIGENETICS AND FETAL PROGRAMMING

Low birthweight and intrauterine growth restriction are associated with increased risk of T2DM. This risk appears to be higher in low-birthweight infants who gain weight more rapidly in the first few years of life. These findings have led to the formulation of the *thrifty phenotype hypothesis,* which postulates that poor fetal nutrition programs these children to maximize storage of nutrients and makes them more prone to future weight gain and development of diabetes. Epigenetic modifications may play a role in this phenomenon, given that so few of the known T2DM genes are associated with low birthweight.

ENVIRONMENTAL AND LIFESTYLE-RELATED RISK FACTORS

Obesity is the most important lifestyle factor associated with development of T2DM. This, in turn, is associated with the intake of high-energy foods, physical inactivity, excess screen time, and low socioeconomic status. Maternal smoking also increases the risk of diabetes and obesity in the offspring. Increasingly, exposure to land pollutants and air pollutants is demonstrated to contribute to insulin resistance. The lipophilic nature of these organic pollutants and their consequent storage in adipose tissue may promote obesity and insulin resistance. In addition, sleep deprivation and psychosocial stress are associated with increased risk of obesity in childhood and with IGT in adults, possibly via overactivation of the hypothalamic-pituitary-adrenal axis. Many antipsychotics (especially the atypical antipsychotics like olanzapine and quetiapine) and antidepressants (both tricyclic antidepressants and newer antidepressants like fluoxetine and paroxetine) induce weight gain. In addition to the risk conferred by increased obesity, some of these medications may also have a direct role in causing insulin resistance, β-cell dysfunction, leptin resistance, and activation of inflammatory pathways.

CLINICAL FEATURES

In the United States, T2DM in children is more likely to be diagnosed in Native American, Hispanic American, and Black American youth, with the highest incidence being reported in Pima Indian youth. Although cases may be seen as young as 4 years of age, most are diagnosed in adolescence; the incidence increases with increasing age. Family history of T2DM is present in most cases. Patients are obese and present with mild symptoms of polyuria and polydipsia or are asymptomatic and T2DM is detected on screening tests. Presentation with DKA occurs in ~10% of cases. Physical examination frequently reveals the presence of acanthosis nigricans, most commonly on the neck and in other flexural areas. Other findings may include striae and an increased waist-to-hip ratio. Laboratory testing reveals elevated HbA_{1c} levels. Hyperlipidemia characterized by elevated triglycerides and low-density lipoprotein cholesterol levels is commonly seen in patients with T2DM at diagnosis. Lipid screening is indicated in all new cases of T2DM. The current recommendation is that blood pressure measurement, random urine

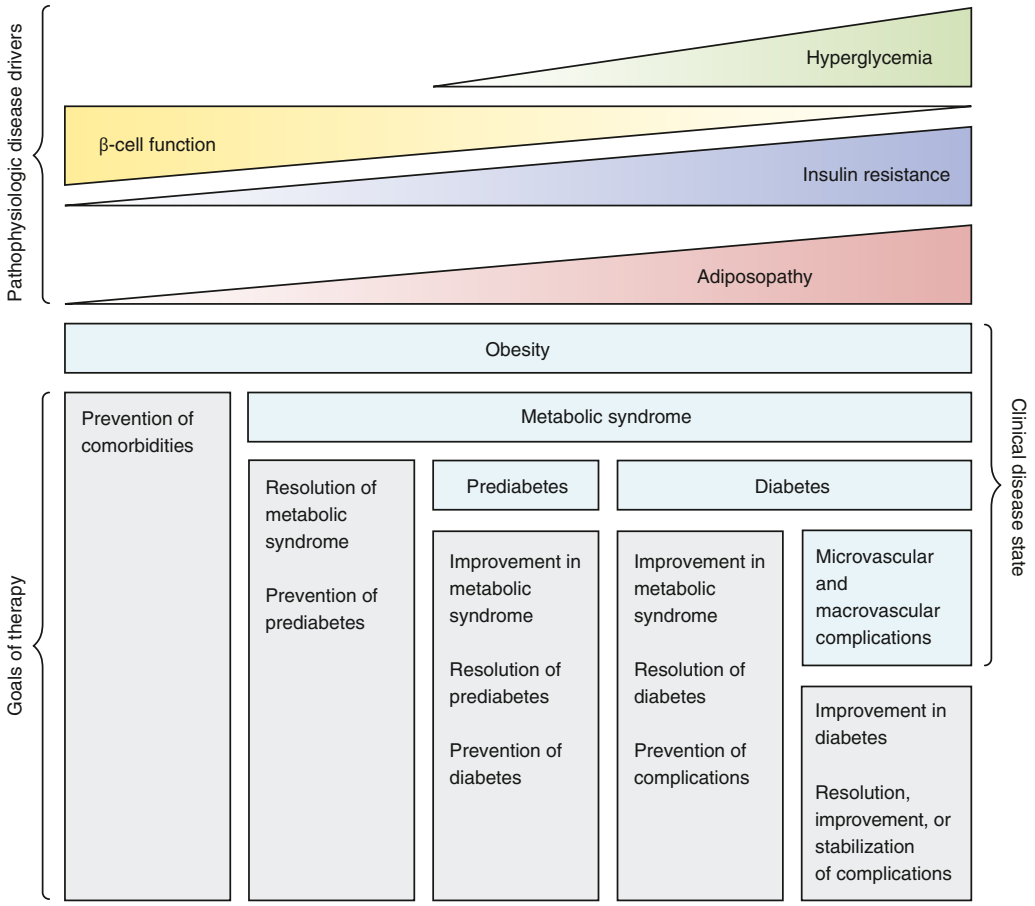

Fig. 629.10 The disease continuum for weight-related type 2 diabetes. *(From Lingvay I, Sumithran P, Cohen RV, le Roux CW. Obesity management as a primary treatment goal for type 2 diabetes: time to reframe the conversation. Lancet. 2022;399:394–404.)*

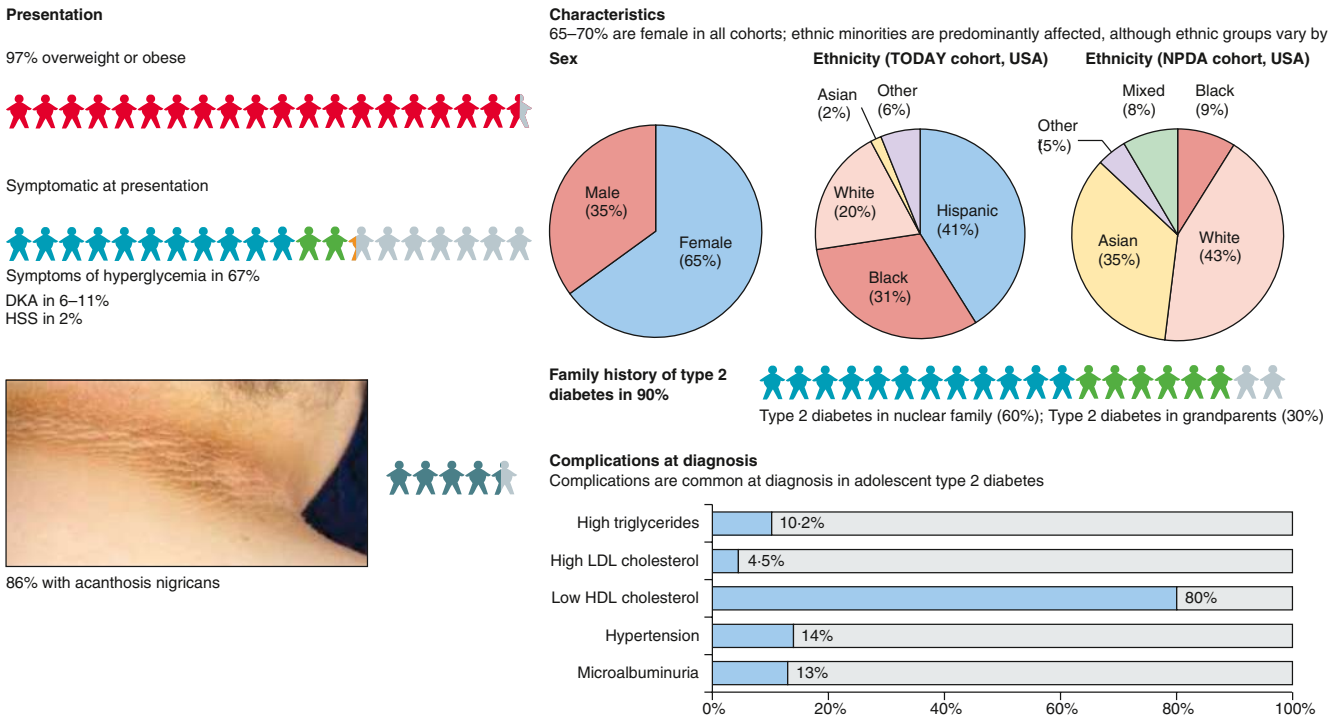

Fig. 629.11 Features of adolescent type 2 diabetes at diagnosis. DKA, diabetic ketoacidosis. Type 2 diabetes in adolescents: a severe phenotype posing major clinical challenges and public health burden. Lancet. 2017;389:2252–2260.)*

albumin-to-creatinine ratio, and a dilated eye examination should be performed at diagnosis.

Because hyperglycemia develops slowly and patients may be asymptomatic for months or years after they develop T2DM, screening is recommended in high-risk children (Table 629.13). All youth who are overweight and have at least one other risk factor should be tested for T2DM beginning at age 10 years or at the onset of puberty. Risk factors include family history of T2DM in first- or second-degree relatives, history of gestational diabetes in the mother, belonging to a high-risk racial or ethnic group (i.e., Native American, Black American, Hispanic, or Asian/Pacific Islander groups), and having signs of insulin resistance (e.g., acanthosis nigricans, hypertension, dyslipidemia, or polycystic ovary syndrome). The current recommendation is to use the HbA_{1c} the screening tool; fasting plasma glucose is also acceptable. In borderline or asymptomatic cases, the diagnosis may be confirmed using a standard OGTT, but this test is not required if typical symptoms are present or fasting plasma glucose or HbA_{1c} is clearly elevated.

TREATMENT

T2DM is a progressive syndrome that gradually leads to complete insulin deficiency during the patient's life. A systematic approach for the treatment of T2DM should be implemented according to the natural course of the disease, including adding insulin when hyperglycemia cannot be controlled by lifestyle and noninsulin pharmacotherapy. Lifestyle modification (diet and exercise) is an essential part of the treatment regimen, and consultation with a dietitian is usually necessary (see Fig. 629.10). An oral agent monotherapy may not maintain lasting glucose control in close to half of those with T2DM.

Recommendations are to implement a comprehensive lifestyle modification plan designed to induce weight loss of 7–10%. There is no specific dietary or exercise regimen that has been conclusively shown to be superior, and practitioners recommend a low-calorie, low-fat diet and 30-60 minutes of physical activity at least 5 times a week. Screen time should be limited to 1-2 hours a day. Education is provided to diminish unhealthy habits such as skipping meals, heavy snacking, and excessive screen time. Adolescents may engage in non–appetite-based eating (i.e., emotional eating, television-cued eating, boredom) and cyclic dieting ("yo-yo" dieting). Treatment in these cases is frequently challenging and may not be successful unless the entire family buys into the need to change their unhealthy lifestyle.

Pharmacologic therapy should be initiated at diagnosis of T2DM. Noninsulin pharmacotherapies used in the treatment of T2DM are shown in Table 629.14; most of these are not approved for use in patients under the age of 18 years. Metformin is the first line of pharmacotherapy and should be started in all patients. Renal insufficiency and liver disease are contraindications to metformin use and may increase the risk of lactic acidosis. Patients with markedly elevated liver transaminases should undergo evaluation by a gastroenterologist/hepatologist before initiating therapy. The starting dose is 500-1000 mg/day, which should be increased over a few weeks to the full therapeutic dose of 2,000 mg daily. Patients who present with significant (HbA_{1c} >8.5%) or symptomatic (e.g., polyuria, polydipsia) hyperglycemia should be started on basal insulin with a long-acting insulin analog, typically at a dose of 0.5 units/kg/day. Those presenting in DKA will require initial treatment with insulin using protocols similar to those used for treating T1DM. Once blood glucose levels are under control, many cases can be managed with hypoglycemic agents and lifestyle interventions, but some patients will continue to require insulin therapy.

Ongoing care should include periodic review of weight and BMI, diet, and physical activity; blood glucose monitoring; and monitoring of HbA_{1c} at 3-month intervals. Frequency of home glucose monitoring can range from 3-4 times daily for those on multiple daily insulin injections to twice daily for those on a stable long-acting insulin regimen or metformin. Alternatively, blood glucose monitoring can be done by CGM. Patients who fail to achieve glycemic targets (typically HbA_{1c} <7%) with lifestyle modification and metformin alone will require escalation of therapy with the addition of basal insulin or liraglutide. Liraglutide is an injectable glucagon-like peptide-1 (GLP-1) analog approved by the FDA for use in children ≥10 years. A potential benefit of liraglutide over basal insulin is that it may promote weight loss. The typical starting dose is 0.6 mg/daily, increased as tolerated by 0.6 mg/day per week until a maximum dose of 1.8 mg is achieved. Gastrointestinal symptoms are the most common side effect. Liraglutide is contraindicated in patients with a personal or family history of medullary thyroid cancer or multiple endocrine neoplasia type 2 (MEN 2), based on animal data showing a dose- and duration-dependent effect to promote thyroid C-cell tumors in rodents.

Other agents such as thiazolidinediones, sulfonylureas, other GLP-1 analogs, dipeptidyl peptidase-4 inhibitors (DPP-4 inhibitors), pramlintide, and sodium-glucose transport protein inhibitors (SGLT2 inhibitors) are used with variable frequency in adults but are infrequently used in children. Sulfonylureas cause insulin release by closing the potassium channel (K_{ATP}) on β cells. They are occasionally used when metformin monotherapy is unsuccessful or contraindicated for some reason (use in certain forms of neonatal diabetes is discussed in the relevant section). Thiazolidinediones increase insulin sensitivity via activation of the peroxisome proliferator-activated receptor pathway, but use is limited because of concerns about adverse cardiac effects. Pramlintide is an analog of islet amyloid polypeptide (IAPP), which delays gastric emptying, suppresses glucagon, and possibly suppresses food intake. It is not approved for pediatric use and increases the risk of hypoglycemia when used with insulin or other hypoglycemic agents.

Incretins are gut-derived peptides like GLP-1, GLP-2, and GIP (glucose-dependent insulinotropic peptide, previously known as *gastric inhibitory protein*) that are secreted in response to meals and act to enhance insulin secretion and action, suppress glucagon production, and delay gastric emptying (among other actions). Other daily and weekly forms of GLP-1 agonists beyond liraglutide are commonly used in adults. DPP-4 inhibitors are oral agents that prolong the action of GLP-1 and are currently being studied for use in children. The SGLT-2 inhibitors act by blocking glucose reabsorption in the proximal renal tubule and are commonly used as second- or third-line agents in adults, with specific benefits in improving cardiorenal outcomes in patients with heart failure or declining renal function. SGLT-2 inhibitors are currently under evaluation for potential use in children. Adults with T2DM have been treated with *double incretion* therapy (tirzepatide) with the combination of a GLP-1 agonist and GIP.

Further rises in HbA_{1c} despite the addition of basal insulin and/or liraglutide will necessitate addition of short-acting insulin at mealtimes. Bariatric surgery is also used in adolescents with moderate to severe obesity and frequently leads to complete remission of T2DM. Guidelines for the routine use of bariatric surgery in adolescents continue to emerge, but expert opinion suggests that adolescents with BMI ≥35 or 120% of the 95th percentile for age and gender with a clinically significant complication (including T2DM) are potential candidates, provided there is access to a quality multidisciplinary center with pediatric experience.

Table 629.13 Testing for Type 2 Diabetes in Children

- **Criteria***

Overweight (body mass index >85th percentile for age and sex
Plus
One or more of the following risk factors:
- Family history of type 2 diabetes in first- or second-degree relative or gestational diabetes in the mother
- High risk racial/ethnic background (Native American, Black American, Hispanic, Asian/Pacific Islander)
- Signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, polycystic ovary syndrome)

- **Age of initiation**: age 10 yr or at onset of puberty if puberty occurs at a younger age
- **Frequency:** every 1-2 yr, based upon clinical suspicion
- **Test:** fasting glucose, HbA_{1c}, or oral glucose tolerance teat

*Clinical judgment should be used to test for diabetes in high-risk patients who do not meet these criteria.

Table 629.14 Noninsulin Pharmacotherapies Used to Treat T2DM

MEDICATIONS	CLASS	MECHANISM OF ACTION	ROUTE	FDA-APPROVED AGE
Pramlintide	Amylin analogue	Increases satiety, slows gastric emptying, and suppresses postprandial glucagon secretion, resulting in decreased postmeal glucose excursions	Subcutaneous injection	>18 yr
Metformin	Biguanide	Improves hepatic insulin sensitivity. Increases GLP-1 and PYY	Oral	>10 yr
Alogliptin Linagliptin Saxagliptin Sitagliptin	DPP-4 inhibitors	Inhibits DPP-4 from degrading GLP-1 and GIP	Oral	>18 yr
Albiglutide Dulaglutide Exenatide Liraglutide Lixisenatide Semaglutide	Glucagon-like peptide agonists	Increase release of GLP-1, which stimulates release of insulin	Subcutaneous injection	>8 yr, with exception of liraglutide, which is >10 yr
Nateglinide Repaglinide	Meglitinides	Causes rapid secretion of insulin by acting on the ATP sensitive potassium channel of pancreatic beta cells	Oral	>18 yr
Canagliflozin Dapagliflozin Empagliflozin Ertugliflozin	Sodium-glucose co-transporter 2 inhibitors	Promotes renal excretion of glucose at the level of the proximal tubule causing an osmotic diuresis	Oral	>18 yr
Gliclazide Glimepiride Glipizide Glyburide	Sulfonylureas	Increase insulin section via interaction with the K-ATP channel in β cells	Oral	>18 yr
Pioglitazone Rosiglitazone	Thiazolidinediones	Increase insulin sensitivity at adipose and muscle tissue	Oral	>18 yr

DPP-4, Dipeptidyl peptidase 4; GIP, glucose-dependent insulinotropic peptide; GLP-1, glucagon-like peptide 1 agonist; PYY, peptide YY.

COMPLICATIONS

In one study of diabetes in youth, 92% of the patients with T2DM had two or more elements of **metabolic syndrome** (hypertension, hypertriglyceridemia, decreased high-density lipoprotein, increased waist circumference), including 70% with hypertension. In addition, the incidence of microalbuminuria and diabetic retinopathy appears to be higher in T2DM than it is in T1DM. In long-term follow-up from another study, the participants at a mean of age 26 years reported a cumulative incidence of hypertension of 68%, dyslipidemia 52%, diabetic kidney disease 55%, and nerve disease 32%.

Given the extremely high risk of diabetes-related comorbidities, routine screening for microalbuminuria, dyslipidemia, hypertension, and retinopathy should commence shortly after diagnosis. Sleep apnea and fatty liver disease are being diagnosed with increasing frequency and may necessitate referral to the appropriate specialists. Complications associated with all forms of diabetes and recommendations for screening are noted in Table 629.12; Table 629.15 lists conditions particularly associated with T2DM.

PREVENTION

The difficulties in achieving good glucose control and preventing diabetes complications make prevention a compelling strategy. This is particularly true for T2DM, which is linked to modifiable risk factors (obesity, a sedentary lifestyle). The Diabetes Prevention Program demonstrated that intensified lifestyle or drug intervention in individuals with IGT prevented or delayed the onset of T2DM. Lifestyle intervention reduced the diabetes incidence by 58%; metformin reduced the incidence by 31% compared with placebo. Lifestyle interventions are believed to have similar beneficial effects in obese adolescents with IGT.

629.4 Other Specific Types of Diabetes

David R. Weber

Most cases of diabetes in children and adults fall into the two broad categories of T1DM and T2DM, but between 1% and 10% of cases are caused by single-gene disorders. These disorders include hereditary defects of β-cell function and insulin action, as well as rare forms of mitochondrial diabetes.

GENETIC DEFECTS OF β-CELL FUNCTION

Transient Neonatal Diabetes Mellitus

Neonatal diabetes is transient in approximately 50% of cases, but after an interim period of normal glucose tolerance, 50–60% of these patients develop permanent diabetes (at an average age of 14 years). It remains to be determined whether this association of transient diabetes in the newborn followed much later in life by classic T1DM is a chance occurrence or causally related (Fig. 629.12).

The syndrome of **transient DM** in the newborn infant has its onset in the first week of life and persists several weeks to months before spontaneous resolution. Median duration is 12 weeks. It occurs most often in infants who are small for gestational age and is characterized by hyperglycemia and pronounced glycosuria, resulting in severe dehydration and, at times, metabolic acidosis, but with only minimal or no ketonemia or ketonuria. There may also be findings such as umbilical hernia or large tongue. Insulin responses to glucose or tolbutamide are low to absent; basal plasma insulin concentrations are normal. After spontaneous recovery, the insulin responses to these same stimuli are brisk and normal, implying a possible functional delay in β-cell maturation with spontaneous resolution. Occurrence of the syndrome in

Table 629.15 Monitoring for Complications and Comorbidities in T2DM

CONDITION	SCREENING TEST	COMMENT
Hypertension	Blood pressure	
Fatty liver	Aspartate aminotransferase, alanine aminotransferase, possibly liver ultrasound	
Polycystic ovary syndrome	Menstrual history, assessment for androgen excess with free/total testosterone, dehydroepiandrosterone sulfate	
Microalbuminuria	Urine albumin concentration and albumin-to-creatinine ratios	
Dyslipidemia	Fasting lipid profile (total, low-density lipoprotein, high-density lipoprotein cholesterol, triglycerides)	Obtain at diagnosis and every 2 yr
Sleep apnea	Polysomnography: Sleep study to assess overnight oxygen saturation, airflow, heart rate, electromyography, and eye movements	

consecutive siblings has been reported. About 70% of cases are the result of abnormalities of an imprinted locus on chromosome 6q24, resulting in overexpression of paternally expressed genes such as *PLAGL1/ZAC* and *HYMAI*. Most of the remaining cases are caused by pathogenic variants in K_{ATP} channels. Variants in K_{ATP} channels also cause many cases of permanent neonatal diabetes, but there is practically no overlap between the variants that lead to transient neonatal DM and those causing permanent neonatal DM. This syndrome of transient neonatal DM should be distinguished from the severe hyperglycemia that may occur in hypertonic dehydration that usually occurs in infants beyond the newborn period and responds promptly to rehydration with minimal or no requirement for insulin.

Administration of insulin is mandatory during the active phase of DM in the newborn. Rehydration and IV insulin are usually required initially; transition to subcutaneous insulin can occur once clinically stable. A variety of regimens, including intermediate- or long-acting insulin given in one to two daily doses or continuous insulin therapy with an insulin pump, have been used successfully. The starting dose is typically 1-2 units/kg/day but will need to be adjusted based upon blood glucose levels. Attempts at gradually reducing the dose of insulin may be made as soon as recurrent hypoglycemia becomes manifested or after 2 months of age.

Permanent Neonatal Diabetes Mellitus

Permanent DM in the newborn period is caused, in approximately 50% of the cases, by pathogenic variants in the *KCNJ11* and *ABCC8* genes (see Figs. 629.12 and 629.13). These genes code for the Kir6.2 and SUR1 subunits of the adenosine triphosphate–sensitive potassium channel, which is involved in an essential step in insulin secretion by the β cell. Some cases are caused by pancreatic agenesis because of homozygous pathogenic variants in *IPF-1* (where heterozygous variants cause MODY4); homozygous variants in the glucokinase gene (where heterozygous variants cause MODY2); and variants in the insulin gene (see Tables 629.1 and 629.12). Almost all these infants are small at birth because of the role of insulin as an intrauterine growth factor. Instances of affected twins and families with more than one affected infant have been reported. Infants with permanent neonatal DM may be initially euglycemic and typically present between birth and 6 months of life (mean age of presentation is 5 weeks), but rarely can present up to 1 year of age. There is a spectrum of severity, and up to 20% have neurologic features. The most severely affected patients have the syndrome of *d*evelopmental delay, *e*pilepsy, and *n*eonatal *d*iabetes (**DEND syndrome**).

Activating pathogenic variants in the *KCNJ11* gene (encoding the adenosine triphosphate–sensitive potassium channel subunit Kir6.2) are associated with both TND and PND, with variants associated with each phenotype. More than 90% of these patients respond to sulfonylureas (at higher doses than those used in T2DM), but patients with severe neurologic disease may be less responsive. Pathogenic variants in *ABCC8* (encoding the SUR1 subunit of this potassium channel) were thought to be less likely to respond to sulfonylureas (because this is the subunit that binds sulfonylurea drugs), but some of these variants are reported to respond; patients have been successfully switched from insulin to oral therapy. Several protocols for switching the patient from insulin to glyburide are available, and patients are usually stabilized on doses ranging from 1 to 2.5 mg/kg/day. Because approximately 50% of neonatal diabetics have potassium-channel variants that can be switched to sulfonylurea therapy, with dramatic improvement in glycemic control, neurologic outcomes, and quality of life, all patients with diabetes diagnosed before 6 months of age (and perhaps even those diagnosed before 12 months of age) in whom insulin dependence persists beyond 7-10 days should have genetic testing (Fig. 629.14).

Maturity-Onset Diabetes of Youth

Several forms of diabetes are associated with **monogenic defects in β-cell function**. Before these genetic defects were identified, this subset was diagnosed on clinical grounds and described by the term *MODY*. This subtype of DM consists of a group of heterogeneous clinical entities that are characterized by onset before 25 years, autosomal dominant inheritance, and a primary defect in insulin secretion. Strict criteria for the diagnosis of MODY include diabetes in at least three generations with autosomal dominant transmission and diagnosis before age 25 years in at least one affected subject. Pathogenic variants have been found in at least 14 different genes, accounting for the dominantly inherited monogenic defects of insulin secretion, for which the term MODY is used (Table 629.16). The ADA groups these disorders together under the broader category of *genetic defects of β-cell function*. Just three of them (MODY2, MODY3, and MODY5) account for 90% of the cases in this category in European populations, but the distribution may be different in other ethnic groups. Except for MODY2 (which is caused by variants in the enzyme glucokinase), all other forms are caused by genetic defects in various transcription factors (see Table 629.16).

MODY2

This is the second most common form of MODY and accounts for approximately 15–30% of all patients diagnosed. Glucokinase plays an essential role in β-cell glucose sensing, and heterozygous pathogenic variants in this gene lead to mild reductions in pancreatic β-cell response to glucose. Homozygotes with the same variants are completely unable to secrete insulin in response to glucose and develop a form of PND. Patients with heterozygous variants have a higher threshold for insulin release but are able to secrete insulin adequately at higher blood glucose levels (typically 125 mg/dL [7 mmol/L] or higher). This results in a relatively mild form of diabetes (HbA_{1c} is usually less than 7%), with mild fasting hyperglycemia and IGT in most patients. MODY2 may be misdiagnosed as T1DM in children, gestational diabetes in pregnant women, or well-controlled T2DM in adults (see Table 629.12). An accurate diagnosis is important because most cases are not progressive, and except for gestational diabetes, may not require treatment. When needed, they can usually be treated with small doses of exogenously administered insulin. Treatment with oral agents (sulfonylureas and related drugs) can be successful and may be more acceptable to many patients.

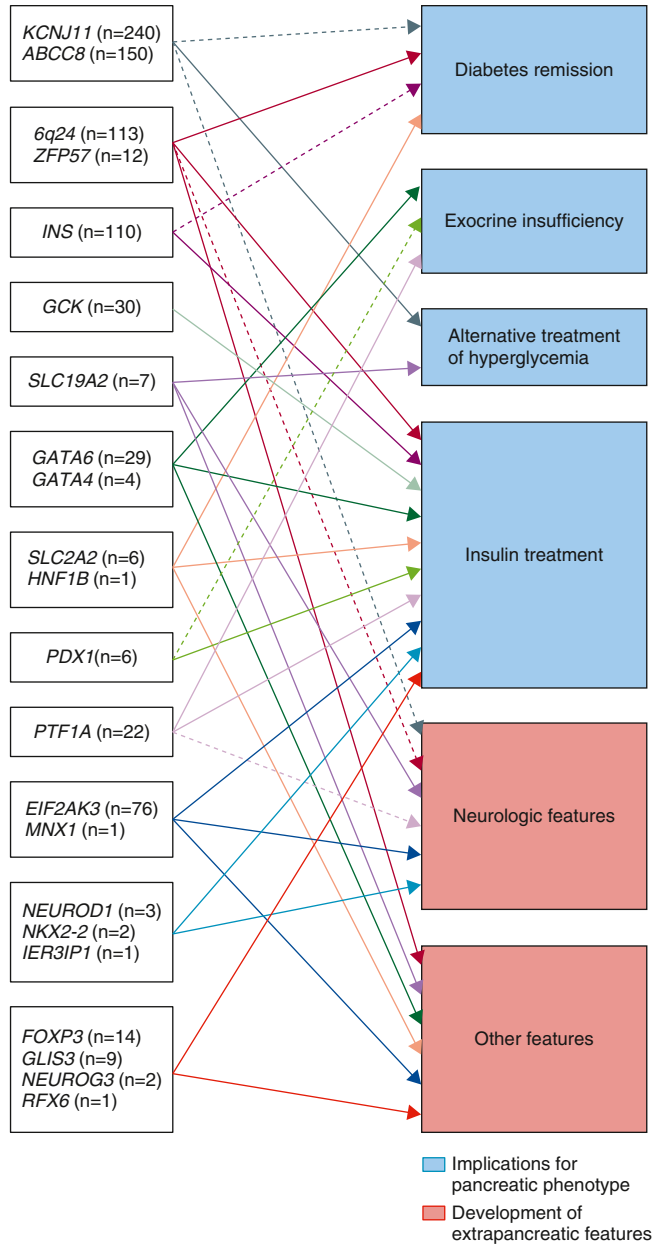

Fig. 629.12 A genetic diagnosis guides clinical management. Schematic representation of genetic causes of neonatal diabetes and the implications of this genetic diagnosis. *n* indicates the number of patients identified with pathogenic variants in each of the genes in the 1,020 neonatal diabetes patient cohort. *Solid arrows* indicate implications for most pathogenic variants in the genes. *Dashed arrows* indicate the implications for specific variants. *(From De Franco E, Flanagan SE, Houghton JAL, et al. The effect of early, comprehensive genomic testing on clinical care in neonatal diabetes: an international cohort study. Lancet. 2015;386:957–963. Fig. 3.)*

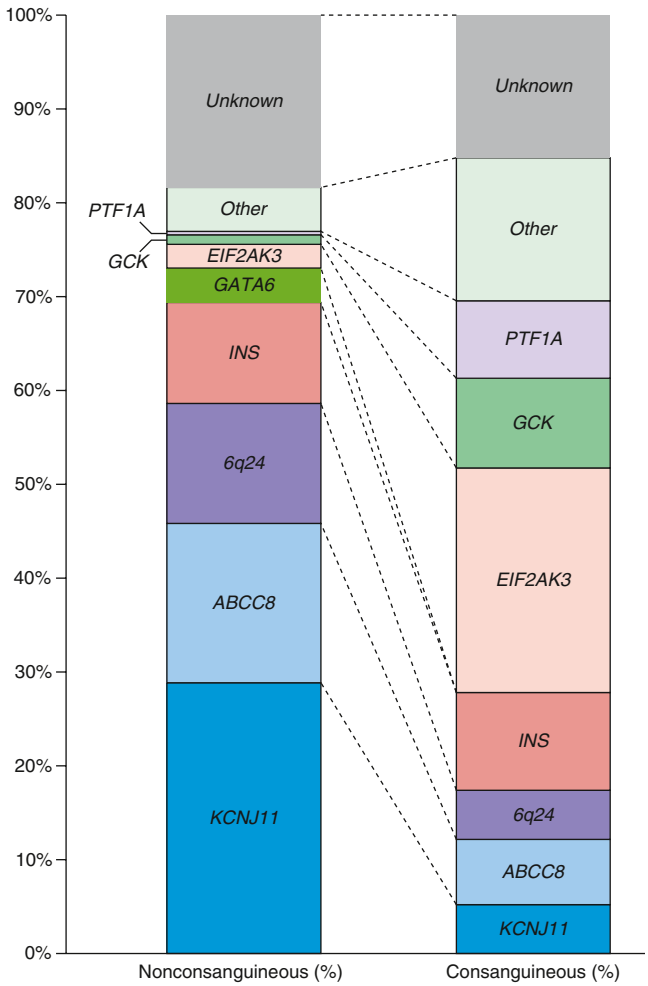

Fig. 629.13 Different genetic causes of neonatal diabetes in patients born to nonconsanguineous and consanguineous parents. Comparison of genetic causes of neonatal diabetes in nonconsanguineous (*n* = 790) and consanguineous groups (*n* = 230). Consanguinity is defined by parents being second cousins or more closely related or by the presence of 1.56% or higher total homozygosity. Genes involved in less than 2.5% of patients in both cohorts were grouped in the other category. *(From De Franco E, Flanagan SE, Houghton JAL, et al. The effect of early, comprehensive genomic testing on clinical care in neonatal diabetes: an international cohort study. Lancet. 2015;386:957–963. Fig. 2.)*

MODY3

Patients affected with pathogenic variants in the transcription factor hepatocyte nuclear factor-1α show abnormalities of carbohydrate metabolism varying from IGT to severe diabetes and often progressing from a mild to a severe form over time. They are also prone to the development of vascular complications. This is the most common MODY subtype and accounts for 30–60% of all cases of MODY. These patients are very sensitive to the action of sulfonylureas and can usually be treated with relatively low doses of these oral agents, at least in the early stages of the disease. In children, this form of MODY is sometimes misclassified as T1DM and treated with insulin. Evaluation of autoimmune markers helps to rule out T1DM; genetic testing for MODY is available and is indicated in patients with relatively mild diabetes and a family history suggestive of autosomal dominant inheritance. Accurate diagnosis can lead to avoidance of unnecessary insulin treatment and specific genetic counseling (see Fig. 629.14).

Less Common Forms of Monogenic Diabetes

Hepatocyte nuclear factor-4α (MODY1), insulin promoter factor (IPF)-1, also known as (PDX-1) (MODY4), hepatocyte nuclear factor 1β/TCF2 (MODY5), and NeuroD1 (MODY6) are all transcription factors that are involved in β-cell development and function, and mutations in these lead to various rare forms of MODY. In addition to diabetes, they can also have specific findings unrelated to hyperglycemia; for example, MODY1 is associated with low triglyceride and lipoprotein levels, and MODY5 is associated with renal cysts and renal dysfunction. In terms of treatment, MODY1 and MODY4 may respond to oral sulfonylureas, but MODY5 does not respond to oral agents and requires treatment with insulin. NeuroD1 defects are extremely rare and not much is known about their natural history.

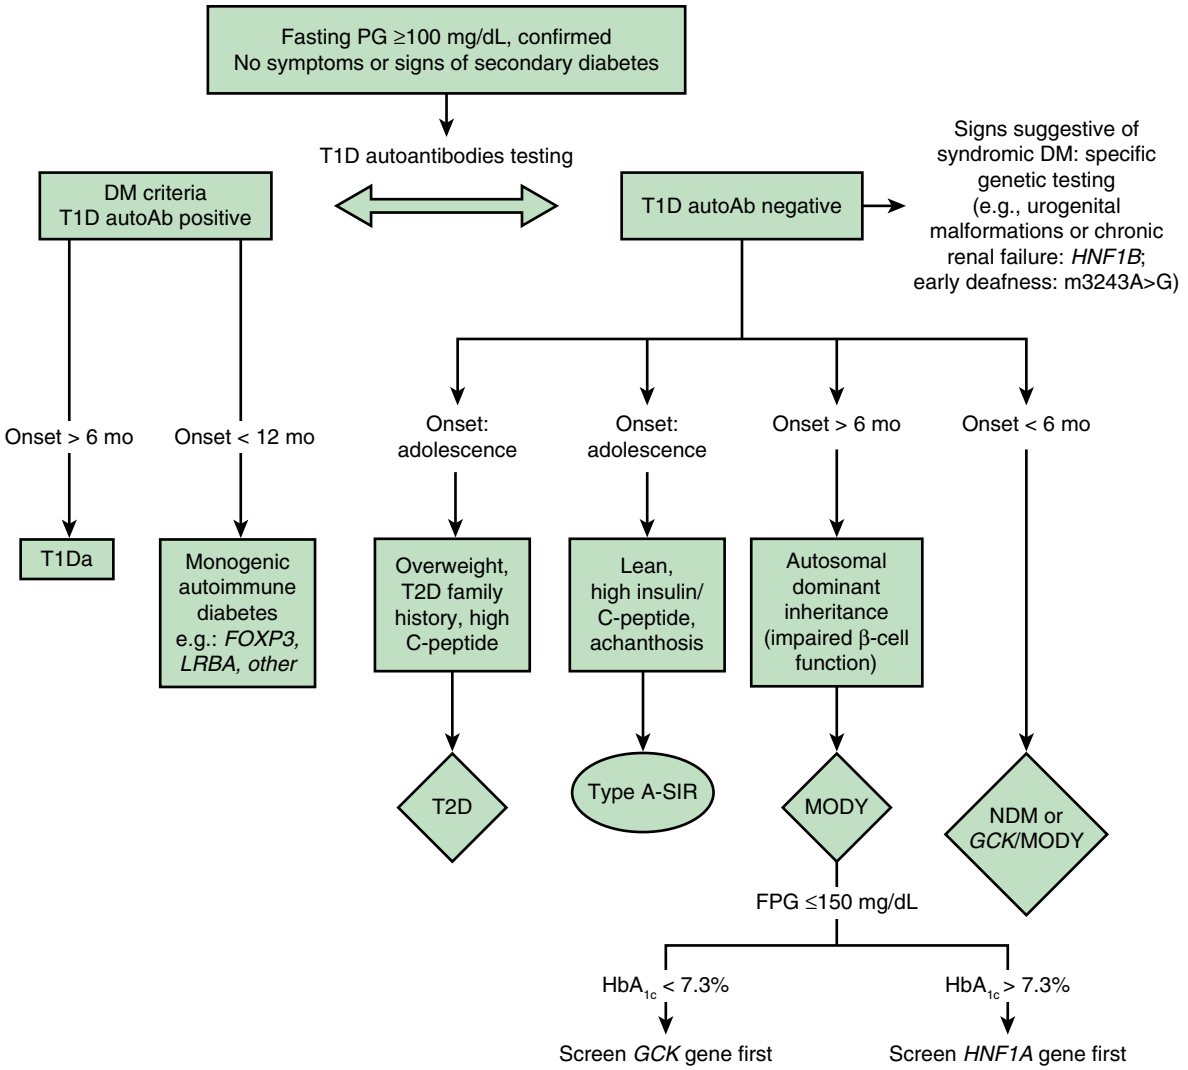

Fig. 629.14 Diagnostic algorithm of monogenic forms of diabetes. Negativity of genetic testing of two common subtypes of MODY in children and adolescents implies that further testing is mandatory if the clinical diagnosis is robust. FPG, fasting plasma glucose; MODY, maturity onset diabetes of the young; NDM, neonatal diabetes mellius; SIR, severe insulin resistance. *(From Barbetti F, D'Annunzio G. Genetic causes and treatment of neonatal diabetes and early childhood diabetes. Best Pract Res Clin Endocrinol Metab. 2018;32[4]:575-591. Fig. 1.)*

Primary or secondary defects in the glucose transporter-2, which is an insulin-independent glucose transporter, may also be associated with diabetes. Diabetes may also be a manifestation of a polymorphism in the glycogen synthase gene. This enzyme is crucially important for storage of glucose as glycogen in muscle. Patients with this defect are notable for marked insulin resistance and hypertension, as well as a strong family history of diabetes.

Another form of IDDM is **Wolfram syndrome** (Table 629.17). Wolfram syndrome 1 is characterized by diabetes insipidus, DM, optic atrophy, and deafness—thus the acronym **DIDMOAD**. Some patients with diabetes appear to have severe insulinopenia, whereas others have significant insulin secretion as judged by C-peptide. The overall prevalence is estimated at 1 in 770,000 live births. The sequence of appearance of the stigmata is as follows: non-autoimmune IDDM in the first decade, central diabetes insipidus and sensorineural deafness in ~65–75% of the patients in the second decade, renal tract anomalies in ~50% of the patients in the third decade, and neurologic complications such as cerebellar ataxia and myoclonus in half to two thirds of the patients in the fourth decade. Other features include primary gonadal atrophy in most males and a progressive neurodegenerative course with neurorespiratory death at a median age of 30 years. Some cases are caused by pathogenic variants in *WFS-1*. Wolfram syndrome 2 has early-onset optic atrophy, DM, deafness, and a shortened life span but no diabetes insipidus; the associated gene is *CISD2*. Other forms of Wolfram syndrome may be caused by variants in mitochondrial DNA. Other syndromes associated with diabetes are noted in Table 629.17.

Mitochondrial Gene Defects

Pathogenic variants in mitochondrial DNA are associated with **maternally inherited DM and deafness**. The most common mitochondrial DNA variant in these cases is the variant m.3243A>G in the transfer RNA leucine gene. This variant is identical to the variant in MELAS (myopathy, encephalopathy, lactic acidosis, and strokelike syndrome), but MELAS syndrome is not associated with diabetes; the phenotypic expression of the same defect varies. Diabetes in most of these cases presents insidiously, but approximately 20% of patients have an acute presentation resembling T1DM. The mean age of diagnosis of diabetes is 37 years, but cases have been reported as young as 11 years; not all patients have deafness. This variant has been estimated to be present in 1.5% of Japanese people with diabetes, which may be higher than the prevalence in other ethnic groups. Metformin should be avoided in these patients because of the theoretical risk of severe lactic acidosis in the presence of mitochondrial dysfunction. Some children with mitochondrial DNA mutations affecting complex I and/or complex IV may also develop diabetes.

Table 629.16 Clinical Characteristics of Maturity-Onset Diabetes of the Young (MODY) Genetic Subtypes

MODY TYPE	GENE NAME (LOCUS)	PREVALENCE (%)	OTHER FEATURES	TREATMENT
MODY 1	*HNF4A* (20ql2)	5–10	Neonatal hyperinsulinemia and hypoglycemia with associated macrosomia, low serum levels of cholesterol	Sensitive to sulfonylureas
MODY 2	*GCK* (7pl3)	30–60	Mild fasting hyperglycemia throughout life, often asymptomatic, gestational diabetes, low birthweight (with unaffected mother)	No treatment outside of pregnancy
MODY 3	*HNF1A* (12q24.2)	30–60	Glycosuria	Sensitive to sulfonylureas
MODY 4	*PDX1* (13ql2.1)	<1	Homozygote: pancreatic agenesis	Diet, OAD, or insulin
MODY 5	*HNFIB* (17q21)	5–10	Diabetes in association with renal and genitourinary abnormalities	Insulin
MODY 6	*NEUROD I* (2q31.3)	<1	Obesity and insulin resistance	OAD or insulin
MODY 7	*KLF11* (2p25)	<1	Impaired glucose tolerance to overt diabetes	OAD or insulin
MODY 8	*CEL* (9p34)	<1	Diabetes and pancreatic exocrine deficiency	OAD or insulin
MODY 9	*PAX4* (7q32)	<1	Ketosis-prone diabetes	Diet, OAD, or insulin
MODY 10	*INS* (llpl5.5)	<1	May result in neonatal diabetes, antibody-negative diabetes, and MODY	OAD or insulin
MODY 11	*BLK* (8p23)	<1	Obesity common	Diet, OAD, or insulin
MODY 12	*ABCC8* (11pl5.1)	<1	Usually associated with neonatal diabetes, rare cause of MODY	Sensitive to sulfonylureas
MODY 13	*KCNJ11* (11p 15.13)	<1	Usually associated with neonatal diabetes, rare cause of MODY	Sensitive to sulfonylureas
MODY 14	*APPL1* (3pl4.3)	<1	Adult-onset diabetes	Diet, OAD, or insulin

ABCC8, ATP-binding cassette, subfamily C (CFTR/MRP), member 8; APPL1, adaptor protein, phosphotyrosine interacting with PH domain and leucine zipper 1; BLK, B-lymphocyte kinase; CEL, carboxyl ester lipase enzyme; GCK, glucokinase; HNF1A, hepatocyte nuclear factor-lα; HNF1B, hepatocyte nuclear factor-lβ; INS, preproinsulin; KCNJ11, potassium channel, inwardly rectifying subfamily J, member 11; KLF11, Kruppel-like factor 11; NEUROD 1, neurogenic differentiation factor 1; OAD, oral antidiabetic; PAX4, paired box gene 4; PDX1, pancreas/duodenum homeobox protein 1.
Modified from Sanyoura M, Philipson LH, Naylor R. Monogenic diabetes in children and adolescents: recognition and treatment options. Curr Diab Rep. 2018;18:58. Table 1.

Abnormalities of the Insulin Gene

Diabetes of variable degrees may also result from pathogenic variants in the insulin gene that impair the effectiveness of insulin at the receptor level. Insulin gene defects are exceedingly rare and may be associated with relatively mild diabetes or even normal glucose tolerance. Diabetes may also develop in patients with faulty processing of proinsulin to insulin (an autosomal dominant defect). These defects are notable for the high concentration of insulin as measured by radioimmunoassay, whereas MODY and glucose transporter-2 defects are characterized by relative or absolute deficiency of insulin secretion for the prevailing glucose concentrations.

GENETIC DEFECTS OF INSULIN ACTION

Various genetic variants in the insulin receptor can impair the action of insulin at the insulin receptor or impair postreceptor signaling, leading to insulin resistance. The mildest form of the syndrome with variants in the insulin receptor was previously known as **type A insulin resistance**. This condition is associated with hirsutism, hyperandrogenism, and cystic ovaries in females, without obesity. Acanthosis nigricans may be present, and life expectancy is not significantly impaired. More severe forms of insulin resistance are seen in two variants in the insulin receptor gene that cause the pediatric syndromes of **Donohue syndrome** (formerly called *leprechaunism*) and **Rabson-Mendenhall syndrome**.

Donohue Syndrome

This is a syndrome characterized by intrauterine growth restriction, fasting hypoglycemia, and postprandial hyperglycemia in association with profound resistance to insulin; severe hyperinsulinemia is seen during an OGTT. Various defects of the insulin receptor have been described, thereby attesting to the important role of insulin and its receptor in fetal growth and possibly in morphogenesis. Many of these patients die in the first year of life. Potential treatments include high-dose insulin, metformin, and continuous IGF-1 via insulin pump.

Rabson-Mendenhall Syndrome

This entity is defined by clinical manifestations that appear to be intermediate between those of acanthosis nigricans with insulin resistance type A and Donohue syndrome. The features include extreme insulin resistance, acanthosis nigricans, abnormalities of the teeth and nails, and pineal hyperplasia. It is not clear whether this syndrome is entirely distinct from Donohue syndrome; however, by comparison, patients with Rabson-Mendenhall tend to live significantly longer. Therapies with modest benefit have included IGF-1 and leptin.

Lipoatrophic Diabetes

Various forms of lipodystrophy are associated with insulin resistance and diabetes (Table 629.18). **Familial partial lipoatrophy**, or **lipodystrophy**, is associated with pathogenic variants in *LMNA*, encoding nuclear envelope proteins lamin A and C. **Severe congenital generalized lipoatrophy** is associated with variants in the seipin and *AGPAT2* genes, but the mechanism by which these variants lead to insulin resistance and diabetes is not known.

Stiff-Person Syndrome

This is an extremely rare autoimmune CNS disorder that is characterized by progressive stiffness and painful spasms of the axial muscles

Table 629.17 Syndromic Forms of Diabetes that May Present in Childhood or Early Childhood
