Other nasal masses include *hemangiomas, congenital nasolacrimal duct obstruction* (which can occur as an intranasal mass) (Fig. 425.5), nasal polyps, and tumors such as rhabdomyosarcoma (see Chapter 549). Nasal polyps are rarely present at birth, but the other masses often present at birth or in early infancy (see Chapter 427).

Poor development of the paranasal sinuses and a narrow nasal airway are associated with recurrent or chronic upper airway infection in Down syndrome (see Chapter 57).

DIAGNOSIS AND TREATMENT

In children with congenital nasal disorders, supportive care of the airway is given until the diagnosis is established. Diagnosis is made through a combination of flexible scoping and imaging studies, primarily CT scan. In the case of surgically correctable congenital problems such as choanal atresia, surgery is performed after the child is deemed healthy and free of life-threatening problems such as congenital heart disease.

Chapter 426

Acquired Disorders of the Nose

Joseph Haddad Jr. and Sonam N. Dodhia

Tumors, septal perforations, and other acquired abnormalities of the nose and paranasal sinuses can manifest with epistaxis. Midface trauma with a nasal or facial fracture may also be accompanied by epistaxis. Trauma to the nose can cause a *septal hematoma;* if treatment is delayed, this can lead to necrosis of septal cartilage and a resultant *saddle nose deformity.* Other abnormalities that can cause a change in the shape of the nose and paranasal bones, with obstruction but few other symptoms, include *fibroosseous lesions* (ossifying fibroma, fibrous dysplasia, cementifying fibroma) and *mucoceles of the paranasal sinuses.* These conditions may be suspected on physical examination and confirmed by CT scan and biopsy. Although these are considered benign lesions, they can all greatly change the anatomy of surrounding bony structures and often require surgical intervention for management.

426.1 Nasal Foreign Bodies

Joseph Haddad Jr. and Sonam N. Dodhia

ETIOLOGY

Foreign bodies (food, beads, crayons, small toys, erasers, paper wads, buttons, batteries, beans, stones, pieces of sponge or capsule sponge toys, and other small objects) are often placed in the nose by young or developmentally delayed children and constitute ≤1% of pediatric emergency department visits. Nasal foreign bodies can go unrecognized for long periods because they initially produce few symptoms and are difficult to visualize. First symptoms include unilateral obstruction, sneezing, relatively mild discomfort, and, rarely, pain. Presenting clinical symptoms include history of insertion of foreign bodies (86%), mucopurulent nasal discharge (24%), foul nasal odor (9%), epistaxis (6%), nasal obstruction (3%), and mouth breathing (2%). Irrigation results in mucosal swelling because some foreign bodies are hygroscopic and increase in size as water is absorbed; signs of local obstruction and discomfort can increase with time. The patient might also present with a generalized body odor known as *bromhidrosis.*

DIAGNOSIS

Unilateral nasal discharge and obstruction should suggest the presence of a foreign body, which can often be seen on examination with a nasal speculum or wide otoscope placed in the nose. Purulent secretions may have to be cleared so that the foreign object can be visualized; a headlight, suction, and topical decongestants are often needed. The object is usually situated anteriorly, but unskilled attempts at removal can force the object deeper into the nose. A long-standing foreign body can become embedded in granulation tissue or mucosa and appear as a nasal mass. A lateral skull radiograph assists in diagnosis if the foreign body is metallic or radiopaque or if foreign body is suspected but physical exam with sinus endoscopy or anterior rhinoscopy is negative.

TREATMENT

An initial examination of the nose is made to determine if a foreign body is present and whether it needs to be removed emergently. Planning is then made for office or operating room extrication of the foreign body. Prompt removal minimizes the danger of aspiration and local tissue necrosis, and this can usually be performed with the aid of topical anesthesia, with forceps or nasal suction. Common noninvasive techniques include simple nose blowing and the "mother's kiss" technique. The "mother's kiss" approach has been successful in acute situations where a person occludes the unaffected nostril and then, with a complete seal over the child's mouth, attempts to dislodge the foreign body by blowing into the mouth. A similar approach uses an Ambu bag over the mouth with the unaffected nostril occluded. Other noninvasive options include blowing air into a drinking straw in a child's mouth and applying high-flow oxygen (10-15 L/min) to the unaffected nostril. Alternatively, a Katz catheter (made specifically for the removal of foreign bodies from the nose and ear) can be inserted above and distal to the object, inflated, and drawn back with gentle traction. If there is marked swelling, bleeding, or tissue overgrowth, general anesthesia may be needed to remove the object. Infection usually clears promptly after the removal of the object, and generally no further therapy is necessary. Magnets can be used to extract metal foreign bodies, 2% lidocaine can be used to kill live insects before removal, and irrigation should be avoided with vegetable matter or sponges because of the risk of foreign body swelling. Age (>5) and disk-shaped foreign body are predictors for operating room removal of foreign body.

COMPLICATIONS

Serious complications include posterior dislodgement and aspiration, trauma caused by the object itself or removal attempts, infection, and choanal stenosis. Infection is common and gives rise to a purulent, malodorous, or bloody discharge. Local tissue damage from long-standing foreign body or alkaline injury from a disk battery can lead to local tissue loss and cartilage destruction. A synechia or scar band can then form, causing nasal obstruction. Loss of septal mucosa and cartilage can cause a septal perforation or saddle nose. Disk batteries are especially dangerous when placed in the nose; they leach base, which causes pain and local tissue destruction in a matter of hours. Magnets also carry a risk of septal perforation and necrosis.

Tetanus is a rare complication of long-standing nasal foreign bodies in nonimmunized children (see Chapter 257). Toxic shock syndrome is also rare and most commonly occurs from nasal surgical packing (see Chapter 227.2); oral antibiotics should be administered when nasal surgical packing is placed.

PREVENTION

Tempting objects, such as round, shiny beads, should be used only under adult supervision. Disk batteries should be stored away from the reach of small children.

426.2 Epistaxis

Joseph Haddad Jr. and Sonam N. Dodhia

Although rare in infancy, nosebleeds are common in children between the ages of 3 and 8, then decline in incidence after puberty. They are also more common during winter months. Diagnosis and treatment depend on the location and cause of the bleeding.

ANATOMY

The most common site of bleeding is the Kiesselbach plexus, an area in the anterior septum where vessels from both the internal carotid (anterior and posterior ethmoid arteries) and external carotid (sphenopalatine and terminal branches of the internal maxillary arteries) converge. The thin mucosa in this area and the anterior location make it prone to exposure to dry air and trauma.

ETIOLOGY

Epistaxis can be classified as primary (idiopathic; majority of cases) or secondary based on cause, and this has implications for diagnosis and management. Common causes of secondary nosebleeds from the anterior septum include digital trauma, foreign bodies, dry air, and inflammation, including upper respiratory tract

infections, sinusitis, and allergic rhinitis (Table 426.1). There is often a family history of childhood epistaxis. Nasal steroid sprays are commonly used in children, and their chronic use may be associated with nasal mucosal bleeding. Young infants with significant gastroesophageal reflux into the nose rarely present with epistaxis secondary to mucosal inflammation. Susceptibility is increased during respiratory infections and in the winter when dry air irritates the nasal mucosa, resulting in formation of fissures and crusting. Severe bleeding may be encountered with congenital vascular abnormalities, such as *hereditary hemorrhagic telangiectasia (HHT)* (see Chapter 481.3), varicosities, hemangiomas, and in children with thrombocytopenia, deficiency of clotting factors, particularly von Willebrand disease (see Chapter 526), hypertension, renal failure, or venous congestion. Screening for HHT is recommended for patients with obvious nasal/oral telangiectasias and those with a personal or familial history of recurrent nosebleeds. Recurrent epistaxis despite cauterization is associated with mild coagulation disorders. The family history may be positive for abnormal bleeding (epistaxis or other sites); specific testing for von Willebrand disease is indicated because the prothrombin time or partial thromboplastin time may be normal despite having a bleeding disorder. Nasal polyps or other intranasal growths may be associated with epistaxis. Recurrent, and often severe, unilateral nosebleeds may be the initial presenting symptom in **juvenile nasal angiofibroma**, which occurs in adolescent males.

CLINICAL MANIFESTATIONS

Epistaxis usually occurs without warning, with blood flowing slowly but freely from one nostril or occasionally from both. In children with nasal lesions, bleeding might follow physical exercise. When bleeding occurs at night, the blood may be swallowed and become apparent only when the child vomits or passes blood in the stools. Posterior epistaxis can manifest as anterior nasal bleeding, or, if bleeding is copious, the patient might vomit blood as the initial symptom.

Table 426.1 Possible Causes of Epistaxis

Epistaxis digitorum (nose picking)
Rhinitis (allergic or viral)
Chronic sinusitis
Foreign bodies
Intranasal neoplasm or polyps
Irritants (e.g., cigarette smoke)
Septal deviation
Septal perforation
Trauma, including child abuse
Vascular malformation or telangiectasia (hereditary hemorrhage telangiectasia)
Hemophilia
von Willebrand disease
Platelet dysfunction
Thrombocytopenia
Hypertension
Leukemia
Liver disease (e.g., cirrhosis)
Medications (e.g., aspirin, anticoagulants, nonsteroidal antiinflammatory drugs, topical corticosteroids)
Cocaine use

From Kucik CJ, Clenney T. Management of epistaxis. *Am Fam Physician*. 2005;71(2):305–311.

TREATMENT

Most nosebleeds stop spontaneously in a few minutes. The nares (lower third of the nose) should be compressed for 5 minutes, and the child kept as quiet as possible, in an upright position with the head tilted forward to avoid blood trickling back into the throat. Cold compresses applied to the nose can also help. If these measures do not stop the bleeding, local application of a solution of oxymetazoline (Afrin) or phenylephrine (Neo-Synephrine) (0.25–1%) may be useful. If bleeding persists, an anterior nasal pack may need to be inserted; if bleeding originates in the posterior nasal cavity, combined anterior and posterior packing is necessary. After bleeding is under control, and if a bleeding site is identified, its obliteration by cautery with silver nitrate may prevent further difficulties. Because the septal cartilage derives its nutrition from the overlying mucoperichondrium, only one side of the septum should be cauterized at a time to reduce the chance of a septal perforation. During the winter, or in a dry environment, a room humidifier, saline drops, and petrolatum (Vaseline) applied to the septum can help to prevent epistaxis. Ointments prevent infection, increase moisture, decrease bleeding, and are commonly used in clinical practice. Patients with severe epistaxis despite conservative medical measures should be considered for surgical ligation techniques or embolization. In patients with severe or repeated epistaxis, blood transfusions may be necessary. Otolaryngologic evaluation is indicated for these children and for those with bilateral bleeding or with hemorrhage that does not arise from the Kiesselbach plexus. For those with recurrent epistaxis, there may be short-term benefits to using bipolar electrocautery over silver nitrate chemical cautery, although treatments were equivocal after 2 years. Secondary epistaxis should be managed by identification of the cause, application of appropriate nasal therapy, and correct systemic medical management. Hematologic evaluation (for coagulopathy and anemia), along with nasal endoscopy and diagnostic imaging, may be needed to make a definitive diagnosis in cases of severe recurrent epistaxis. Replacement of deficient clotting factors may be required for patients who have an underlying hematologic disorder (see Chapter 525). Profuse unilateral epistaxis associated with a nasal mass in an adolescent boy near puberty might signal a **juvenile nasopharyngeal angiofibroma**. This unusual tumor has also been reported in a 2-year-old and in 30- to 40-year-olds, but the incidence peaks in adolescent and preadolescent boys. CT with contrast medium enhancement and magnetic resonance imaging (MRI) are part of the initial evaluation; arteriography, embolization, and extensive surgery may be needed.

Surgical intervention may also be needed for bleeding from the internal maxillary artery or other vessels that can cause bleeding in the posterior nasal cavity.

PREVENTION

The discouragement of nose picking and attention to proper humidification of the bedroom during dry winter months help to prevent many nosebleeds. Prompt attention to nasal infections and allergies is beneficial to nasal hygiene. Prompt cessation of nasal steroid sprays prevents ongoing bleeding.

Chapter 427

Nasal Polyps

Joseph Haddad Jr.

Nasal polyps are benign pedunculated tumors formed from edematous, usually chronically inflamed nasal mucosa. They commonly arise from the ethmoidal sinus and occur in the middle meatus. Occasionally they appear within the maxillary antrum and can extend to the nasopharynx (antrochoanal polyp).

It is estimated that between 1% and 4% of the population will develop nasal polyps at some point; the incidence of nasal polyps increases with age. Antrochoanal polyps represent only 4–6% of all nasal polyps in the general population but account for approximately one third of polyps in the pediatric population. Large or multiple polyps can completely obstruct the nasal passage. The polyps originating from the ethmoidal sinus are usually smaller and multiple as compared with the large and usually single antrochoanal polyp.

Cystic fibrosis (CF; see Chapter 454) is the most common childhood cause of nasal polyposis, and up to 50% of CF patients experience obstructing nasal polyposis, which is rare in non-CF children. Therefore CF should be suspected in any child younger than 12 years old with nasal polyps, even in the absence of typical respiratory and digestive symptoms. Nasal polyposis is also associated with chronic sinusitis (see Chapter 429) and allergic rhinitis. Large population studies have noted a significant familial risk in having chronic rhinosinusitis with polyposis. In the *Samter triad,* nasal polyps are associated with aspirin sensitivity and asthma; this condition is rare in children.

CLINICAL MANIFESTATIONS

Obstruction of nasal passages is prominent, with associated hyponasal speech and mouth breathing. Profuse unilateral mucoid or mucopurulent rhinorrhea may also be present. An examination of the nasal passages shows glistening, gray, grapelike masses squeezed between the nasal turbinates and the septum.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Examination of the external nose and rhinoscopy should be performed. Ethmoidal polyps can be readily distinguished from the well-vascularized turbinate tissue, which is pink or red; antrochoanal polyps may have a fleshier appearance (Fig. 427.1). Antrochoanal polyps may prolapse into the nasopharynx; flexible nasopharyngoscopy can assist in making this diagnosis. Prolonged presence of ethmoidal polyps in a child can widen the bridge of the nose and erode adjacent osseous structures. Tumors of the nose cause more local destruction and distortion of the anatomy. CT scan of the midface is key to diagnosis and planning for surgical treatment (Fig. 427.2).

TREATMENT

Local or systemic decongestants are not usually effective in shrinking the polyps, although they may provide symptomatic relief from the associated mucosal edema. Intranasal steroid sprays, and sometimes systemic steroids, can provide some shrinkage of nasal polyps with symptomatic relief and have proved useful in children with CF and adults with nasal polyps. Topical nasal steroid therapy, fluticasone, mometasone, and budesonide appear to result in nasal symptom improvement but were found to have no effect on those with CF. Dupilumab inhibits interleukin (IL)-4 and IL-13, proinflammatory cytokines involved in polyp formation, and is approved in patients ≥18 years of age for the treatment of chronic rhinosinusitis with nasal polyps.

Polyps should be removed surgically if complete obstruction, uncontrolled rhinorrhea, or deformity of the nose appears. If the underlying pathogenic mechanism cannot be eliminated (such as CF), the polyps may soon return. Functional endoscopic sinus surgery provides more complete polyp removal and treatment of other associated nasal disease; in some cases, this has reduced the need for frequent surgeries. Nasal steroid sprays should also be started preventively, once postsurgical healing occurs.

Antrochoanal polyps do not respond to medical measures and must be removed surgically, typically via endoscopic sinus surgery, or, alternatively, with a mini-Caldwell procedure. Because these types of polyps are not associated with any underlying disease process, the recurrence rate is much less than for other types of polyps.

Chapter 428

The Common Cold

Katherine M. Richardson and Jennifer E. Schuster

The common cold is an acute viral infection of the upper respiratory tract in which the symptoms of rhinorrhea and nasal obstruction are prominent. Systemic symptoms and signs such as headache, myalgia, and fever are absent or mild. The common cold is frequently referred to as *infectious rhinitis* but may also include self-limited involvement of the sinus mucosa and is more correctly termed *rhinosinusitis*.

ETIOLOGY

The most common pathogens associated with the common cold are the more than 200 types of human rhinoviruses (see Chapter 310), but the syndrome can be caused by many different virus families (Table 428.1). Human rhinoviruses (HRVs) are associated with more than 50% of colds in adults and children. In young children, other viral etiologies of the common cold include respiratory syncytial virus (RSV; see Chapter 307), human metapneumovirus (MPV; see Chapter 308), parainfluenza viruses (PIVs; see Chapter 306), seasonal coronaviruses (see Chapter 311), and adenoviruses (see Chapter 309). Common cold symptoms may also be caused by influenza viruses and nonpolio enteroviruses. Many viruses that cause rhinitis are also associated with other symptoms and signs such as cough, wheezing, and fever.

EPIDEMIOLOGY

Colds occur year-round, but the incidence is greatest from the early fall until the late spring, reflecting the seasonal prevalence of the viral pathogens associated with cold symptoms. In the Northern Hemisphere, the highest incidence of HRV infection occurs in the early fall (August-October) and in the late spring (April-May); however, HRVs are typically detected year-round. Historically, the seasonal incidence for PIV usually peaks in the summer, fall, and late spring and is highest between December and April for RSV, influenza viruses, MPV, and coronaviruses. Adenoviruses are detected at a low prevalence throughout the cold season, and enteroviruses may also be detected during summer months or throughout the year.

Young children have an average of six to eight colds per year, but 10–15% of children have at least 12 infections per year. The incidence of illness decreases with increasing age, with two to three illnesses per year by adulthood. The incidence of infection is primarily a function of exposure to the virus. Children in out-of-home daycare centers during the first year of life have 50% more colds than children cared for only at home. The difference in the incidence of illness between these groups of children decreases as the length of time spent in daycare increases, and in fact many children in daycare have asymptomatic viral infections. However, the incidence of illness remains higher in the daycare group through at least the first 3 years of life. When they begin primary school, children who attended daycare have less frequent colds than those who did not. Mannose-binding lectin deficiency with impaired innate immunity may be associated with an increased incidence of colds in children.

PATHOGENESIS

Viruses that cause the common cold are spread by three mechanisms: direct hand contact (self-inoculation of one's own nasal mucosa or conjunctivae after touching a contaminated person or object), inhalation of small-particle aerosols that are airborne from coughing, or deposition of large-particle aerosols that are expelled during a sneeze and land on nasal or conjunctival mucosa. Although the different common cold pathogens could be spread by any of these mechanisms, some routes of transmission appear to be more efficient than others for particular viruses. Studies of HRV and RSV indicate that direct contact is an efficient mechanism of transmission of these viruses, although transmission by large-particle aerosols can also occur. By contrast, influenza viruses and coronaviruses appear to be most efficiently spread by small-particle aerosols.

The respiratory viruses have evolved different mechanisms to avoid host defenses. Infections with HRV and adenoviruses result in the development of serotype-specific protective immunity. Repeated infections with these pathogens occur because there are a large number of distinct serotypes of each virus. Influenza viruses change the antigens presented on the surface of the virus because of genetic drift and thus behave as though there were multiple viral serotypes. The interaction of coronaviruses (see Chapter 311) with host immunity is not well defined, but it appears that multiple distinct strains of coronaviruses are capable of inducing at least short-term protective immunity, with possibility for some cross protection between different coronaviruses. There are four types of PIV, two antigenic subgroups of RSV, and four genotypes of MPV. In addition to antigenic diversity, many of these viruses are able to reinfect the upper airway because mucosal immunoglobulin A (IgA) induced by previous infection is short lived, and the brief incubation period of these viruses allows the establishment of infection before immune memory is able to respond. Although reinfection is not completely prevented by the adaptive host response to these viruses, the severity of illness is moderated by preexisting immunity.

Table 428.1 Pathogens* Associated with the Common Cold

ASSOCIATION	PATHOGEN	RELATIVE FREQUENCY**	OTHER COMMON SYMPTOMS AND SIGNS
Agents primarily associated with the common cold	Rhinoviruses	Frequent	Wheezing/bronchiolitis
	Coronaviruses, including SARS-CoV-2 variants	Frequent	
Agents primarily associated with other clinical syndromes that also cause common cold symptoms	Respiratory syncytial virus	Occasional	Bronchiolitis in children <2 yr of age
	Human metapneumovirus	Occasional	Pneumonia and bronchiolitis
	Bocavirus	Occasional	Uncertain role
	Influenza viruses	Uncommon	Influenza-like illness, pneumonia, croup
	Parainfluenza viruses	Uncommon	Croup, bronchiolitis
	Adenoviruses	Uncommon	Pharyngoconjunctival fever (palpebral conjunctivitis, watery eye discharge, pharyngeal erythema)
	Enteroviruses Coxsackievirus A Other nonpolio enteroviruses	Uncommon	Herpangina (fever and ulcerated papules on posterior oropharynx) Aseptic meningitis

*It is not unusual to have one or more respiratory pathogens.
**Relative frequency of colds caused by the agent.

Viral infection of the nasal epithelium can be associated with destruction of the epithelial lining, as with influenza viruses and adenoviruses, or there can be no apparent histologic damage, as with HRV, coronaviruses, and RSV. Regardless of the histopathologic findings, infection of the nasal epithelium is associated with an acute inflammatory response characterized by release of a variety of inflammatory cytokines, such as interleukin-8, that attract polymorphonuclear cells into the nasal submucosa and epithelium and infiltration of the mucosa by inflammatory cells. This acute inflammatory response appears to be partially or largely responsible for many of the symptoms associated with the common cold, rather than direct damage to the respiratory tract by the virus. Viral shedding of most respiratory viruses peaks 3-5 days after inoculation, often coinciding with symptom onset; low levels of viral shedding may persist for up to 3 weeks in the otherwise recovering healthy host. Inflammation can obstruct the sinus ostia or eustachian tube, predisposing to bacterial sinusitis or otitis media, respectively.

CLINICAL MANIFESTATIONS

Symptoms of the common cold vary by age and virus. In infants, fever and nasal discharge may predominate. Fever is uncommon in older children and adults. The onset of common cold symptoms typically occurs 1-3 days after viral infection. The first symptom noted is often sore or scratchy throat, followed closely by nasal obstruction and rhinorrhea. The sore throat usually resolves quickly, and, by the second and third day of illness, nasal symptoms predominate. Cough is associated with two thirds of colds in children and usually begins after the onset of nasal symptoms. Cough may persist for an additional 1-2 weeks after resolution of other symptoms. Influenza viruses, RSV, MPV, and adenoviruses are more likely than HRV or coronaviruses to be associated with fever and other constitutional symptoms, and HRV is more commonly associated with wheezing, particularly in older children. Other symptoms of a cold may include headache, hoarseness, irritability, difficulty sleeping, or decreased appetite. Vomiting and diarrhea are uncommon. The usual cold persists for approximately 1 week, although 10% last for 2 weeks.

The physical findings of the common cold are limited to the upper respiratory tract. Increased nasal secretion is usually obvious; a change in the color or consistency of the secretions is common during the course of the illness and does not indicate sinusitis or bacterial superinfection, but may indicate accumulation of polymorphonuclear cells. Examination of the nasal cavity might reveal swollen, erythematous nasal turbinates, although this finding is nonspecific and of limited diagnostic value. Abnormal middle ear pressure is common during a cold. Anterior cervical lymphadenopathy or conjunctival injection may also be noted on exam.

DIAGNOSIS

The most important task of the physician caring for a patient with a cold is to exclude other conditions that are potentially more serious or treatable. The differential diagnosis of the common cold includes noninfectious disorders and other upper respiratory tract infections (Table 428.2).

Table 428.2 Conditions that Can Mimic the Common Cold

CONDITION	DIFFERENTIATING FEATURES
Allergic rhinitis	Prominent itching and sneezing, nasal eosinophils; Hansel stain can aid diagnosis
Vasomotor rhinitis	May be triggered by irritants, weather changes, spicy foods, etc.
Rhinitis medicamentosa	History of nasal decongestant use
Foreign body	Unilateral, foul-smelling secretions
	Bloody nasal secretions
Sinusitis	Presence of fever, headache or facial pain, or periorbital edema or persistence of rhinorrhea or cough for longer than 10-14 days
Streptococcosis	Mucopurulent nasal discharge that excoriates the nares, no cough
Pertussis	Onset of persistent or severe paroxysmal cough
Congenital syphilis	Persistent rhinorrhea with onset in the first 3 mo of life

LABORATORY FINDINGS

Routine laboratory studies are not helpful for the diagnosis and management of the common cold. A nasal smear for eosinophils (Hansel stain) may be useful if allergic rhinitis is suspected (see Chapter 184). A predominance of polymorphonuclear cells in the nasal secretions is characteristic of uncomplicated colds and *does not* indicate bacterial superinfection. Self-limited radiographic abnormalities of the paranasal sinuses are common during an uncomplicated cold; imaging is not indicated for most children with simple rhinitis.

The viral pathogens associated with the common cold can be detected by polymerase chain reaction (PCR), culture, antigen detection, or serologic methods. These studies are generally not indicated in patients with colds, because a specific etiologic diagnosis is useful only when treatment with an antiviral agent is contemplated, such as for influenza viruses. Bacterial cultures, PCR, or antigen detection are useful only when group A streptococcus (see Chapter 229) or *Bordetella pertussis* (see Chapter 243) is suspected. The isolation of bacterial pathogens from nasopharyngeal specimens is not an indication of bacterial nasal infection and is not a specific predictor of the etiologic agent in sinusitis.

TREATMENT

The management of the common cold consists primarily of supportive care and anticipatory guidance.

Antiviral Treatment

Specific antiviral therapy is not available for HRV infections. The neuraminidase inhibitors oseltamivir, zanamivir, and peramivir, as well as polymerase acidic endonuclease inhibitor baloxavir marboxil, have a modest effect on the duration of symptoms associated with influenza viral infections in children. The difficulty of distinguishing influenza from other common cold pathogens and the necessity that therapy be started early in the illness (within 48 hours of onset of symptoms) to be beneficial are practical limitations to the use of these agents for mild upper respiratory tract infections. Antibacterial therapy is of no benefit in the treatment of the common cold and should be avoided to minimize possible adverse effects and the development of antibiotic resistance.

Supportive Care and Symptomatic Treatment

Supportive interventions are frequently recommended by providers. Maintaining adequate oral hydration may help to prevent dehydration and to thin secretions and soothe respiratory mucosa. The common home remedy of ingesting warm fluids may soothe mucosa, increase nasal mucus flow, or loosen respiratory secretions. Topical nasal saline may temporarily remove secretions, and saline nasal irrigation may reduce symptoms. Cool, humidified air has not been well studied but may loosen nasal secretions; however, cool-mist humidifiers and vaporizers must be cleaned after each use. The World Health Organization suggests that neither steam nor cool-mist therapy be used in treatment of a cold.

The use of oral nonprescription therapies (often containing antihistamines, antitussives, and decongestants) for cold symptoms in children is controversial. Although some of these medications are effective in adults, no study demonstrates a significant effect

in children, and there may be serious side effects. Young children cannot participate in the assessment of symptom severity, so studies of these treatments in children have generally been based on observations by parents or other observers, a method that is likely to be insensitive for detection of treatment effects. Because of the lack of direct evidence for effectiveness and the potential for unwanted side effects, it is recommended that nonprescription cough and cold products not be used for infants and children younger than 4 years of age. A decision whether to use these medications in older children must consider the likelihood of clinical benefit compared with the potential adverse effects of these drugs. The prominent or most bothersome symptoms of colds vary in the course of the illness. If symptomatic treatments are used, it is reasonable to target therapy to specific bothersome symptoms, and care should be taken to ensure that caregivers understand the intended effect and can determine the proper dosage of the medications. It is also important to instruct caregivers to read labels carefully in case multiple medications are present in one formula to avoid overdose.

Zinc, given as oral lozenges to previously healthy patients, reduces the duration but not the severity of symptoms of a common cold if begun within 24 hours of symptoms. The function of the HRV 3C protease, an essential enzyme for HRV replication, is inhibited by zinc, but there has been no evidence of an antiviral effect of zinc in vivo. The effect of zinc on symptoms has been inconsistent, with some studies reporting dramatic treatment effects (in adults), whereas other studies find no benefit. Side effects are common and include decreased taste, bad taste, and nausea.

Fever

Fever is not usually associated with an uncomplicated common cold, and antipyretic treatment is generally not indicated**.** Nonsteroidal anti-inflammatory drugs (NSAIDs) may decrease discomfort from cold-related headache or myalgias.

Nasal Obstruction

Either topical or oral adrenergic agents may be used as nasal decongestants in older children and adults. Effective topical adrenergic agents such as xylometazoline, oxymetazoline, or phenylephrine are available as either intranasal drops or nasal sprays. Reduced-strength formulations of these medications are available for use in younger children, although they are not recommended for use in children younger than 6 years old. Systemic absorption of the imidazolines (oxymetazoline, xylometazoline) has very rarely been associated with bradycardia, hypotension, and coma. Prolonged use of the topical adrenergic agents should be avoided to prevent the development of **rhinitis medicamentosa**, an apparent rebound effect that causes the sensation of nasal obstruction when the drug is discontinued. The oral adrenergic agents are less effective than the topical preparations and are occasionally associated with systemic effects such as central nervous system stimulation, hypertension, and palpitations. Pseudoephedrine may be more effective than phenylephrine as an oral agent to treat nasal congestion—its benefit seems to be greatest in the first day of treatment; after this it does not show much benefit over placebo. Aromatic vapors (such as menthol) for external rub may improve the perception of nasal patency but do not affect spirometry.

Saline nose drops (wash, irrigation) can improve nasal symptoms and may be used in all age-groups.

Rhinorrhea

The first-generation antihistamines may reduce rhinorrhea by 25–30%. The effect of the antihistamines on rhinorrhea appears to be related to the anticholinergic rather than the antihistaminic properties of these drugs, and therefore the second-generation or nonsedating antihistamines have no effect on common cold symptoms. The major adverse effects associated with the use of the antihistamines are sedation or paradoxical hyperactivity. Overdose may be associated with respiratory depression or hallucinations. Rhinorrhea may also be treated with ipratropium bromide, a topical anticholinergic agent. This drug produces an effect comparable to the antihistamines but is not associated with sedation. The most common side effects of ipratropium are nasal irritation and bleeding.

Sore Throat

The sore throat associated with colds is generally not severe, but treatment with mild analgesics is occasionally indicated, particularly if there is associated myalgia or headache. The use of acetaminophen during HRV infection is associated with suppression of neutralizing antibody responses, but this observation has no apparent clinical significance. Aspirin *should not* be given to children with respiratory infections because of the risk of Reye syndrome in children with influenza (see Chapter 305). NSAIDs are somewhat effective in relieving discomfort caused by a cold, but there is no clear evidence of an effect on respiratory symptoms.

Cough

Cough suppression is generally not necessary in patients with colds. Cough in some patients appears to be from upper respiratory tract irritation associated with postnasal drip. Cough in these patients is most prominent during the time of greatest nasal symptoms, and treatment with a first-generation antihistamine may be helpful. Cough lozenges or hard candy may be temporarily effective and are unlikely to be harmful in children for whom they do not pose risk of aspiration (older than age 6 years). **Honey** has a modest effect on relieving nocturnal cough and is unlikely to be harmful in children older than 1 year of age. Honey should be avoided in children younger than 1 year of age because of the risk for botulism (see Chapter 237).

In some patients, cough may be a result of **virus-induced reactive airways disease**. These patients can have cough that persists for days to weeks after the acute illness and might benefit from bronchodilator or other therapy. Dextromethorphan hydrobromide has no effect on cough from colds and has potential enhanced toxicity. Expectorants such as guaifenesin are not effective antitussive agents.

Ineffective Treatments

Vitamin C, guaifenesin, and inhalation of warm, humidified air are no more effective than placebo for the treatment of cold symptoms.

Echinacea is a popular herbal treatment for the common cold. Although echinacea extracts have biologic effects, echinacea is not effective as a common cold treatment. The lack of standardization of commercial products containing echinacea also presents a formidable obstacle to the rational evaluation or use of this therapy.

There is no evidence that the common cold or persistent acute purulent rhinitis of less than 10 days in duration benefits from antibiotics. In fact, there is evidence that antibiotics cause significant adverse effects when given for acute purulent rhinitis.

COMPLICATIONS

The most common complication of a cold is **acute otitis media** (AOM; see Chapter 680), which may be indicated by new-onset fever and earache after the first few days of cold symptoms. AOM is reported in 5–30% of children who have a cold, with the higher incidence occurring in young infants and in children cared for in a group daycare setting. Symptomatic treatment of the common cold symptoms has no effect on the subsequent development of AOM, which can be viral or bacterial.

Sinusitis is another complication of the common cold (see Chapter 429). Self-limited sinus inflammation is a part of the pathophysiology of the common cold, but 0.5–2% of viral upper respiratory tract infections in adults and 5–9% in children are complicated by acute bacterial sinusitis. The differentiation of common cold symptoms from bacterial sinusitis may be difficult. The diagnosis of bacterial sinusitis should be considered if rhinorrhea or daytime cough persists without improvement for at least 10-14 days; if acute symptoms worsen over time; or if acute signs of more severe sinus involvement

such as fever, facial pain, or facial swelling develop. There is no evidence that symptomatic treatment of the common cold alters the frequency of development of bacterial sinusitis. Bacterial pneumonia is an uncommon complication of the common cold; however, both RSV and HRV have been implicated in pneumonia, especially in developing and emerging countries.

Exacerbation of **asthma** is a potentially serious complication of colds. The majority of asthma exacerbations in children are associated with common cold viruses. There is no evidence that treatment of common cold symptoms prevents this complication; however, studies are underway in patients with underlying asthma to determine effectiveness of preventive or acute treatment at the onset of upper respiratory tract infection symptoms.

PREVENTION

Chemoprophylaxis or immunoprophylaxis is generally not available for the common cold. Immunization or chemoprophylaxis against influenza can prevent colds caused by this pathogen, but influenza is responsible for only a small proportion of all colds. Palivizumab is recommended to prevent severe RSV lower respiratory infection in high-risk infants but does not prevent upper respiratory infections from this virus. Vitamin C, garlic, or echinacea do not prevent the common cold. Zinc sulfate taken for a minimum of 5 months may reduce the rate of cold development. However, because of duration of use and adverse effects of bad taste and nausea, this is not a recommended prevention modality in children.

Hand-to-hand transmission of HRV followed by self-inoculation may be prevented by frequent handwashing and avoiding touching one's mouth, nose, and eyes. Some studies report the use of alcohol-based hand sanitizers and virucidal hand treatments were associated with decreased transmission. In the experimental setting, virucidal disinfectants or virucidal-impregnated tissues also reduce transmission of cold viruses; under natural conditions none of these interventions prevents common colds.

Chapter 429

Sinusitis

Diane E. Pappas and Sarah R. Boggs

Sinusitis is a common illness of childhood and adolescence. There are two common etiologies of acute sinusitis—viral and bacterial—with significant acute and chronic morbidity as well as the potential for serious complications. Fungal sinusitis is rare in immunocompetent patients but can also occur. The common cold produces a viral, self-limited *rhinosinusitis* (see Chapter 428). Approximately 6–7% of viral upper respiratory tract infections in children and adolescents are complicated by acute symptomatic bacterial sinusitis. Some children with underlying predisposing conditions (cystic fibrosis, primary ciliary dyskinesia, immunoglobulin deficiencies) have chronic sinus disease that may or may not be infectious.

Typically, the ethmoidal and maxillary sinuses are present at birth, but only the ethmoidal sinuses are pneumatized. The maxillary sinuses are not pneumatized until 4 years of age. The sphenoidal sinuses are present by 5 years of age, whereas the frontal sinuses begin development at age 7-8 years and are not completely developed until adolescence. The ostia draining the sinuses are narrow (1-3 mm) and drain into the ostiomeatal complex in the middle meatus. The paranasal sinuses are normally sterile and maintained by the mucociliary clearance system.

The bacterial pathogens causing **acute bacterial sinusitis** in children and adolescents include *Streptococcus pneumoniae* (~30%; see Chapter 228), nontypeable *Haemophilus influenzae* (~50%; see Chapter 240), and *Moraxella catarrhalis* (~10%; see Chapter 242). Approximately 50% of *H. influenzae* and 100% of *M. catarrhalis* are β-lactamase positive. As a result of routine use of pneumococcal conjugate vaccine (PCV) 13 in children, nontypeable *H. influenzae* is the most common cause of acute bacterial sinusitis in children; *S. pneumoniae* resistance has also decreased. Similarly, as a result of routine use of the *H. influenzae* type b vaccination in children, almost all *H. influenzae* infections are nontypeable *H. influenzae*. Approximately 25% of *S. pneumoniae* may be penicillin resistant. *Staphylococcus aureus,* other streptococci, and anaerobes are uncommon causes of *acute* bacterial sinusitis in children. Although *S. aureus* (see Chapter 227.1) is an uncommon pathogen for acute sinusitis in children, the increasing prevalence of methicillin-resistant *S. aureus* is a significant concern. *H. influenzae*, α- and β-hemolytic streptococci, *M. catarrhalis, S. pneumoniae,* and coagulase-negative staphylococci are commonly recovered from children with *chronic* sinus disease. *Fusobacterium necrophorum* and *Streptococcus anginosus* are emerging pathogens causing sinusitis with high potential for intracranial extension.

EPIDEMIOLOGY

Acute bacterial sinusitis can occur at any age, though it is more common in older children and adolescents as the sinus cavities become pneumatized. Predisposing conditions may include viral upper respiratory tract infections (associated with out-of-home daycare or a school-age sibling), allergic rhinitis, and tobacco smoke exposure. Children with immune deficiencies, particularly of antibody production (immunoglobulin [Ig]G, IgG subclasses, IgA; see Chapter 166), cystic fibrosis (see Chapter 454), ciliary dysfunction (see Chapter 455), abnormalities of phagocyte function, gastroesophageal reflux, anatomic defects (cleft palate), nasal polyps, cocaine abuse, and nasal foreign bodies (including nasogastric tubes), can develop chronic or recurrent sinus disease. Immunosuppression for bone marrow transplantation or malignancy with profound neutropenia and lymphopenia predisposes to severe fungal *(Aspergillus, Mucor)* sinusitis, often with intracranial extension. Patients with nasotracheal intubation or nasogastric tubes may have obstruction of the sinus ostia and develop sinusitis with the multiple-drug-resistant organisms of the intensive care unit.

Acute sinusitis is defined by a duration of <30 days, subacute by a duration of 1-3 months, and chronic by a duration of longer than 3 months.

PATHOGENESIS

Acute bacterial sinusitis typically follows a viral upper respiratory tract infection (including COVID-19 infection). Initially, the viral infection produces a viral rhinosinusitis; magnetic resonance imaging (MRI) evaluation of the paranasal sinuses demonstrates abnormalities (mucosal thickening, edema, inflammation) of the paranasal sinuses in 68% of healthy children in the normal course of the common cold. Nose blowing has been demonstrated to generate sufficient force to propel nasal secretions into the sinus cavities. Bacteria from the nasopharynx that enter the sinuses are normally cleared readily, but during viral rhinosinusitis, inflammation and edema can block sinus drainage and impair mucociliary clearance of bacteria. The growth conditions are favorable, and high titers of bacteria are produced.

CLINICAL MANIFESTATIONS

Children and adolescents with sinusitis can present with nonspecific complaints, including nasal congestion, purulent nasal discharge

Table 429.1 Symptoms of Acute Bacterial Sinusitis

MAJOR SYMPTOMS	MINOR SYMPTOMS
Purulent anterior nasal discharge	Headache
Purulent or discolored posterior nasal discharge	Ear pain, pressure, or fullness
Nasal congestion or obstruction	Halitosis
Facial congestion or fullness	Dental pain
Facial pain or pressure alone or exacerbated by bending forward	Cough
Hyposmia or anosmia	Fever (for subacute or chronic sinusitis)
Fever (for acute sinusitis only)	Fatigue

Modified from Chow AW, Benninger MS, Brook I, et al. IDSA clinical practice guideline for acute bacterial rhinosinusitis in children and adults. *CID*. 2012;54:e72–e112, Table 2.

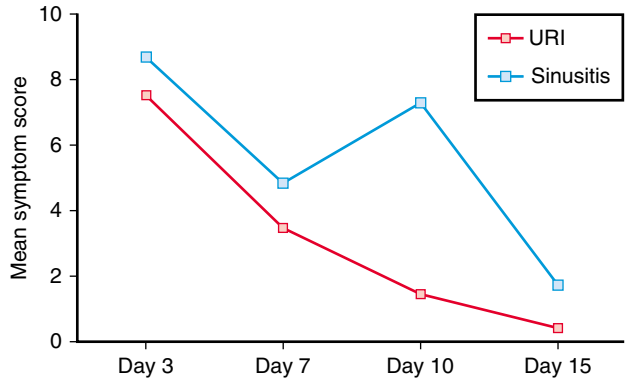

Fig. 429.1 Sinusitis vs URI biphasic symptoms. Mean symptom score by day of illness. *(Modified from DeMuri GP, Eickhoff JC, Gern JC, Wald ER. Clinical and virological characteristics of acute sinusitis in children. Clin Infect Dis. 2019;69:1764–1770, Fig. 1.)*

(unilateral or bilateral), fever, and cough. Less common symptoms include bad breath (halitosis), a decreased sense of smell (hyposmia), and periorbital edema (Table 429.1). Complaints of headache and facial pain are rare in children. Additional symptoms include maxillary tooth discomfort and facial pain or pressure exacerbated by bending forward. Physical examination might reveal erythema and swelling of the nasal mucosa with purulent nasal discharge. Sinus tenderness may be detectable in adolescents and adults.

DIAGNOSIS

The clinical diagnosis of *acute* bacterial sinusitis is based on history, which unfortunately overlaps significantly with that of the common cold. In order to differentiate between the two, current pediatric guidelines define acute bacterial sinusitis as either (1) persistent symptoms of upper respiratory tract infection (rhinitis, common cold), including nasal discharge and/or daytime cough for longer than 10 days without improvement, (2) sudden worsening or new symptoms, known as two-phase illness, or "double sickening," including nasal discharge, daytime cough, or fever after initial improvement (Fig. 429.1), or (3) severe onset with temperature of at least 39°C (102°F) and purulent nasal discharge for 3-4 consecutive days. Bacteria are recovered from maxillary sinus aspirates in 70% of children with such persistent or severe symptoms. Children with *chronic* sinusitis have a history of persistent respiratory symptoms, including cough, nasal discharge, or nasal congestion, lasting longer than 90 days.

Sinus aspirate culture is the only accurate method of diagnosis but is not practical for routine use for immunocompetent patients. It may be a necessary procedure for immunosuppressed patients with suspected fungal sinusitis. In adults, *rigid nasal endoscopy* is a less invasive method for obtaining culture material from the sinus but detects a great excess of positive cultures compared with aspirates. Findings on radiographic studies (sinus plain films, computed tomography [CT] scans), including opacification, mucosal thickening, or presence of an air-fluid level, are not diagnostic and are not recommended in otherwise healthy children. Such findings can confirm the presence of sinus inflammation but cannot be used to differentiate among viral, bacterial, or allergic causes of inflammation.

Given the nonspecific clinical picture, differential diagnostic considerations include viral upper respiratory tract infection (including COVID-19), allergic rhinitis, nonallergic rhinitis, and nasal foreign body. Viral upper respiratory tract infections are characterized by clear and usually nonpurulent nasal discharge, cough, and initial fever; symptoms do not usually persist beyond 10-14 days, although a few children (10%) have persistent symptoms even at 14 days. In a study using nasal sampling, new viruses were present in 29% of sinusitis episodes in children, suggesting sequential upper respiratory infections (URIs) as the cause of persistent symptoms in many cases. Allergic rhinitis can be seasonal; evaluation of nasal secretions should reveal significant eosinophilia.

TREATMENT

It is unclear whether antimicrobial treatment of clinically diagnosed acute bacterial sinusitis offers any substantial benefit. Two randomly controlled trials in children with acute bacterial sinusitis showed improvement after antibiotic therapy, whereas a third found that antimicrobial therapy did not affect resolution of symptoms, duration of symptoms, or days missed from school. A similar study in adults demonstrated improved symptoms at day 7 but not day 10 of treatment. Approximately 50% of children with acute bacterial sinusitis recover without antimicrobial treatment. Centers for Disease Control and Prevention (CDC) guidelines offer that either (1) antibiotic treatment is initiated at the time of diagnosis or (2) the clinician/family may choose continued observation for an additional 3 days, with the caveat that antibiotic therapy will be initiated if symptoms worsen or do not improve. Continued observation is generally not recommended for children with persistent symptoms treated with antibiotics in the preceding 30 days or those with underlying conditions.

Due to the high prevalence of antibiotic-resistant *S. pneumoniae* in some communities, amoxicillin-clavulanate is recommended by some authorities as the preferred initial therapy for acute bacterial sinusitis; high-dose amoxicillin alone may also be considered. In a large cohort of pediatric and adolescent patients from a nationwide healthcare utilization database, both antibiotics were equally effective (equivalent treatment failure rates), but those who received amoxicillin-clavulanate had a higher rate of adverse events. Alternative treatments for the penicillin-allergic patient include cefpodoxime, cefdinir, or levofloxacin. *Azithromycin and trimethoprim-sulfamethoxazole are no longer indicated because of a high prevalence of antibiotic resistance.* Ceftriaxone (50 mg/kg, IV or IM) may be given to children who are vomiting or who are at risk for poor compliance; it should be followed by a course of oral antibiotics. For those with worsening symptoms or failure to improve after 3 days of antibiotic therapy, antibiotic therapy may be changed or the child may be referred to an otolaryngologist for further evaluation (maxillary sinus aspiration for culture and susceptibility testing may be necessary) (Table 429.3). The appropriate duration of therapy for sinusitis has yet to be determined; individualization of therapy is a reasonable approach, with treatment recommended in children for a minimum of 10 days or 7 days after resolution of symptoms. Frontal sinusitis can rapidly progress to serious intracranial complications and may necessitate initiation of parenteral ampicillin-sulbactam, ceftriaxone, or levofloxacin until substantial clinical improvement is achieved (Figs. 429.2 and 429.3). Treatment is then completed with oral antibiotic therapy.

The use of decongestants, antihistamines, mucolytics, and intranasal corticosteroids has not been adequately studied in children and is not recommended for the treatment of acute uncomplicated bacterial sinusitis. Likewise, saline nasal washes or nasal sprays can help liquefy secretions and act as a mild vasoconstrictor, but the effects have not been systematically evaluated in children.

Table 429.2 Antimicrobial Regimens for Acute Bacterial Rhinosinusitis in Children

INDICATION	TREATMENT
Initial empirical therapy for mild to moderate disease*	Amoxicillin-clavulanate (45 mg amoxicillin/kg/day PO divided bid, max 4 g amoxicillin/day) × 10 days*
Initial therapy for acute worsening ("double sickening") of symptoms OR severe disease†	Amoxicillin-clavulanate (90 mg amoxicillin/kg/day PO divided bid, max 4 g amoxicillin/day) × 10 days
β-Lactam allergy	
Type I hypersensitivity	Levofloxacin (10-20 mg/kg/day PO divided every 12-24 hr, max 500 mg/day) × 10 days
Non–type I hypersensitivity	Cefpodoxime‡ (10 mg/kg/day PO divided bid) × 10 days
Severe infection requiring hospitalization	Ampicillin/sulbactam (200-400 mg ampicillin/kg/day IV divided every 6 hr, max 8g ampicillin/day) Ceftriaxone (50 mg/kg/day IV divided every 12 hr, max 4 g/day) Levofloxacin (10-20 mg/kg/day IV divided every 12-24 hr, max 500 mg/day)

*Amoxicillin 90 mg/kg/day, divided bid, max 4g/day, can also be considered.
†Acute worsening ("double sickening") OR severe disease: worsening nasal discharge, daytime cough, or fever starting after a period of initial improvement OR severe onset with temperature of at least 39°C (102°F) and purulent nasal discharge for 3-4 consecutive days.
‡Cefdinir (14 mg/kg/day in one or two divided doses, max 600 mg/day) is an alternative that is more palatable in liquid form than cefpodoxime but has less coverage of bacterial sinusitis pathogens.

Table 429.3 Indications for Referral to a Specialist

- Severe infection (high persistent fever with temperature >39°C [>102°F], orbital edema, severe headache, visual disturbance, altered mental status, meningeal signs)
- Recalcitrant infection with failure to respond to extended courses of antimicrobial therapy
- Immunocompromised host
- Multiple medical problems that might compromise response to treatment (e.g., hepatic or renal impairment, hypersensitivity to antimicrobial agents, organ transplant)
- Unusual or resistant pathogens
- Fungal sinusitis or granulomatous disease
- Nosocomial infection
- Anatomic defects causing obstruction and requiring surgical intervention
- Multiple recurrent episodes of acute bacterial rhinosinusitis (three to four episodes per year) suggesting chronic sinusitis
- Chronic rhinosinusitis (with or without polyps or asthma) with recurrent acute bacterial rhinosinusitis exacerbations
- Evaluation of immunotherapy for allergic rhinitis

From Chow AW, Benninger MS, Brook I, et al. IDSA clinical practice guideline for acute bacterial rhinosinusitis in children and adults. *CID*. 2021;54:e72–e112, Table 14.

COMPLICATIONS

Because of the close proximity of the paranasal sinuses to the brain and eyes, serious orbital and/or **intracranial complications** can result from acute bacterial sinusitis and progress rapidly. Organisms causing orbital and/or intracranial complications of bacterial sinusitis in children include members of the *Streptococcus anginosus* group, *S. aureus, S. pneumoniae,* methicillin-resistant *S. aureus* (MRSA), and methicillin-sensitive *S. aureus* (MSSA); ~30% of infections were polymicrobial.

Orbital complications, including periorbital cellulitis and more often orbital cellulitis (see Chapter 674), are most often secondary to acute bacterial ethmoiditis. *Periorbital* cellulitis produces erythema and swelling of the tissues surrounding the globe, whereas *orbital* cellulitis involves the intraorbital structures and produces proptosis, chemosis, decreased visual acuity, double vision and impaired extraocular movements, and eye pain (Fig. 429.4). In addition to IV antibiotics, orbital cellulitis may require surgical drainage of the ethmoid sinuses or orbit.

Intracranial complications can include epidural abscess, meningitis, cavernous sinus thrombosis, subdural empyema, and brain abscess (see Chapter 644). Children with altered mental status, nuchal rigidity, severe headache, focal neurologic findings, or signs of increased intracranial pressure (headache, vomiting) require immediate CT scan with contrast of the brain, orbits, and sinuses to evaluate for the presence of intracranial complications of acute bacterial sinusitis. Diagnosis of intracranial complications may be challenging, as many patients present with nonspecific symptoms present for the preceding 7-10 days (most commonly headache, fever, congestion, nausea, and vomiting); typically, patients will have been seen by a healthcare provider one or more times before diagnosis. About 50% of patients will present with an abnormal neurologic exam, although only ~30% of patients will present with neurologic symptoms (altered mental status, seizures).

Treatment with broad-spectrum IV antibiotics (usually cefotaxime or ceftriaxone combined with vancomycin and metronidazole) should be initiated immediately, pending culture and susceptibility results. Abscesses can require surgical drainage; endoscopic sinus surgery (ESS) without powered instruments and proper personal protective equipment (PPE) are recommended to minimize risks of aerosolization. Other complications include osteomyelitis of the frontal bone **(Pott puffy tumor)**, which is characterized by edema and swelling of the forehead (see Fig. 429.2), and **mucoceles**, which are chronic inflammatory lesions commonly located in the frontal sinuses that can expand, causing displacement of the eye with resultant diplopia. Surgical drainage is usually required.

PREVENTION

Prevention is best accomplished by frequent handwashing and avoiding persons with colds. This was confirmed most recently in New Zealand: when strict nonpharmaceutical infection control measures were implemented during the COVID-19 pandemic, infections caused by common cold viruses (influenza, respiratory syncytial virus [RSV], human metapneumovirus, enterovirus, adenovirus, parainfluenza virus, and rhinovirus) were greatly reduced. Once restrictions were eased, only rhinovirus infections quickly increased, whereas the prevalence of other respiratory viral infections remained reduced. This may be because of the fact that most rhinovirus infections are transmitted in the home where public restrictions are not in place. Commercially available alcohol-based hand sanitizers have been shown in vitro to be effective against COVID-19 and the common cold viruses.

Because acute bacterial sinusitis can be a complication of influenza infection, prevention of influenza infection by yearly influenza vaccine will prevent some cases of complicating sinusitis. Chemoprophylaxis against influenza with oseltamivir or zanamivir may be useful for prevention of influenza-associated sinusitis.

The sinuses. In Slovis T, ed. Caffey's Pediatric Diagnostic Imaging, 11th ed. Philadelphia: Mosby; 2008: Fig. 43-7, p. 573.)*

Chapter 430

Acute Pharyngitis

Joseph Gigante

Pharyngitis refers to inflammation of the pharynx, including erythema, edema, exudates, or an enanthem (ulcers, vesicles). Pharyngeal inflammation can be related to environmental exposures, such as tobacco smoke, air pollutants, and allergens; from contact with caustic substances, hot food, and liquids; and from infectious agents. The pharynx and mouth can be involved in various inflammatory conditions such as periodic fever, aphthous stomatitis, pharyngitis, adenitis (PFAPA) syndrome, Kawasaki disease, multisystem inflammatory syndrome in children (MIS-C), inflammatory bowel disease (IBD), Stevens-Johnson syndrome, and systemic lupus erythematous (SLE). Noninfectious etiologies are typically evident from history and physical exam, but it can be more challenging to distinguish from among the numerous infectious causes of acute pharyngitis.

Acute infections of the upper respiratory tract account for a substantial number of visits to pediatricians, and many feature sore throat as a symptom or evidence of pharyngitis on physical examination. The usual clinical task is to distinguish important, potentially serious, and treatable causes of acute pharyngitis from those that are self-limited and require no specific treatment or follow-up. Specifically, identifying patients who have **group A streptococcus** (GAS; *Streptococcus pyogenes*; see Chapter 229) pharyngitis and treating them with antibiotics forms the core of the management paradigm.

INFECTIOUS ETIOLOGIES

Viruses

In North America and most industrialized countries, GAS is the most important bacterial cause of acute pharyngitis, but viruses predominate as acute infectious causes of pharyngitis. Viral upper respiratory tract infections are typically spread by contact with oral or respiratory secretions and occur most commonly in fall, winter, and spring—that is, the respiratory season. Important viruses that cause pharyngitis include influenza, parainfluenza, adenoviruses, coronaviruses, enteroviruses, rhinoviruses, respiratory syncytial virus (RSV), cytomegalovirus, Epstein-Barr virus (EBV), herpes simplex virus (HSV), and human metapneumovirus (HMPV) (Table 430.1). Most viral pharyngitis, except mononucleosis, is mild. Common nonspecific symptoms such as rhinorrhea and cough develop gradually before they become prominent. However, specific findings are sometimes helpful in identifying the infectious viral agent (Table 430.2). Sore throat is also seen in COVID-19 infection and MIS-C; it is rare to be the only symptom and is part of the multisystem involvement in both disorders.

Table 430.1 Infectious Agents that Cause Pharyngitis

VIRUSES	BACTERIA
Adenovirus	*Streptococcus pyogenes* (group A streptococcus)
Coronavirus including COVID-19	*Arcanobacterium haemolyticum*
Cytomegalovirus	*Fusobacterium necrophorum*
Epstein-Barr virus	*Corynebacterium diphtheriae*
Enteroviruses	*Neisseria gonorrhoeae*
Herpes simplex virus (1 and 2)	Group C streptococci
Human immunodeficiency virus	Group G streptococci
Human metapneumovirus	*Francisella tularensis*
Influenza viruses (A and B)	*Yersinia pestis*
Measles virus	*Chlamydophila pneumoniae*
Parainfluenza viruses	*Chlamydia trachomatis*
Respiratory syncytial virus	*Mycoplasma pneumoniae*
Rhinoviruses	Mixed anaerobes (Vincent angina)

Gingivostomatitis and ulcerating vesicles throughout the anterior pharynx and on the lips and perioral skin are seen in primary oral HSV infection. High fever and difficulty taking oral fluids are common. This infection can last for 14 days.

Discrete **papulovesicular** lesions or **ulcerations** in the posterior oropharynx, severe throat pain, and fever are characteristic of **herpangina**, caused by various enteroviruses. In **hand-foot-mouth disease**, there are vesicles or ulcers throughout the oropharynx, on the palms and soles, and sometimes on the trunk and extremities. Coxsackie A16 is the most common agent, but enterovirus 71 and Coxsackie A6 can also cause this syndrome. Enteroviral infections are most common in the summer.

Various adenoviruses cause pharyngitis. When there is concurrent **conjunctivitis**, the syndrome is called *pharyngoconjunctival fever*. The pharyngitis tends to resolve within 7 days, but conjunctivitis may persist for up to 14 days. Pharyngoconjunctival fever can be epidemic or sporadic; outbreaks have been associated with exposure in swimming pools.

Intense, diffuse pharyngeal erythema and Koplik spots, the pathognomonic enanthem, occur in advance of the characteristic rash of measles. Splenomegaly, lymphadenopathy, or hepatomegaly may be the clue to EBV infectious mononucleosis in an adolescent with exudative tonsillitis. Primary infection with HIV can manifest as **acute retroviral syndrome**, with nonexudative pharyngitis, fever, arthralgia, myalgia, adenopathy, and often a maculopapular rash.

Bacteria Other than Group A Streptococcus

In addition to GAS, bacteria that cause pharyngitis include group C and group G streptococcus, *Arcanobacterium haemolyticum, Francisella tularensis, Neisseria gonorrhoeae, Mycoplasma pneumoniae, Chlamydophila (formerly Chlamydia) pneumoniae, Chlamydia trachomatis, Fusobacterium necrophorum,* and *Corynebacterium diphtheriae. Haemophilus influenzae* and *Streptococcus pneumoniae* may be cultured from the throats of children with pharyngitis, but their role in causing pharyngitis has not been established.

Group C and group G streptococcus and *A. haemolyticum* pharyngitis have been diagnosed most commonly in adolescents and adults.

Table 430.2 Epidemiologic and Clinical Features Suggestive of Group A Streptococcal and Viral Pharyngitis

FEATURE, BY SUSPECTED ETIOLOGIC AGENT
Group A Streptococcal
• Sudden onset of sore throat • Age 5-15 yr • Fever • Headache • Nausea, vomiting, abdominal pain • Tonsillopharyngeal inflammation • Patchy tonsillopharyngeal exudates • Palatal petechiae • Anterior cervical adenitis (tender nodes) • Winter and early spring presentation • History of exposure to strep pharyngitis • Scarlatiniform rash • No cough or coryza
Viral
• Conjunctivitis • Coryza • Cough • Diarrhea • Hoarseness • Discrete ulcerative stomatitis • Viral exanthema • As part of the spectrum of COVID-19 and MIS-C

From Shulman ST, Bisno AL, Clegg HW, et al. Clinical practice guideline for the diagnosis and management of group A streptococcal pharyngitis: 2012 update by the Infectious Diseases Society of America. *Clin Infect Dis.* 2012;55(10):e86–e102, Table 4.

They resemble group A β-hemolytic streptococcus (GABHS) pharyngitis. A scarlet fever–like rash may be present with *A. haemolyticum* infections.

F. necrophorum is an important etiology of pharyngitis in older adolescents and adults (15-30 years old). Prevalence in studies has varied from 10% to 48% of patients with non-GABHS pharyngitis, but large surveillance studies have not been performed. *F. necrophorum* was detected by polymerase chain reaction (PCR) in 20.5% of patients with pharyngitis in a study based in a university health clinic and in 9.4% of an asymptomatic convenience sample; some patients had more than one bacterial species detected by PCR. Pharyngitis patients with *F. necrophorum* had signs and symptoms similar to GAS pharyngitis: ~30% had fever, ~30% had tonsillar exudates, ~65% had anterior cervical adenopathy, and most did not have cough. This organism is difficult to culture from the throat, and diagnostic testing with PCR is not generally available. *F. necrophorum* pharyngitis is associated with the development of **Lemierre syndrome** (see Chapter 432): internal jugular vein septic thrombophlebitis. Approximately 80% of cases of Lemierre syndrome are caused by this bacterium. Patients present initially with fever, sore throat, exudative pharyngitis, and/or peritonsillar abscess. The symptoms may persist, neck pain and swelling develop, and the patient appears toxic. Septic shock may ensue, along with metastatic complications from septic emboli that can involve the lungs, bones and joints, central nervous system, abdominal organs, and soft tissues. The case fatality rate is 4–9%.

Gonococcal pharyngeal infections are usually asymptomatic but can cause acute ulcerative or exudative pharyngitis with fever and cervical lymphadenitis. Young children with proven gonococcal disease should be evaluated for sexual abuse.

Diphtheria is extremely rare in most developed countries because of extensive immunization with diphtheria toxoid. However, it remains endemic in many areas of the world, including the former Soviet bloc countries, Africa, Asia, the Middle East, and Latin America. It can be considered in patients with recent travel to or from these areas and in unimmunized patients. Key physical findings are bull neck (extreme neck swelling) and a gray pharyngeal pseudomembrane that can cause respiratory obstruction.

Ingestion of water, milk, or undercooked meat contaminated by *F. tularensis* can lead to oropharyngeal tularemia. Severe throat pain, tonsillitis, cervical adenitis, oral ulcerations, and a pseudomembrane (as in diphtheria) may be present. *M. pneumoniae* and *C. pneumoniae* cause pharyngitis, but other upper and lower respiratory infections are more important and more readily recognized. Development of a severe or persistent cough subsequent to pharyngitis may be the clue to infection with one of these organisms.

Group A Streptococcus

Streptococcal pharyngitis is relatively uncommon before 2-3 years of age, is quite common among children 5-15 years old, and declines in frequency in late adolescence and adulthood. Illness occurs throughout the year but is most prevalent in winter and spring. It is readily spread among siblings and schoolmates. GAS causes 15–30% of pharyngitis in school-age children.

Colonization of the pharynx by GAS can result in either asymptomatic carriage or acute infection. After an incubation period of 2-5 days, pharyngeal infection with GAS classically presents as rapid onset of significant sore throat and fever (see Table 430.2). The pharynx is red, and the tonsils are enlarged and often covered with a white, grayish, or yellow exudate that may be blood-tinged. There may be petechiae or doughnut lesions on the soft palate and posterior pharynx, and the uvula may be red and swollen. The surface of the tongue can resemble a strawberry when the papillae are inflamed and prominent (strawberry tongue). Initially, the tongue is often coated white, and with the swollen papillae, it is called a *white strawberry tongue*. When the white coating is gone after a few days, the tongue is often quite red and is called a *red strawberry tongue*. Enlarged and tender anterior cervical lymph nodes are frequently present. Headache, abdominal pain, and vomiting are frequently associated with the infection, but in the absence of clinical pharyngitis, gastrointestinal signs and symptoms should not be attributed to GAS. Ear pain is a frequent complaint, but the tympanic membranes are usually normal. Diarrhea, cough, coryza, ulcerations, croup/laryngitis/hoarseness, and conjunctivitis *are not* associated with GAS pharyngitis and increase the likelihood of a viral etiology (see Table 430.2).

Patients infected with GAS that produce streptococcal pyrogenic exotoxin A, B, or C may demonstrate the fine, red, papular (sandpaper) rash of **scarlet fever**. It begins on the face and then becomes generalized. The cheeks are red, and the area around the mouth is less intensely red (more pale), giving the appearance of circumoral pallor. The rash blanches with pressure, and it may be more intense in skin creases, especially in the antecubital fossae, axillae, and inguinal creases (Pastia lines or sign). Pastia lines are sometimes petechial or slightly hemorrhagic. Capillary fragility can cause petechiae distal to a tourniquet or constriction from clothing, a positive tourniquet test or Rumpel-Leeds phenomenon. Erythema fades in a few days, and when the rash resolves, it typically peels like a mild sunburn. Sometimes there is sheetlike desquamation around the free margins of the fingernails. Streptococcal pyrogenic exotoxin A, encoded by the gene *spe A,* is the exotoxin most commonly associated with scarlet fever.

The M protein is an important GAS virulence factor that facilitates resistance to phagocytosis. The M protein is encoded by the *emm* gene and determines the M type (or *emm* type). Molecular methods have identified more than 240 *emm* genes (*emm* types, M types). The M protein is immunogenic and protects against reinfection with the homologous M type; an individual can experience multiple episodes of GAS pharyngitis in a lifetime because natural immunity is M type–specific and does not prevent infection with a new M type. Numerous GAS M types can circulate in a community simultaneously, and they enter and leave communities unpredictably and for unknown reasons.

DIAGNOSIS

The clinical presentations of streptococcal and viral pharyngitis often overlap. In particular, the pharyngitis of mononucleosis can be difficult to distinguish from GAS pharyngitis. Physicians relying solely on clinical judgment often overestimate the likelihood of a streptococcal etiology. Various clinical scoring systems have been described to assist in identifying patients who are likely to have GAS pharyngitis. Criteria developed for adults by Centor and modified for children by McIsaac give one point for each of the following criteria: history of temperature >38°C (100.4°F), absence of cough, tender anterior cervical adenopathy, tonsillar swelling or exudates, and age 3-14 years. It subtracts a point for age ≥45 years. At best, a McIsaac score ≥4 is associated with a positive laboratory test for GAS in less than 70% of children with pharyngitis (Table 430.3), so it, too, overestimates the likelihood of GAS. *Consequently, laboratory testing is essential for an accurate diagnosis.* Clinical findings and/or scoring systems can best be used to assist the clinician in identifying patients in need of testing. Evaluating patients indiscriminately can lead to overdiagnosis and overtreatment. Streptococcal antibody tests are not useful in assessing patients with acute pharyngitis.

Throat culture, rapid antigen-detection tests (RADTs), or PCR tests are the diagnostic tests for GAS most available in routine clinical care. Throat culture plated on blood agar remains the gold standard for diagnosing streptococcal pharyngitis. There are both false-negative cultures as a consequence of sampling errors or prior antibiotic treatment and false-positive cultures as a consequence of misidentification of other bacteria as GAS. Streptococcal RADTs detect the group A carbohydrate of GAS. They are used by the vast majority of office-based pediatricians. All RADTs have very high specificity, generally ≥95%, so when a RADT is positive, it is assumed to be accurate and throat culture is unnecessary. Because RADTs are generally much less sensitive than culture, confirming a negative rapid test with a throat culture is recommended. RADTs and throat culture exhibit spectrum bias: they are more sensitive when the pretest probability of GAS is high (signs and symptoms are typical of GAS infection, higher McIsaac scores) and less sensitive when the pretest probability is low. Avoidance of testing when patients have signs and symptoms more suggestive of a viral infection is recommended by expert guidelines.

Table 430.3 Positive Predictive Value of McIsaac Score in Children in Clinical Studies*

SCORE	McISAAC, 2004 (n = 454) (%)	EDMONSON, 2005 (n = 1184) (%)	TANZ, 2009 (n = 1848) (%)	FINE, 2012 (n = 64,789) (%)
0	–	–	7	17
1	–	0.5	19	23
2	20.5	8.9	20	34
3	27.5	42.4	29	50
≥4	67.8	48.2	49	68
GAS prevalence	34	38	30	37

*One point is given for each of the following criteria: history of temperature >38°C (100.4°F), absence of cough, tender anterior cervical adenopathy, tonsillar swelling or exudates, and age 3-14 yr.
Note that the Centor score lacks only the age criterion. Positive predictive value refers to the proportion of patients with documented GAS by rapid antigen-detection test and/or throat culture.

Many laboratories have replaced throat culture with one of the highly sensitive and specific **GAS molecular tests**. A variety of methods are available to amplify the DNA of a specific GAS gene from a throat swab in less than 1 hour. In studies both sensitivity and specificity are reported to be ≥98% when compared with standard throat culture. PCR usually matches the molecular test when used to adjudicate discrepancies between the culture and molecular test results. Some of these nucleic acid amplification tests are approved by the FDA for use in physician office laboratories and can be used as the initial test for GAS or as a confirmatory test when the RADT is negative. Unlike throat culture and RADTs, molecular tests may not exhibit spectrum bias—that is, although test sensitivity is extremely high, it is independent of the pretest probability that GAS is the cause of illness (using signs and symptoms, McIsaac score), thus increasing the potential to identify a chronic GAS carrier who actually has an intercurrent illness not caused by GAS (discussed later). However, the ability of these stand-alone tests to deliver a definitive result in less than 1 hour makes them attractive (there is one test that takes 15 minutes)—the potential to swab symptomatic children, have them wait or send them home, and electronically prescribe an antibiotic when the test is positive can speed initiation of therapy and subsequent return to school and activities. Concerns about molecular tests include the following: (1) they are so sensitive they may cause unnecessary treatment of more patients who are carriers than would ordinarily occur with RADT and/or culture; (2) unless rigorous technique is followed, they may be prone to contamination with exogenous GAS DNA from other swabs, a particular concern in physician offices when performed by staff who are not trained laboratory technologists; and (3) they are much more expensive than throat culture.

Testing for bacteria other than GAS is performed infrequently and should be reserved for patients with persistent symptoms and symptoms suggestive of a specific non-GAS bacterial pharyngitis—for example, when there is concern for gonococcal infection or sexual abuse. Special culture media and a prolonged incubation are required to detect *A. haemolyticum.* A complete blood cell count showing many atypical lymphocytes and a positive mononucleosis slide agglutination test can help confirm a clinical suspicion of EBV infectious mononucleosis. Viral cultures are often unavailable and are generally too expensive and slow to be clinically useful. PCR is more rapid, and multiplex PCR (respiratory viral panel) testing for respiratory pathogens can identify a variety of viral and bacterial agents within a few hours. This may be useful in determining the isolation needs of hospitalized patients, assisting in patient prognosis, and epidemiology, but in the absence of specific treatment for most viral infections, such testing is usually not necessary or useful. In fact, interpreting such tests can be difficult unless the patient has signs or symptoms characteristic of a specific pathogen.

TREATMENT

Specific therapy is unavailable for most viral pharyngitis. However, nonspecific, symptomatic therapy can be an important part of the overall treatment plan. An oral antipyretic/analgesic agent (acetaminophen or ibuprofen) can relieve fever and sore throat pain. Anesthetic sprays and lozenges (often containing benzocaine, phenol, or menthol) can provide local relief in children who are developmentally appropriate to use them. Systemic corticosteroids are sometimes used in children who have evidence of upper airway compromise caused by mononucleosis. Although corticosteroids are used commonly in adults with pharyngitis, large-scale studies capable of providing safety and efficacy data are lacking in children. *Corticosteroids cannot be recommended for treatment of most cases of pediatric pharyngitis.*

Antibiotic therapy of bacterial pharyngitis depends on the organism identified. On the basis of in vitro susceptibility data, oral penicillin is often suggested for patients with group C streptococcal isolates, and oral erythromycin is recommended for patients with *A. haemolyticum,* but the clinical benefit of such treatment is uncertain.

Most untreated episodes of GAS pharyngitis resolve uneventfully within a few days, but early antibiotic therapy hastens clinical recovery by 12-24 hours and also reduces suppurative complications of GAS pharyngitis such as peritonsillar abscess and cervical adenitis. *The primary benefit and intent of antibiotic treatment is the prevention of acute rheumatic fever (ARF)*; it is highly effective when started within 10 days of onset of illness. Antibiotic therapy does not prevent acute poststreptococcal glomerulonephritis (APSGN). Antibiotic treatment should not be delayed for children with symptomatic pharyngitis and a positive test for GAS. Presumptive antibiotic treatment can be started when there is a clinical diagnosis of scarlet fever, a symptomatic child has a household contact with documented streptococcal pharyngitis, or there is a history of ARF in the patient or a family member, but a diagnostic test should be performed to confirm the presence of GAS, and antibiotics should be discontinued if GAS is not identified.

A variety of antimicrobial agents are effective for GAS pharyngitis (Table 430.4). Group A streptococci are universally susceptible to penicillin and all other β-lactam antibiotics. Penicillin is inexpensive, has a narrow spectrum of activity, and has few adverse effects. Amoxicillin is often preferred for children because of its taste, availability as chewable tablets and liquid, and the convenience of once-daily dosing. The duration of oral penicillin and amoxicillin therapy is 10 days. A single intramuscular dose of benzathine penicillin or a benzathine–procaine penicillin G combination is effective and ensures compliance. Follow-up testing for GAS is unnecessary after completion of therapy and is not recommended unless symptoms recur.

Patients allergic to the penicillins can be treated with a 10-day course of a narrow-spectrum, first-generation cephalosporin (cephalexin or cefadroxil) if the previous reaction to penicillin was not an immediate, type I hypersensitivity reaction. Frequently, penicillin-allergic patients are treated for 10 days with erythromycin, clarithromycin, or clindamycin, or for 5 days with azithromycin.

The increased use of macrolides and related antibiotics for a variety of infections, especially the azalide azithromycin, is associated with increased rates of resistance to these drugs among GAS in many

Table 430.4 Recommended Treatment for Acute Streptococcal Pharyngitis

MOST PATIENTS				
	WEIGHT <27 KG	**WEIGHT ≥27 KG**	**ROUTE**	**DURATION**
Amoxicillin	50 mg/kg once daily (maximum 1,000 mg)		Oral	10 days
Penicillin V	250 mg bid	500 mg bid	Oral	10 days
Benzathine penicillin G	600,000 units	1.2 million units	IM	Once
Benzathine penicillin G + procaine penicillin G	900,000 units + 300,000 units	900,000 units + 300,000 units	IM	Once
PENICILLIN-ALLERGIC PATIENTS				
	ORAL DOSE	**FREQUENCY**	**DURATION**	
Cephalosporins*	Varies with agent chosen		10 days	
Erythromycins				
Ethylsuccinate	40 mg/kg/day up to 1,000 mg/day	bid	10 days	
Estolate	20-40 mg/kg/day up to 1,000 mg/day	bid	10 days	
Clarithromycin	15 mg/kg/day up to 500 mg/day	bid	10 days	
Azithromycin†	12 mg/kg day 1; 6 mg/kg days 2-5	qd	5 days	
Clindamycin	20 mg/kg/day up to 1.8 g/day	tid	10 days	

*First-generation cephalosporins are preferred; dosage and frequency vary among agents. Do not use in patients with a history of immediate (anaphylactic) hypersensitivity to penicillin or other β-lactam antibiotics.
†Maximum dose is 500 mg the first day and 250 mg subsequent days.

countries. Approximately 5% of GAS in the United States and more than 10% in Canada are macrolide-resistant (macrolide resistance includes azalide resistance), but there is considerable local variation in both countries. Rates are much higher in many European and Asian countries. Some macrolide-resistant GAS isolates are also resistant to clindamycin. Although not a major hindrance for treatment of pharyngitis, clindamycin resistance may be important in management of invasive GAS infections. The use of macrolides and related antibiotics should be restricted to patients who cannot safely receive a β-lactam drug for GAS pharyngitis. Tetracyclines, fluoroquinolones, or sulfonamides should *not* be used to treat GAS pharyngitis.

CHRONIC GROUP A STREPTOCOCCUS CARRIERS

Streptococcal carriers are patients who continue to harbor GAS in the pharynx despite appropriate antibiotic therapy or when they are well. They have little or no evidence of an inflammatory response to the organism. The pathogenesis of chronic carriage is not known; it is assuredly not related to penicillin resistance or nonadherence to therapy, and there is little direct evidence to support the concept of co-pathogenicity (presence of β-lactamase–producing organisms in the pharynx). Carriage generally poses little risk to patients and their contacts, but it can confound testing in subsequent episodes of sore throat. A child who is chronically colonized with GAS (streptococcal carrier) can have a positive test for GAS if it is obtained when the child is evaluated for pharyngitis that is actually caused by a viral infection. Patients with repeated test-positive pharyngitis create anxiety among their families and physicians. It is usually unnecessary to attempt to eliminate chronic carriage. Instead, evaluation and treatment of clinical pharyngitis should be undertaken without regard for chronic carriage, using clinical criteria to determine the need for testing, treating test-positive patients in routine fashion, and avoiding antibiotics in patients who have negative tests. This approach often requires considerable effort to reassure the patient and family that chronic carriage is not a significant health risk. Expert opinion suggests that eradication might be attempted in select circumstances: a community outbreak of ARF or APSGN; personal or family history of ARF; an outbreak of GAS pharyngitis in a closed or semiclosed community, nursing home, or healthcare facility; repeated episodes of symptomatic GAS pharyngitis in a family with ping pong spread among family members despite adequate therapy; when tonsillectomy is being considered because of chronic carriage or recurrent streptococcal pharyngitis; and extreme, unmanageable anxiety related to GAS carriage ("streptophobia") among family members. Clindamycin given by mouth for 10 days is effective therapy (20 mg/kg/day divided in three doses; adult dose 150-450 mg tid). Amoxicillin-clavulanate (40 mg amoxicillin/kg/day up to 2,000 mg amoxicillin/day divided tid for 10 days) and 4 days of oral rifampin (20 mg/kg/day up to 600 mg divided in two doses) plus either intramuscular benzathine penicillin given once or oral penicillin given for 10 days have also been used (rifampin is started on the first day of penicillin therapy).

RECURRENT PHARYNGITIS

True recurrent GAS pharyngitis can occur for several reasons: reinfection with the same M type if type-specific antibody has not developed, poor compliance with oral antibiotic therapy, macrolide resistance if a macrolide was used for treatment, and infection with a new M type. Unfortunately, determining the GAS M type in an acute infection is not available to the clinician. Treatment with intramuscular benzathine penicillin eliminates nonadherence to therapy. Apparent recurrences can represent pharyngitis of another cause in the presence of streptococcal carriage. Chronic GAS carriage is particularly likely if the illnesses are mild and otherwise atypical for GAS pharyngitis.

Tonsillectomy may lower the incidence of pharyngitis for 1-2 years among children with frequent episodes of documented pharyngitis (≥7 episodes in the previous year or ≥5 in each of the preceding 2 years, or ≥3 in each of the previous 3 years). However, the frequency of pharyngitis (GAS and non-GAS) generally declines over time without tonsillectomy. By 2 years posttonsillectomy, the incidence of pharyngitis in severely affected children is similar among those who have tonsillectomy and those who do not. Few children are so severely affected, and the limited clinical benefit of tonsillectomy for most must be balanced against the risks of anesthesia and surgery. *Undocumented history of recurrent pharyngitis is an inadequate basis for recommending tonsillectomy.*

Recurrent GAS pharyngitis is rarely, if ever, a sign of an immune disorder. However, recurrent pharyngitis can be part of a recurrent fever or autoinflammatory syndrome such as PFAPA syndrome. Prolonged

pharyngitis (>1 week) can occur in infectious mononucleosis and Lemierre syndrome, but it also suggests the possibility of another disorder such as neutropenia, a recurrent fever syndrome, or an autoimmune disease such as SLE or IBD. In such instances, pharyngitis would be one of a number of clinical findings that together should suggest the underlying diagnosis.

COMPLICATIONS AND PROGNOSIS

Viral respiratory tract infections can predispose to bacterial middle ear infections and bacterial sinusitis. The complications of GAS pharyngitis include local suppurative complications, such as parapharyngeal abscess, and subsequent nonsuppurative illnesses, such as ARF, APSGN, poststreptococcal reactive arthritis, and possibly pediatric autoimmune neuropsychiatric disorders associated with streptococci (PANDAS, sometimes referred to as *CANS* [childhood acute neuropsychiatric symptoms] or *PANS* [pediatric acute-onset neuropsychiatric syndrome], recognizing that many infections other than GAS may predispose to these syndromes).

PREVENTION

Vaccines intended to prevent infection with various viruses (e.g., RSV) and GAS are being developed. A recombinant multivalent GAS M-type vaccine uses the terminal portions of various M proteins to take advantage of their immunogenicity. Other GAS vaccines are based on more conserved epitopes in order to avoid the necessity of matching the vaccine with the M types prevalent in a community or target population. None of the investigational GAS vaccines are near licensing for use. A recent comprehensive study of the immune response to childhood GAS pharyngeal acquisition raises questions about how to best design effective vaccines. This is complicated by the variety of clinical scenarios and clinical syndromes associated with GAS and the need to determine the intended clinical benefit(s) of vaccination. Antimicrobial prophylaxis with daily oral penicillin prevents recurrent GAS infections but is recommended only to prevent recurrences of ARF.

Chapter 431

Tonsils and Adenoids

Karen B. Zur

The *Waldeyer ring* (the lymphoid tissue surrounding the opening of the oral and nasal cavities into the pharynx) comprises the palatine tonsils, the pharyngeal tonsil or adenoid, lymphoid tissue surrounding the eustachian tube orifice in the lateral walls of the nasopharynx, the lingual tonsil at the base of the tongue, and scattered lymphoid tissue throughout the remainder of the pharynx, particularly behind the posterior pharyngeal pillars and along the posterior pharyngeal wall. The *palatine tonsil* consists of lymphoid tissue located between the palatoglossal fold (anterior tonsillar pillar) and the palatopharyngeal fold (posterior tonsillar pillar). This lymphoid tissue is separated from the surrounding pharyngeal musculature by a thick fibrous capsule. The *adenoid* is a single aggregation of lymphoid tissue that occupies the space between the nasal septum and the posterior pharyngeal wall. A thin fibrous capsule separates it from the underlying structures; the adenoid does not contain the complex crypts that are found in the palatine tonsils, but rather more simple crypts. Lymphoid tissue at the base of the tongue forms the *lingual tonsil* that also contains simple tonsillar crypts.

NORMAL FUNCTION

Located at the opening of the pharynx to the external environment, the tonsils and adenoid are well situated to provide primary defense against foreign matter. The immunologic role of the tonsils and adenoids is to induce secretory immunity and to regulate the production of the secretory immunoglobulins. Deep crevices within tonsillar tissue form tonsillar crypts that are lined with squamous epithelium and host a concentration of lymphocytes at their bases. The lymphoid tissue of the Waldeyer ring is most immunologically active between 4 and 10 years of age, with a decrease after puberty. Adenotonsillar hypertrophy is greatest between ages 3 and 6 years; in most children tonsils begin to involute after age 8 years. No major immunologic deficiency has been demonstrated after removal of either or both of the tonsils and adenoid.

PATHOLOGY

Acute Infection

Most episodes of acute pharyngotonsillitis are caused by viruses (see Chapter 430). Group A β-hemolytic streptococcus (GABHS) is the most common cause of bacterial infection in the pharynx (see Chapter 229).

Chronic Infection

The tonsils and adenoids can be chronically infected by multiple microbes, which can include a high incidence of β-lactamase–producing organisms. Both aerobic species, such as streptococci and *Haemophilus influenzae,* and anaerobic species, such as *Peptostreptococcus, Prevotella,* and *Fusobacterium,* contribute. The tonsillar crypts can accumulate desquamated epithelial cells, lymphocytes, bacteria, and other debris, causing cryptic tonsillitis. With time, these cryptic plugs can calcify into tonsillar concretions or tonsilloliths. Biofilms appear to play a role in chronic inflammation of the tonsils.

Upper Airway Obstruction

Enlargement of the tonsils and/or adenoids is a major cause of upper airway obstruction in children. Airway obstruction in children is typically manifested in sleep-disordered breathing, including obstructive sleep apnea, obstructive sleep hypopnea, and upper airway resistance syndrome (see Chapter 31). Sleep-disordered breathing secondary to adenotonsillar hypertrophy is a cause of growth failure. Solid dysphagia can also be seen in this group of patients, with symptoms such as prolonged chewing, pocketing of solids in the mouth, choking or gagging when swallowing solids, and weight loss.

Tonsillar Neoplasm

Rapid enlargement of one tonsil is highly suggestive of a tonsillar malignancy, typically lymphoma, in children.

CLINICAL MANIFESTATIONS

Acute Infection

Symptoms of GABHS infection include odynophagia, dry throat, malaise, fever and chills, dysphagia, referred otalgia, headache, muscular aches, and enlarged cervical nodes. Signs include dry tongue, erythematous enlarged tonsils, tonsillar or pharyngeal exudate, palatine petechiae, and enlargement and tenderness of the jugulodigastric lymph nodes (Fig. 431.1; see Chapter 229).

Chronic Infection

Children with chronic or cryptic tonsillitis often present with halitosis, chronic sore throats, foreign-body sensation, or a history of expelling foul-tasting and foul-smelling cheesy lumps. Examination reveals tonsils of a range of sizes, often containing copious debris within the crypts. The offending organism is not usually GABHS.

Airway Obstruction

The diagnosis of airway obstruction (see Chapter 31) can frequently be made by history and physical examination. Daytime symptoms of airway obstruction secondary to adenotonsillar hypertrophy include chronic mouth breathing, nasal obstruction, hyponasal speech, hyposmia,

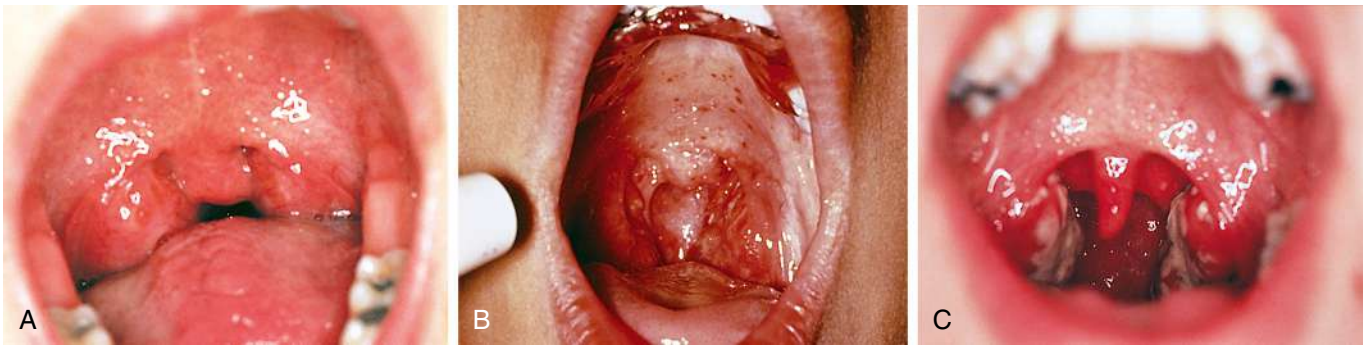

Fig. 431.1 Pharyngotonsillitis. This common condition has a number of causative pathogens and a wide spectrum of severity. **A,** The diffuse tonsillar and pharyngeal erythema seen here is a nonspecific finding that can be produced by a variety of pathogens. **B,** This intense erythema, seen in association with acute tonsillar enlargement and palatal petechiae, is highly suggestive of group A β-streptococcal infection, though other pathogens can produce these findings. **C,** This picture of exudative tonsillitis is most commonly seen with either group A streptococcal or Epstein-Barr virus infection. *(B courtesy Michael Sherlock, MD, Lutherville, MD. From Yellon RF, McBride TP, Davis HW. Otolaryngology. In Zitelli BJ, Davis HW, eds. Atlas of Pediatric Physical Diagnosis, 4th ed. Philadelphia: Mosby; 2002:852.)*

decreased appetite, poor school performance, hyperactivity, and, rarely, symptoms of right-sided heart failure. Nighttime symptoms consist of loud snoring, choking, gasping, frank apnea, restless sleep, abnormal sleep positions, sleep walking, night terrors, diaphoresis, enuresis, and sleep talking. Large tonsils are typically seen on examination, although the absolute size might not indicate the degree of obstruction. The size of the adenoid tissue can be demonstrated on a lateral neck radiograph or with flexible endoscopy. Other signs that can contribute to airway obstruction include the presence of a craniofacial syndrome or hypotonia.

These daytime and nocturnal comorbidities should be explored in patients with enlarged tonsils and/or adenoids. Sleep studies (polysomnograms, PSG) are not routinely recommended unless significant co-morbidities exist.

Tonsillar Neoplasm

The rapid unilateral enlargement of a tonsil, especially if accompanied by systemic signs of night sweats, fever, weight loss, and lymphadenopathy, is highly suggestive of a tonsillar malignancy. The diagnosis of a tonsillar malignancy should also be entertained if the tonsil appears grossly abnormal. Among 54,901 patients undergoing tonsillectomy, 54 malignancies were identified (0.087% prevalence); all but 6 malignancies had been suspected based on suspicious anatomic features preoperatively.

TREATMENT

Medical Management

The treatment of acute pharyngotonsillitis is discussed in Chapter 430 and antibiotic treatment of GABHS in Chapters 229 and 430. Because copathogens such as staphylococci or anaerobes can produce β-lactamase that can inactivate penicillin, the use of cephalosporins or clindamycin may be more efficacious in the treatment of *chronic* throat infections. A tonsillolith or debris may be expressed manually with either a cotton-tipped applicator, gargling after meals, or the use of a water jet.

Tonsillectomy

The American Academy of Otolaryngology (AAO)–Head and Neck Surgery *Taskforce on Clinical Practice Guidelines: Tonsillectomy in Children* most recently issued evidence-based guidelines in 2019 (Table 431.1, Fig. 431.2).

Tonsillectomy alone is most often performed for recurrent or chronic pharyngotonsillitis, and in young children is often accompanied by an adenoidectomy (see next section). Tonsillectomy has been shown to be effective in reducing the number of infections and the symptoms of chronic tonsillitis such as halitosis, persistent or recurrent sore throats, and recurrent cervical adenitis in severely affected patients. In resistant cases of cryptic tonsillitis, tonsillectomy may be curative. The 2019 guidelines recommend watchful waiting for recurrent throat infections if there have been <7 episodes in the past year, <5 episodes/yr in the past 2 years, or <3 episodes/yr in the past 3 years (see Table 431.1 and Fig. 431.2).

Table 431.1 Paradise Criteria for Tonsillectomy

CRITERION	DEFINITION
Minimum frequency of sore throat episodes	At least seven episodes in the previous year **OR** at least five episodes in each of the previous 2 years **OR** at least three episodes in each of the previous 3 years
Clinical features	Sore throat *plus* at least one of the following features qualifies as a counting episode: • Temperature of greater than 38.3°C (101°F) ***OR*** • Cervical adenopathy (tender lymph nodes or lymph node size >2 cm) ***OR*** • Tonsillar exudate ***OR*** • Culture positive for group A β-hemolytic streptococcus
Treatment	Antibiotics had been administered in the conventional dosage for proven or suspected streptococcal episodes
Documentation	Each episode of throat infection and its qualifying features substantiated by contemporaneous notation in a medical record ***OR*** If the episodes are *not fully documented* in the patient record, subsequent observation by a physician of two episodes of throat infection with patterns of frequency and clinical features consistent with the initial history*

*Allows for tonsillectomy recommendation in patients who meet all but the documentation criterion. A 12-mo observation period is usually recommended before consideration of tonsillectomy because of the tendency to improve with time.
Adapted from Mitchell RB, Archer SM, Ishman SL, et al. Clinical practice guideline: tonsillectomy in children (update). *Otolaryngol Head Neck Surg.* 2019;160(1S):S1–S42, Table 5.

Rarely in children, tonsillectomy is indicated for biopsy of a unilaterally enlarged tonsil to exclude a neoplasm or to treat recurrent hemorrhage from superficial tonsillar blood vessels.

Tonsillectomy has not been shown to offer clinical benefit over conservative treatment in children with mild infectious symptoms 2 years after surgery unless other factors or comorbidities exist. However, the 2019 Clinical Practice Guidelines did recommend assessing for additional modifying factors that may favor the need for a tonsillectomy,

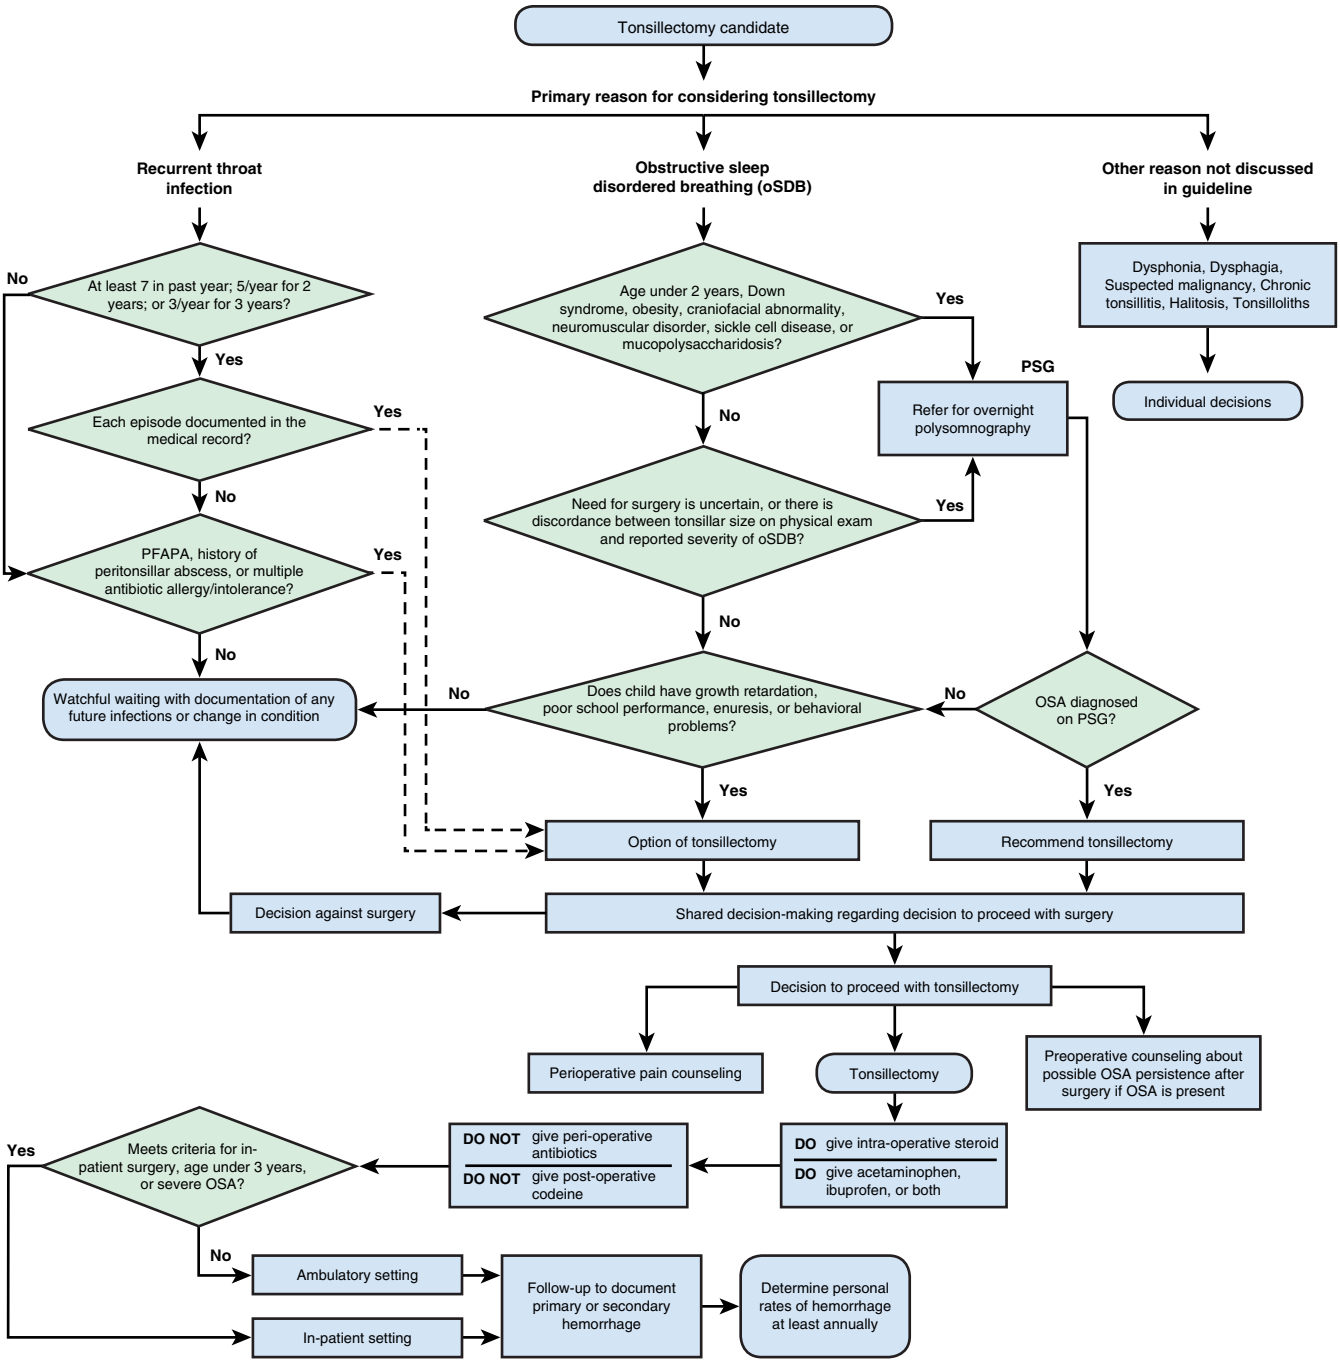

Fig. 431.2 Tonsillectomy in children: clinical practice algorithm. OSA, Obstructive sleep apnea; PFAPA, periodic fever, aphthous stomatitis, pharyngitis, and adenitis; PSG, polysomnography. *(Modified from Mitchell RB, Archer SM, Ishman SL, et al. Clinical practice guideline: tonsillectomy in children, update. Otolaryngol Head Neck Surg. 2019;160:S1–S42, Fig. 2.)*

including intolerance or allergies to antibiotics, PFAPA (periodic fever, aphthous stomatitis, pharyngitis, adenitis), or a history of more than one peritonsillar abscess (PTA).

Adenoidectomy

Adenoidectomy alone may be indicated for the treatment of chronic nasal infection (chronic adenoiditis), chronic sinus infections that have failed medical management, and recurrent bouts of acute otitis media, including those in children with tympanostomy tubes who suffer from recurrent otorrhea. Adenoidectomy may be helpful in children with chronic or recurrent otitis media with effusion. Adenoidectomy alone may be curative in the management of patients with nasal obstruction, chronic mouth breathing, and loud snoring suggesting sleep-disordered breathing. Adenoidectomy may also be indicated for children in whom upper airway obstruction is suspected of causing craniofacial or occlusive developmental abnormalities.

Tonsillectomy and Adenoidectomy

The criteria for a tonsillectomy and adenoidectomy (T&A) for recurrent infections are the same as those for tonsillectomy alone. The other major indication for performing both procedures together is upper airway obstruction secondary to adenotonsillar hypertrophy that results in sleep-disordered breathing, failure to thrive, craniofacial or occlusive developmental abnormalities, speech abnormalities, or, rarely, cor pulmonale. A high proportion of children with failure to thrive in the context of adenotonsillar hypertrophy resulting in sleep-disordered

Table 431.2 Role of PSG in Assessing High-Risk Populations Before Tonsillectomy for oSDB

ROLE OF PSG	RATIONALE
Avoid unnecessary or ineffective surgery in children with primarily nonobstructive events	Identify primarily nonobstructive events or central apnea that may not have been suspected before the study and may not benefit from surgery
Confirm the presence of obstructive events that would benefit from surgery	The increased morbidity of surgery in high-risk children requires diagnostic certainty before proceeding
Define the severity of oSDB to assist in preoperative planning	Children with severe OSA may require preoperative cardiac assessment, pulmonary consultation, anesthesia evaluation, or postoperative inpatient monitoring in an intensive care setting
Provide a baseline PSG for comparison after surgery	Persistent OSA despite surgery is more common in high-risk patients than in otherwise healthy children
Document the baseline severity of oSDB	High-risk patients are more prone to complications of surgery or anesthesia

OSA, Obstructive sleep apnea; oSDB, obstructive sleep-disordered breathing; PSG, polysomnography.
From Mitchell RB, Archer SM, Ishman SL, et al. Clinical practice guideline: tonsillectomy in children (update). *Otolaryngol Head Neck Surg.* 2019;160(IS):S1–S42, Table 6.

breathing experience significant growth acceleration after a T&A. Most children do not require a sleep study before surgery; however, in a high-risk population, polysomnography may help in the decision for or against surgery (Table 431.2). High risk factors include age under 2 years, Down syndrome, obesity, craniofacial abnormality, neuromuscular disorder, sickle cell disease, and mucopolysaccharidosis.

COMPLICATIONS

Poststreptococcal Glomerulonephritis and Acute Rheumatic Fever

The two major complications of untreated GABHS infection are poststreptococcal glomerulonephritis and acute rheumatic fever (see Chapters 559.4 and 229).

Peritonsillar Infection

Peritonsillar infection can occur as either cellulitis or a frank abscess in the region superior and lateral to the tonsillar capsule (see Chapter 432). These infections usually occur in children with a history of recurrent tonsillar infection and are polymicrobial, including both aerobes and anaerobes. Unilateral throat pain, referred otalgia, drooling, and trismus are presenting symptoms. The affected tonsil is displaced down and medially with swelling of the anterior tonsillar pillar and palate. The diagnosis of an abscess can be confirmed by CT or by needle aspiration, the contents of which should be sent for culture.

Retropharyngeal Space Infection

Infections in the retropharyngeal space develop in the lymph nodes that drain the oropharynx, nose, and nasopharynx (see Chapter 432).

Parapharyngeal Space Infection

Tonsillar infection can extend into the parapharyngeal space, causing symptoms of fever, neck pain and stiffness, and signs of swelling of the lateral pharyngeal wall and neck on the affected side. The diagnosis is confirmed by contrast medium–enhanced CT, and treatment includes intravenous antibiotics and external incision and drainage if an abscess is demonstrated on CT (see Chapter 432). Septic thrombophlebitis of the jugular vein, **Lemierre syndrome**, manifests with fever, toxicity, neck pain and stiffness, and respiratory distress caused by multiple septic pulmonary emboli and is a complication of a parapharyngeal space or odontogenic infection from *Fusobacterium necrophorum*. Concurrent Epstein-Barr virus mononucleosis (see Chapter 301) can be a predisposing event before the sudden onset of fever, chills, and respiratory distress in an adolescent patient. Treatment includes high-dose intravenous antibiotics (ampicillin-sulbactam, clindamycin, penicillin, or ciprofloxacin) and anticoagulation.

Table 431.3 Risks of Tonsillectomy or Adenoidectomy or Both

Cost
Risk of anesthetic events
- Malignant hyperthermia
- Cardiac arrhythmia
- Vocal cord trauma
- Aspiration with resulting bronchopulmonary obstruction or infection
- Postoperative nausea and vomiting (PONV)

Risk of miscellaneous surgical or postoperative complications
- Pain
- Dysphagia
- Hemorrhage
- Airway obstruction from edema of tongue, palate, or nasopharynx, or retropharyngeal hematoma
- Prolonged muscular paralysis
- Dehydration
- Palatopharyngeal insufficiency
- Facial edema
- Trauma: dental, larynx, vessels, pharyngeal wall, soft palate
- Laryngospasm
- Mediastinitis
- Cardiac arrest

Modified from Bluestone CD, ed. *Pediatric Otolaryngology*, 4th ed. Philadelphia: WB Saunders; 2003:1213.

Recurrent or Chronic Pharyngotonsillitis

See Chapter 430.

CHRONIC AIRWAY OBSTRUCTION

Although rare, children with chronic airway obstruction from enlarged tonsils and adenoids can present with cor pulmonale.

The effects of chronic airway obstruction and mouth breathing on facial growth remain a subject of controversy. Studies of chronic mouth breathing, both in humans and animals, have shown changes in facial development, including prolongation of the total anterior facial height and a tendency toward a retrognathic mandible, the so-called *adenoid facies*. Adenotonsillectomy can reverse some of these abnormalities. Other studies have disputed these findings.

Tonsillectomy and Adenoidectomy

The risks and potential benefits of surgery must be considered (Table 431.3). The mortality is low (~0.007%); most often associated with other complex medical conditions. Dehydration caused by odynophagia (painful swallowing) is not uncommon in the first postoperative week. The child is encouraged to drink liquids; however, early resumption of a solid diet is also recommended to help with the pain and return of oral function.

Postoperative pain needs to be managed, and opioid-free tonsillectomies are now recommended. Clinicians are encouraged to counsel the caregivers about the importance of hydration and managing postoperative pain with nonsteroidal antiinflammatory drugs (NSAIDs) and acetaminophen and to reinforce this information on the day of surgery. The child is encouraged to hydrate, chew, and rest. Codeine is associated with excessive sedation and fatalities and *is not* recommended.

Bleeding can occur in the immediate postoperative period or be delayed after separation of the eschar. The risk of bleeding is variable among institutions, ranging in the literature from 0.1 to 7.5% and averaging around 4.2% in the first 10 days after surgery. Although recurrent bleeding is unlikely, a bleeding diathesis should be ruled out if it occurs.

The updated Clinical Guidelines for Tonsillectomy include a recommendation for a single intravenous dose of intraoperative dexamethasone (0.5 mg/kg), which decreases postoperative nausea and vomiting and reduces swelling. There is no evidence that use of dexamethasone in postoperative tonsillectomy patients results in an increased risk of postoperative bleeding, and it could be used as a supplement to the pain management regimen.

Routine use of antibiotics in the postoperative period is ineffective, and thus the AAO Clinical Practice Guidelines advise against its use.

Swelling of the tongue and uvula can lead to acute airway obstruction and globus sensation in the first few hours after surgery. Children with underlying hypotonia (trisomy 21) or craniofacial anomalies are at greater risk for suffering this complication.

Rare complications include anesthesia-related issues (malignant hyperthermia, arrhythmias, intubation trauma, aspiration), velopharyngeal insufficiency, nasopharyngeal or oropharyngeal stenosis, torticollis, and, very rarely, death from uncontrolled bleeds.

Chapter 432

Retropharyngeal Abscess, Lateral Pharyngeal (Parapharyngeal) Abscess, and Peritonsillar Cellulitis/ Abscess

Diane E. Pappas and Sarah R. Boggs

The *retropharyngeal* and the *lateral pharyngeal lymph nodes* that drain the mucosal surfaces of the upper airway and digestive tracts are located in the neck within the *retropharyngeal space* (located between the pharynx and the cervical vertebrae and extending down into the superior mediastinum) and the *lateral pharyngeal space* (bounded by the pharynx medially, the carotid sheath posteriorly, and the muscles of the styloid process laterally). The lymph nodes in these deep neck spaces communicate with each other, allowing bacteria from either cellulitis or node abscess to spread to other nodes. Infection of the nodes usually occurs as a result of extension from a localized infection of the oropharynx. A **retropharyngeal abscess** can also result from penetrating trauma to the oropharynx, dental infection, and vertebral osteomyelitis. Once infected, the nodes may progress through three stages: *cellulitis, phlegmon,* and *abscess.* Infection in the retropharyngeal and lateral pharyngeal spaces can result in airway compromise or posterior mediastinitis, making timely diagnosis important.

RETROPHARYNGEAL AND LATERAL PHARYNGEAL ABSCESS

Retropharyngeal abscess occurs most commonly in children younger than 3-4 years of age; as the retropharyngeal nodes involute after 5 years of age, infection in older children and adults is much less common. In the United States, abscess formation occurs most commonly in winter and early spring. Males are affected more often than females, and approximately two thirds of patients have a history of recent ear, nose, or throat infection.

Clinical manifestations of retropharyngeal abscess are nonspecific and include fever, irritability, decreased oral intake, and drooling. Neck stiffness, torticollis, and refusal to move the neck may also be present. The verbal child might complain of sore throat and neck pain. Other signs can include muffled voice, stridor, respiratory distress, or even obstructive sleep apnea. Physical examination can reveal bulging of the posterior pharyngeal wall, although this is present in <50% of infants with retropharyngeal abscess. Cervical lymphadenopathy may also be present. Lateral pharyngeal abscess commonly presents as fever, dysphagia, and a prominent bulge of the lateral pharyngeal wall, sometimes with medial displacement of the tonsil. The differential diagnosis includes acute epiglottitis and foreign body aspiration. In the young child with limited neck mobility, meningitis must also be considered. Other possibilities include lymphoma, hematoma, and vertebral osteomyelitis.

Incision and drainage and culture of an abscessed node provides the definitive diagnosis, but CT can be useful in identifying the presence of a retropharyngeal, lateral pharyngeal, or parapharyngeal abscess (Figs. 432.1 and 432.2). Deep neck infections can be accurately identified and localized with CT scans, but CT accurately identifies abscess formation in only 63% of patients. Soft tissue neck films taken during inspiration with the neck extended might show increased width or an air-fluid level in the retropharyngeal space. CT with contrast medium enhancement can reveal central lucency, ring enhancement, or scalloping of the walls of a lymph node. Scalloping of the lymph node wall is thought to be a late finding and predicts abscess formation.

Retropharyngeal and lateral pharyngeal infections are most often polymicrobial; the usual pathogens include group A streptococcus (see Chapter 229), oropharyngeal anaerobic bacteria (see Chapter 259), and *Staphylococcus aureus* (see Chapter 227.1). In children younger than age 2 years, there has been an increase in the incidence of retropharyngeal abscess, particularly with *S. aureus,* including methicillin-resistant strains. Other pathogens can include *Haemophilus influenzae, Klebsiella,* and *Mycobacterium avium-intracellulare.* When a retropharyngeal abscess is associated with cervical osteomyelitis, it may be secondary to retropharyngeal extension to the vertebral body (often polymicrobial) or a primary osteomyelitis with extension to the retropharyngeal space. In endemic areas and among patients at risk for tuberculosis, Pott disease should be considered (Fig. 432.3).

Treatment options include intravenous antibiotics with or without surgical drainage. Empiric antibiotic coverage should be guided by local susceptibility patterns for *S. aureus.* Initial therapy should include either ampicillin-sulbactam (50 mg ampicillin/kg every 6 hours, max 2000 mg ampicillin/dose) or clindamycin (15 mg/kg every 8 hours, max 600 mg/dose). For patients who are ill-appearing at presentation or who do not improve after 24-48 hours of antibiotic therapy, consideration should be given to the addition of either vancomycin or linezolid for coverage of methicillin-resistant *S. aureus* (MRSA). When narrowing antibiotic selection based on culture results, it is important to remember that these infections are typically polymicrobial and some pathogens, particularly oral anaerobes, may not be easily cultured.

Studies show that >50% of children with retropharyngeal or lateral pharyngeal abscess as identified by CT can be successfully treated without surgical drainage; the older the child, the more likely it is that antimicrobial treatment alone will be successful. Drainage is necessary in the patient with respiratory distress or failure to improve with intravenous antibiotic treatment. The typical treatment course is intravenous antibiotic therapy for several days until the patient has begun to improve, followed by a course of oral antibiotics for an additional 14 days. Amoxicillin-clavulanate (90 mg amoxicillin/kg/day, divided every 12 hours, max 2000 mg amoxicillin/dose) or clindamycin (13 mg/kg every 8 hours, max 450 mg/dose) are recommended oral regimens. Complications of retropharyngeal or lateral pharyngeal abscess include significant upper airway obstruction, rupture leading to

Bleeding can occur in the immediate postoperative period or be delayed after separation of the eschar. The risk of bleeding is variable among institutions, ranging in the literature from 0.1 to 7.5% and averaging around 4.2% in the first 10 days after surgery. Although recurrent bleeding is unlikely, a bleeding diathesis should be ruled out if it occurs.

The updated Clinical Guidelines for Tonsillectomy include a recommendation for a single intravenous dose of intraoperative dexamethasone (0.5 mg/kg), which decreases postoperative nausea and vomiting and reduces swelling. There is no evidence that use of dexamethasone in postoperative tonsillectomy patients results in an increased risk of postoperative bleeding, and it could be used as a supplement to the pain management regimen.

Chapter 432

Retropharyngeal Abscess, Lateral Pharyngeal (Parapharyngeal) Abscess, and Peritonsillar Cellulitis/ Abscess

Diane E. Pappas and Sarah R. Boggs

The *retropharyngeal* and the *lateral pharyngeal lymph nodes* that drain the mucosal surfaces of the upper airway and digestive tracts are located in the neck within the *retropharyngeal space* (located between the pharynx and the cervical vertebrae and extending down into the superior mediastinum) and the *lateral pharyngeal space* (bounded by the pharynx medially, the carotid sheath posteriorly, and the muscles of the styloid process laterally). The lymph nodes in these deep neck spaces communicate with each other, allowing bacteria from either cellulitis or node abscess to spread to other nodes. Infection of the nodes usually occurs as a result of extension from a localized infection of the oropharynx. A **retropharyngeal abscess** can also result from penetrating trauma to the oropharynx, dental infection, and vertebral osteomyelitis. Once infected, the nodes may progress through three stages: *cellulitis, phlegmon,* and *abscess.* Infection in the retropharyngeal and lateral pharyngeal spaces can result in airway compromise or posterior mediastinitis, making timely diagnosis important.

RETROPHARYNGEAL AND LATERAL PHARYNGEAL ABSCESS

Retropharyngeal abscess occurs most commonly in children younger than 3-4 years of age; as the retropharyngeal nodes involute after 5 years of age, infection in older children and adults is much less common. In the United States, abscess formation occurs most commonly in winter and early spring. Males are affected more often than females, and approximately two thirds of patients have a history of recent ear, nose, or throat infection.

Clinical manifestations of retropharyngeal abscess are nonspecific and include fever, irritability, decreased oral intake, and drooling. Neck stiffness, torticollis, and refusal to move the neck may also be present. The verbal child might complain of sore throat and neck pain. Other signs can include muffled voice, stridor, respiratory distress, or even obstructive sleep apnea. Physical examination can reveal bulging of the posterior pharyngeal wall, although this is present in <50% of infants with retropharyngeal abscess. Cervical lymphadenopathy may also be present. Lateral pharyngeal abscess commonly presents as fever, dysphagia, and a prominent bulge of the lateral pharyngeal wall, sometimes with medial displacement of the tonsil. The differential diagnosis includes acute epiglottitis and foreign body aspiration. In the young child with limited neck mobility, meningitis must also be considered. Other possibilities include lymphoma, hematoma, and vertebral osteomyelitis.

Incision and drainage and culture of an abscessed node provides the definitive diagnosis, but CT can be useful in identifying the presence of a retropharyngeal, lateral pharyngeal, or parapharyngeal abscess (Figs. 432.1 and 432.2). Deep neck infections can be accurately identified and localized with CT scans, but CT accurately identifies abscess formation in only 63% of patients. Soft tissue neck films taken during inspiration with the neck extended might show increased width or an air-fluid level in the retropharyngeal space. CT with contrast medium enhancement can reveal central lucency, ring enhancement, or scalloping of the walls of a lymph node. Scalloping of the lymph node wall is thought to be a late finding and predicts abscess formation.

Retropharyngeal and lateral pharyngeal infections are most often polymicrobial; the usual pathogens include group A streptococcus (see Chapter 229), oropharyngeal anaerobic bacteria (see Chapter 259), and *Staphylococcus aureus* (see Chapter 227.1). In children younger than age 2 years, there has been an increase in the incidence of retropharyngeal abscess, particularly with *S. aureus,* including methicillin-resistant strains. Other pathogens can include *Haemophilus influenzae, Klebsiella,* and *Mycobacterium avium-intracellulare.* When a retropharyngeal abscess is associated with cervical osteomyelitis, it may be secondary to retropharyngeal extension to the vertebral body (often polymicrobial) or a primary osteomyelitis with extension to the retropharyngeal space. In endemic areas and among patients at risk for tuberculosis, Pott disease should be considered (Fig. 432.3).

Treatment options include intravenous antibiotics with or without surgical drainage. Empiric antibiotic coverage should be guided by local susceptibility patterns for *S. aureus.* Initial therapy should include either ampicillin-sulbactam (50 mg ampicillin/kg every 6 hours, max 2000 mg ampicillin/dose) or clindamycin (15 mg/kg every 8 hours, max 600 mg/dose). For patients who are ill-appearing at presentation or who do not improve after 24-48 hours of antibiotic therapy, consideration should be given to the addition of either vancomycin or linezolid for coverage of methicillin-resistant *S. aureus* (MRSA). When narrowing antibiotic selection based on culture results, it is important to remember that these infections are typically polymicrobial and some pathogens, particularly oral anaerobes, may not be easily cultured.

Studies show that >50% of children with retropharyngeal or lateral pharyngeal abscess as identified by CT can be successfully treated without surgical drainage; the older the child, the more likely it is that antimicrobial treatment alone will be successful. Drainage is necessary in the patient with respiratory distress or failure to improve with intravenous antibiotic treatment. The typical treatment course is intravenous antibiotic therapy for several days until the patient has begun to improve, followed by a course of oral antibiotics for an additional 14 days. Amoxicillin-clavulanate (90 mg amoxicillin/kg/day, divided every 12 hours, max 2000 mg amoxicillin/dose) or clindamycin (13 mg/kg every 8 hours, max 450 mg/dose) are recommended oral regimens. Complications of retropharyngeal or lateral pharyngeal abscess include significant upper airway obstruction, rupture leading to

aspiration pneumonia, and extension to the mediastinum with resultant mediastinitis. Thrombophlebitis of the internal jugular vein and erosion of the carotid artery sheath can also occur.

An uncommon but characteristic infection of the parapharyngeal space is **Lemierre disease**, in which infection from the oropharynx extends to cause septic thrombophlebitis of the internal jugular vein and embolic abscesses in the lungs (Fig. 432.4). The causative pathogen is *Fusobacterium necrophorum,* an anaerobic bacterial constituent of the oropharyngeal flora. The typical presentation is that of a previously healthy adolescent or young adult with a history of recent pharyngitis who becomes acutely ill with fever and septic pulmonary emboli producing hypoxia, tachypnea, and respiratory distress. Other upper respiratory infections (parotitis, otitis media, mastoiditis, sinusitis, and dental infections) are much less likely to precipitate Lemierre disease. There is a known association with recent Epstein-Barr infection.

Chest x-ray or CT demonstrates multiple cavitary nodules, often bilateral and often accompanied by pleural effusion. Blood culture may be positive. Treatment involves prolonged intravenous antibiotic therapy with either piperacillin-tazobactam, imipenem or meropenem, or ceftriaxone *plus* metronidazole; vancomycin should be added in areas with a high prevalence of MRSA. Surgical drainage of extrapulmonary metastatic abscesses may occasionally be necessary (see Chapters 430 and 431).

Cervical spine radiography, lateral view, showed prevertebral soft tissue anterior to the C1-C7 level *(white arrow),* focal destruction of the C3 vertebra *(black arrow),* and straightening of the cervical spine. *(Modified from Hsu HE, Chen CY. Tuberculous retropharyngeal abscess with Pott disease and tuberculous abscess of the chest wall – a case report. Medicine. 2019;98:e16280, Fig. 1A.)*

PERITONSILLAR CELLULITIS AND/OR ABSCESS

Peritonsillar cellulitis and/or abscess, which is relatively common compared to the deep neck infections, is caused by bacterial invasion through the capsule of the tonsil, leading to cellulitis and/or abscess formation in the surrounding tissues. The typical patient with a peritonsillar abscess is an adolescent with a recent history of acute pharyngotonsillitis. Clinical manifestations include sore throat, fever, trismus, muffled or garbled voice, and dysphagia. Physical examination reveals an asymmetric tonsillar bulge with displacement of the uvula. An asymmetric tonsillar bulge is diagnostic, but it may be poorly visualized because of trismus. CT is helpful for revealing the abscess, but small studies in adults and children have demonstrated that ultrasound may be used to differentiate

Fig. 432.4 CT of Lemierre disease. **A**, CT demonstrating the nodular appearance of pulmonary infiltrates *(arrow)*. **B**, CT of the neck demonstrating thrombosis of the right internal jugular vein *(arrow)*. *(From Plymyer MR, Zoccola DC, Tallarita G. peritonsillar abscess from peritonsillar cellulitis and avoids radiation exposure, as well as the need for sedation that CT often necessitates in children. Group A streptococci and mixed oropharyngeal anaerobes are the most common pathogens, with more than four bacterial isolates per abscess typically recovered by needle aspiration.

A study in Britain evaluating the impact of outpatient management recommendations (increased outpatient or short-stay management, drainage under local anesthetic, prompt discharge) found that admissions were reduced by over 50% and aspiration under local anesthetic increased with no change in readmission or mortality rates. Similarly, a U.S. study found that initial outpatient management is associated with greater use of antibiotics alone and less frequent use of incision and drainage; the recurrence rate was the same regardless of inpatient or outpatient management. These studies suggest that initial outpatient management of peritonsillar abscess in pediatric patients should be considered, especially for older patients who have mild to moderate symptoms; inpatient therapy is indicated for younger patients and those presenting with more severe illness, including trismus and odynophagia. Either amoxicillin-clavulanate or clindamycin would be an acceptable oral regimen.

Inpatient therapy is indicated for younger patients and for those presenting with more severe illness, including significant trismus and odynophagia. If outpatient management with antibiotics alone is unsuccessful or if inpatient management is indicated initially, treatment consists of surgical drainage or needle aspiration along with intravenous antibiotic therapy. As with retropharyngeal abscesses, empiric antibiotic therapy should include either ampicillin-sulbactam or clindamycin, with the addition of vancomycin in patients who are not improving or in areas with high rates of MRSA.

Surgical drainage may be accomplished through needle aspiration, incision and drainage, or tonsillectomy. Needle aspiration can involve aspiration of the superior, middle, and inferior aspects of the tonsil to locate the abscess. Intraoral ultrasound can be used to diagnose and guide needle aspiration of a peritonsillar abscess. General anesthesia may be required for the uncooperative patient. Approximately 95% of peritonsillar abscesses resolve after needle aspiration and antibiotic therapy. A small percentage of these patients require a repeat needle aspiration. The 5% with infections that fail to resolve after needle aspiration require incision and drainage. Tonsillectomy should be considered if there is failure to improve within 24 hours of antibiotic therapy and needle aspiration, history of recurrent peritonsillar abscess or recurrent tonsillitis, or complications from peritonsillar abscess. The feared, albeit rare, complication is rupture of the abscess, with resultant aspiration pneumonitis. There is a 10% recurrence risk for peritonsillar abscess.

Chapter 433

Acute Inflammatory Upper Airway Obstruction (Croup, Epiglottitis, Laryngitis, and Bacterial Tracheitis)

Kristine Knuti Rodrigues and Genie E. Roosevelt

Airway resistance is inversely proportional to the fourth power of the radius (see Chapter 421). Because the lumen of an infant's or child's airway is narrow, minor reductions in cross-sectional area resulting from mucosal edema or other inflammatory processes cause an exponential increase in airway resistance and a significant increase in the work of breathing. The larynx is composed of four major cartilages (epiglottic, arytenoid, thyroid, and cricoid cartilages, ordered from superior to inferior) and the soft tissues that surround them. The cricoid cartilage encircles the airway just below the vocal cords and defines the narrowest portion of the upper airway in children younger than 10 years of age.

Inflammation involving the vocal cords and structures inferior to the cords is called **laryngitis**, **laryngotracheitis**, or **laryngotracheobronchitis**, and inflammation of the structures superior to the cords (i.e., arytenoids, aryepiglottic folds ["false cords"], epiglottis) is called **supraglottitis**. The term **croup** refers to a heterogeneous group of mainly acute and infectious processes that are characterized by a barklike or metallic/brassy cough and may be associated with hoarseness, inspiratory stridor, and respiratory distress. **Stridor** is a harsh, high-pitched respiratory sound that is usually inspiratory but can be biphasic and is produced by turbulent airflow; it is not a diagnosis, but a sign of upper airway obstruction (see Chapter 421). Croup typically affects the larynx, trachea, and bronchi. When the involvement of the larynx is sufficient to produce symptoms, these symptoms dominate the clinical picture more so than the tracheal and bronchial signs. A distinction has been made between spasmodic or recurrent croup and laryngotracheobronchitis. Some clinicians believe that spasmodic croup might have an allergic component and improves rapidly without treatment, whereas laryngotracheobronchitis is always associated with a viral infection of the respiratory tract. Others believe that the signs and symptoms are similar enough to consider them within the spectrum of a single disease because studies have documented viral etiologies in both acute and recurrent croup.

433.1 Infectious Upper Airway Obstruction

Kristine Knuti Rodrigues and Genie E. Roosevelt

With the exceptions of diphtheria (see Chapter 233), bacterial tracheitis, and epiglottitis, most other acute infections of the upper airway are caused by viruses. The parainfluenza viruses (types 1, 2, and 3; see Chapter 306) account for approximately 75% of cases; other viruses associated with croup include influenza A and B, adenovirus, respiratory syncytial virus, COVID-19, and measles. Influenza A is associated with severe laryngotracheobronchitis. *Mycoplasma pneumoniae* has rarely been isolated from children with croup and causes mild disease (see Chapter 269). Most patients with croup are between the ages of 3 months and 5 years, with the peak in the second year of life. The incidence of croup is higher in males. It occurs most commonly in the late fall and winter but can occur throughout the year. Approximately 15% of patients have a strong family history of croup. Recurrences are frequent from 3 to 6 years of age and decrease with growth of the airway. Recurrent croup is defined as two or more crouplike episodes. Patients with recurrent croup have a higher incidence of asthma, allergies, and gastroesophageal reflux; less than 9% of patients with recurrent croup demonstrate clinically significant findings on bronchoscopy (e.g., subglottic stenosis, reflux changes, bronchomalacia/tracheomalacia).

In the past, *Haemophilus influenzae* type b was the most commonly identified etiology of **acute epiglottitis**. Since the widespread use of the *H. influenzae* type b vaccine, invasive disease caused by *H. influenzae* type b in pediatric patients has been reduced by 99% (see Chapter 240). Therefore other agents, such as *Streptococcus pyogenes, Streptococcus pneumoniae,* nontypable *H. influenzae,* and *Staphylococcus aureus,* represent a larger portion of pediatric cases of epiglottitis in vaccinated children. In the prevaccine era, the typical patient with epiglottitis caused by *H. influenzae* type b was 2-4 years of age, although cases were seen in the first year of life and in patients as old as 7 years of age. Currently, the most common presentation of epiglottitis is an adult with a sore throat, although cases still do occur in underimmunized children or with other less common bacteria; vaccine failures have rarely been reported.

CLINICAL MANIFESTATIONS

Croup (Laryngotracheobronchitis)

Viruses typically cause croup, the most common form of acute upper respiratory obstruction. The term *laryngotracheobronchitis* refers to viral infection of the glottic and subglottic regions. Some clinicians use the term *laryngotracheitis* for the most common and most typical form of croup and reserve the term *laryngotracheobronchitis* for the more severe form that is considered an extension of laryngotracheitis associated with bacterial superinfection that occurs 5-7 days into the clinical course.

Most patients have an upper respiratory tract infection with some combination of rhinorrhea, pharyngitis, mild cough, and low-grade fever for 1-3 days before the signs and symptoms of upper airway obstruction become apparent. The child then develops the characteristic barking cough, hoarseness, and inspiratory stridor. The low-grade fever can persist, although temperatures may occasionally reach 39–40°C (102.2–104°F); some children are afebrile. Symptoms are characteristically worse at night and often recur with decreasing intensity for several days and resolve completely within a week. Agitation and crying greatly aggravate the symptoms and signs. The child may prefer to sit up in bed or be held upright. Other family members might have mild respiratory illnesses with laryngitis. Most young patients with croup progress only as far as stridor and slight dyspnea before they start to recover.

Physical examination can reveal a hoarse voice, coryza, normal to moderately inflamed pharynx, and a slightly increased respiratory rate. Patients vary substantially in their degrees of respiratory distress. Rarely, the upper airway obstruction progresses and is accompanied by an increasing respiratory rate; nasal flaring; suprasternal, infrasternal, and intercostal retractions; and continuous stridor. Croup is a disease of the upper airway, and alveolar gas exchange is usually normal.

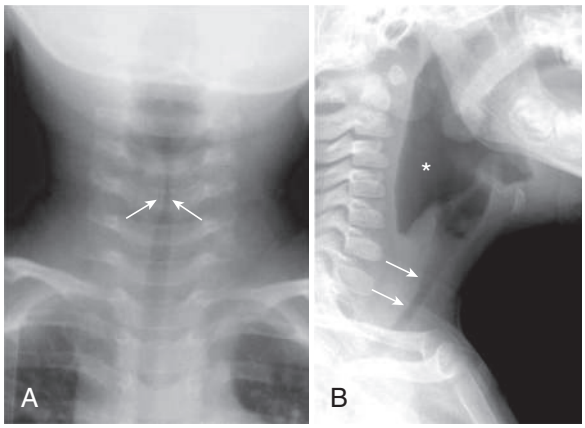

Fig. 433.1 Croup. **A,** Frontal soft tissue neck radiograph demonstrates a "steeple" appearance of the subglottic trachea *(arrows).* **B,** Lateral soft tissue neck radiograph in another patient shows a dilated hypopharynx *(asterisk),* along with haziness and narrowing of the subglottic region *(arrows). (From Laya BF, Lee EY. Upper airway disease. In Coley BD, ed. Caffey's Pediatric Diagnostic Imaging, 13th ed. Philadelphia: Elsevier; 2019: Fig. 51.8, p. 481.)*

Hypoxia and low oxygen saturation are seen only when complete airway obstruction is imminent. *The child who is hypoxic, cyanotic, pale, or obtunded needs immediate airway management.* Occasionally, the pattern of severe laryngotracheobronchitis is difficult to differentiate from epiglottitis, despite the usually more acute onset and rapid course of the latter.

Croup is a clinical diagnosis and does not require a radiograph of the neck. Radiographs of the neck can show the typical subglottic narrowing, or steeple sign, of croup on the posteroanterior view (Fig. 433.1). However, the steeple sign may be absent in patients with croup, may be present in patients without croup as a normal variant, and may rarely be present in patients with epiglottitis. The radiographs do not correlate well with disease severity. Radiographs should be considered only after airway stabilization in children who have an atypical presentation or clinical course. Radiographs may be helpful in distinguishing between severe laryngotracheobronchitis and epiglottitis, but airway management should always take priority.

Acute Epiglottitis (Supraglottitis)

This now rare, but still dramatic and potentially lethal, condition is characterized by an acute rapidly progressive and potentially fulminating course of high fever, sore throat, dyspnea, and rapidly progressing respiratory obstruction. The degree of respiratory distress at presentation is variable. The initial lack of respiratory distress can deceive the unwary clinician; respiratory distress can also be the first manifestation. Often, the otherwise healthy child suddenly develops a sore throat and fever. Within a matter of hours, the patient appears toxic, swallowing is difficult, and breathing is labored. Drooling is usually present, and the neck is hyperextended in an attempt to maintain the airway. The child may assume the tripod position, sitting upright and leaning forward with the chin up and mouth open while bracing on the arms. A brief period of air hunger with restlessness may be followed by rapidly increasing cyanosis and coma. Stridor is a late finding and suggests near-complete airway obstruction. Complete obstruction of the airway and death can ensue unless adequate treatment is provided. *The barking cough typical of croup is rare.* Usually, no other family members are ill with acute respiratory symptoms.

The diagnosis requires visualization under controlled circumstances of a large, cherry red, swollen epiglottis by laryngoscopy. Occasionally, the other supraglottic structures, especially the aryepiglottic folds, are more involved than the epiglottis itself. In a patient in whom the

diagnosis is certain or probable based on clinical grounds, laryngoscopy should be performed expeditiously in a controlled environment such as an operating room or intensive care unit. Anxiety-provoking interventions such as phlebotomy, intravenous line placement, placing the child supine, or direct inspection of the oral cavity should be avoided until the airway is secure. If epiglottitis is thought to be possible but not certain in a patient with acute upper airway obstruction, the patient may first undergo lateral radiographs of the upper airway. Classic radiographs of a child who has epiglottitis show the thumb sign (Fig. 433.2). Proper positioning of the patient for the lateral neck radiograph is crucial to avoid some of the pitfalls associated with interpretation of the film. Adequate hyperextension of the head and neck is necessary. In addition, the epiglottis can appear to be round if the lateral neck is taken at an oblique angle. If the concern for epiglottitis still exists after the radiographs, direct visualization should be performed. A physician skilled in airway management and use of intubation equipment should accompany patients with suspected epiglottitis at all times. An older cooperative child might voluntarily open the mouth wide enough for a direct view of the inflamed epiglottis.

Establishing an airway by endotracheal or nasotracheal intubation or, less often, by tracheostomy is indicated in patients with epiglottitis, regardless of the degree of apparent respiratory distress, because as many as 6% of children with epiglottitis without an artificial airway die compared with <1% of those with an artificial airway. No clinical features have been recognized that predict mortality. Pulmonary edema can be associated with acute airway obstruction. The duration of intubation depends on the clinical course of the patient and the duration of epiglottic swelling, as determined by frequent examination using direct laryngoscopy or flexible fiberoptic laryngoscopy. In general, children with acute epiglottitis are intubated for 2-3 days, because the response to antibiotics is usually rapid. Most patients have concomitant bacteremia; occasionally, other infections are present, such as pneumonia, cervical adenopathy, or otitis media. Meningitis, arthritis, and other invasive infections with *H. influenzae* type b are rarely found in conjunction with epiglottitis (but bacteremia is present).

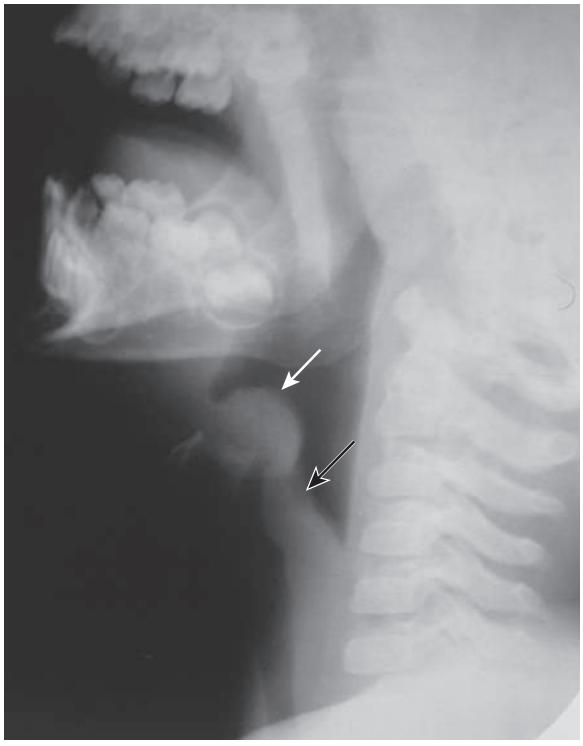

Fig. 433.2 Epiglottitis in a 5-yr-old male with respiratory distress and drooling. A lateral soft tissue neck radiograph shows a markedly thickened epiglottis *(white arrow)*, which is referred to as the "thumb" sign. The aryepiglottic folds *(black arrow)* also are thickened. *(From Laya BF, Lee EY. Upper airway disease. In Coley BD, ed. Caffey's Pediatric Diagnostic Imaging, 13th ed. Philadelphia: Elsevier; 2019: Fig. 51.2, p. 477.)*

Acute Infectious Laryngitis

Laryngitis is a common illness. Viruses cause most cases; diphtheria is an exception but is extremely rare in highly developed, industrialized countries (see Chapter 233). The onset is usually characterized by an upper respiratory tract infection during which sore throat, cough, and hoarseness appear. The illness is generally mild; respiratory distress is unusual except in the young infant. Hoarseness and loss of voice may be out of proportion to systemic signs and symptoms. The physical examination is usually not remarkable except for evidence of pharyngeal inflammation. Inflammatory edema of the vocal cords and subglottic tissue may be demonstrated laryngoscopically. The principal site of obstruction is usually the subglottic area.

Spasmodic Croup

Spasmodic croup occurs most often in children 1-3 years of age and is clinically similar to acute laryngotracheobronchitis, except that the history of a viral prodrome and fever in the patient and family are often absent. The cause is viral in some cases, but allergic and other factors may also contribute.

Occurring most commonly in the evening or nighttime, spasmodic croup begins with a sudden onset that may be preceded by mild to moderate coryza and hoarseness. The child awakens with a characteristic barking, metallic/brassy cough, noisy inspiration, and respiratory distress and appears anxious and frightened. The patient is usually afebrile. The severity of the symptoms generally diminishes within several hours, and the following day, the patient often appears well except for slight hoarseness and cough. Similar, but usually less severe, attacks without extreme respiratory distress can occur for another night or two. Such episodes often recur several times. Spasmodic croup might represent more of an allergic reaction to viral antigens than direct infection, although the pathogenesis is unknown.

DIFFERENTIAL DIAGNOSIS

These four syndromes must be differentiated from one another and from a variety of other entities that can present as upper airway obstruction. **Bacterial tracheitis** is the most important differential diagnostic consideration and has a high risk of airway obstruction. Diphtheritic croup is extremely rare in North America and Europe, although a major epidemic of diphtheria occurred in countries of the former Soviet Union beginning in 1990 from the lack of routine immunization. Early symptoms of **diphtheria** include malaise, sore throat, anorexia, and low-grade fever. Within 2-3 days, pharyngeal examination reveals the typical gray-white membrane, which can vary in size from covering a small patch on the tonsils to covering most of the soft palate. The membrane is adherent to the tissue, and forcible attempts to remove it cause bleeding. The course is usually insidious, but respiratory obstruction can occur suddenly. **Measles** croup almost always coincides with the full manifestations of systemic disease, and the course may be fulminant (see Chapter 293).

Sudden onset of respiratory obstruction can be caused by aspiration of a **foreign body** (see Chapter 435). The child is usually 6 months to 3 years of age. Choking and coughing occur suddenly, usually without prodromal signs of infection, although children with a viral infection can also aspirate a foreign body. A **retropharyngeal** or **peritonsillar abscess** can mimic respiratory obstruction (see Chapter 432). CT scans of the upper airway are helpful in evaluating for possible retropharyngeal abscess. A peritonsillar abscess is a clinical diagnosis. Other possible causes of upper airway obstruction include extrinsic compression of the airway (laryngeal web, vascular ring) and intraluminal obstruction from masses (laryngeal papilloma, subglottic hemangioma); these tend to have chronic or recurrent symptoms.

Upper airway obstruction is occasionally associated with **angioedema** of the subglottic areas as part of anaphylaxis and generalized allergic reactions, edema after endotracheal intubation for either general anesthesia or respiratory failure, hypocalcemic tetany, infectious mononucleosis, trauma, and tumors or malformations of the larynx. A

crouplike cough may be an early sign of asthma. Vocal cord dysfunction can also occur. Epiglottitis, with the characteristic manifestations of drooling or dysphagia and stridor, can also result from the accidental ingestion of very hot liquid.

COMPLICATIONS

Complications occur in approximately 15% of patients with viral croup. The most common is extension of the infectious process to involve other regions of the respiratory tract, such as the middle ear, the terminal bronchioles, or the pulmonary parenchyma. Bacterial tracheitis may be a complication of viral croup rather than a distinct disease. If associated with toxin-producing *S. aureus* or *S. pyogenes,* toxic shock syndrome can develop. **Bacterial tracheitis** may have a biphasic illness, with the second phase after a crouplike illness associated with high fever, toxicity, and airway obstruction. Alternatively, the onset of tracheitis occurs without a second phase and appears as a continuation of the initial crouplike illness, but with higher fever and worsening respiratory distress rather than the usual recovery after 2-3 days of viral croup. Pneumonia, cervical lymphadenitis, otitis media, or, rarely, meningitis or septic arthritis can occur during the course of epiglottitis. Pneumomediastinum and pneumothorax are the most common complications of tracheotomy.

TREATMENT

The mainstay of treatment for children with **croup** is airway management and treatment of hypoxemia. Treatment of the respiratory distress should take priority over any testing. Most children with either acute spasmodic croup or infectious croup can be managed safely at home. Despite the observation that cold night air is beneficial, a Cochrane review has found no evidence supporting the use of cool mist in the emergency department for the treatment of croup.

Nebulized racemic epinephrine is the established treatment for moderate and severe croup. The mechanism of action is believed to be constriction of the precapillary arterioles through the β-adrenergic receptors, causing fluid resorption from the interstitial space and a decrease in the laryngeal mucosal edema. Traditionally, racemic epinephrine, a 1:1 mixture of the D- and L-isomers of epinephrine, has been administered. A dose of 0.25-0.5 mL of 2.25% racemic epinephrine in 3 mL of normal saline can be used as often as every 20 minutes. Racemic epinephrine was initially chosen over the more active and more readily available L-epinephrine to minimize anticipated cardiovascular side effects such as tachycardia and hypertension. Current evidence does not favor racemic epinephrine over L-epinephrine (5 mL of 1:1,000 solution) in terms of efficacy or safety.

The indications for the administration of nebulized epinephrine include moderate to severe stridor at rest, the possible need for intubation, respiratory distress, and/or hypoxemia. The duration of activity of racemic epinephrine is <2 hours. Consequently, observation is mandated. The symptoms of croup might reappear, but racemic epinephrine does not cause rebound worsening of the obstruction. Patients can be safely discharged home after a 2- to 3-hour period of observation provided they have no stridor at rest; have received steroids; and have normal air entry, normal pulse oximetry, and normal level of consciousness. Nebulized epinephrine should still be used cautiously in patients with tachycardia, heart conditions such as tetralogy of Fallot, and ventricular outlet obstruction because of possible side effects.

The effectiveness of oral corticosteroids in viral croup is well established. Corticosteroids decrease the edema in the laryngeal mucosa through their antiinflammatory action. Oral steroids are beneficial, even in mild croup, as measured by improved symptoms at 2 hours, reduced return visits, reduced hospitalization, shorter duration of hospitalization, and reduced need for subsequent interventions such as epinephrine administration. Most studies that demonstrated the efficacy of oral dexamethasone used a single dose of 0.6 mg/kg to a maximum dose of 16 mg; a dose as low as 0.15 mg/kg may be just as effective. More randomized controlled trials are needed to further evaluate the effectiveness of lower dose dexamethasone compared to 0.6 mg/kg. Prednisolone at a dose of 1 mg/kg has also been found to be noninferior to standard and low-dose dosing of dexamethasone. Intramuscular dexamethasone and nebulized budesonide have an equivalent clinical effect; oral dosing of dexamethasone is as effective as intramuscular administration. The only adverse effect in the treatment of croup with corticosteroids is the development of *Candida albicans* laryngotracheitis in a patient who received dexamethasone 1 mg/kg/24 hr for 8 days. Corticosteroids should not be administered to children with varicella or tuberculosis (unless the patient is receiving appropriate antituberculosis therapy) because they worsen the clinical course.

Antibiotics are not indicated in croup. Nonprescription cough and cold medications should not be used in children younger than 6 years of age. A helium-oxygen mixture (heliox) may be considered in the treatment of children with severe croup for whom intubation is being considered, although the evidence is inconclusive. Children with croup should be hospitalized for any of the following: progressive stridor, severe stridor at rest, respiratory distress, hypoxemia, cyanosis, depressed mental status, poor oral intake, persistent moderate croup symptoms (stridor and/or retractions at rest without agitation) after 4 hours after one dose of nebulized epinephrine and systemic glucocorticoids requiring more than one dose of nebulized epinephrine, or the need for reliable observation.

Epiglottitis is a medical emergency and warrants immediate treatment with an artificial airway placed under controlled conditions, either in an operating room or intensive care unit. All patients should receive oxygen en route unless the mask causes excessive agitation. Racemic epinephrine and corticosteroids are ineffective. Cultures of blood, epiglottic surface, and, in selected cases, cerebrospinal fluid should be collected after the airway is stabilized. Ceftriaxone (dose 100 mg/kg/24 hr in one or two divided doses) plus vancomycin (dose 15 mg/kg/24 hr every 8 hours) should be given parenterally, pending culture and susceptibility reports, because 10–40% of *H. influenzae* type b cases are resistant to ampicillin. After insertion of the artificial airway, the patient should improve immediately, and respiratory distress and cyanosis should disappear. Epiglottitis resolves after a few days of antibiotics, and the patient may be extubated; antibiotics should be continued for at least 10 days. Chemoprophylaxis is not routinely recommended for household, childcare, or nursery contacts of patients with invasive *H. influenzae* type b infections, but careful observation is mandatory, with prompt medical evaluation when exposed children develop a febrile illness. **Indications for rifampin prophylaxis** (20 mg/kg orally once a day for 4 days; maximum dose: 600 mg) for all household members include if a child within the home is younger than 4 years of age and incompletely immunized, is younger than 12 months of age and has not completed the primary vaccination series, or is immunocompromised.

Acute laryngeal swelling on an **allergic basis** responds to epinephrine (1 mg/mL concentration, previously referred to as 1:1,000 dilution, in dosage of 0.01 mL/kg to a maximum of 0.5 mL/dose) administered intramuscularly or racemic epinephrine (dose of 0.5 mL of 2.25% racemic epinephrine in 3 mL of normal saline) (see Chapter 190). Corticosteroids may be considered, although there is little evidence of benefit (1-2 mg/kg/24 hr of prednisone for 1-2 days). However, patients who require hospitalization or have a history of asthma may benefit from corticosteroids. After recovery, the patient and parents should be discharged with a preloaded syringe of epinephrine to be used in emergencies. Reactive mucosal swelling, severe stridor, and respiratory distress unresponsive to mist therapy may follow endotracheal intubation for general anesthesia in children. Racemic epinephrine and corticosteroids are helpful.

Endotracheal/Nasotracheal Intubation and Tracheotomy

With the introduction of routine intubation or, less often, tracheotomy for epiglottitis, the mortality rate for epiglottis has decreased to almost zero. These procedures should always be performed in an operating room or intensive care unit if time permits; prior intubation and general anesthesia greatly facilitate performing a tracheotomy without complications. The use of an endotracheal or nasotracheal tube that is 0.5-1.0 mm smaller than estimated by age or height is recommended to facilitate intubation and reduce long-term sequelae. The choice of procedure should be based on the local expertise and experience with the procedure and postoperative care.

Intubation or, less often, tracheotomy is required for most patients with bacterial tracheitis and all young patients with epiglottitis. It is rarely required for patients with laryngotracheobronchitis, spasmodic croup, or laryngitis. Severe forms of laryngotracheobronchitis that require intubation in a high proportion of patients have been reported during severe measles and influenza A virus epidemics. Assessing the need for these procedures requires experience and judgment because they should not be delayed until cyanosis and extreme restlessness have developed (see Chapter 86). An endotracheal or nasotracheal tube that is 0.5-1.0 mm smaller than estimated by age or height is recommended.

The endotracheal tube or tracheostomy must remain in place until edema and spasm have subsided and the patient is able to handle secretions satisfactorily. It should be removed as soon as possible, usually within a few days. Adequate resolution of epiglottic inflammation that has been accurately confirmed by fiberoptic laryngoscopy, permitting much more rapid extubation, often occurs within 24 hours. Racemic epinephrine and dexamethasone (0.5 mg/kg/dose 6-12 hr before extubation with a maximum dose of 16 mg) may be useful in the treatment of upper airway edema seen postintubation.

PROGNOSIS

In general, the length of hospitalization and the mortality rate for cases of acute infectious upper airway obstruction increase as the infection extends to involve a greater portion of the respiratory tract, except in epiglottitis, in which the localized infection itself can prove to be fatal. Most deaths from croup are caused by a laryngeal obstruction or by the complications of tracheotomy. Rarely, fatal out-of-hospital arrests caused by viral laryngotracheobronchitis have been reported, particularly in infants and in patients whose course has been complicated by bacterial tracheitis. Untreated epiglottitis has a mortality rate of 6% in some series, but if the diagnosis is made and appropriate treatment is initiated before the patient is moribund, the prognosis is excellent. The outcome of acute laryngotracheobronchitis, laryngitis, and spasmodic croup is also excellent.

433.2 Bacterial Tracheitis

Kristine Knuti Rodrigues and Genie E. Roosevelt

Bacterial tracheitis is an acute bacterial infection of the upper airway that is potentially life-threatening. *S. aureus* (see Chapter 227.1) is the most commonly isolated pathogen, with isolated reports of methicillin-resistant *S. aureus*, *S. pneumoniae, S. pyogenes, Moraxella catarrhalis,* and nontypable *H. influenzae*; anaerobic organisms have also been implicated. The mean age is between 5 and 7 years. There is a slight male predominance. Bacterial tracheitis often follows a viral respiratory infection (especially laryngotracheitis or influenza virus infection), so it may be considered a bacterial complication of a viral disease, rather than a primary bacterial illness. This life-threatening entity is more common than epiglottitis in vaccinated populations.

CLINICAL MANIFESTATIONS

Typically, the child has a metallic/brassy cough, apparently as part of a viral laryngotracheobronchitis. High fever and toxicity with respiratory distress can occur immediately or after a few days of apparent improvement. The patient can lie flat, does not drool, and does not have the dysphagia associated with epiglottitis. The usual treatment for croup (racemic epinephrine) is ineffective. Intubation or tracheostomy may be necessary, but only 50–60% of patients require intubation for management, with younger patients more likely to need intubation. The major pathologic feature appears to be mucosal swelling at the level of the cricoid cartilage, complicated by copious, thick, purulent secretions, sometimes causing pseudomembranes. Suctioning these secretions, although occasionally affording temporary relief, usually does not sufficiently obviate the need for an artificial airway.

DIAGNOSIS

The diagnosis is based on evidence of bacterial upper airway disease, which includes high fever, purulent airway secretions, and an absence of the classic findings of epiglottitis. X-rays are not needed but can show the classic findings (Fig. 433.3); purulent material is noted below the cords during endotracheal intubation (Fig. 433.4).

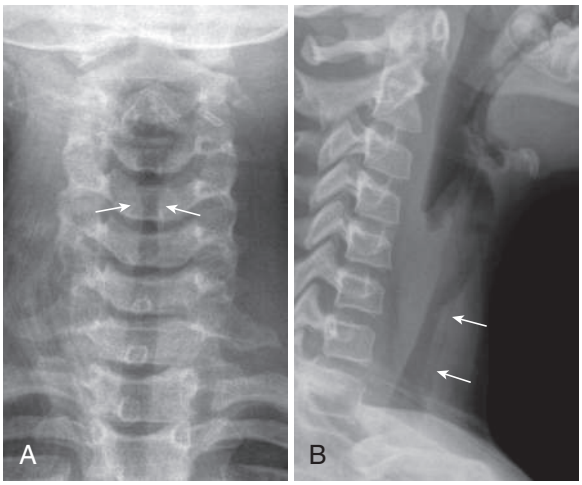

Fig. 433.3 Bacterial tracheitis in a 9-yr-old female with a high fever, cough, and stridor. **A,** Frontal soft tissue neck radiograph shows subglottic tracheal narrowing *(arrows).* **B,** Lateral soft tissue neck radiograph shows irregular linear membranous debris within the trachea *(arrows). (From Laya BF, Lee EY. Upper airway disease. In Coley BD, ed. Caffey's Pediatric Diagnostic Imaging, 13th ed. Philadelphia: Elsevier; 2019: Fig. 51.9, p. 481.)*

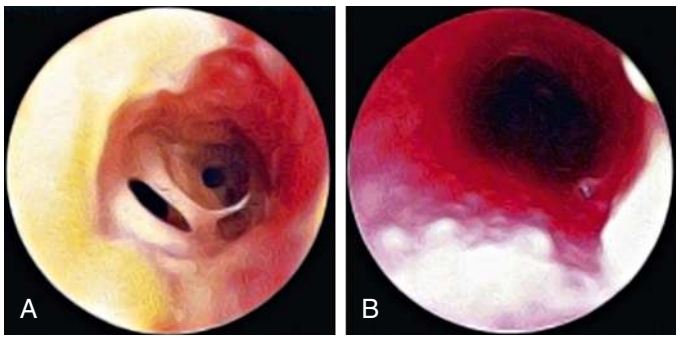

Fig. 433.4 Thick tracheal membranes seen on rigid bronchoscopy. The supraglottis was normal. **A,** Thick adherent membranous secretions. **B,** The distal tracheobronchial tree is unremarkable. In contrast to croup, tenacious secretions are seen throughout the trachea, and in contrast to bronchitis, the bronchi are not affected. *(From Salamone FN, Bobbitt DB, Myer CM, et al. Bacterial tracheitis reexamined: is there a less severe manifestation? Otolaryngol Head Neck Surg. 2004;131:871–876.Copyright 2004 American Academy of Otolaryngology–Head and Neck Surgery Foundation, Inc.)*

TREATMENT

Appropriate antimicrobial therapy, which usually includes antistaphylococcal agents, should be instituted in any patient whose course suggests bacterial tracheitis. Empiric therapy recommendations for bacterial tracheitis include vancomycin or clindamycin and a third- or fourth-generation cephalosporin (e.g., ceftriaxone or cefepime). When bacterial tracheitis is diagnosed by direct laryngoscopy or is highly suspected on clinical grounds, an artificial airway should be strongly considered. Supplemental oxygen is usually necessary.

COMPLICATIONS

Chest radiographs often show patchy infiltrates and may show focal densities. Subglottic narrowing and a rough and ragged tracheal air column can often be demonstrated radiographically. If airway management is not optimal, cardiorespiratory arrest can occur. Toxic shock syndrome has been associated with staphylococcal and group A streptococcal tracheitis (see Chapter 227.2).

PROGNOSIS

The prognosis for most patients is excellent. Patients usually become afebrile within 2-3 days of the institution of appropriate antimicrobial therapy, but prolonged hospitalization may be necessary. In recent years, there appears to be a trend toward a less morbid condition. With a decrease in mucosal edema and purulent secretions, extubation can be accomplished safely, and the patient should be observed carefully while antibiotics and oxygen therapy are continued.

Chapter 434

Congenital Anomalies of the Larynx, Trachea, and Bronchi

Michael Gorelik and James W. Schroeder Jr.

The larynx functions as a breathing passage, a valve to protect the lungs during swallowing, and the primary organ of communication. Symptoms related to congenital anomalies of the larynx include airway obstruction, noisy breathing, difficulty feeding, and abnormalities of phonation (see Chapter 421). Obstructive congenital lesions of the upper airway create turbulent airflow according to the laws of fluid dynamics. Turbulent airflow across a narrowed segment of the respiratory tract produces distinctive sounds that are diagnostically useful. The location of the obstruction produces characteristic changes in the sound of inspiration and/or expiration. Intrathoracic lesions typically cause expiratory wheezing and/or stridor, often masquerading as asthma or other pulmonary processes. The expiratory wheezing contrasts to the inspiratory stridor caused by the extrathoracic lesions of congenital laryngeal anomalies, specifically laryngomalacia and bilateral vocal cord paralysis. Stertor describes the low-pitched inspiratory snoring sound typically produced by soft tissue from nasal or nasopharyngeal obstruction.

The timing of noisy breathing in relation to the sleep–wake cycle is important. Obstruction of the pharyngeal airway (by enlarged tonsils, adenoids, pharyngeal soft tissue, tongue, or syndromes with midface hypoplasia) typically produces worse obstruction during sleep than during waking. Obstruction that is worse when awake is typically laryngeal, tracheal, or bronchial and is exacerbated by exertion. The location of the obstruction dictates the respiratory phase, tone, and nature of the sound, and these qualities direct the differential diagnosis.

With airway obstruction, the degree of the obstructing lesion and the resulting work of breathing determine the necessity for diagnostic procedures and surgical intervention. Obstructive symptoms vary from mild to severe stertor or stridor with episodes of apnea, cyanosis, suprasternal (tracheal tugging) and subcostal retractions, dyspnea, and tachypnea. Significant congenital anomalies of the trachea and bronchi can create serious respiratory difficulties from the first minute of life and may sometimes be diagnosed in the prenatal period. If a severe obstruction is suspected prenatally, an airway birth plan should be developed by a high-risk maternal–fetal medicine expert, a neonatologist, and a pediatric airway surgeon. *Congenital high airway obstruction syndrome,* or *CHAOS,* can lead to immediate postnatal distress (see Chapters 117 and 118). Chronic obstruction can cause failure to thrive and chronic hypoxemia and may have long-term effects on growth and development.

434.1 Laryngomalacia

Michael Gorelik and James W. Schroeder Jr.

Laryngomalacia accounts for 45–75% of congenital laryngeal anomalies in children with stridor. Stridor is inspiratory and can vary from high- to low-pitched. It can be present at rest and exacerbated by any exertion: crying, agitation, or feeding. The stridor is caused, in part, by decreased laryngeal tone leading to supraglottic collapse during inspiration, which creates a narrow airway and turbulent airflow. Symptoms usually appear within the first 2 weeks and increase in severity for up to 6 months, although gradual improvement can begin at any time. Many infants who do not require surgical intervention often have spontaneous resolution of stridor around 7-9 months of age, and the majority will have complete resolution of stridor by 18 months of age. Gastroesophageal reflux disease, laryngopharyngeal reflux disease, and neurologic disease with associated muscle hypotonia can influence the severity of the disease and thereby the clinical course.

DIAGNOSIS

The diagnosis is made primarily based on clinical symptoms and is confirmed by outpatient, awake flexible laryngoscopy (Fig. 434.1). When the work of breathing is moderate to severe, airway films and chest radiographs are indicated. Laryngomalacia can contribute to feeding difficulties and dysphagia in some children because of decreased laryngeal sensation and poor suck-swallow-breath coordination. When the inspiratory stridor sounds wet or is associated with a cough or when there is a history of repeat upper respiratory illness or pneumonia, dysphagia should be considered. When dysphagia is suspected, a contrast swallow study and/or a fiberoptic endoscopic evaluation of swallowing (FEES) may be considered. Because 15–60% of infants with laryngomalacia have synchronous airway anomalies, complete bronchoscopy is undertaken for patients with moderate to severe obstruction.

TREATMENT

Expectant observation is suitable for most infants because most symptoms resolve spontaneously as the child and airway grow. Laryngopharyngeal reflux is managed with antireflux medications, such as histamine H_2-receptor antagonists or proton pump inhibitors (PPIs).

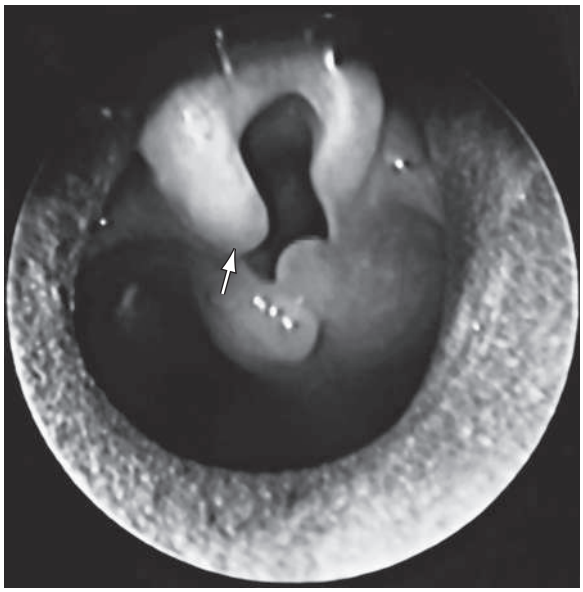

Fig. 434.1 Endoscopic example of laryngomalacia. On inspiration, the epiglottic folds collapse into the airway. The lateral tips of the epiglottis are also collapsing inward *(arrow)*. *(From Slovis T, ed. Caffey's Pediatric Diagnostic Imaging, 11th ed. Philadelphia: Mosby; 2008.)*

The risk-to-benefit ratio should be assessed in each patient because these medications, particularly PPIs, have been associated with iron-deficiency anemia and increased incidence of pneumonia, gastroenteritis, and *Clostridium difficile* infections, among others. In 15–20% of patients with laryngomalacia, symptoms are severe enough to cause progressive respiratory distress, cyanosis, failure to thrive, or cor pulmonale. In these patients, surgical intervention via supraglottoplasty is considered. Supraglottoplasty is 90% successful in relieving upper airway obstruction caused by laryngomalacia. Some comorbidities, such as cardiac disease, neurologic disease, pulmonary disorders, or craniofacial anomalies, may be poor prognostic indicators that would suggest earlier intervention.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

434.2 Congenital Subglottic Stenosis

Michael Gorelik and James W. Schroeder Jr.

Congenital subglottic stenosis is the second most common cause of stridor. The subglottis is the narrowest part of the upper airway in a child and is located in the space extending from the undersurface of the true vocal folds to the inferior margin of the cricoid cartilage. Subglottic stenosis is a narrowing of the subglottic larynx and in a term newborn is defined as a cricoid diameter of less than 3.5 mm resulting from malformation of the cricoid cartilage. Subglottic stenosis manifests in the infant with respiratory distress and biphasic or primarily inspiratory stridor. It may be congenital or acquired. Symptoms may present spontaneously with a higher degree of stenosis but manifest after a respiratory tract infection because of edema and thickened secretions of a narrow and already compromised airway leading to recurrent or persistent crouplike symptoms.

Biphasic or primarily inspiratory stridor is the typical presenting symptom for congenital subglottic stenosis. In a child with recurrent bronchiolitis or croup, a diagnosis of congenital subglottic stenosis should be considered. The stenosis can be caused by an abnormally shaped elliptical cricoid cartilage; by a first tracheal ring that becomes trapped underneath the cricoid cartilage; or by soft tissue thickening caused by ductal cysts, submucosal gland hyperplasia, or fibrosis. Acquired subglottic stenosis refers to stenosis caused by extrinsic factors, most commonly resulting from prolonged intubation, and is discussed in further detail in Chapter 436.

DIAGNOSIS

The diagnosis made by airway radiographs is confirmed by direct laryngoscopy and bronchoscopy. During diagnostic laryngoscopy, the subglottic larynx is visualized directly and sized objectively using endotracheal tubes (Fig. 434.2). The percentage of stenosis is determined by comparing the size of the patients' larynx to a standard of laryngeal dimensions based on age. Stenosis >50% is usually symptomatic and often requires treatment. As with all cases of upper airway obstruction, tracheostomy is avoided when possible. Subglottic stenosis is typically measured using the Myer-Cotton system, with grade I through grade IV subglottic stenosis indicating the severity of narrowing. Other factors to consider aside from the degree of narrowing are whether the stenotic segment is soft or firm, which can determine the appropriate type of surgical intervention. Dilation and endoscopic laser surgery can be attempted in grade I and II, although they may not be effective because most congenital stenoses are cartilaginous. Anterior cricoid split, anterior-posterior cricoid split, tracheostomy, or laryngotracheal reconstruction with cartilage graft augmentation are surgical options typically reserved for grade III and IV subglottic stenosis. The differential diagnosis includes other anatomic anomalies, as well as a subglottic hemangiomas or respiratory papillomatosis.

434.3 Vocal Cord Paralysis

Michael Gorelik and James W. Schroeder Jr.

Vocal cord paralysis is the third most common congenital laryngeal anomaly that produces stridor in infants and children. Congenital central nervous system lesions such as Chiari malformation, myelomeningocele, and hydrocephalus or birth trauma may be associated with bilateral paralysis. Additionally, congenital anomalies of the heart or great vessels can be associated with vocal cord paralysis. Bilateral vocal cord paralysis produces airway obstruction at the level of the glottis and is manifested by respiratory distress and high-pitched inspiratory stridor, aphonatory or dysphonic sound, or inspiratory weak cry. More than 50% of cases of vocal cord paralysis in children are bilateral.

Unilateral vocal cord paralysis is most often iatrogenic, as a result of surgical treatment for aerodigestive (tracheoesophageal fistula) and cardiovascular (patent ductus arteriosus repair) anomalies and thyroid or parathyroid surgery, although it may also be idiopathic. Unilateral paralysis can lead to aspiration, coughing, and choking. Often the cry is weak and breathy, whereas stridor and other symptoms of airway obstruction are less common. Vocal cord paralysis in older children may be the result of a Chiari malformation or tumors compressing the vagus or recurrent laryngeal nerve. Vocal cord paralysis/palsies have also been reported in patients with Guillain-Barré syndrome (GBS) and its Miller Fisher variant either as an isolated finding or associated with other features of GBS. Other neurologic disorders producing vocal cord paralysis include stroke, multiple sclerosis, and other polyneuropathies. The prognosis for spontaneous recovery is better for unilateral, acquired, and right-sided paralysis.

DIAGNOSIS

The diagnosis of vocal cord paralysis is made by awake flexible laryngoscopy. The examination will demonstrate an inability or weakness to abduct the involved vocal cord. A thorough investigation for the underlying primary cause is indicated. Because of the association with other congenital lesions, evaluation includes neurology and cardiology consultations, imaging of the course of the recurrent laryngeal nerve, and diagnostic endoscopy of the larynx, trachea, and bronchi. During endoscopy, it is critical to palpate the cricoarytenoid joint to rule out joint fixation, which can be

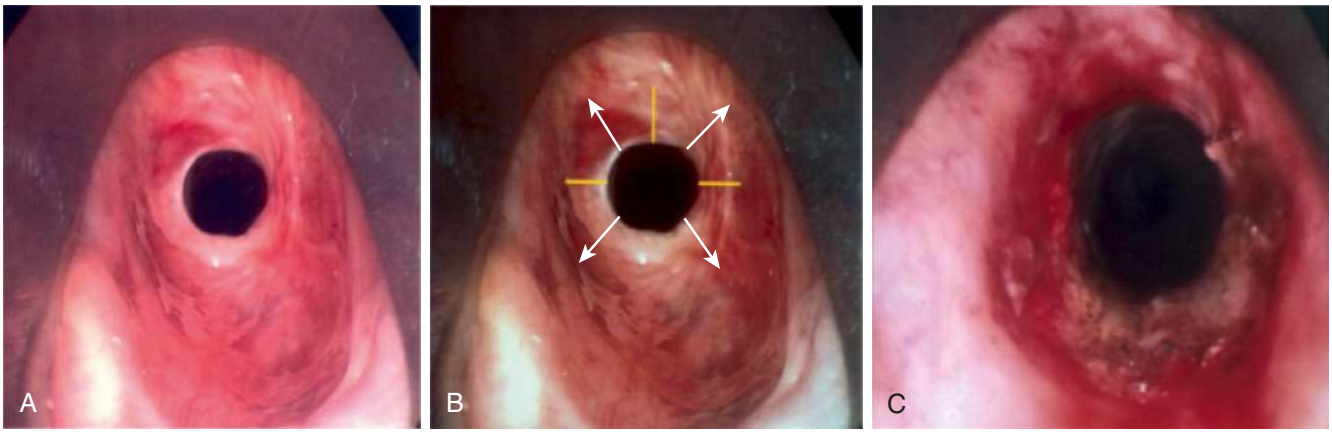

Fig. 434.2 Endoscopic repair of subglottic stenosis with radial cuts at 12, 3, and 9 o'clock positions using a laryngeal sickle knife or laser. **A,** Preoperative view. **B,** Diagram of planned incisions. **C,** After cuts and balloon dilation. *(From Lawlor CM, Rahbar R, Choi SS. Glottic and subglottic stenosis and related voice disorders. In: Lesperance MM, ed. Cummings Pediatric Otolaryngology, 2nd ed. Philadelphia: Elsevier; 2022: Fig. 28.8, p. 409.)*

mistaken for bilateral vocal fold paralysis. Intraoperative laryngeal electromyography (EMG) is the most specific and sensitive test to determine the presence of vocal cord paralysis.

TREATMENT

Treatment is based on the severity of the symptoms. Idiopathic vocal cord paralysis in infants usually resolves spontaneously within 6-12 months. If it is not resolved by 2-3 years of age, function typically does not recover. Patients with unilateral vocal cord paralysis often do not require intervention secondary to spontaneous recovery or compensation for the contralateral vocal cord. If there is persistent dysphonia or aspiration, surgical options include vocal fold injection, surgical medialization, or reinnervation using the ansa cervicalis, which has been successful in regaining unilateral vocal cord function. Postoperative voice therapy is helpful to achieve optimum results.

Bilateral paralysis may require temporary tracheotomy in 50% of patients. Airway augmentation procedures in bilateral vocal cord paralysis typically focus on widening the posterior glottis, such as an endoscopically placed or open posterior glottis cartilage graft, arytenoidectomy, or arytenoid lateralization, sometimes in conjunction with cordotomy. These procedures are generally successful in reducing the obstruction; however, they may result in dysphagia and aspiration.

434.4 Congenital Laryngeal Webs and Atresia

Michael Gorelik and James W. Schroeder Jr.

Congenital laryngeal webs account for about 5% of congenital laryngeal anomalies. They are typically located in the anterior glottis with subglottic extension and associated subglottic stenosis. During early embryogenesis, laryngeal webs form if the laryngotracheal lumen fails to fully recannulate. The clinical presentation ranges from asymptomatic, to dysphonia, to severe airway compromise secondary to the degree of obstruction caused by the web. Laryngeal webs are categorized from type I to type IV, which is the most severe.

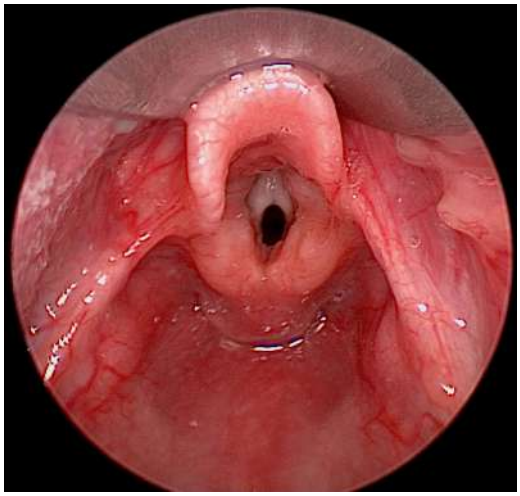

Fig. 434.3 Anterior glottic web, endoscopic view. *(Courtesy Dr. Jeff Rastatter, Division of Pediatric Otolaryngology, Lurie Children's Hospital, Chicago, IL.)*

Laryngeal atresia occurs as a complete glottic web due to failure of laryngeal and tracheal recanalization and may be associated with tracheal agenesis and tracheoesophageal fistula. Laryngeal atresia may be detected in the prenatal period, and preparations should be made for establishment of definitive airway, either before or at birth. Other times, congenital laryngeal atresia is a cause of respiratory distress in the newborn and is diagnosed only upon initial direct laryngoscopy.

Diagnosis is made by direct laryngoscopy (Fig. 434.3). Thick webs may be suspected in lateral radiographs of the airway. Chromosomal and congenital cardiovascular anomalies, as well as chromosome 22q11 deletion, are common in patients with laryngeal webs. Treatment may require only incision or dilation for thin webs. Thick webs can require laryngofissure and temporary stenting. Webs with associated subglottic stenosis are likely to require cartilage augmentation of the cricoid cartilage (laryngotracheal reconstruction). Voice outcomes are variable after surgical management.

434.5 Congenital Subglottic Hemangioma

Michael Gorelik and James W. Schroeder Jr.

See also Chapter 438.3.

Subglottic infantile hemangiomas are benign vascular malformations and a rare cause of early infancy respiratory distress. They present more commonly in females than in males, with symptoms of a barky cough and inspiratory or biphasic stridor in the absence of dysphonia. Symptoms typically present within the first 1-6 months of life. The most common presenting symptom is biphasic stridor, somewhat more prominent during inspiration. This is exacerbated by crying and acute viral illnesses. A barking cough, hoarseness, and symptoms of recurrent or persistent croup are typical and can mask the diagnosis. Roughly 50% of those with a subglottic hemangioma will have a cutaneous hemangioma, but only 1% of children who have cutaneous hemangiomas will have a subglottic hemangioma (see Chapter 691). However, a facial hemangioma in the beard distribution (preauricular area, lips, chin, and neck) is associated with a much higher incidence of subglottic hemangiomas and, when present, should prompt further investigation. Chest and neck radiographs can show the characteristic asymmetric narrowing of the subglottic larynx. CT and MRI can also assist with the diagnosis. Airway vascular lesions may also be associated with **PHACES syndrome**, characterized by posterior fossa malformations, hemangioma, arterial lesions of the head and neck, cardiac anomalies, eye anomalies, and sternal cleft (see Chapter 691). More than 50% of children with PHACES syndrome have an airway vascular lesion. Treatment options range from conservative monitoring, medical management, steroid injection, laser treatment, and open surgical resection to tracheotomy and airway reconstruction. Propranolol has become a mainstay in initial therapy of subglottic hemangioma; however, it is estimated that up to 50% of patients with subglottic hemangioma may not have a long-term response to propranolol, indicating a need for close airway monitoring in these patients (Fig. 434.4). Treatment is further discussed in Chapter 438.3.

434.6 Laryngoceles and Saccular Cysts

Michael Gorelik and James W. Schroeder Jr.

Saccular cysts and laryngoceles are uncommon etiologies of pediatric airway obstruction. A laryngocele is an abnormal air-filled dilation of the laryngeal saccule that arises vertically between the false vocal cord, the base of the epiglottis, and the inner surface of the thyroid cartilage. As there is open communication with the laryngeal lumen when it intermittently fills with air, this can lead to hoarseness and dyspnea. Laryngoceles may be confined to the larynx or extend into the neck and are described as internal, external, or both. A saccular cyst (congenital cyst of the larynx) is distinguished from the laryngocele in that its lumen is isolated from the interior of the larynx and it contains mucus, not air. Saccular cysts can be located in the anterior and lateral portions of the glottis and supraglottis. In infants and children, laryngoceles cause hoarseness and dyspnea that may increase with crying. Saccular cysts may cause respiratory distress and stridor at birth and may require early airway intervention. Infection of saccular cysts can lead to rapid expansion and acute airway compromise. Intubation can be challenging because the supraglottic and laryngeal anatomy may be distorted. In addition, complete airway obstruction may occur on induction with neuromuscular blockade because of decreased laryngeal tone. A saccular cyst may be visible on radiography, but the diagnosis is made by laryngoscopy (Fig. 434.5). Needle aspiration of the cyst confirms the diagnosis but rarely provides a cure. Surgical excision is the therapy of choice for management of saccular cysts and laryngoceles. Approaches include endoscopic CO_2 laser excision, endoscopic extended ventriculotomy (marsupialization or unroofing), or, traditionally, external excision.

Fig. 434.5 Endoscopic photograph of a saccular cyst. *(From Ahmad SM, Soliman AMS. Congenital anomalies of the larynx. Otolaryngol Clin North Am. 2007;40:177–191, Fig. 3.)*

434.7 Posterior Laryngeal Cleft and Laryngotracheoesophageal Cleft

Michael Gorelik and James W. Schroeder Jr.

The posterior laryngeal cleft is the result of a deficiency in the midline of the posterior larynx caused by a failure of fusion of the posterior cricoid lamina. This results in an abnormal communication between the posterior larynx and esophagus leading to aspiration. Posterior laryngeal clefts are categorized into four types depending how far inferiorly the cleft extends. A **type I cleft** extends to, but not beyond, the vocal cords. A **type II cleft** extends beyond the vocal cords to, but not through, the cricoid cartilage. A **type III cleft** extends through the cricoid cartilage into the cervical trachea. A

type IV cleft extends into the thoracic trachea. Laryngeal clefts can occur in families and are likely to be associated with tracheal agenesis, tracheoesophageal fistula, and multiple congenital anomalies, including Opitz-Frias syndrome, Townes-Brock syndrome, chromosome 1q43 deletion, trisomy 21, and Pallister-Hall syndrome.

Type I clefts may cause mild symptoms, but at least 60% of these will cause no symptoms and will not require surgical repair. Type I and, more commonly, type II clefts can present with feeding problems, recurrent aspiration, pneumonias, or respiratory complaints. Infants with type III and IV clefts will present more commonly in the newborn period with significant aspiration and respiratory distress.

Diagnostic workup includes an esophagogram, which is undertaken to evaluate the presence of aspiration or laryngeal penetration of ingested contrast material. A FEES exam may be undertaken by an otolaryngologist with the assistance of a speech-language and pathology team to observe patterns of liquid spillage during swallow and may identify a cleft. However, the gold standard of diagnosis remains operative laryngoscopy and bronchoscopy with palpation of the posterior larynx. This assists in determining the length of the cleft and guides treatment options.

Treatment is based on the cleft type and the symptoms; in general, a type I cleft may be managed endoscopically, whereas higher grades may require an open procedure. Stabilization of the airway is the first priority. Gastroesophageal reflux must be controlled, and a careful assessment for other congenital anomalies is undertaken before repair. Several endoscopic and open cervical and transthoracic surgical repairs have been described.

434.8 Vascular and Cardiac Anomalies

Michael Gorelik and James W. Schroeder Jr.

Aberrant cardiopulmonary vascular anatomy may directly affect the trachea and bronchi, resulting in respiratory and feeding problems (Fig. 434.6). The aberrant innominate artery is the most common cause of secondary tracheomalacia (see Chapter 481). It may be asymptomatic and discovered incidentally, or it may cause severe symptoms. Expiratory wheezing and cough occur and, rarely, reflex apnea or "dying spells." Surgical intervention is rarely necessary. Infants are most commonly treated expectantly because the problem is often self-limited.

The term *vascular ring* is used to describe vascular anomalies that result from abnormal development of the aortic arch complex. Vascular rings are categorized as complete or incomplete. Double aortic arch is the most common type of complete vascular ring, followed by right aortic arch with aberrant left subclavian artery and left ligamentum arteriosum. These account for more than 95% of complete rings. The double aortic arch encircles and compresses both the trachea and esophagus. With few exceptions, these patients are symptomatic by 3 months of age. Respiratory symptoms predominate, but dysphagia may be present. The diagnosis is established by barium esophagogram that shows a posterior indentation of the esophagus by the vascular ring (see Fig. 434.6). CT or MRI with angiography provides the cardiothoracic surgeon the information needed. Surgical treatment for symptomatic patients entails division of the vascular ring.

Other vascular anomalies include the pulmonary artery sling, which also requires surgical correction. The most common open (incomplete) vascular ring is the left aortic arch with aberrant right subclavian artery. It is usually asymptomatic, although dysphagia lusoria has been described. This is characterized as dysphagia caused by an aberrant subclavian artery coursing behind the esophagus, leading to esophageal compression and difficulty with bolus transit.

Congenital cardiac defects are likely to compress the left main bronchus or lower trachea. Any condition that produces significant pulmonary hypertension increases the size of the pulmonary arteries, which in turn causes compression of the left main bronchus. Surgical correction of the underlying pathology to relieve pulmonary hypertension relieves the airway compression.

434.9 Tracheal Stenoses, Webs, and Atresia

Michael Gorelik and James W. Schroeder Jr.

Long-segment congenital tracheal stenosis with *complete* tracheal rings typically presents within the first year of life, usually after a crisis has been precipitated by an acute respiratory illness. The diagnosis may be suggested by plain radiographs. CT with contrast delineates associated intrathoracic anomalies such as the pulmonary artery sling (in ~30%) or other cardiac anomalies (in about 25%), which can occur in one third of patients to one fourth of patients, respectively. Bronchoscopy is the best method to define the degree and extent of the stenosis and the associated abnormal bronchial branching pattern. Care must be taken to avoid traumatic passage of a telescope or bronchoscope through a stenotic or edematous segment, as even minor mucosal trauma may precipitate complete airway obstruction. Treatment of clinically significant stenosis involves tracheal resection of short-segment stenosis, slide tracheoplasty for long-segment stenosis, or tracheal rings. Total autologous tracheal replacement is another option. Congenital soft tissue stenosis and thin webs are rare. Dilation may be all that is required.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

434.10 Foregut Cysts

Michael Gorelik and James W. Schroeder Jr.

The embryologic foregut gives rise to the pharynx, lower respiratory tract, esophagus, stomach, duodenum, and hepatobiliary tract. Foregut duplication cysts arise if heterotopic rests of foregut-derived epithelium persist anywhere along this tract. Foregut duplications account for approximately one third of all duplications. The bronchogenic cyst, intramural esophageal cyst (esophageal duplication), and enteric cyst can all produce symptoms of respiratory obstruction and dysphagia. The diagnosis is suspected when chest radiographs or CT scan delineates the mass and, in the case of enteric cyst, the associated vertebral anomaly. The treatment of all foregut cysts is surgical excision.

Chapter 435

Foreign Bodies in the Airway

Michael Gorelik and James W. Schroeder Jr.

Choking is a leading cause of morbidity and mortality among children, especially those younger than 4 years of age. From 2001 to 2009, an average of 12,435 children ages 0-14 years in the United States were treated in emergency departments for choking on food without fatality. The majority of children found to have foreign body aspiration are older infants and toddlers (Fig. 435.1), with males being 1.7 times more likely than females to aspirate a foreign body. Roughly 80% of airway foreign body aspirations occur in children younger than 3 years old, with a peak in incidence between ages 1 and 2. Food items ranging from nuts, seeds, popcorn, and food particles to hardware and pieces of toys account for 59.5–81% of all cases. Nonfood and inorganic objects such as coins, paper clips, pen caps, or small toys are more commonly aspirated by older children. Globular, compressible, or round objects such as hot dogs, grapes, nuts, balloons, marshmallows, meats, and candies are particularly hazardous because of their ability to completely occlude the airway.

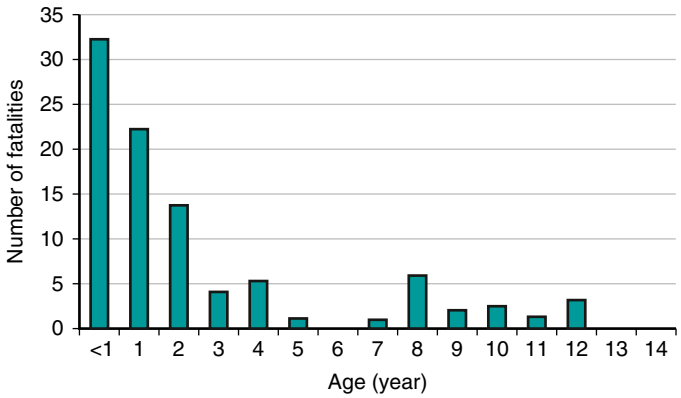

Fig. 435.1 Number of fatalities versus victim age, all fatality types. *(From Milkovich SM, Altkorn R, Chen X, et al. Development of the small parts cylinder: lessons learned. Laryngoscope. 2008;118[11]:2082–2086.)*

Younger children are at a higher risk for foreign body aspiration largely secondary to their developmental vulnerabilities and immature swallow function. Infants and toddlers often use their mouths to explore their surroundings, and children are more likely to be distracted, playing, or ambulatory while eating. Infants have the ability to suck and swallow and are equipped with basic involuntary reflexes (gag, cough, and glottis closure) that help to protect against aspiration during swallowing. Dentition develops at approximately 6 months of age with the eruption of the incisors, whereas molars do not erupt until approximately 1.5 years of age. Mature mastication takes longer to develop.

Despite these various protective mechanisms, a child's airway is more vulnerable to obstruction than an adult's airway. Young children are more likely to experience significant obstruction by small foreign bodies because of the smaller diameter of the pediatric airway. Mucus and secretions may form a seal around the foreign body, making it more difficult to dislodge by forced exhalation. In addition, the force of air generated by an infant's or young child's cough is less effective in dislodging an airway obstruction. For these reasons, it is recommended that children younger than 5 years of age avoid foods like hard candy or chewing gum and that raw fruits and vegetables be cut into small pieces. Additionally, children with developmental delays or neurologic and muscular disorders are at higher risk for foreign body aspiration.

CLINICAL MANIFESTATIONS

Foreign bodies of the airway have variable presentations and complications, depending on the characteristics, duration, and location of the foreign body. The clinical manifestations range from an asymptomatic state to severe respiratory distress. A high index of suspicion is often required, as delayed presentation is common, with more than 50% of cases presenting after 24 hours of the suspected aspiration event. The most serious complication of foreign body aspiration is complete obstruction of the airway, which may be recognized in the conscious child as sudden respiratory distress followed by an inability to speak or cough.

There are typically three stages of symptoms that result from aspiration of an object into the airway:

1. **Initial event:** Paroxysms of coughing, choking, gagging, and possible airway obstruction occur immediately after aspiration of the foreign body. This may be accompanied by tachypnea and stridor. The child is sometimes able to expel the foreign body during this stage.
2. **Asymptomatic interval:** The foreign body becomes lodged, reflexes fatigue, and the immediate irritating symptoms subside. The lack of symptoms can be particularly misleading to the provider when a child presents in this stage and accounts for a large percentage of delayed diagnoses and overlooked foreign bodies. Some patients with delayed presentation may eventually develop dyspnea, wheezing, or chronic cough.
3. **Complications:** Obstruction, erosion, or infection develops, which again directs attention to the presence of a foreign body. In this third stage, complications include fever, cough, hemoptysis, pneumonia, and atelectasis. Acute or chronic complications have been reported in almost 15% of cases of foreign bodies of the airway.

DIAGNOSIS

The clinical history is the most important factor in determining the need for operative bronchoscopy. A positive history must never be ignored, but a negative history can be misleading. Because nuts and seeds are the most common bronchial foreign bodies, the physician should specifically question the child's parents about these items, though it is important to keep in mind that aspiration events can be unwitnessed. Choking or coughing episodes accompanied by new-onset wheezing and asymmetric breath sounds are highly suggestive of a foreign body in the airway, and bronchoscopy should be carried out promptly. A comprehensive physical exam is also essential, including examination of the nose, oral cavity, pharynx, neck, and lungs. Several reliable physical exam findings for airway foreign bodies include cough, decreased lung sounds, and wheezing. In addition to history and physical examination, radiology studies have an important role in diagnosing foreign bodies in the airway. Plain films are typically recommended first, although many foreign bodies are radiolucent (80–96%), and therefore providers often must rely on secondary findings (such as air trapping, asymmetric hyperinflation, obstructive emphysema, atelectasis, mediastinal shift, and consolidation) to indicate suspicion of a foreign body. Expiratory or lateral decubitus films can assist in revealing these suggestive secondary findings. The indication for computed tomography of the chest is currently being explored because of its high sensitivity and specificity, its ability to detect radiolucent objects, and its potential to eliminate the need for anesthesia and a procedure. However, with the known risks of radiation and the time-sensitive need for intervention, advanced imaging is rarely obtained. However, even in the absence of radiologic evidence on plain films, when the history and physical examination are suggestive of aspiration, bronchoscopy should be pursued.

TREATMENT

The treatment of choice for airway foreign bodies is prompt endoscopic removal with rigid instruments by a specialist (otolaryngologist or pulmonologist). Bronchoscopy is deferred only until providers have obtained preoperative studies and the patient has been prepared by adequate hydration and emptying of the stomach, though this can depend on the acuity of the clinical scenario. Airway foreign bodies are usually removed the same day the diagnosis is first considered. As with any treatment modality, providers must give careful consideration to the risks and benefits of the bronchoscopy procedure when the diagnosis is unclear. Potential complications of rigid bronchoscopy include bronchospasm, desaturation, bleeding, and airway edema; need for intubation; repeat procedures; and the inherent risks of anesthesia. Many surgeons maintain a lower threshold for intervention with the appropriate clinical history given the high risk of complications for a missed foreign body. Beyond the understanding of diagnosis and management of airway foreign bodies, there is a strong need and push for awareness, education, and prevention among caregivers, healthcare providers, and manufacturers of food and toys.

435.1 Laryngeal Foreign Bodies

Michael Gorelik and James W. Schroeder Jr.

Although laryngeal foreign bodies are less common (2–12% of cases) than bronchial or tracheal foreign bodies, they are particularly dangerous because of the risk of complete laryngeal obstruction, which can lead to asphyxiation unless it is promptly relieved with the Heimlich maneuver (see Chapter 79 and Figs. 79.6 and 79.7). As with airway foreign bodies in other locations, the presenting symptoms of laryngeal foreign bodies are determined by the size, shape, nature, and degree of obstruction. Objects that conform to the larynx can lead to complete obstruction, whereas with smaller objects the presentation can range from dysphonia, aphonia, stridor, cough, dyspnea, cyanosis, hemoptysis, and crouplike symptoms.

Clinical history is critical to establish an early diagnosis, and prompt intervention is critical.

435.2 Tracheal Foreign Bodies

Michael Gorelik and James W. Schroeder Jr.

Tracheal foreign bodies account for 3–12% of airway foreign body cases. Children who have tracheal foreign bodies can present with dysphonia, dysphagia, dry cough, or biphasic stridor. Posteroanterior and lateral soft tissue neck radiographs (airway films) are abnormal in 92% of children, whereas chest radiographs are abnormal in only 58% of these cases.

435.3 Bronchial Foreign Bodies

Michael Gorelik and James W. Schroeder Jr.

The majority of airway foreign bodies lodge in a bronchus (80–90% of cases) with a propensity to the right side. Occasionally, fragments of a foreign body may produce bilateral involvement or shifting infiltrates if they move from lobe to lobe. Some children with bronchial foreign bodies present asymptomatically, whereas others have asymmetric breath sounds, cough, and wheezing. Posteroanterior and lateral chest radiographs (including the abdomen) are standard in the diagnostic evaluation of infants and children suspected of having aspirated a foreign object. An expiratory posteroanterior chest film is most helpful. During expiration, the bronchial foreign body obstructs the exit of air from the obstructed lung, producing obstructive emphysema and air trapping. The persistent inflation of the obstructed lung causes a shift of the mediastinum toward the opposite side (Fig. 435.2). Air trapping is an immediate complication, whereas atelectasis is a late finding. Lateral decubitus chest films or fluoroscopy can provide the same information as expiratory films but are often unnecessary. Low-dose CT is considered by some a standard imaging study if previous conventional imaging is nondiagnostic. Clinical history and physical examination, not radiographs, ultimately determine the indication for bronchoscopy.

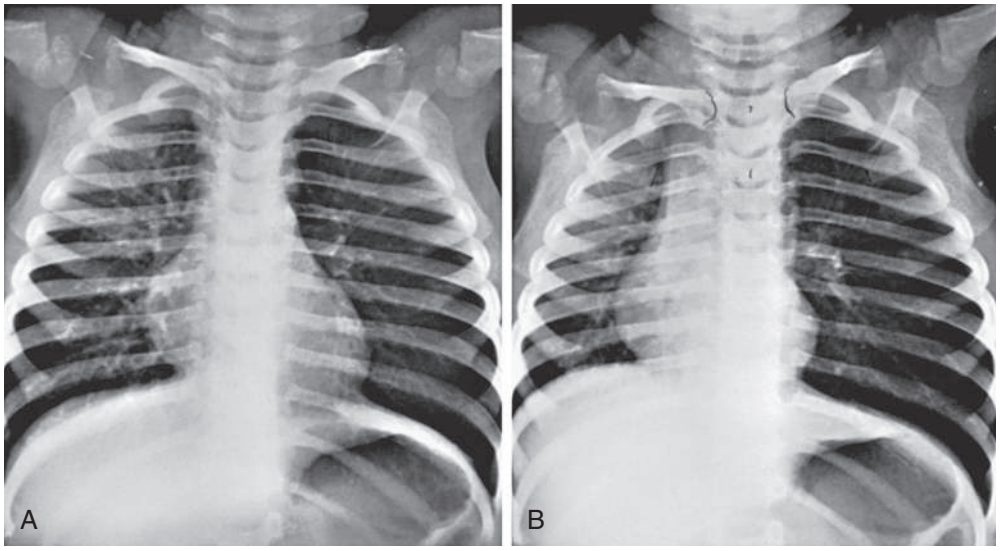

Fig. 435.2 A, Normal inspiratory chest radiograph in a toddler with a peanut fragment in the left main bronchus. B, Expiratory radiograph of the same child showing the classic obstructive emphysema (air trapping) on the involved (left) side. Air leaves the normal right side, allowing the lung to deflate. The medium shifts toward the unobstructed side.

Chapter 436

Laryngotracheal Stenosis and Subglottic Stenosis

Taher S. Valika and James W. Schroeder Jr.

Laryngotracheal stenosis is the second most common cause of stridor in neonates and is the most common cause of airway obstruction requiring tracheostomy in infants. The glottis (vocal cords) and the upper trachea are compromised in most cases of laryngeal stenosis, particularly those that develop after endotracheal intubation. Subglottic stenosis is a narrowing of the subglottic larynx, which is the space extending from the undersurface of the true vocal cords to the inferior margin of the cricoid cartilage. **Subglottic stenosis** is considered congenital when there is no other apparent cause such as a history of laryngeal trauma or intubation. Approximately 90% of cases manifest in the first year of life. Management relies on optimizing the airway, while ensuring the patient continues to grow. Knowledge of preventive measures is imperative to all healthcare members.

436.1 Congenital Subglottic Stenosis

See Chapter 434.2.

436.2 Acquired Laryngotracheal Stenosis

Taher S. Valika and James W. Schroeder Jr.

Ninety percent of acquired stenoses are a result of endotracheal intubation. The narrowest portion of the pediatric larynx is the subglottic region because of the narrow cricoid cartilage. When the pressure of the endotracheal tube against the cricoid mucosa is greater than the capillary pressure, ischemia occurs, followed by necrosis and ulceration. Secondary infection and perichondritis develop with exposure of cartilage (Fig. 436.1). Granulation tissue forms around the ulcerations. These changes and edema throughout the larynx usually resolve spontaneously after extubation. Chronic edema and fibrous stenosis develop in only a small percentage of cases.

A number of factors predispose to the development of laryngeal stenosis. Laryngopharyngeal reflux of acid and pepsin from the stomach is known to exacerbate endotracheal tube trauma. More damage is caused in areas left unprotected, owing to loss of mucosa. Congenital subglottic stenosis narrows the larynx, which makes the patient more likely to develop acquired subglottic stenosis because significant injury is more likely to occur with use of an endotracheal tube of age-appropriate size. *Other risk factors for the development of acquired subglottic stenosis include sepsis, malnutrition, chronic inflammatory disorders, and immunosuppression.* An oversized endotracheal tube is the most common factor contributing to laryngeal injury. A tube that allows a small air leak at the end of the inspiratory cycle minimizes potential trauma. Other extrinsic factors—traumatic intubation, multiple reintubations, movement of the endotracheal tube, and duration of intubation—can contribute to varying degrees in individual patients.

CLINICAL MANIFESTATIONS

Symptoms of acquired and congenital stenosis are similar. Spasmodic croup, the sudden onset of severe croup in the early morning hours, is usually caused by laryngopharyngeal reflux with transient laryngospasm and subsequent laryngeal edema. These frightening episodes resolve rapidly, often before the family and child reach the emergency department. Other presentations can also involve neonates who fail extubation, despite multiple attempts, and children with permanent dyspnea, stridor, or dysphonia.

Fig. 436.1 Bronchoscopy in a 2-mo-old infant showing mucosal erosion and cartilage exposure in the subglottic region. The child was intubated with an age-appropriate tube but with an excess of air in the cuff. *(Courtesy Dr. Taher S. Valika, Division of Pediatric Otolaryngology, Ann & Robert H. Lurie Children's Hospital of Chicago.)*

DIAGNOSIS

The diagnosis can be made by posteroanterior and lateral airway radiographs. The gold standard to confirm the diagnosis is via direct laryngoscopy and bronchoscopy in the operating room. High-resolution CT imaging and ultrasonography are of limited value. This is similar to the workup associated with congenital subglottic stenosis.

TREATMENT

The severity, location, and type (cartilaginous or soft tissue) of the stenosis determine the treatment. Mild cases can be managed without operative intervention because the airway will improve as the child grows. Moderate soft tissue stenosis is treated by endoscopy using gentle dilations or CO_2 laser. Severe laryngotracheal stenosis is likely to require laryngotracheal reconstructive (expansion) surgery or resection of the narrowed portion of the laryngeal and tracheal airway (cricotracheal resection). Every effort is made to avoid tracheotomy using endoscopic techniques or open surgical procedures.

Fundamental knowledge of the airway can help reduce the incidence of stenoses. The use of age-appropriate tubes and cuffless tubes, treatment of gastroesophageal reflux, and reducing the duration of mechanical ventilation have led to an overall decrease in laryngotracheal stenoses in the past decade.

Chapter 437
Bronchomalacia and Tracheomalacia

Jonathan D. Finder

Tracheomalacia and bronchomalacia refer to *chondromalacia* of a central airway, leading to insufficient cartilage to maintain airway patency throughout the respiratory cycle. These are common causes of persistent wheezing in infancy. Tracheomalacia and bronchomalacia can be either primary or secondary (Table 437.1). Primary tracheomalacia and bronchomalacia are often seen in premature infants, although most affected patients are born at term. Secondary tracheomalacia and bronchomalacia refer to the situation in which the central airway is compressed by an adjacent structure (e.g., vascular ring; see Fig. 434.6) or is deficient in cartilage because of tracheoesophageal fistula (see Chapter 365). Bronchomalacia is common after lung transplantation, assumed to be secondary to the loss of bronchial artery supply leading to ischemia of the bronchial cartilage. This form of bronchomalacia may take months to

Table 437.1 Classification of Tracheomalacia

PRIMARY TRACHEOMALACIA
Congenital absence of tracheal-supporting cartilages
SECONDARY TRACHEOMALACIA
Esophageal atresia, tracheoesophageal fistula
Vascular rings (double aortic arch)
Tracheal compression from an aberrant innominate artery
Tracheal compression from mediastinal masses
Abnormally soft tracheal cartilages associated with connective tissue disorders
Prolonged mechanical ventilation, chronic lung disease

From McNamara VM, Crabbe DC. Tracheomalacia. *Paediatr Respir Rev.* 2004;5:147–154.

436.2 Acquired Laryngotracheal Stenosis

Taher S. Valika and James W. Schroeder Jr.

Ninety percent of acquired stenoses are a result of endotracheal intubation. The narrowest portion of the pediatric larynx is the subglottic region because of the narrow cricoid cartilage. When the pressure of the endotracheal tube against the cricoid mucosa is greater than the capillary pressure, ischemia occurs, followed by necrosis and ulceration. Secondary infection and perichondritis develop with exposure of cartilage (Fig. 436.1). Granulation tissue forms around the ulcerations. These changes and edema throughout the larynx usually resolve spontaneously after extubation. Chronic edema and fibrous stenosis develop in only a small percentage of cases.

A number of factors predispose to the development of laryngeal stenosis. Laryngopharyngeal reflux of acid and pepsin from the stomach is known to exacerbate endotracheal tube trauma. More damage is caused in areas left unprotected, owing to loss of mucosa. Congenital subglottic stenosis narrows the larynx, which makes the patient more likely to develop acquired subglottic stenosis because significant injury is more likely to occur with use of an endotracheal tube of age-appropriate size. *Other risk factors for the development of acquired subglottic stenosis include sepsis, malnutrition, chronic inflammatory disorders, and immunosuppression.* An oversized endotracheal tube is the most common factor contributing to laryngeal injury. A tube that allows a small air leak at the end of the inspiratory cycle minimizes potential trauma. Other extrinsic factors—traumatic intubation, multiple reintubations, movement of the endotracheal tube, and duration of intubation—can contribute to varying degrees in individual patients.

Chapter 437
Bronchomalacia and Tracheomalacia

Jonathan D. Finder

Tracheomalacia and bronchomalacia refer to *chondromalacia* of a central airway, leading to insufficient cartilage to maintain airway patency throughout the respiratory cycle. These are common causes of persistent wheezing in infancy. Tracheomalacia and bronchomalacia can be either primary or secondary (Table 437.1). Primary tracheomalacia and bronchomalacia are often seen in premature infants, although most affected patients are born at term. Secondary tracheomalacia and bronchomalacia refer to the situation in which the central airway is compressed by an adjacent structure (e.g., vascular ring; see Fig. 434.6) or is deficient in cartilage because of tracheoesophageal fistula (see Chapter 365). Bronchomalacia is common after lung transplantation, assumed to be secondary to the loss of bronchial artery supply leading to ischemia of the bronchial cartilage. This form of bronchomalacia may take months to

Table 437.1 Classification of Tracheomalacia

PRIMARY TRACHEOMALACIA
Congenital absence of tracheal-supporting cartilages
SECONDARY TRACHEOMALACIA
Esophageal atresia, tracheoesophageal fistula
Vascular rings (double aortic arch)
Tracheal compression from an aberrant innominate artery
Tracheal compression from mediastinal masses
Abnormally soft tracheal cartilages associated with connective tissue disorders
Prolonged mechanical ventilation, chronic lung disease

From McNamara VM, Crabbe DC. Tracheomalacia. *Paediatr Respir Rev.* 2004;5:147–154.

present after transplantation. Laryngomalacia can accompany primary bronchomalacia or tracheomalacia. Involvement of the entire central airway (laryngotracheobronchomalacia) is also seen.

CLINICAL MANIFESTATIONS

Primary tracheomalacia and bronchomalacia are principally disorders of infants, with a male:female ratio of 2:1. The dominant finding—low-pitched, monophonic wheezing heard predominantly during expiration—is most prominent over the central airways. Parents often describe persistent respiratory congestion even in the absence of a viral respiratory infection. When the lesion involves only one main bronchus (more commonly the left), the wheezing is louder on that side and there may be unilateral palpable fremitus. In cases of tracheomalacia, the wheeze is loudest over the trachea. Hyperinflation and/or subcostal retractions do not occur unless the patient has concurrent dysphagia with chronic aspiration, viral bronchiolitis, asthma, or other causes of peripheral airway obstruction. In the absence of asthma, patients with tracheomalacia and bronchomalacia are not helped by administration of a bronchodilator. Acquired tracheomalacia and bronchomalacia are seen in association with vascular compression (vascular rings, slings, and innominate artery compression) or in association with the loss of bronchial artery supply in lung transplantation. Persistent tracheomalacia is the rule after correction of tracheoesophageal fistula. Other causes of acquired tracheomalacia and bronchomalacia (especially left-sided) include cardiomegaly. The importance of the physical exam cannot be understated; one study found that pediatric pulmonologists made a correct assessment of malacia based on symptoms, history, and lung function before bronchoscopy in ~70% of cases. The cough in tracheomalacia and bronchomalacia can lead to collapse of the airway, which can lead to difficulty in airway clearance. The cough in tracheomalacia and bronchomalacia often has a barking, croupy quality. This can be managed in older patients with handheld positive expiratory pressure devices. Persistent cough in older children with tracheomalacia can cause irritation of the airway mucosa from the physical trauma and induce some degree of habitual cough.

DIAGNOSIS

Definitive diagnoses of tracheomalacia and bronchomalacia are established by flexible or rigid bronchoscopy (Fig. 437.1). The lesion is difficult to detect on plain radiographs. Although fluoroscopy can demonstrate dynamic collapse and avoid the need for invasive diagnostic techniques, it is poorly sensitive. Pulmonary function testing can show a pattern of decreased peak flow and flattening of the flow-volume loop. Other important diagnostic modalities include MRI and CT scanning. Dynamic airway assessment using three-dimensional CT reconstruction at end-inspiration and end-expiration can be diagnostic and avoid the need for invasive evaluation. MRI with angiography is especially useful when there is a possibility of vascular ring and should be performed when a right aortic arch is seen on plain film radiography.

TREATMENT

Postural drainage can help with clearance of secretions. β-Adrenergic agents *should be avoided* in the absence of asthma because they can exacerbate loss of airway patency due to decreased airway tone. Nebulized ipratropium bromide may be useful. Endobronchial stents have been used in severely affected patients but have a high incidence of complications, ranging from airway obstruction caused by granulation tissue to erosion into adjacent vascular structures. Continuous positive airway pressure via tracheostomy may be indicated for severe cases. A surgical approach (aortopexy and bronchopexy) is rarely required and only for patients who have life-threatening apnea, cyanosis, and bradycardia (cyanotic spells) from airway obstruction and/or who demonstrated vascular compression. Reports of creation and use of three-dimensional (3D) printed, bioresorbable external tracheobronchial stents in pediatric patients with life-threatening tracheobronchomalacia have shown great promise.

PROGNOSIS

Primary bronchomalacia and tracheomalacia have excellent prognoses because airflow improves as the child and the airways grow. Patients with primary airway malacia usually take longer to recover from common respiratory infections. Wheezing at rest usually resolves by age 3 years. Prolonged bacterial bronchitis has been reported as a complication of bronchomalacia. The prognosis in secondary and acquired forms varies with cause. Patients with concurrent asthma need considerable supportive treatment and careful monitoring of respiratory status.

Chapter 438

Neoplasms of the Larynx, Trachea, and Bronchi

Saied Ghadersohi, Lauren D. Holinger, and James W. Schroeder Jr.

438.1 Vocal Nodules

Saied Ghadersohi and James W. Schroeder Jr.

Vocal nodules, which are not true neoplasms, are the most common cause of chronic hoarseness in children. Chronic vocal abuse or misuse (i.e., frequent yelling and screaming) produces localized vascular congestion, edema, hyalinization, and epithelial thickening in the bilateral vocal cords. This grossly appears as nodules that disrupt the normal vibration of the cords during phonation. Vocal abuse is the main factor, and the voice is worse in the evenings. The differential diagnosis can include unilateral lesions such as vocal cord cysts and polyps; however, these usually have an acute inciting event and are rarer in children.

Diagnosis is typically via laryngoscopy and stroboscopy to assess the characteristics of the bilateral nodules. Occasionally biopsy is needed in atypical-behaving/-appearing lesions. Treatment is primarily nonsurgical, with voice therapy used in children >4 years of age who can participate in therapy and clinical monitoring with behavioral therapy in younger children or those with developmental delay. In addition, laryngopharyngeal reflux commonly exacerbates vocal abuse–induced irritation of the cord; therefore antireflux therapy can also be implemented (see Chapter 369). Surgical excision of vocal cord nodules in children is controversial and is rarely indicated but may be necessary if the child is unable to communicate adequately, becomes aphonic, or requires tension and straining to make an utterance.

438.2 Recurrent Respiratory Papillomatosis

Saied Ghadersohi and James W. Schroeder Jr.

Papillomas are the most common respiratory tract neoplasms in children, occurring in 4.3 in 100,000. They are simply warts—benign tumors—caused by the human papillomavirus (HPV), most commonly types 6 and 11 (see Chapter 313). Seventy-five percent of recurrent respiratory papilloma (RRP) cases occur in children younger than age 5 years, but the diagnosis may be made at any age. In general, neonatal-onset disease is a poor prognostic factor with higher mortality and need for tracheostomy. Sixty-seven percent of children with RRP are born to mothers who had condylomas during pregnancy or parturition. The mode of HPV transmission is still not clear but is thought to be through exposure to HPV when traversing the birth canal of an infected mother. Other identified risk factors include first born, >10 hours of labor, and a young mother. However, HPV exposure is fairly common and RRP remains rare; additionally, in mothers with vaginal condylomata, only 1 in 231-400 vaginal births go on to develop respiratory papillomatosis. Therefore other risk factors contribute to transmission, and cesarean-section delivery for prevention cannot be recommended. However, preventive measures can include the prospective widespread use of the quadrivalent HPV vaccine to help eliminate maternal and paternal HPV reservoirs and possibly decrease cases of RRP caused by HPV-6 and -11.

CLINICAL MANIFESTATIONS

The clinical course involves remissions and exacerbations of recurrent papilloma, most commonly on the larynx (usually the vocal cords), causing progressively worsening hoarseness, sleep-disordered breathing, exertional dyspnea, stridor, and, if left untreated, eventually severe airway obstruction (Fig. 438.1). Although it is a benign disease, lesions can spread throughout the aerodigestive tract in 31% of patients, most commonly the oral cavity, trachea, and bronchi. Rarely these lesions can undergo malignant conversion (1.6%); however, some patients may have spontaneous remission. Patients may be initially diagnosed with asthma, croup, vocal nodules, or allergies.

Fig. 438.1 Laryngoscopic view of respiratory papillomas causing near-complete obstruction at glottic level. *(From Derkay CS, Wiatrak B. Recurrent respiratory papillomatosis: a review. Laryngoscope. 2008;118:1236–1245.)*

DIAGNOSIS AND TREATMENT

Diagnosis of RRP is via laryngoscopy and bronchoscopy. Biopsy should be obtained at the initial surgical intervention and regular intervals to rule out malignancy and to subtype the HPV, as it can affect prognosis. Treatment of RRP is endoscopic surgical removal with three goals. First, debulking/complete removal of the lesions; second, preservation of normal structures; and finally, prevention of scar formation in the affected areas. Most surgeons in North America prefer the microdebrider, although microsurgery, CO_2, and KTP laser techniques have been described. Despite these techniques, some form of adjunct therapy may be needed in up to 20% of cases. The most widely accepted indications for adjunct therapy are a need for more than four surgical procedures per year, rapid regrowth of papillomata with airway compromise, or distal multisite spread of disease. Adjunct therapies can be inhaled or administered intralesionally or systemically and include antiviral modalities (interferon, ribavirin, acyclovir, cidofovir), antiangiogenic agents such as bevacizumab (Avastin), photodynamic therapy, dietary supplement (indole-3-carbinol), nonsteroidal antiinflammatory drugs (COX-2 inhibitors, Celebrex), retinoids, and mumps vaccination.

438.3 Congenital Subglottic Hemangioma

Saied Ghadersohi and James W. Schroeder Jr.

See also Chapter 434.5.

Typically, congenital subglottic hemangiomas are symptomatic within the first 2 months of life, with almost all occurring before 6 months of age. Much like the cutaneous infantile hemangiomas, these lesions have two phases: a **proliferative phase** with rapid growth in the first 6 months of life and then they stabilize by 1 year and a slow **involution phase** typically by age 3. Patients present with usually inspiratory but sometimes biphasic stridor. The infant can have a barking cough and temporarily respond to steroids, similar to persistent croup. Fifty percent of congenital subglottic hemangiomas are associated

with facial lesions, but the converse is not true. Radiographs classically delineate an asymmetric subglottic narrowing. The diagnosis is made by direct laryngoscopy.

DIAGNOSIS AND TREATMENT

The diagnosis of subglottic hemangioma is based on history and laryngoscopic exam. MRI imaging with contrast can also be obtained to confirm the diagnosis of a vascular lesion. If the lesion does not respond to medical therapy, then biopsy (with GLUT1 staining; positive suggests hemangioma) may be indicated to rule out other vascular tumors. Subglottic hemangiomas are treated similarly to cutaneous hemangiomas (see Chapter 691). Propranolol is the first-line treatment of cutaneous and subglottic infantile hemangiomas. Typically, treatment is with 1-3 mg/kg/day of propranolol for 4-12 months (see Chapter 691). Prescreening patients with cardiology workup (i.e., electrocardiogram) is advised. Side effects include hypotension, bradycardia, bronchospasm, and hypoglycemia, which can be avoided by giving the medication with a feed.

There remains a role for systemic steroids, racemic epinephrine, and helium/oxygen treatment in the acute management of the airway and in lesions that are slow or nonresponsive to propranolol treatment (i.e., large hemangiomas with critical airway narrowing).

Surgical management is offered in severe cases or those not responsive to medical therapy. Interventions can range from intralesional steroid injection to avoid systemic steroid side effects, CO_2, or KTP laser endoscopic excision or open surgical excision, and ultimately as a last resort tracheostomy can establish a safe airway, allowing time for the lesion to involute per its natural course.

438.4 Vascular Malformations

Saied Ghadersohi and James W. Schroeder Jr.

Based on the International Society for the Study of Vascular Anomalies classification system, these lesions can be classified into vascular malformations and vascular tumors. The most common vascular tumors are infantile/subglottic hemangiomas. Vascular malformations are not true neoplastic lesions. They have a normal rate of endothelial turnover and various channel abnormalities. They are subcategorized based on high or low flow and by their predominant type (capillary, venous, arterial, lymphatic, or a combination thereof). Overall, vascular malformations are uncommon, and they rarely occur in the larynx and airway. When they do occur, they are often an extension from elsewhere in the head and neck. It should be noted that these lesions can expand with a viral upper respiratory infection or hemorrhage into the lesion. They can be diagnosed with direct visualization during laryngoscopy or bronchoscopy or seen on CT/MRI imaging. Treatment usually entails a tailored multidisciplinary team approach with early surgery, laser resection, or sclerotherapy.

438.5 Other Laryngeal Neoplasms

James W. Schroeder Jr. and Lauren D. Holinger

Neurofibromatosis (see Chapter 636.1) rarely involves the larynx. When children are affected, limited local resection is undertaken to maintain an airway and optimize the voice. Complete surgical extirpation is virtually impossible without debilitating resection of vital laryngeal structures. Most surgeons select the option of less aggressive symptomatic surgery because of the poorly circumscribed and infiltrative nature of these fibromas. **Rhabdomyosarcoma** (see Chapter 549) and other malignant tumors of the larynx are rare. Symptoms of hoarseness and progressive airway obstruction prompt initial evaluation by flexible laryngoscopy in the office.

438.6 Tracheal Neoplasms

Saied Ghadersohi, James W. Schroeder Jr., and Lauren D. Holinger

Tracheal tumors are extremely rare and include malignant and benign neoplasms; they may initially be misdiagnosed as asthma. The two most common benign tumors are inflammatory pseudotumor and hamartoma. The **inflammatory pseudotumor** is probably a reaction to a previous bronchial infection or traumatic insult. Growth is slow, and the tumor may be locally invasive. Hamartomas are tumors of primary tissue elements that are abnormal in proportion and arrangement.

Tracheal neoplasms manifest with stridor, wheezing, cough, or pneumonia and are rarely diagnosed until 75% of the lumen has been obstructed (Fig. 438.2). Chest radiographs or airway films can identify the obstruction. Pulmonary function studies demonstrate an abnormal flow-volume loop. A mild response to bronchodilator therapy may be misleading. Treatment is based on the histopathology.

438.7 Bronchial Tumors

Saied Ghadersohi and James W. Schroeder Jr.

Bronchial tumors are rare. In one series, carcinoid tumors were the most common, followed by mucoepidermoid and inflammatory pseudotumors. These patients can present with persistent pneumonia despite adequate treatment. The diagnosis is confirmed at bronchoscopy and biopsy; treatment depends on the histopathology.

Chapter 439
Wheezing, Bronchiolitis, and Bronchitis

439.1 Wheezing in Infants: Bronchiolitis

Samantha A. House and Shawn L. Ralston

Wheezing, the production of a musical continuous sound that originates in narrowed airways, is heard on expiration as a result of airway obstruction. Infants are more likely to wheeze than are older children as a result of differing lung mechanics. Obstruction of airflow is affected by both airway size and compliance of the infant lung. Resistance to airflow through a tube is inversely related to the radius of the tube to the fourth power. In children younger than 5 years, small-caliber peripheral airways can contribute up to 50% of the total airway resistance. Marginal additional narrowing, such as that caused by inflammation related to viral infection, is then more likely to result in wheezing.

Infant chest wall compliance is also quite high; thus the inward pressure produced in normal expiration subjects the intrathoracic airways to collapse. Differences in tracheal cartilage and airway smooth muscle tone increase the collapsibility of the infant airways in comparison with older children. These mechanisms combine to make the infant more susceptible to airway obstruction, increased resistance, and subsequent wheezing. The mechanical portion of the infant propensity to wheeze resolves with normal growth and muscular development.

Although wheezing in infants most frequently results from inflammation due to acute viral infections, there are many potential causes of wheezing (Table 439.1).

Acute Bronchiolitis

Acute bronchiolitis is a diagnostic term used to describe the clinical picture produced by multiple different viral lower respiratory tract infections in infants and very young children. The respiratory findings observed in bronchiolitis include tachypnea, wheezing, crackles, and rhonchi, which result from inflammation of the small airways (Fig. 439.1). Despite its commonality, a universal set of diagnostic criteria for bronchiolitis does not exist, with significant disagreement about the upper age limit for appropriate use of the diagnosis. Some clinicians restrict the term to children younger than 1 year, and others extend it to the age of 2 years or beyond.

The pathophysiology of acute bronchiolitis is characterized by bronchiolar obstruction with edema, mucus, and cellular debris (see Fig. 439.1). Resistance in the small air passages is increased during both inspiration and exhalation, but because the radius of an airway is smaller during expiration, the resultant respiratory obstruction leads to expiratory wheezing, air trapping, and lung hyperinflation. If obstruction becomes complete, trapped distal air will be resorbed and the child will develop atelectasis. Hypoxemia may result from ventilation-perfusion mismatch. Hypercapnia may develop with severe obstructive disease.

Respiratory syncytial virus (RSV) is responsible for more than 50% of cases of bronchiolitis. Other causal agents include human metapneumovirus, rhinovirus, parainfluenza, influenza, coronavirus, bocavirus, and adenovirus, among others. Viral *co-infection* can occur; the impact of co-infection on severity and clinical manifestations of bronchiolitis remains unclear. Respiratory viruses can be identified in more than one third of asymptomatic patients younger than the age of 1 year, calling into question the specificity of nucleic acid amplification tests for active infection with some viruses. Although bacterial pneumonia is sometimes confused clinically with bronchiolitis, viral bronchiolitis is only rarely followed by bacterial superinfection.

Over 100,000 young children are typically hospitalized annually in the United States with the diagnosis of bronchiolitis, making it the most common diagnosis resulting in hospitalization for children younger than 1 year of age in the United States over the past several decades. Hospitalization rates have been relatively stable in pre–COVID-19 pandemic years despite introduction and routine use of RSV immunoprophylaxis in selected high-risk populations. Nonetheless, variants of COVID-19 have been associated with a bronchiolitis-like syndrome. In addition, a robust RSV surge was observed in the late-pandemic period. Co-infection with COVID-19 has been observed,

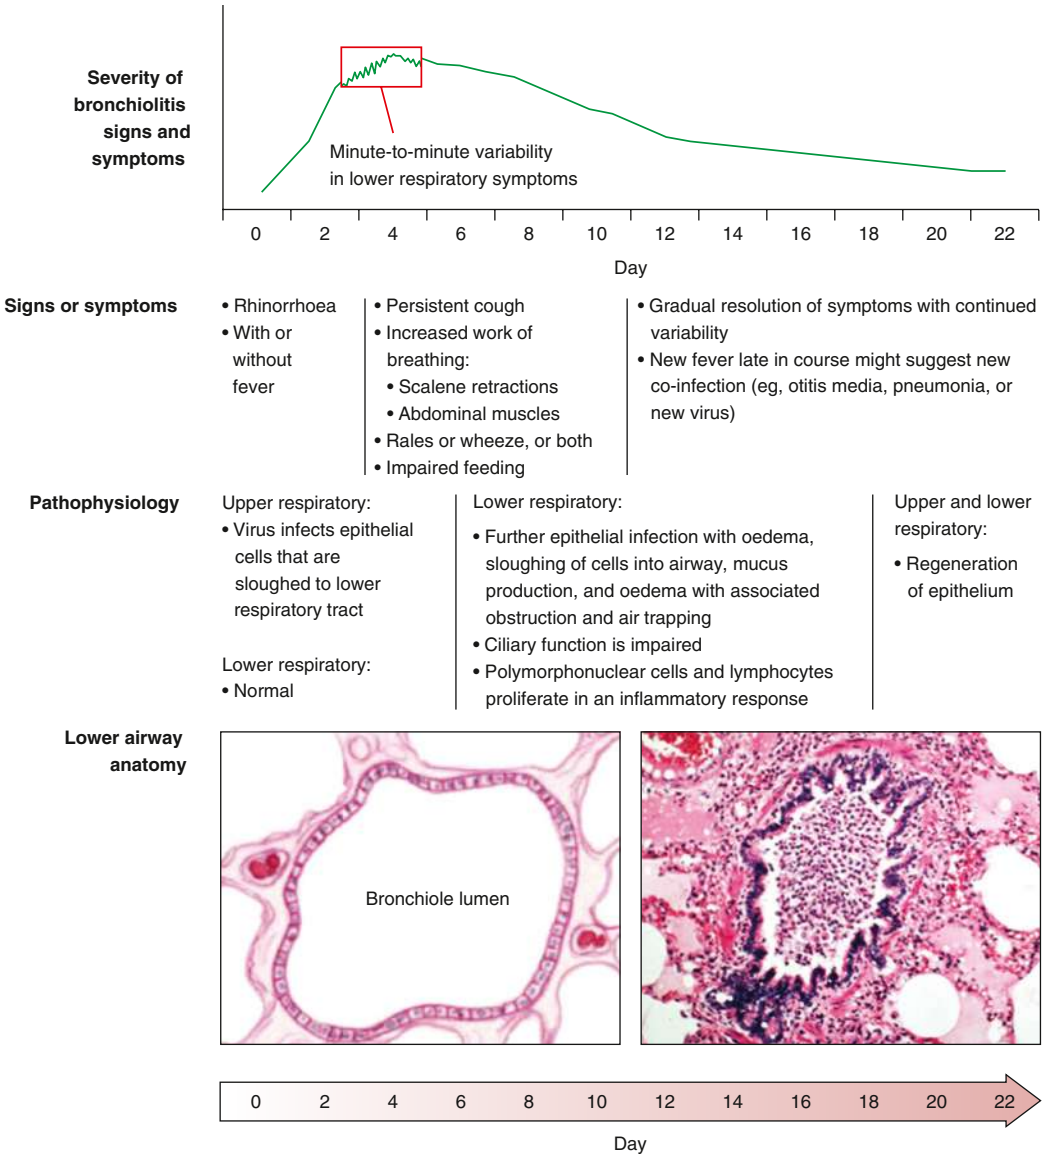

Fig. 439.1 Typical clinical course and pathophysiology of viral bronchiolitis. *(From Florin TA, Plint PC, Zorc JJ. Viral bronchiolitis. Lancet. 2017;389:211–224, Fig. 1.)*

but its implications on disease presentation and severity are not well characterized.

Bronchiolitis is more common in males, those exposed to secondhand tobacco smoke, those who have not been breastfed, and those living in crowded conditions. The risk is also higher for infants with mothers who smoked during pregnancy. Older family members, including older siblings, are a common source of infection; they might experience only minor upper respiratory symptoms (colds) given that bronchiolar edema may be less clinically apparent as airway size increases.

Asthma (see Chapter 185) is another important cause of wheezing, and the possibility of this diagnosis complicates the treatment of young children with bronchiolitis, although diagnosing asthma in the very young can be difficult. In prospective, longitudinal population cohort studies of infants, up to half of the cohort experienced a wheezing illness before school age, although when followed into adulthood only about 5–8% of patients prove to have asthma. In the largest U.S. cohort, three patterns of infant wheezing were proposed: transient early wheezing, comprising about 20% of the cohort, characterized by lower lung function at birth that improves with growth, resulting in resolution of wheezing by age 3; persistent wheezing, comprising about 14% of the cohort, characterized by declining lung function and wheezing before and after age 3; and late-onset wheezing, comprising 15% of the cohort, characterized by relatively stable lung function and wheezing that does not begin until after age 3. The remaining 50% of the population did not suffer a wheezing illness. Following the cohort into adulthood revealed continued declines in the rates of persistent symptoms. Similar patterns are also seen in birth cohort studies in other countries.

Multiple studies attempting to predict which infants suffering from early wheezing illnesses will go on to have asthma in later life have failed to achieve discriminant validity. Interestingly, in both U.S. and UK prospective cohorts, wheezing with an onset *after* the first 18-36 months of life is one of the strongest predictors of eventual asthma in both cohorts. Other proposed risk factors for persistent wheezing include parental history of asthma and allergies, maternal smoking, persistent rhinitis (apart from acute upper respiratory tract infections), allergen sensitization, eczema, and peripheral eosinophilia, although no single factor is strongly discriminative. There is no evidence that early administration of systemic or inhaled corticosteroids to high-risk populations can prevent the development of asthma.

Table 439.2 Pertinent Medical History in the Wheezing Infant

Did the onset of symptoms begin at birth or thereafter?
Is the infant a noisy breather, and when is it most prominent?
Is the noisy breathing present on inspiration, expiration, or both?
Is there a history of cough apart from wheezing?
Was there an earlier lower respiratory tract infection?
Is there a history of recurrent upper or lower respiratory tract infections?
Have there been any emergency department visits, hospitalizations, or intensive care unit admissions for respiratory distress?
Is there a history of eczema?
Does the infant cough after crying or cough at night?
How is the infant growing and developing?
Is there associated failure to thrive?
Is there a history of electrolyte abnormalities?
Are there signs of intestinal malabsorption, including frequent, greasy, or oily stools?
Is there a maternal history of genital herpes simplex virus infection?
What was the gestational age at delivery?
Was the patient intubated as a neonate?
Does the infant bottle-feed in the bed or the crib, especially in a propped position?
Are there any feeding difficulties, including choking, gagging, arching, or vomiting with feeds?
Is there any new food exposure?
Is there a toddler in the home or lapse in supervision in which foreign body aspiration could have occurred?
Is there a change in caregivers or a chance of nonaccidental trauma?

Clinical Manifestations

The initial history of a wheezing infant should explore the onset, duration, and associated factors (Table 439.2), as well as *birth history* (weeks of gestation, neonatal complications including history of intubation or oxygen requirement, maternal complications) and prenatal smoke exposure. Past medical history, including any comorbid conditions, should be assessed. *Family history* of cystic fibrosis, immunodeficiencies, asthma in a first-degree relative, or any other recurrent respiratory conditions in children should be obtained. *Social history* should include any tobacco or other smoke exposure, daycare exposure, number of siblings, pets, and concerns regarding the home environment (e.g., dust mites, construction dust, heating and cooling techniques, mold, cockroaches). The patient's growth chart should be reviewed for signs of failure to thrive.

Acute bronchiolitis is usually preceded by exposure (daycare, preschool, siblings) to contacts with a minor respiratory illness within the previous week (see Fig. 439.1). The infant first develops signs of upper respiratory tract infection with sneezing and clear rhinorrhea. This may be accompanied by diminished appetite and fever. Gradually, respiratory distress ensues, with paroxysmal cough, dyspnea, and irritability. The infant is often tachypneic, which can interfere with feeding. Though rare, apnea may occur in very young infants and may precede lower respiratory signs early in the disease. Infants at a postconceptual age of <44 weeks are at highest risk for *apneic* events, with premature birth providing an additional risk factor.

On physical examination, evaluation of the patient's vital signs with special attention to the respiratory rate and oxygen saturation is an important initial step. The exam is often dominated by wheezing and crackles. Expiratory time may be prolonged. Work of breathing may be markedly increased, with nasal flaring and retractions. *Complete obstruction to airflow can eliminate the turbulence that causes wheezing; thus the lack of audible wheezing is not reassuring if the infant shows other signs of respiratory distress.* Poorly audible breath sounds suggest severe disease with nearly complete bronchiolar obstruction.

Diagnostic Evaluation

Evaluation of wheezing in infancy and early childhood depends on suspected etiology. The diagnosis of **acute bronchiolitis** is clinical and should be considered in an infant presenting with a first episode of wheezing after a period of upper respiratory symptoms. Chest radiography is not routinely indicated in children with suspected bronchiolitis. Areas of atelectasis associated with bronchiolitis are often observed on chest radiographs and may be difficult to distinguish from bacterial pneumonia; as a result, obtaining chest radiography in a patient whose clinical course and exam are consistent with bronchiolitis may lead to unnecessary antibiotic use. Laboratory testing is also not routinely indicated; the white blood cell and differential counts are usually normal and are not predictive of bacterial superinfection. Viral testing (polymerase chain reaction or rapid immunofluorescence) is not routinely recommended in the diagnosis of bronchiolitis but may be helpful if such testing prevents more invasive evaluations or treatments. Concurrent serious bacterial infection (sepsis, pneumonia, meningitis) is unlikely, although confirmation of viral bronchiolitis may obviate the need for a sepsis evaluation in the young febrile infant. Otitis media may complicate bronchiolitis.

For young children with wheezing in whom the presentation does not clinically fit with the diagnosis of bronchiolitis, including those without other signs of viral infection, with very severe presentation, or with a complicated clinical course, further workup should be considered and should be dictated by individual clinical context. Children with recurrent or refractory episodes of wheezing in infancy, particularly if associated with failure to thrive, may require evaluation for chronic disorders such as cystic fibrosis or immunodeficiency.

Treatment

The treatment of children with viral bronchiolitis is supportive management. Those who are experiencing hypoxia, respiratory distress (inability to feed, extreme tachypnea, or significantly increased work of breathing), or apnea should be hospitalized. Risk factors for severe disease include younger age, preterm birth, or underlying comorbidity. Hypoxemic children should receive supplemental oxygen. There is a developing consensus surrounding target oxygen saturations; national guidelines in the United States propose a threshold of 90%. Oxygen can be administered via a number of delivery devices, and some children with severe disease may require positive pressure ventilation. High-flow nasal oxygen cannula (HFNC) use has become common, though studies to date have failed to demonstrate a consistent benefit on clinical outcomes. Despite an apparent stabilization with HFNC, such therapy has not consistently shortened the length of hospital stay or duration of oxygen therapy. Continuous pulse oximetry monitoring can be discontinued once patients are no longer requiring supplemental oxygen and are clinically improving.

Some children may also require support with supplemental hydration. Fluid can be administered intravenously or enterally via nasogastric tube, with some preference given to the latter because of an association between better outcomes with continued provision of enteral nutrition. If intravenous fluids are administered, care should be taken to use isotonic fluids because of the risk of hyponatremia. Frequent suctioning of nasal and oral secretions often provides relief of distress and improves work of breathing and ability to feed, although this should be limited to the nares or oropharynx because deep tracheal suctioning does not provide additional benefit and may cause harm. Chest physiotherapy has been extensively evaluated and provides *no benefit* to children with bronchiolitis.

Pharmacologic agents have largely proven *ineffective* in the management of bronchiolitis. Multiple systematic reviews and meta-analyses have failed to demonstrate any impact on clinical outcomes with use of albuterol or corticosteroids in bronchiolitis; neither are currently recommended for management. Response to bronchodilators is unlikely and unpredictable in children younger than 1 year. The use of inhaled or oral steroids in very young children with wheezing has not been shown to affect the disease trajectory or prevent the progression of childhood wheezing or development of asthma. There is debate over the use of

inhaled hypertonic saline in children with bronchiolitis, although most studies and meta-analyses fail to demonstrate any major benefit. Racemic epinephrine has not been found to improve the length of stay or clinical outcomes among inpatients with bronchiolitis, although there is some evidence to suggest that it may reduce the risk of hospitalization when used in the outpatient setting. Ribavirin, the only currently available antiviral medication targeting RSV, is also *not* currently recommended because of minimal impact on disease outcomes and because it is costly, difficult to administer, and associated with important toxicities.

PROGNOSIS

Infants with acute bronchiolitis are generally considered to be at highest risk for further respiratory compromise in the first 72 hours after onset of cough and dyspnea. The case fatality rate is <1% in developed countries, with death attributable to respiratory arrest and/or failure or severe dehydration and electrolyte disturbances. *A majority of deaths caused by bronchiolitis occur in children with complex medical conditions or comorbidities such as bronchopulmonary dysplasia, congenital heart disease, or immunodeficiency.* The median duration of symptoms in ambulatory patients is approximately 14 days; 10% may be symptomatic for 3 weeks. Severe lower respiratory tract infection at an early age has been identified as a possible risk factor for the development of asthma, although most children with early childhood wheezing will not go on to suffer from asthma. It is unclear whether viral infections causing bronchiolitis incite an immune response that manifests as asthma later in life or whether those infants have an inherent predilection for asthma that is first manifested as viral bronchiolitis.

PREVENTION (See also Chapter 307)

Meticulous hand hygiene is the best measure to prevent transmission of the viruses responsible for bronchiolitis. Nirsevimab, a one dose long-acting monoclonal antibody, is approved for prevention of RSV infection in newborns and infants. Nirsevimab is indicated for infants < 8 months of age born during or entering their first RSV season (in the continental US this may be October to March, although there may be regional differences), including those previously recommended to receive palivizumab (which is not given). Nirsevimab dose in the first RSV season is 50 mg if < 5 kg and 100 mg in infants ≥ 5 kg. In addition, older infants (8-19 months) who are at increased risk of severe RSV infection entering their second RSV season should also receive nirsevimab. These older infants include those with:

- Chronic lung disease of prematurity that requires chronic steroid or diuretic therapy or supplemental oxygen
- Severe immunocompromising conditions
- Cystic fibrosis with severe lung disease or poor weight gain
- American Indian and Alaska Native

The single dose of nirsevimab in the second RSV season is 200 mg given as two 100 mg injections in different sites. Nirsevimab may be coadministered with other routine childhood immunizations. Because of the availability of nirsevimab, immunization of high-risk populations with palivizumab is no longer recommended even if they received palivizumab in the previous RSV season.

In addition to immunization after birth, there is an FDA-approved maternal vaccine to prevent neonatal and infant RSV infections. The one dose vaccine (bivalent RSV prefusion F protein) is approved for use in women between 32-36 weeks' gestation. Nirsevimab is the only recommended approach to RSV prevention by the ACIP (CDC) and the AAP.

439.2 Bronchitis

Samantha A. House and Shawn L. Ralston

Nonspecific bronchial inflammation is termed *bronchitis* and can occur in multiple childhood conditions. Acute bronchitis is a clinical syndrome, usually viral in origin, with cough as a prominent feature. *Acute tracheobronchitis* is a term used when the trachea is prominently involved, such as with pertussis, parainfluenza, or diphtheria.

ACUTE BRONCHITIS

Acute bronchitis often follows a viral upper respiratory tract infection. It is more common in the winter when respiratory viral syndromes predominate. The tracheobronchial epithelium is invaded by the infectious agent, leading to activation of inflammatory cells and release of cytokines. Constitutional symptoms, including fever and malaise, follow. The tracheobronchial epithelium can become damaged or hypersensitized, leading to a protracted cough lasting 1-3 weeks.

The child first presents with nonspecific upper respiratory infectious symptoms, such as rhinitis. Three to four days later, a frequent, hacking cough develops, which may or may not be productive. After several days, the sputum can become purulent, indicating leukocyte migration but not necessarily bacterial infection. Many children swallow their sputum, which can produce emesis. Chest pain may be a prominent complaint in older children and is exacerbated by coughing. The mucus gradually thins, usually within 5-10 days, and then the cough gradually abates. The entire episode usually lasts about 2 weeks and seldom longer than 3 weeks.

Findings on physical examination vary with the age of the patient and stage of the disease. Early findings include no or low-grade fever and upper respiratory signs such as nasopharyngitis, conjunctivitis, and rhinitis. Auscultation of the chest may be unremarkable at this early phase. As the syndrome progresses and cough worsens, breath sounds become coarse, with coarse and fine crackles and scattered wheezing possible. Chest radiographs may be normal or may demonstrate increased bronchial markings.

The principal objective of the clinician is to exclude bacterial illnesses requiring antibiotic treatment, such as pneumonia, pertussis, or bacterial tracheitis. Obtaining sputum can be difficult in young children, and isolation of bacteria may not always indicate infection; thus sputum cultures are not generally recommended outside of specific diseases such as cystic fibrosis. Absence of vital sign abnormalities (tachycardia, tachypnea, fever) and a normal physical examination of the chest reduce the likelihood of pneumonia.

Differential Diagnosis

Persistent or recurrent symptoms should lead the clinician to consider entities other than acute bronchitis. Many entities manifest with cough as a prominent symptom (Table 439.3).

Table 439.3 Disorders with Cough as a Prominent Finding

CATEGORY	DIAGNOSES
Inflammatory	Asthma
Chronic pulmonary processes	Bronchopulmonary dysplasia Postinfectious bronchiectasis Cystic fibrosis Tracheomalacia or bronchomalacia Primary ciliary dyskinesia Other chronic lung diseases
Other chronic disease or congenital disorders	Laryngeal cleft Swallowing disorders Gastroesophageal reflux Airway compression (such as a vascular ring or hemangioma) Congenital heart disease
Infectious or immune disorders	Immunodeficiency Eosinophilic lung disease Tuberculosis Allergy Sinusitis Tonsillitis or adenoiditis *Chlamydia, Ureaplasma* (infants) *Bordetella pertussis* *Mycoplasma pneumoniae*
Acquired	Foreign body aspiration, tracheal or esophageal

Treatment

There is no specific therapy for acute bronchitis. The disease is typically a response to a viral infection and is self-limited. Antibiotics, although often prescribed, do not hasten improvement. Frequent shifts in position can facilitate pulmonary drainage in infants. Older children are sometimes more comfortable with humidity, but this does not shorten the disease course. Cough suppressants are contraindicated in the youngest children, and although they may relieve symptoms, they can also increase the risk of superinfection and therefore should be used judiciously. Antihistamines and expectorants are not indicated. Nonprescription cough and cold medicines should not be used in children younger than 4 years of age, and their use is cautioned in children age 4-11 years.

CHRONIC BRONCHITIS

Chronic bronchitis is well recognized in adults, formally defined as 3 months or longer of productive cough each year for 2 or more years. The disease can develop insidiously, with episodes of acute obstruction alternating with quiescent periods. Some predisposing conditions can lead to progression of airflow obstruction or chronic obstructive pulmonary disease, with smoking as the major factor (up to 80% of patients have a smoking history). Other conditions include air pollution, occupational exposures, and repeated infections.

The applicability of this definition to children is unclear. The existence of chronic bronchitis as a distinct entity in children is controversial. Like adults, children with chronic inflammatory diseases or those with toxic exposures can develop damaged pulmonary epithelium. Thus chronic or recurring cough in children should lead the clinician to search for underlying pulmonary or systemic disorders (see Table 439.3). One proposed entity that shares characteristics with asthma and other forms of suppurative lung disease is persistent or protracted bacterial bronchitis. Protracted bacterial bronchitis is defined as three or more of the following criteria: (1) continuous wet or productive cough >4 weeks, (2) no signs or symptoms to suggest other causes, and (3) cough resolves with appropriate course of oral antibiotics.

CIGARETTE SMOKING AND AIR POLLUTION

Exposure to environmental irritants, such as tobacco smoke and air pollution, can incite or aggravate cough. There is a well-established association between tobacco exposure and pulmonary disease, including bronchitis and wheezing. This can occur through cigarette smoking or by exposure to secondhand smoke. Marijuana smoke, electronic cigarettes, and other inhalants are irritants sometimes overlooked when eliciting a history.

A number of pollutants compromise lung development and likely precipitate lung disease, including particulate matter, ozone, acid vapor, and nitrogen dioxide. Proximity to motor vehicle traffic is an important source of these pollutants. Because these substances coexist in the atmosphere, the relative contribution of any one to pulmonary symptoms is difficult to discern.

Chapter 440

Plastic Bronchitis

Brett J. Bordini

Plastic bronchitis is a rare condition characterized by recurrent episodes of airway obstruction secondary to the formation of large proteinaceous branching casts that take on the shape of and obstruct the tracheobronchial tree. It is not a single disease entity, but rather represents a state of altered respiratory epithelial function and is most frequently encountered in the setting of underlying pulmonary or cardiac disease, although plastic bronchitis may also arise in lymphatic disorders, pulmonary infections, and the acute chest syndrome of sickle cell disease (Table 440.1). In comparison with the smaller bronchial and bronchiolar casts seen with mucus plugging, the lesions of plastic bronchitis are more extensive, with casts that can outline large segments of the airway to the level of the terminal bronchioles (Fig. 440.1). These casts may be spontaneously expectorated or may require bronchoscopic removal for relief of potentially fatal airway obstruction. Cast composition varies, although it typically consists of either a fibrin-predominant or mucin-predominant laminated matrix with or without inflammatory cell infiltration. Plastic bronchitis may be classified according to an associated disease, the cast histology, or a combination.

Table 440.1 Conditions Associated with Plastic Bronchitis

PROVEN CONDITIONS
Congenital heart disease with Fontan physiology
Pulmonary lymphatic anomalies
Influenza A pulmonary infection
Adenovirus infection
Mycoplasma pneumoniae infection
POSSIBLE CONDITIONS
Toxic inhalation
Sickle cell acute chest syndrome
Hypersecretory and near-fatal asthma (eosinophilic casts)
Noonan syndrome
UNLIKELY AND UNPROVEN CONDITIONS
Bacterial pneumonia
Bronchiectasis
Cystic fibrosis
Chronic obstructive pulmonary disease
Nephrotic syndrome

Modified from Rubin BK. Plastic bronchitis. *Clin Chest Med.* 2016;37:405–408, Box 1.

Fig. 440.1 Tracheobronchial casts after bronchoscopic extraction. Casts show branched architecture corresponding to the bronchial tree. *(From Corrin B, Nicholson AG. Pathology of the Lungs, 3rd ed. London: Churchill Livingstone; 2011: Fig. 3.20.)*

EPIDEMIOLOGY

Plastic bronchitis is rare, with an estimated prevalence of 6.8 cases per 100,000 pediatric patients. Prevalence varies according to the underlying associated disease with rates as high as 14% in patients who have undergone staged palliation of complex congenital heart disease and much lower rates in patients with asthma and atopic disease. A slight male predominance exists for cast formation in the setting of structural heart disease, whereas cast formation in the setting of asthma and atopic disease demonstrates a female predominance. Children with single-ventricle Fontan physiology are at high risk for developing plastic bronchitis.

PATHOGENESIS

The mechanism of cast formation is unclear, although it is believed to vary based on the underlying disease association and cast type. One

classification system differentiates type 1 inflammatory casts, composed primarily of fibrin with neutrophilic or, more often, eosinophilic infiltration, and type 2 acellular casts, composed primarily of mucin with little to no cellular infiltration. Type 1 casts tend to be associated with inflammatory and infectious disorders of the lung, whereas type 2 casts tend to be associated with surgically palliated structural heart disease, particularly single-ventricle lesions. However, these distinctions are not absolute; patients with structural heart disease can have fibrin-predominant casts, and patients with asthma or atopic disease can have mucin-predominant casts, with both mucin casts and fibrin casts demonstrating various degrees of cellular infiltration.

Cast formation in the setting of structural heart disease may result from alterations in pulmonary blood flow or lymphatic drainage, particularly after staged surgical palliation. Under these circumstances, increased central venous pressure is believed to compromise the integrity of the bronchial mucosa, impeding lymphatic flow and resulting in the development of collateral lymphatic vessels and potentially of lymphoalveolar fistulae that may exude proteinaceous material into the airway lumen.

CLINICAL MANIFESTATIONS

Patients with plastic bronchitis may present with cough, dyspnea, wheeze, or pleuritic chest pain. Depending on the degree of airway obstruction, patients may be hypoxemic or in severe respiratory distress. The expectoration of large, branched casts that are often tan in color and rubbery in consistency is pathognomonic for plastic bronchitis. Lung examination may reveal diminished breath sounds or wheezing in the affected area. Rarely, auscultation may reveal a sound similar to a flag flapping in the wind *(bruit de drapeau)*, believed to be related to the free end of a cast striking the bronchial wall during inspiration or expiration. Further examination may provide clues to underlying comorbidities.

DIAGNOSIS

The expectoration or endoscopic discovery of large tracheobronchial casts is pathognomonic for plastic bronchitis. History should be directed at assessing for conditions known to have an associated risk of tracheobronchial cast formation, such as uncorrected or surgically palliated complex congenital heart disease (Fontan physiology); a history of atopic disease or asthma; lymphatic disorders such as Noonan syndrome, Turner syndrome, lymphangiectasia, and yellow nail syndrome; sickle cell disease; and infectious exposures, particularly to tuberculosis, adenovirus, influenza, or atypical mycobacteria. Other predisposing conditions include cystic fibrosis, allergic bronchopulmonary aspergillosis, bronchiectasis, toxic inhalants, and granulomatous lung diseases.

Physical examination may provide indications of an underlying diagnosis. Digital clubbing of the fingers or toes may suggest long-standing hypoxemia associated with cardiac or pulmonary disease. Cardiac examination may provide information suggesting the presence of unrecognized structural heart disease.

Chest radiography may demonstrate collapse of the involved areas of the lung or areas of bronchiectasis distal to sites of long-standing obstruction.

There should be a high index of suspicion for plastic bronchitis in patients with known comorbidities who present with sudden respiratory decompensation. In the absence of cast expectoration, direct visualization of casts via bronchoscopy is required for diagnosis and is potentially therapeutic in relieving airway obstruction. Cast histology should be defined to allow for specific therapies directed at alleviating residual obstruction or preventing recurrence. In particular, the predominant component of the cast's laminated matrix—either fibrin or mucin—should be defined, and signs of inflammation or infiltration, such as the presence of neutrophils, eosinophils, or Charcot-Leyden crystals, should be documented.

TREATMENT

Treatment is directed at correcting the underlying condition associated with the development of plastic bronchitis, at relieving acute airway obstruction secondary to the presence of casts, and at preventing the development of further casts. Rigid or flexible bronchoscopy is typically required for cast removal, and if the predominant content of the cast is known, therapy with either fibrinolytics such as tissue plasminogen activator or mucolytics such as *N*-acetylcysteine or deoxyribonuclease may be considered as an adjunct to direct removal. Aerosolized heparin or mucolytics have also been used for treatment or prevention of recurrence, with varying success.

In the setting of inflammatory airway disease, additional preventive measures include inhaled or systemic corticosteroids, low-dose azithromycin, and leukotriene inhibitors to minimize airway inflammation. Bronchodilators have not been shown to prevent cast formation or aid in their removal, though may be used in the setting of concomitant bronchospasm.

In patients with surgically palliated complex congenital heart disease, measures aimed at decreasing central venous pressure, such as sildenafil or Fontan conduit fenestration, have had varied success. Lymphangiography may be undertaken to identify aberrant lymphatic vessels contributing to plastic bronchitis in the setting of congenital heart disease or lymphangitic disorders. MRI-guided selective lymphatic embolization of these channels has led to resolution of plastic bronchitis while preserving central lymphatic flow. Thoracic duct ligation has been helpful in patients in whom selective embolization has failed. Mammalian target of rapamycin (mTOR) inhibitors such as sirolimus have been used to treat lymphatic malformations, with varying success. Octreotide and low-fat diets have demonstrated modest success in adult patients. Cardiac transplantation typically results in resolution of plastic bronchitis in the setting of repaired complex congenital heart disease.

COMPLICATIONS AND PROGNOSIS

Prognosis is related primarily to the underlying condition associated with the development of plastic bronchitis. Patients whose plastic bronchitis is related to surgically palliated complex congenital heart disease are at high risk for plastic bronchitis–related mortality. Mortality can be high if casts obstruct significant portions of the airway, regardless of underlying etiology. Mortality estimates vary from 6% to 50% in the setting of asthma or atopic disease and from 14% to 50% in the setting of complex congenital heart disease, with central airway obstruction leading to death in the majority of patients.

Chapter 441

Emphysema and Overinflation

Steven R. Boas and Vicki K. Masson

Pulmonary emphysema consists of distention of air spaces with irreversible disruption of the alveolar septa. It can involve part or all of a lung. **Overinflation** is distention with or without alveolar rupture and is often reversible. **Compensatory overinflation** can be acute or chronic and occurs in normally functioning pulmonary tissue when, for any reason, a sizable portion of the lung is removed or becomes partially or completely airless, which can occur with pneumonia, atelectasis, empyema, and pneumothorax. **Obstructive overinflation** results from partial obstruction of a bronchus or bronchiole, when it becomes more difficult for air to leave the alveoli than to enter. Air gradually accumulates distal to the obstruction, the so-called *bypass, ball-valve,* or *check-valve* type of obstruction.

LOCALIZED OBSTRUCTIVE OVERINFLATION

When a ball-valve type of obstruction partially occludes the main stem bronchus, the entire lung becomes overinflated; individual lobes are affected when the obstruction is in lobar bronchi. Segments or subsegments are affected when their individual bronchi are blocked. When most or all of a lobe is involved, the percussion note is hyperresonant over the area and the breath sounds are decreased in intensity. The distended lung can extend across the mediastinum into the opposite hemithorax. Under fluoroscopic scrutiny during exhalation, the overinflated area does not decrease and the heart and the mediastinum shift to the opposite side because the unobstructed lung empties normally.

Unilateral Hyperlucent Lung

The differential diagnosis for this resultant **unilateral hyperlucent lung** is quite broad and can involve the lung parenchyma, airways, pulmonary vasculature, chest wall (see Chapter 467), and mediastinum. Localized obstructions that can be responsible for overinflation include airway foreign bodies and the inflammatory reaction to them (see Chapter 435), abnormally thick mucus (cystic fibrosis, see Chapter 454), endobronchial tuberculosis or tuberculosis of the tracheobronchial lymph nodes (see Chapter 261), and endobronchial or mediastinal tumors.

Patients with unilateral hyperlucent lung can present with clinical manifestations of pneumonia, but in some patients the condition is discovered only when a chest radiograph is obtained for an unrelated reason. A few patients have hemoptysis. Physical findings can include hyperresonance and a small lung with the mediastinum shifted toward the more abnormal lung.

Swyer-James or Macleod Syndrome

The condition is thought to result from an insult to the lower respiratory tract after, most commonly, adenovirus (see Chapter 309) or respiratory syncytial virus (see Chapter 307), *Mycoplasma pneumoniae* (see Chapter 269), or measles (see Chapter 293). The infection can cause pulmonary vascular hypoplasia with resultant hypoperfusion, leading to unilateral hyperlucent lung (underdevelopment). Clinically, children with this condition often have chronic cough, recurrent pneumonia, hemoptysis, and wheezing, although some are asymptomatic. Some patients show a classic mediastinal shift away from the lesion with exhalation. CT scanning or bronchography can often demonstrate bronchiectasis. Thoracoscopic evaluation may be useful. The triad of unilateral hyperlucent lung, diffusely decreased ventilation, and matching decreased perfusion of the affected lung supports the diagnosis. In some patients, previous chest radiographs have been normal or have shown only an acute pneumonia, suggesting that a hyperlucent lung is an acquired lesion. For those with recurrent infection or severe lung destruction, treatment may include immunization with influenza and pneumococcal vaccines, as well as surgical resection. However, without treatment, some individuals may become less symptomatic with time.

Congenital Lobar Emphysema (Congenital Large Hyperlucent Lobe)

Congenital lobar emphysema (CLE) can result in severe respiratory distress in early infancy and can be caused by localized obstruction. Familial occurrence has been reported. In 50% of cases, a cause of CLE can be identified (Table 441.1). Congenital deficiency of the bronchial cartilage, external compression by aberrant vessels, bronchial stenosis, redundant bronchial mucosal flaps, and kinking of the bronchus caused by herniation into the mediastinum have been described as leading to bronchial obstruction and subsequent CLE and commonly affect the left upper lobe. Extrapulmonary lesions are noted in Table 441.2.

Clinical manifestations usually become apparent in the neonatal period but are delayed for as long as 5-6 years in 5% of patients. Many cases are diagnosed by antenatal ultrasonography. Infants with prenatally diagnosed cases are not always symptomatic at birth. In some patients, CLE remains undiagnosed until school age or beyond. Clinical signs range from mild tachypnea and wheeze to severe dyspnea with cyanosis. CLE can affect one or more lobes; it affects the upper and middle lobes, and the left upper lobe is the most common site. The affected lobe is essentially nonfunctional because of the overdistention, and atelectasis of the ipsilateral normal lung can ensue. With further distention, the mediastinum is shifted to the contralateral side, with impaired function seen as well

Table 441.1 Etiology of Congenital Lobar Emphysema

1. Idiopathic (50%)
2. Bronchial cartilage absence, hypoplasia, or dysplasia (25%)
3. Parenchymal diseases

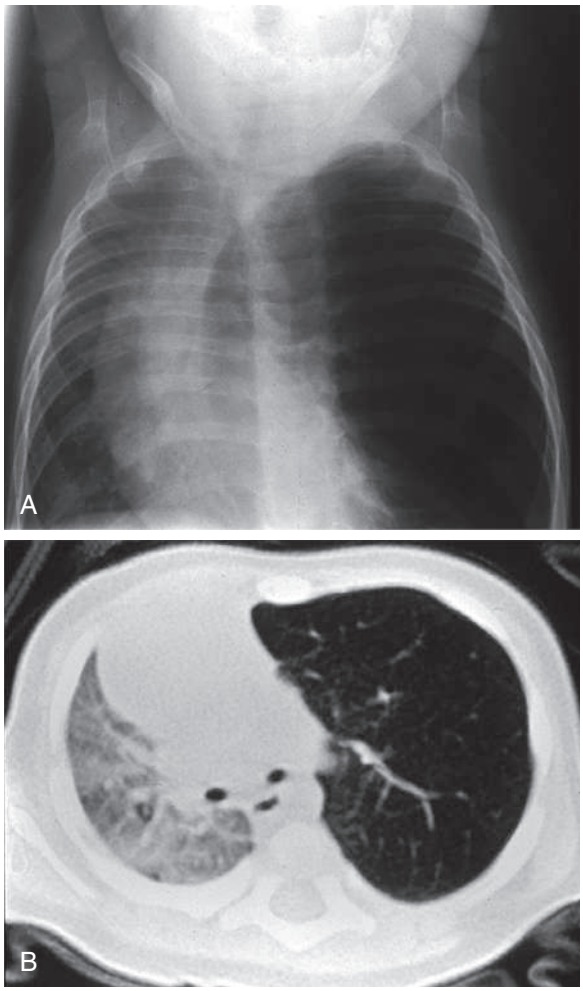

Fig. 441.1 Chest x-ray (A) and CT scan (B) of a congenital large hyperlucent lobe (congenital lobar emphysema). *(From Bush A, Abel R, Chitty L, et al. Congenital lung disease. In: Wilmott RW, Deterding RR, Li A, et al., eds. Kendig's Disorders of the Respiratory Tract in Children, 9th ed. Philadelphia: Elsevier; 2019: Fig. 18.32.)*

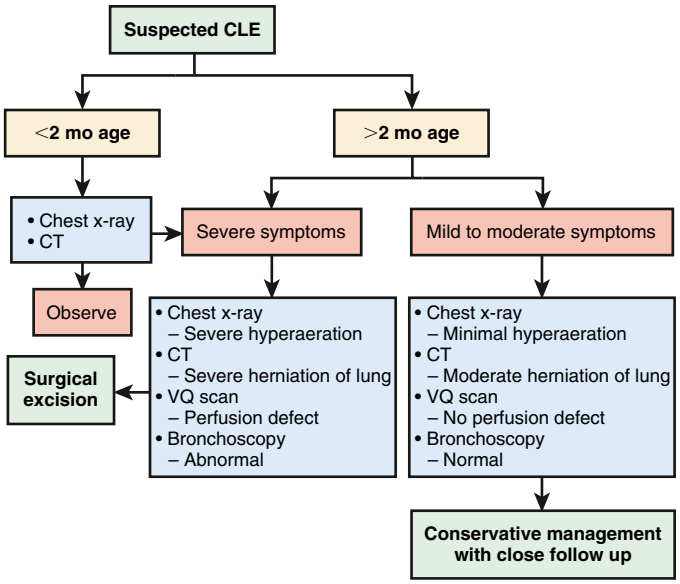

Fig. 441.2 Algorithm for evaluation and treatment of congenital lobar emphysema (CLE). *(Adapted from Karnak I, Senocak ME, Ciftci AO, et al. Congenital lobar emphysema: diagnostic and therapeutic considerations. J Pediatr Surg. 1999;34:1347–1351, Fig. 4.)*

(Fig. 441.1). A radiolucent lobe and a mediastinal shift are often revealed by radiographic examination. A CT scan can demonstrate the aberrant anatomy of the lesion, and MRI or MR angiography can demonstrate any vascular lesions that might be causing extraluminal compression. Nuclear imaging studies are useful to demonstrate perfusion defects in the affected lobe. Figure 441.2 outlines the evaluation of an infant presenting with suspected CLE. The differential diagnosis includes pneumonia with or without an effusion, pneumothorax, and cystic adenomatoid malformation.

Treatment by immediate surgery and excision of the lobe may be lifesaving when cyanosis and severe respiratory distress are present, but some patients respond to medical treatment. Selective intubation of the unaffected lung may be of value. Some children with apparent CLE have reversible overinflation, without the classic alveolar septal rupture implied in the term *emphysema.* Bronchoscopy can reveal an endobronchial lesion.

Pulmonary Vascular Abnormalities

Unilateral hyperlucency may result from **unilateral pulmonary agenesis** (see Chapter 444) that typically presents in the neonatal period. Volume loss of the affected lung results in a mediastinal shift with hyperinflation of the contralateral lung. An **anomalous origin of the left pulmonary artery** (see Chapter 481), also known as a *pulmonary artery sling,* can impinge the right main stem bronchus with resultant right-sided hyperinflation or atelectasis producing hyperlucency on either the ipsilateral or contralateral side. **Pulmonary venolobar syndrome** (see Chapter 475), also known as **scimitar syndrome**, can also result in a hyperlucent contralateral lung dependent on the extent of hypoplasia of the right lung.

GENERALIZED OBSTRUCTIVE OVERINFLATION

Acute generalized overinflation of the lung results from widespread involvement of the bronchioles and is usually reversible. It occurs more commonly in infants than in children and may be secondary to a number of clinical conditions, including asthma, cystic fibrosis, acute bronchiolitis, interstitial pneumonitis, atypical forms of acute laryngotracheobronchitis, aspiration of zinc stearate powder, chronic passive congestion secondary to a congenital cardiac lesion, and miliary tuberculosis.

Pathology

In chronic overinflation, many of the alveoli are ruptured and communicate with one another, producing distended saccules. Air can also enter the interstitial tissue (i.e., interstitial emphysema), resulting in pneumothorax and pneumomediastinum (see Chapters 461 and 462).

Clinical Manifestations

Generalized obstructive overinflation is characterized by dyspnea, with difficulty in exhaling. The lungs become increasingly overdistended, and the chest remains expanded during exhalation. An increased respiratory rate and decreased respiratory excursion result from the overdistention of the alveoli and their inability to be emptied normally through the narrowed bronchioles. Air hunger is responsible for forced respiratory movements. Overaction of the accessory muscles of respiration results in retractions at the suprasternal notch, the supraclavicular spaces, the lower margin of the thorax, and the intercostal spaces. Unlike the flattened chest during inspiration and exhalation in cases of laryngeal obstruction, minimal reduction in the size of the overdistended chest during exhalation is observed. The percussion note is hyperresonant. On auscultation, the inspiratory phase is usually less prominent than the expiratory phase, which is prolonged and roughened. Fine or medium crackles may be heard. Cyanosis is more common in the severe cases.

Fig. 441.3 Increased transradiancy in the right lower zone. A large emphysematous bulla occupies the lower half of the right lung, and the apical changes are in keeping with previous tuberculosis. *(From Padley SPG, Hansell DM. Imaging techniques. In: Albert RK, Spiro SG, Jett JR, eds. Clinical Respiratory Medicine, 3rd ed. Philadelphia: Mosby; 2008: Fig. 1.48.)*

Diagnosis

Radiographic and fluoroscopic examinations of the chest assist in establishing the diagnosis. Both leaves of the diaphragm are low and flattened, the ribs are farther apart than usual, and the lung fields are less dense. The movement of the diaphragm during exhalation is decreased, and the excursion of the low, flattened diaphragm in severe cases is barely discernible. The anteroposterior diameter of the chest is increased, and the sternum may be bowed outward.

Bullous Emphysema

Bullous emphysematous blebs or cysts (pneumatoceles) result from overdistention and rupture of alveoli during birth or shortly thereafter, or they may be sequelae of pneumonia and other infections. They have been observed in tuberculosis lesions during specific antibacterial therapy and in end-stage cystic fibrosis lung disease. Bullous emphysema can also result from inhalational marijuana use. These emphysematous areas presumably result from rupture of distended alveoli, forming a single or multiloculated cavity. The cysts can become large and might contain some fluid; an air-fluid level may be demonstrated on the radiograph (Fig. 441.3). The cysts should be differentiated from pulmonary abscesses. In most cases, treatment is not required, as the cysts disappear spontaneously within a few months, although they can persist for a year or more. Aspiration or surgery is not indicated except in cases of severe respiratory and cardiac compromise.

Subcutaneous Emphysema

Subcutaneous emphysema results from any process that allows free air to enter into the subcutaneous tissue (Fig. 441.4). The most common causes include pneumothorax or pneumomediastinum (see Chapters 461 and 462). In addition, it can be a complication of fracture of the orbit, which permits free air to escape from the nasal sinuses. In the neck and thorax, subcutaneous emphysema can follow tracheotomy, deep ulceration in the pharyngeal region, esophageal wounds, or any perforating lesion of the larynx or trachea. It is occasionally a complication of thoracentesis, asthma, or abdominal surgery. Rarely, air is formed in the subcutaneous tissues by gas-producing bacteria.

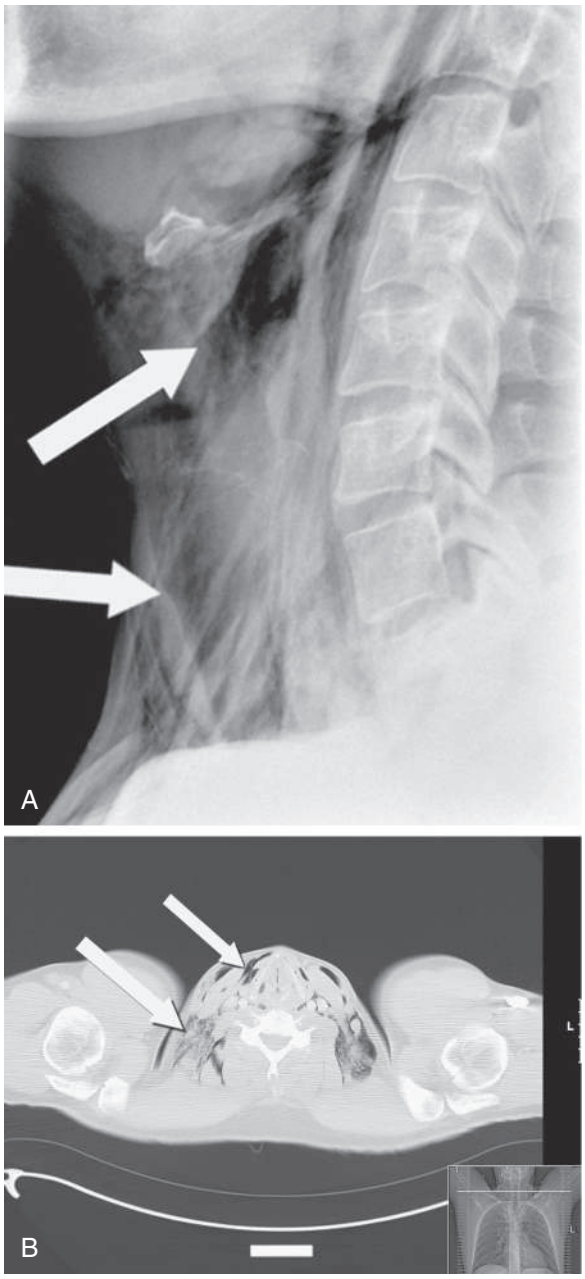

Fig. 441.4 A, Lateral x-ray of neck showing subcutaneous emphysema. B, Axial section CT neck/thorax showing subcutaneous emphysema and pneumomediastinum. *(From Zakaria R, Khwaja H. Subcutaneous emphysema in a case of infective sinusitis: a case report. J Med Case Rep. 2010;4:235, Figs. 1 and 2.)*

Tenderness over the site of emphysema and a crepitant quality on palpation of the skin are classic manifestations. Subcutaneous emphysema is usually a self-limited process and requires no specific treatment. Minimization of activities that can increase airway pressure (cough, performance of high-pressure pulmonary function testing maneuvers) is recommended. Resolution occurs by resorption of subcutaneous air after elimination of its source. Rarely, dangerous compression of the trachea by air in the surrounding soft tissue requires surgical intervention.

Chapter 442

α_1-Antitrypsin Deficiency and Emphysema

Vicki K. Masson and Steven R. Boas

Homozygous deficiency of α_1-antitrypsin (α_1-AT) rarely produces lung disease in children, but it is an important cause of early-onset severe panacinar pulmonary emphysema in adults in the third and fourth decades of life and a significant cause of liver disease in children (see Chapter 405.5). It is associated with panniculitis and antineutrophil cytoplasmic antibody (cANCA)–associated vasculitis in adults with the PI MZ phenotype.

PATHOGENESIS

The type and concentration of α_1-AT are inherited as a series of codominant alleles on chromosomal segment 14q31-32.3. (See Chapter 405.5 for a discussion of genotypes and liver disease.) The autosomal recessive deficiency affects 1 in 1,600-5,000 people, but it remains underdiagnosed. Worldwide there are an estimated 116,000,000 carriers and 1,100,000 subjects with severe α_1-AT deficiency. The normal α_1-AT PiM protein is secreted by the liver into the circulation at a rate of approximately 34 mg/kg/day; it is also produced by lung epithelial cells and monocytes. Pathogenic variant proteins are not produced (null) or are misfolded (PiZ and others); they can polymerize in the endoplasmic reticulum or be degraded, with subsequent low serum levels. Early adult-onset emphysema associated with α_1-AT deficiency occurs most commonly with PiZZ (pathogenic variant in *SERPINA1* gene), although Pi (null) (null) and, to a lesser extent, other pathogenic Pi types such as SZ have been associated with emphysema.

α_1-AT and other serum antiproteases help to inactivate proteolytic enzymes released from dead bacteria or leukocytes in the lung. Deficiency of these antiproteases leads to an accumulation of proteolytic enzymes in the lung, resulting in destruction of pulmonary tissue with subsequent development of emphysema. Polymerized pathogenic proteins in the lungs may also be proinflammatory, and there is evidence of increased oxidative stress. The concentration of proteases (elastase) in an individual's leukocytes may also be an important factor in determining the severity of clinical pulmonary disease with a given level of α_1-AT.

CLINICAL MANIFESTATIONS

Most patients who have the PiZZ defect have little or no detectable pulmonary disease during childhood. A few have early onset of chronic pulmonary symptoms, including dyspnea, wheezing, and cough, and panacinar emphysema has been documented by lung biopsy; it is probable that these findings occur secondarily to infection, which caused inflammation with consequent early disease. Smoking increases the risk of emphysema in patients with mutant Pi types. A newborn screen to identify children with the PiZZ phenotype provides useful guidance in support of smoking cessation for close contacts and reduces adolescent smoking rates.

Physical examination in *childhood* is usually normal. Affected children rarely have growth failure, an increased anteroposterior diameter of the chest with a hyperresonant percussion note, crackles to indicate active infection, or clubbing. Severe emphysema can depress the diaphragm, making the liver and spleen more easily palpable.

LABORATORY FINDINGS

Serum immunoassay measures low levels of α_1-AT; normal serum levels are ~80-220 mg/dL. Serum electrophoresis reveals the phenotype, and genotype is determined by polymerase chain reaction; whole gene sequencing is possible. In the rare patient with lung disease in adolescence, chest radiograph reveals overinflation with depressed diaphragms. Chest CT can show more hyperexpansion in the lower lung zones, with occasional bronchiectasis; CT densitometry can be a sensitive method to follow changes in lung disease. Lung function testing is usually normal in children, but it can show airflow obstruction and increased lung volumes, particularly in adolescents who smoke.

TREATMENT

Therapy for α_1-AT deficiency is intravenous replacement **(augmentation)** with enzyme derived from pooled human plasma. A level of 80 mg/dL is protective for emphysema. This target level for augmentation therapy is usually achieved with initial doses of 60 mg/kg IV weekly and results in the appearance of the transfused antiprotease in pulmonary lavage fluid. The Food and Drug Administration has approved the use of purified blood-derived human enzyme for ZZ and null-null patients. Replacement therapy is indicated for those with moderately severe obstructive lung disease (forced expiratory volume in 1 second is 30–65% of predicted) or those with mild lung disease experiencing a rapid decline in lung function. Augmentation therapy is not indicated for persons with the PiMZ type who have pulmonary disease, because their disease is not from enzyme deficiency. Recombinant sources of α_1-AT are under development, but current products are rapidly cleared from the circulation when given intravenously; they may be useful for inhalation therapy. Inhalation of the plasma-derived product is under evaluation. Lung transplantation has been performed for end-stage disease. Multiple strategies for gene therapy are under development.

SUPPORTIVE THERAPY

Standard supportive therapy for chronic lung disease includes aggressive treatment of pulmonary infection, routine use of pneumococcal and influenza vaccines, bronchodilators, and advice about the serious risks of smoking and smoke exposure. Such treatment is also indicated for asymptomatic family members found to have PiZZ or null-null phenotypes but not those with the PiMZ type. The clinical significance of the PiSZ type is unclear, but nonspecific treatment is reasonable. All persons with low levels of serum antiprotease should be warned that the development of emphysema is partially mediated by environmental factors and that cigarette smoking is particularly deleterious. Although early identification of affected persons could help to prevent development of obstructive lung disease, population screening programs are being considered but are currently suspended.

Chapter 443

Other Distal Airway Diseases

443.1 Bronchiolitis Obliterans

Catherine Kier and Steven R. Boas

Bronchiolitis obliterans (BO) is a histopathologic diagnosis characterized by chronic obstructive lung disease of the bronchioles and smaller airways resulting from an insult to the lower respiratory tract leading to inflammation and fibrosis of the small airways. In the nontransplant patient, BO most commonly occurs in the pediatric population after respiratory infections, particularly adenovirus (see Chapter 309), but also *Mycoplasma pneumoniae* (see Chapter 269), measles (see Chapter 293), *Legionella pneumophila* (see Chapter 254), influenza (see Chapter 305), and pertussis (see Chapter 243); other causes include inflammatory diseases (juvenile idiopathic arthritis, systemic lupus erythematosus [see Chapter 199], scleroderma [see Chapter 201], Stevens-Johnson syndrome [see Chapter 193]) and inhalation of toxic fumes or particulate exposure (NO_2, incinerator fly ash, NH_3, diacetyl flavorings from microwave popcorn, papaverine, fiberglass) (Table 443.1). Postinfectious BO (PIBO) may be more common in the Southern Hemisphere. BO is also commonly seen in post lung or bone marrow transplant recipients.

Bronchiolitis obliterans syndrome (BOS) is a clinical diagnosis related to graft deterioration after transplantation, defined as a progressive decline in lung function based on forced expiratory volume in 1 second (FEV_1). The airway obstruction is generally irreversible. BOS is considered once other causes of airway obstruction are excluded. It is recognized as a long-term complication of both lung and bone marrow transplantation, with more than one third of survivors of lung transplantation developing this disorder. Risk factors for the development of BOS include the presence of cytomegalovirus (CMV) pneumonitis, *Aspergillus* colonization, primary graft dysfunction, gastroesophageal reflux, and community-acquired respiratory viruses, as well as prolonged transplantation ischemic time.

PATHOGENESIS

After the initial insult, inflammation affecting terminal bronchioles, respiratory bronchioles, and alveolar ducts can result in the obliteration of the airway lumen (Fig. 443.1). Epithelial damage resulting in abnormal repair is characteristic of BO. Complete or partial obstruction of the airway lumen can result in air trapping or atelectasis. Parenchymal involvement is not seen. **Bronchiolitis obliterans organizing pneumonia (BOOP)**, or what is now termed **cryptogenic organizing pneumonia (COP)**, is a histopathologic diagnosis. Although it is similar to many of the histologic features of BO, COP is also characterized by extension of the inflammatory process from distal alveolar ducts into alveoli with proliferation of fibroblasts (parenchymal involvement).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Cough, fever, cyanosis, dyspnea, chest pain, and respiratory distress followed by initial or no improvement with antibiotics may be the early signs of BO. In this phase, BO is easily confused with pneumonia, bronchitis, or bronchiolitis. Progression of the disease can ensue, with increasing dyspnea, chronic cough, sputum production, and wheezing. Physical examination findings are usually nonspecific and can include wheezing, hypoxemia, and crackles. Chest radiographs may be relatively normal compared with the extent of physical findings but can demonstrate hyperlucency and patchy infiltrates. Occasionally, Swyer-James syndrome (unilateral hyperlucent lung; see Chapter 441) develops. Pulmonary function tests demonstrate variable findings but typically show signs of airway obstruction with a variable degree of bronchodilator response, although more commonly irreversible. Exercise testing shows reduced exercise capacity and impaired oxygen consumption. Ventilation-perfusion scans reveal a typical moth-eaten appearance of multiple matched defects in ventilation and perfusion. High-resolution chest CT often demonstrates patchy areas or a mosaic pattern of hyperlucency, air trapping, and bronchiectasis (Fig. 443.2). Table 443.2 provides an overview of CT findings of BO and related disorders. Physical and radiologic signs can wax and wane over weeks or months. Open lung biopsy or transbronchial biopsy remains the best means of establishing the diagnosis of BO or COP.

TREATMENT

Treatment is a combination of optimal supportive care and anti-inflammatory therapy to impair lymphocyte proliferation. For PIBO, it is recommended that bronchoscopy with bronchoalveolar lavage be performed to rule out persistent viral, bacterial, or fungal pathogens before initiation of systemic antiinflammatory treatment. Corticosteroids should be given early, pulse steroid therapy with methylprednisolone is preferred, and a prolonged course of oral steroids should be avoided to minimize severe side effects and complications or mortality from infections. Immunomodulatory agents, such as sirolimus, tacrolimus, aerosolized cyclosporine, hydroxychloroquine, and macrolide antibiotics, have been used in post–lung transplantation recipients with BO with variable success. Supportive measures with oxygen, antibiotics for secondary infections, and bronchodilators are adjunct therapies. The role of gastroesophageal reflux and its association with BO has been raised, with treatment suggested whenever the diagnosis is made. Azithromycin may be effective in patients with BOS. A combination of fluticasone, azithromycin, montelukast, and pulse steroid may halt pulmonary progression of BOS. Potential future treatment options include using mesenchymal stem/stromal cells (MSCs) for immunomodulatory and possibly profibrotic effects and extracorporeal photopheresis (ECP) and total lymphoid irradiation (TLI) for BOS, but additional trials and studies are needed. Patients with asymptomatic or nonprogressive COP can be observed.

PROGNOSIS

Some patients with BO experience rapid deterioration in their condition and die within weeks of the initial symptoms; most nontransplant patients survive with chronic disability. BO tends to be severe once progression ensues. In contrast to BO, a better prognosis exists for patients with COP, with complete recovery seen in many patients, although outcome depends on the underlying systemic disease. COP can relapse, especially if treatment duration is <1 year; COP is amenable to repeat courses of oral corticosteroids. Unlike the more common idiopathic COP, progressive COP characterized by acute respiratory distress syndrome is rare but is aggressive in its clinical course, leading to death.

infiltration of the walls of bronchi and bronchioles. The disease presents early and is associated with immune dysregulation. Autoantibodies have been found in some children, and in a few patients, disease-causing pathogenic variants have been found in *COPA*. Most children present with symptoms in the first 2 years of life, but with a lag time of diagnosis to about 4 years. Cough, moderate respiratory distress, fever, and fine crackles are common clinical findings. Fine crackles generally persist over time, and recurrence of symptoms is common. Chest radiographs may be relatively benign initially (air trapping, peribronchial thickening) but evolve into the typical interstitial pattern. Chest CT can show hilar lymphadenopathy, pulmonary nodules, ground-glass opacity, focal consolidation, and bronchiectasis but can also appear normal (see Table 443.2). Definitive diagnosis is made by open lung biopsy (Fig. 443.3). Treatment is limited—systemic steroids, intravenous pulse or oral, showed high response rates. Prognosis is related to early diagnosis and treatment, which are critical to improve the outcome. Some patients have significant progression of pulmonary disease, and others develop only mild obstructive airway disease.

443.3 Pulmonary Alveolar Microlithiasis

Catherine Kier and Steven R. Boas

Pulmonary alveolar microlithiasis (PAM) is a rare disease characterized by the formation of lamellar concretions of calcium phosphate, or "microliths," within the alveoli, creating a classic pattern on the radiograph (Fig. 443.4).

EPIDEMIOLOGY AND ETIOLOGY

Although the mean age at the time of diagnosis is in the mid-30s, the onset of the disease can occur in childhood and in newborns. PAM is inherited in an autosomal recessive disorder and is caused by a pathogenic variant in the type II sodium phosphate cotransporter NPT2b *(SCL34A2)*. To date, there are 27 identified pathogenic variants. This gene is expressed in high levels in the lungs,

predominantly on the surface of alveolar type II cells. Although the precise role of this protein is unknown, it is speculated that it helps to remove phosphate generated from surfactant metabolism in the alveolar space, as well as functioning as a phosphate regulator in other organs.

In some families, progression of disease is rapid. An equal male and female incidence is noted. Although PAM is found throughout the world, there is a high incidence in Turkey and a lesser incidence in Italy and Japan.

CLINICAL MANIFESTATIONS

In early stages of the disease, patients are usually asymptomatic. When symptomatic, patients with PAM usually complain of dyspnea on exertion, nonproductive cough, and fever. Physical examination of the lungs can reveal fine inspiratory crackles and diminished breath sounds. Clubbing occurs, although this is usually a more advanced sign. Discordance between the clinical and radiographic manifestations is common. Many children are often asymptomatic on initial presentation and present with symptoms during adulthood. Complications of pneumothorax, pleural adhesions and calcifications, pleural fibrosis, apical bullae, and extrapulmonary sites of microliths have been reported (kidneys, prostate, gallbladder, sympathetic chain, and testes). Progression to respiratory failure may occur.

DIAGNOSIS

Chest radiography typically reveals bilateral infiltrates with a fine micronodular appearance or sandstorm appearance with greater density in the lower and middle lung fields (see Fig. 443.4). CT of the chest shows diffuse micronodular calcified densities, with thickening of the microliths along the septa and around distal bronchioles, especially in the inferior and posterior regions (see Table 443.2). Diffuse uptake of technetium-99 methylene diphosphonate by nuclear scan has been reported. Bronchoalveolar lavage (BAL) may be helpful. Open lung and transbronchial lung biopsy reveal 0.1- to 0.3-mm laminated calcific concretions within the alveoli. Although the alveoli are often normal initially, progression to pulmonary fibrosis with advancing disease usually ensues. Sputum expectoration might reveal small microliths, although this finding is not diagnostic for PAM and is not typically seen in children. Detection of calcium deposits in BAL fluid on bronchoscopy supports the diagnosis. Pulmonary function testing reveals restrictive lung disease with impaired diffusing capacity as the disease progresses, whereas exercise testing demonstrates arterial oxygen desaturation.

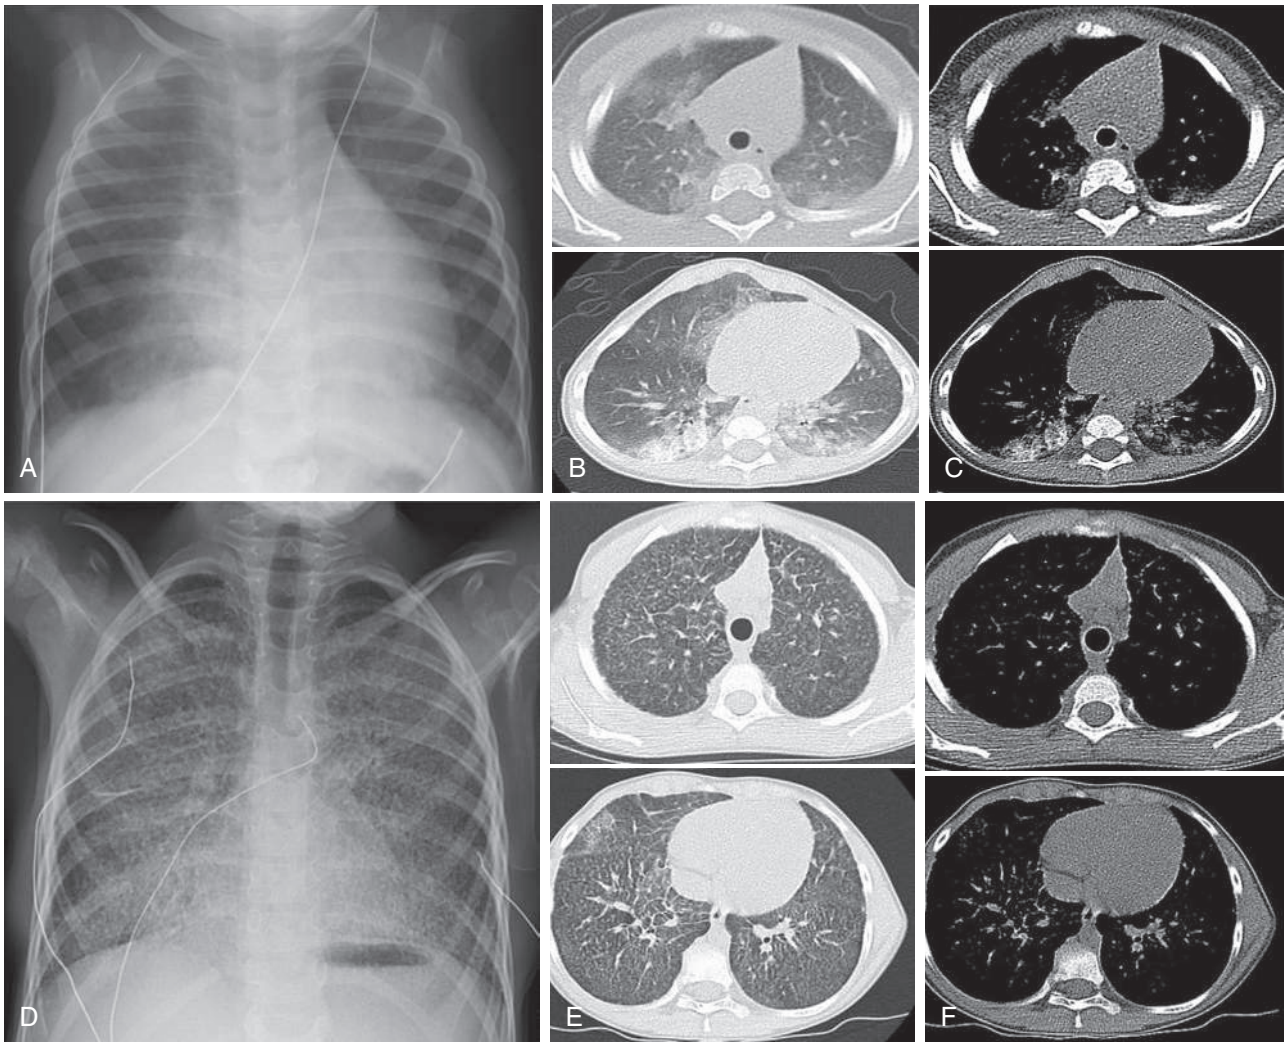

Fig. 443.4 Pulmonary alveolar microlithiasis. Chest radiograph and high-resolution CT performed at the age of 1 year and 8 years. **A,** Chest radiograph shows bilateral alveolo-interstitial opacities with middle lobe consolidation. Chest CT imaging shows diffuse but patchy ground-glass opacities, alveolar consolidations in the middle and lower lobes, and calcifications in the lower lobes, at parenchymal (**B**) and mediastinal (**C**) windows. **D,** Chest radiograph shows diffuse, even predominant in the lower and middle lobes, dense reticulonodular opacities. Chest CT imaging shows patchy ground-glass opacities, homogenous miliary consolidations with micronodular calcifications and subpleural and interlobular reticulations, parenchymal retractions, and architectural distortion suggestive of fibrosis onset mostly in the upper lobes, at parenchymal (**E**) and mediastinal (**F**) windows. *(From Sigur E, Roditis L, Labouret G, et al. Pulmonary alveolar microlithiasis in children less than 5 years of age. J Pediatr. 2020;217:158–164.e1, Fig. 1.)*

The diagnosis can usually be established radiographically. However, lung tissue biopsy, BAL, and detection of a pathogenic variant in the *SCL34A2* gene can also be used to help confirm the diagnosis. The differential diagnosis includes sarcoidosis, miliary tuberculosis, hemosiderosis, healed disseminated histoplasmosis, pulmonary calcinosis, and metastatic pulmonary calcifications.

TREATMENT

No specific treatment is effective, although some clinicians have used glucocorticosteroids, etidronate disodium, and bronchopulmonary lavage with limited success. Lung transplantation has been performed for this condition without recurrence in the transplanted lung.

PROGNOSIS

Progressive cardiopulmonary disease can ensue, leading to cor pulmonale, superimposed infections, and subsequent death in mid-adulthood. Because of the familial nature of this disease, counseling and chest radiographs of family members are indicated.

Chapter 444

Congenital Disorders of the Lung

444.1 Pulmonary Agenesis and Aplasia

Joshua A. Blatter and Jonathan D. Finder

Pulmonary agenesis differs from hypoplasia in that agenesis entails the complete absence of a lung. Agenesis differs from aplasia by the absence of a bronchial stump or carina that is seen in aplasia. Bilateral pulmonary agenesis is incompatible with life, manifesting as severe respiratory distress and failure. Pulmonary agenesis is thought to be an autosomal recessive trait, with an estimated incidence of 1 in 10,000-15,000 births.

CLINICAL MANIFESTATIONS AND PROGNOSIS

Unilateral agenesis or hypoplasia can have few symptoms and nonspecific findings, resulting in only 33% of the cases being diagnosed while the patient is living. Symptoms tend to be associated with central airway complications of compression, stenosis, and/or tracheobronchomalacia. In patients in whom the right lung is absent, the aorta can compress the trachea and lead to symptoms of central airway compression. Right lung agenesis has a higher morbidity and mortality than left lung agenesis. Pulmonary agenesis is often seen in association with other congenital anomalies such as the **VACTERL sequence** (*v*ertebral anomalies, *a*nal atresia, *c*ongenital heart disease, *t*racheoesophageal fistula, *r*enal anomalies, and *l*imb anomalies), ipsilateral facial and skeletal malformations, and central nervous system and cardiac malformations. Compensatory growth of the remaining lung allows improved gas exchange, but the mediastinal shift can lead to scoliosis and airway compression. Scoliosis can result from unequal thoracic growth.

DIAGNOSIS AND TREATMENT

Chest radiographic findings of unilateral lung or lobar collapse with a shift of mediastinal structures toward the affected side can prompt referral for suspected foreign body aspiration, mucus plug occlusion, or other bronchial mass lesions. The diagnosis requires a high index of suspicion to avoid the unnecessary risks of bronchoscopy, including potential perforation of the rudimentary bronchus. CT of the chest is diagnostic, although the diagnosis may be suggested by chronic changes in the contralateral aspect of the chest wall and lung expansion on chest radiographs. Because pulmonary agenesis can be associated with a wide variety of congenital lesions, whole body MRI can be useful to determine whether other systems (e.g., cardiac, gastrointestinal) are affected. Conservative treatment is usually recommended, although surgery has offered benefit in selected cases. Referral for management of scoliosis may be necessary.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

444.2 Pulmonary Hypoplasia

Joshua A. Blatter and Jonathan D. Finder

Pulmonary hypoplasia involves a decrease in both the number of alveoli and the number of airway generations. The hypoplasia may be bilateral in the setting of bilateral lung constraint, as in oligohydramnios or thoracic dystrophy. Pulmonary hypoplasia is usually secondary to other intrauterine disorders that produce an impairment of normal lung development (see Chapter 124). Conditions such as deformities of the thoracic spine and rib cage (thoracic dystrophy), pleural effusions with fetal hydrops, congenital pulmonary airway malformation, and congenital diaphragmatic hernia physically constrain the developing lung. Any condition that produces oligohydramnios (fetal renal insufficiency or prolonged premature rupture of membranes) can also lead to diminished lung growth. In these conditions, airway and arterial branching are inhibited, thereby limiting the capillary surface area. Large unilateral lesions, such as congenital diaphragmatic hernia or pulmonary airway malformation, can displace the mediastinum and thereby produce a contralateral hypoplasia, although usually not as severe as that seen on the ipsilateral side. **Fetal akinesia deformation syndrome** is also associated with pulmonary hypoplasia, in part because of decreased fetal breathing movements.

CLINICAL MANIFESTATIONS

Pulmonary hypoplasia is usually recognized in the newborn period, owing to either the respiratory insufficiency or the presentation of persistent pulmonary hypertension (see Chapter 130). Later presentation (tachypnea) with stress or respiratory viral infection can be seen in infants with mild pulmonary hypoplasia.

DIAGNOSIS AND TREATMENT

A variety of imaging techniques, including MRI and ultrasound, with estimation of oligohydramnios, can be helpful to identify hypoplasia but not to predict pulmonary function. Mechanical ventilation and oxygen may be required to support gas exchange. Specific therapy to control associated pulmonary hypertension, such as inhaled nitric oxide, may be useful. In cases of severe hypoplasia, the limited capacity of the lung for gas exchange may be inadequate to sustain life. Extracorporeal membrane oxygenation can provide gas exchange for a critical period of time and permit survival. Rib-expanding devices (vertically expansible prosthetic titanium ribs and magnetic expansion control rods) can improve the survival of patients with thoracic dystrophies (see Chapter 741).

444.3 Congenital Pulmonary Airway Malformation (Congenital Cystic Adenomatoid Malformation)

Joshua A. Blatter and Jonathan D. Finder

Congenital pulmonary airway malformation **(CPAM)**, formerly known as *cystic adenomatoid malformation,* consists of hamartomatous or dysplastic lung tissue mixed with more normal lung, usually confined to one lobe. This congenital pulmonary disorder occurs in approximately 1-4 in 100,000 births. Prenatal ultrasonographic findings are classified as **macrocystic** (single or multiple cysts >5 mm) or **microcystic** (echogenic cysts <5 mm). Five histologic and location patterns have been described (Fig. 444.1). **Type 0** (acinar dysplasia) is least common (<2%) and consists of microcystic disease throughout the lungs. The prognosis is poorest for this type, and infants die at birth. **Type 1** (60–70%) is macrocystic and consists of a single or several large (>2 cm in diameter) cysts lined with ciliated pseudostratified epithelium; the lesion is localized involving only a part of one lobe. One third of cases have mucus-secreting cells. Presentation is in utero or in the newborn period. Cartilage is rarely seen in the wall of the cyst. This type has a good prognosis for survival. **Type 2** (15–20%) is microcystic and consists of multiple small cysts with histology similar to that of the type 1 lesion. Type 2 is associated with other serious congenital anomalies (renal, cardiac, diaphragmatic hernia, esophageal atresia, skeletal) and carries a poor prognosis. **Type 3** (5–10%) is seen mostly in males; the lesion is a mixture of microcysts and solid tissue with bronchiole-like structures lined with cuboidal ciliated epithelium and separated by areas of nonciliated cuboidal epithelium. The prognosis for this type, like type 0, is poor. **Type 4** (~10%) is commonly macrocystic and lacks mucus cells. It is associated with malignancy (type 1

pleuropulmonary blastoma) and can present either in childhood or in asymptomatic adults.

ETIOLOGY

The lesion probably results from an embryologic injury before the 35th day of gestation, with maldevelopment of terminal bronchiolar structures. Histologic examination reveals little normal lung and many glandular elements. Cysts are common; cartilage is rare. The presence of cartilage might indicate a somewhat later embryologic insult, perhaps extending into the 10th to 24th week. Although growth factor interactions and signaling mechanisms have been implicated in altered lung-branching morphogenesis, the exact roles in the maldevelopment seen here remain obscure.

DIAGNOSIS

Cystic airway malformations can be diagnosed in utero by ultrasonography (Fig. 444.2). To better define and differentiate the lesion from other congenital lung malformations, fetal MRI is indicated (Fig. 444.3). Fetal cystic lung abnormalities can include CPAM (40%), pulmonary sequestration (14%) (see Chapter 444.4), or both (26%); the median age at diagnosis is usually 21 weeks of gestation. In one series, only 7% had severe signs of fetal distress, including hydrops, pleural effusion, polyhydramnios, ascites, or severe facial edema; 96% of the fetuses were born alive, two of whom died in the neonatal period. CPAM volume ratio (CVR)—CPAM volume divided by head circumference—can be used to predict the risk of fetal hydrops. A CVR >1.6 is a high-risk factor for developing hydrops. Lesions causing fetal hydrops have a poor prognosis. Large lesions, by compressing adjacent lung, can produce pulmonary hypoplasia in nonaffected lobes (see Chapter 444.2). Even lesions that appear large in early gestation can regress considerably or decrease in relative size and be associated with good pulmonary function in childhood. MRI allows accurate diagnosis and sizing of the lesion and is indicated even in asymptomatic neonates.

CLINICAL MANIFESTATIONS

Patients can present in the newborn period or early infancy with respiratory distress, recurrent respiratory infection, and pneumothorax. The lesion may be confused with a diaphragmatic hernia (see Chapter 131). Neonatal presentations include respiratory distress, cyanosis, tachypnea, or a pneumothorax; hydrops is the most severe presentation. Patients with smaller lesions are usually asymptomatic until mid-childhood, when episodes of recurrent or persistent pulmonary infection or chest pain occur. Breath sounds may be diminished, with mediastinal shift away from the lesion on physical examination. Chest radiographs reveal a cystic mass, sometimes with mediastinal shift (Fig. 444.4). Occasionally, an air-fluid level suggests a lung abscess (see Chapter 453).

TREATMENT

Antenatal intervention in severely affected infants is controversial but can include excision of the affected lobe for microcystic lesions, aspiration of macrocystic lesions, and, rarely, open fetal surgery. Maternal therapy with intravenous betamethasone may inhibit CPAM growth and reverse hydrops. If hydrops persists, a thoracoamniotic shunt may

be indicated. In the postnatal period, surgery is indicated for symptomatic patients. Although surgery may be delayed for asymptomatic infants because postnatal resolution has been reported, true resolution appears to be quite rare in that abnormalities usually remain detectable on CT or MRI. Sarcomatous and carcinomatous degeneration have been described in patients with CPAM, so surgical resection by 1 year of age is typically recommended to limit malignant potential. If surgery is not performed, the child should have imaging at least yearly to track progression of the lesion. The mortality rate is <10%. Another indication for surgery is to rule out **pleuropulmonary blastoma (PPB)**, a malignancy that can appear radiographically similar to type 1 CPAM or appear concurrently in a type 4 CPAM (mixed lesion). PPB is associated with germline or somatic pathogenic variants in *DICER1*. PPB usually has a systemic feeding vessel and is not connected to the bronchial tree. However, it is often difficult to distinguish a PPB from a CPAM without surgery. In addition to the risk of malignancy, "asymptomatic" patients may have chronic inflammation with subtle systemic manifestations, which parents report resolves after the lesion is resected.

444.4 Pulmonary Sequestration

Joshua A. Blatter and Jonathan D. Finder

Pulmonary sequestration is a congenital anomaly of lung development that can be intrapulmonary or extrapulmonary, according to the location within the visceral pleura. The majority of sequestrations are intrapulmonary.

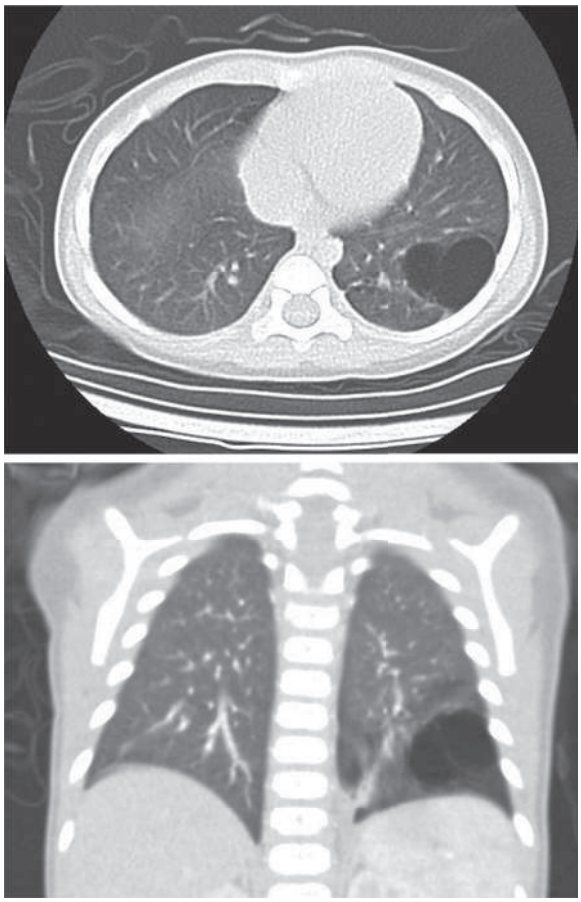

Fig. 444.4 CT scans of CPAM in the left lower lobe of the lung. *(From Wong KKY, Flake AW, Tibboel D, et al. Congenital pulmonary airway malformation: advances and controversies. Lancet Child Adolesc. 2018;2:290–296, Fig. 1.)*

PATHOPHYSIOLOGY

The lung tissue in a sequestration does not connect to a bronchus and receives its arterial supply from the systemic arteries (commonly off the aorta) and returns its venous blood to the right side of the heart through the inferior vena cava **(extralobar)** or pulmonary veins **(intralobar)**. The sequestration functions as a space-occupying lesion within the chest; it does not participate in gas exchange and does not lead to a left-to-right shunt or alveolar dead space. Communication with the airway can occur as the result of rupture of infected material into an adjacent airway. Collateral ventilation within intrapulmonary lesions via pores of Kohn can occur. Pulmonary sequestrations can arise through the same pathoembryologic mechanism as a remnant of a diverticular outgrowth of the esophagus. Some propose that intrapulmonary sequestration is an acquired lesion primarily caused by infection and inflammation; inflammation leads to cystic changes and hypertrophy of a feeding systemic artery. This is consistent with the rarity of this lesion in an autopsy series of newborns. Gastric or pancreatic tissue may be found within the sequestration. Cysts also may be present. Other associated congenital anomalies, including CPAM (see Chapter 444.3), diaphragmatic hernia (see Chapter 131), and esophageal cysts, are not uncommon. Some believe that intrapulmonary sequestration is often a manifestation of CPAM and have questioned the existence of intrapulmonary sequestration as a separate entity.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Recurrent pneumonia in the same lung location is suggestive of a sequestration. Physical findings in patients with sequestration include an area of dullness to percussion and decreased breath sounds over the lesion. During infection, crackles may also be present. A continuous or purely systolic murmur may be heard over the back. If findings on routine chest radiographs are consistent with the diagnosis, further delineation is indicated before surgical intervention (Fig. 444.5). CT with contrast can demonstrate both the extent of the lesion and its vascular supply. MR angiography is also useful. Ultrasonography can help to rule out a diaphragmatic hernia and demonstrate the systemic artery. Surgical removal is recommended. Identifying the blood supply before surgery avoids inadvertently severing its systemic artery. Coil embolization (transumbilical in neonates; arterial in older patients) has been successful in treating patients with sequestration.

Intrapulmonary sequestration is generally found in a lower lobe and does not have its own pleura. Patients usually present with infection. In older patients, hemoptysis is common. A chest radiograph during a period when there is no active infection reveals a mass lesion; an air-fluid level may be present. During infection, the margins of the lesion may be blurred. There is no difference in the incidence of this lesion in each lung.

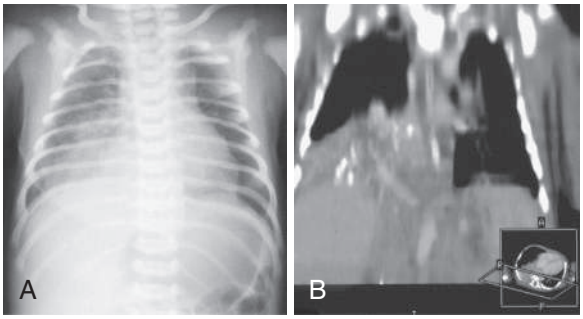

Fig. 444.5 A, Plain chest x-ray showing changes in the region of the right lower/middle lobe of the lung. B, CT showing parenchymal changes in the right lower lobe of the lung in keeping with a sequestration. *(From Corbett HJ, Humphrey GME. Pulmonary sequestration. Paediatr Respir Rev. 2004;5:59–68.)*

Extrapulmonary sequestration is much more common in boys and almost always involves the left lung. This lesion is enveloped by a pleural covering and is associated with diaphragmatic hernia and other abnormalities such as colonic duplication, vertebral abnormalities, and pulmonary hypoplasia. Many of these patients are asymptomatic when the mass is discovered by routine chest radiography. Other patients present with respiratory symptoms or heart failure. Subdiaphragmatic extrapulmonary sequestration can manifest as an abdominal mass on prenatal ultrasonography. The advent of prenatal ultrasonography has also enabled evidence that fetal pulmonary sequestrations can spontaneously regress.

TREATMENT

Treatment of intrapulmonary sequestration is surgical removal of the lesion, a procedure that usually requires excision of the entire involved lobe. Segmental resection occasionally suffices. Surgical resection of the involved area is often recommended for extrapulmonary sequestration as well, but observation can be considered for asymptomatic patients with small lesions. Coil embolization of the feeding artery has also been successful.

444.5 Bronchogenic Cysts

Joshua A. Blatter and Jonathan D. Finder

ETIOLOGY AND PATHOLOGY

Bronchogenic cysts arise from abnormal budding of the tracheal diverticulum of the foregut before the 16th week of gestation and are originally lined with ciliated epithelium. They are more commonly found on the right and near a midline structure (trachea, esophagus, carina), but peripheral lower lobe and perihilar intrapulmonary cysts are not infrequent. Diagnosis may be precipitated by enlargement of the cyst, which causes symptoms by pressure on an adjacent airway. When the diagnosis is delayed until an infection occurs, the ciliated epithelium may be lost, and accurate pathologic diagnosis is then impossible. Cysts are rarely demonstrable at birth. Later, some cysts become symptomatic by becoming infected or by enlarging and compromising the function of an adjacent airway.

CLINICAL MANIFESTATIONS AND TREATMENT

Fever, chest pain, and productive cough are the most common presenting symptoms. Dysphagia may be present; some bronchogenic cysts are asymptomatic. A chest radiograph reveals the cyst, which can contain an air-fluid level (Fig. 444.6). CT scan or MRI is obtained in most cases to better demonstrate the anatomy and extent of the lesion before surgical resection. Treatment of symptomatic cysts is surgical excision after appropriate antibiotic management. Asymptomatic cysts are generally excised in view of the high rate of infection.

444.6 Congenital Pulmonary Lymphangiectasia

Joshua A. Blatter and Jonathan D. Finder

Congenital pulmonary lymphangiectasia is characterized by greatly dilated lymphatic ducts throughout the lung. It can occur in three pathologic circumstances: **pulmonary venous obstruction** that produces an elevated transvascular pressure and engorges the pulmonary lymphatics and **generalized lymphangiectasia**, as a generalized disease of several organ systems, including lymphedema, lungs, and the intestines either associated with other syndromes (Noonan, Hennekam, yellow nail, trisomy 21) or nonsyndromic. Gorham-Stout disease (vanishing bone disease) presents with pulmonary and abdominal chylous effusions, destructive bone cysts, and multiple lymphangiomas; **primary lymphangiectasia** limited to the lung is the third type, which is a manifestation of an abnormality in lymphatic development.

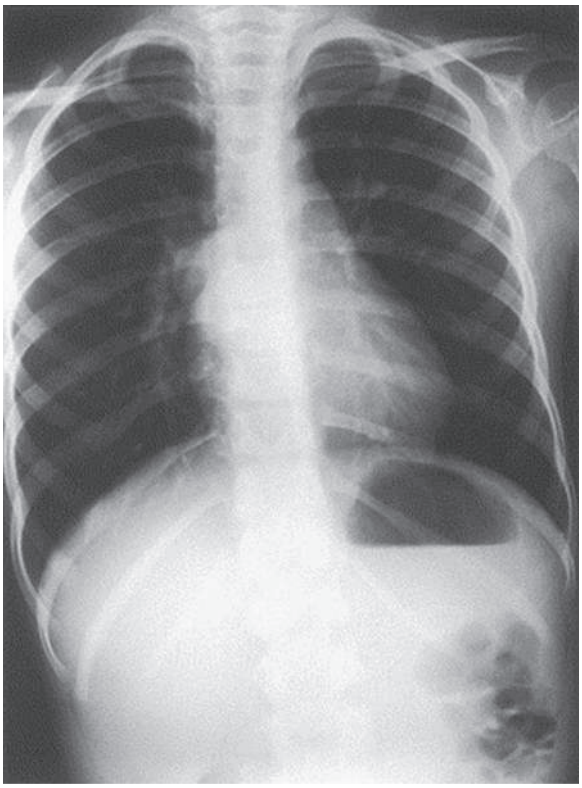

Fig. 444.6 Chest x-ray showing an ovoid, well-defined soft tissue density causing splaying of the carina because of a bronchogenic cyst. *(From Williams HJ, Johnson KJ. Imaging of congenital cystic lung lesions. Paediatr Respir Rev. 2002;3:120–127.)*

CLINICAL MANIFESTATIONS AND TREATMENT

Children with pulmonary venous obstruction or severe pulmonary lymphangiectasia present with dyspnea and cyanosis in the newborn period. Hydrops fetalis may be diagnosed antenatally. Chest radiographs reveal diffuse, dense, reticular densities with prominence of Kerley B lines. Pleural effusions are common; thoracentesis will reveal **chylothorax** in this setting. If the lung is not completely involved, the spared areas appear hyperlucent. Respiration is compromised because of impaired diffusion and decreased pulmonary compliance. The diagnosis can be suggested by CT scan and/or cardiac catheterization; definitive diagnosis requires lymphangiography, lymphoscintigraphy, or lung biopsy (either thoracoscopic or open) (Fig. 444.7).

Treatment is supportive and includes administration of oxygen, mechanical ventilation, nutritional support (including gastrostomy placement and use of feedings containing medium-chain triglycerides), and careful fluid management with diuretics. Octreotide, the somatostatin analog, can reduce chylous effusion in some patients. Primary pulmonary lymphangiectasia in the neonate can produce severe pulmonary dysfunction that can require long-term mechanical ventilation; long-term survival and resolution of respiratory insufficiency are possible even in severe cases, especially if the chylous effusions can be managed. Occasionally, the pulmonary venous obstruction is secondary to left-sided cardiac lesions; relief of the latter can produce improvement in pulmonary dysfunction. Sildenafil may reduce pulmonary venous resistance and decrease lymphatic congestion. Sirolimus, which suppresses lymphangiogenesis, may also be beneficial. Lymphangiographic-directed lymphatic injection with ethiodized oil may be another therapeutic option. Generalized lymphangiectasia produces milder pulmonary dysfunction, and survival to mid-childhood and beyond is not unusual.

444.7 Lung Hernia

Joshua A. Blatter and Jonathan D. Finder

A lung hernia is a protrusion of the lung beyond its normal thoracic boundaries. Approximately 20% are congenital, with the remainder being noted after chest trauma or thoracic surgery or in patients with pulmonary diseases such as cystic fibrosis (see Chapter 454) or asthma (see Chapter 185), which cause frequent cough and generate high intrathoracic pressure. A congenital weakness of the suprapleural membrane (Sibson fascia) or musculature of the neck can play a role in the appearance of a lung hernia. More than half of congenital lung hernias and almost all acquired hernias are cervical. Congenital cervical hernias usually occur anteriorly through a gap between the scalenus anterior and sternocleidomastoid muscles. Cervical herniation is usually prevented by the trapezius muscle (posteriorly, at the thoracic inlet) and by the three scalene muscles (laterally).

CLINICAL MANIFESTATIONS AND TREATMENT

The presenting sign of a cervical hernia (Sibson hernia) is usually a neck mass noticed while straining or coughing. Some lesions are asymptomatic and detected only when a chest film is taken for another reason. Findings on physical examination are normal except during Valsalva maneuver, when a soft bulge may be noticed in the neck. In most cases, no treatment is necessary, although these hernias can cause problems during attempts to place a central venous catheter through the jugular or subclavian veins. They can resolve spontaneously.

Paravertebral or parasternal hernias are usually associated with rib anomalies. Intercostal hernias usually occur parasternally, where the external intercostal muscle is absent. Posteriorly, despite the seemingly inadequate internal intercostal muscle, the paraspinal muscles usually prevent herniation. Straining, coughing, or playing a musical instrument can have a role in causing intercostal hernias, but in most cases, there is probably a preexisting defect in the thoracic wall.

Surgical treatment for lung hernia is occasionally justified for cosmetic reasons. In patients with severe chronic pulmonary disease and chronic cough and for whom cough suppression is contraindicated, permanent correction might not be achieved.

444.8 Other Congenital Malformations of the Lung

Joshua A. Blatter and Jonathan D. Finder

CONGENITAL LOBAR EMPHYSEMA AND PULMONARY CYSTS

See Chapter 441.

PULMONARY ARTERIOVENOUS MALFORMATION

See Chapters 481 and 493.

BRONCHOBILIARY FISTULA

A bronchobiliary fistula consists of a fistulous connection between the right middle lobe bronchus and the left hepatic ductal system (Fig. 444.8). Although diagnosis can be delayed until adulthood, this rare anomaly typically manifests with life-threatening bronchopulmonary infections in early infancy. Females are more commonly affected. Definitive diagnosis requires endoscopy or exploratory surgery. Treatment includes surgical excision of the entire intrathoracic portion of the fistula. If the hepatic portion of the fistula does not communicate with the biliary system or duodenum, the involved segment might also have to be resected. Bronchobiliary communications also occur as acquired lesions resulting from hepatic disease complicated by infection.

Chapter 445

Pulmonary Edema

Brandon T. Woods

Pulmonary edema is an abnormal fluid collection in the interstitium and air spaces of the lung resulting in oxygen desaturation, decreased lung compliance, and respiratory distress. The condition is common in the acutely ill child.

PATHOPHYSIOLOGY

Although pulmonary edema is traditionally separated into two categories according to cause (*cardiogenic* and *noncardiogenic*), the end result of both processes is a net fluid accumulation within the interstitial and alveolar spaces. Noncardiogenic pulmonary edema in its most severe state is also known as *acute respiratory distress syndrome* (see Chapters 86 and 421).

The *hydrostatic pressure* and colloid *osmotic (oncotic) pressure* on either side of a pulmonary vascular wall, along with vascular permeability, are the forces and physical factors that determine fluid movement through the vessel wall. Baseline conditions lead to a net filtration of fluid from the intravascular space into the interstitium. This extra interstitial fluid is usually rapidly reabsorbed by pulmonary lymphatics. Conditions that lead to altered vascular permeability, increased pulmonary vascular pressure, and decreased intravascular oncotic pressure increase the net flow of fluid out of the vessel (Table 445.1). Once the capacity of the lymphatics for fluid removal is exceeded, water accumulates in the lung.

To understand the sequence of lung water accumulation, it is helpful to consider its distribution among four distinct compartments, as follows:

- *Vascular compartment:* This compartment consists of all blood vessels that participate in fluid exchange with the interstitium. The vascular compartment is separated from the interstitium by capillary endothelial cells. Several endogenous inflammatory mediators, as well as exogenous toxins, are implicated in the pathogenesis of pulmonary capillary endothelial damage, leading to the leakiness seen in several systemic processes.
- *Interstitial compartment:* The importance of this space lies in its interposition between the alveolar and vascular compartments. As fluid leaves the vascular compartment, it collects in the interstitium before overflowing into the air spaces of the alveolar compartment.
- *Alveolar compartment:* This compartment is lined with type 1 and type 2 epithelial cells. These epithelial cells have a role in active fluid transport from the alveolar space, and they act as a barrier to exclude fluid from the alveolar space. The potential fluid volume of the alveolar compartment is many times greater than that of the interstitial space, perhaps providing another reason that alveolar edema clears more slowly than interstitial edema.
- *Pulmonary lymphatic compartment:* There is an extensive network of pulmonary lymphatics. Excess fluid present in the alveolar and interstitial compartments is drained via the lymphatic system. When the capacity for drainage of the lymphatics is surpassed, fluid accumulation occurs.

ETIOLOGY

The specific clinical findings vary according to the underlying mechanism (see Table 445.1).

Transudation of fluid as a result of increased pulmonary vascular pressure *(capillary hydrostatic pressure)* occurs in several cardiac processes. A significant left-to-right shunting lesion, such as a septal defect, leads to a pressure and volume load on the pulmonary vasculature. The resultant pulmonary edema is one of the hallmarks of congestive heart failure. Left ventricular failure, mitral valve disease, and pulmonary venous obstructive lesions cause increased backpressure in the pulmonary vasculature. This results in an increase in pulmonary capillary pressure.

Table 445.1 Etiology of Pulmonary Edema

INCREASED PULMONARY CAPILLARY PRESSURE
Cardiogenic, such as left ventricular failure
Noncardiogenic, as in pulmonary venoocclusive disease, pulmonary venous fibrosis, mediastinal tumors
INCREASED CAPILLARY PERMEABILITY
Bacterial and viral pneumonia
Acute respiratory distress syndrome
Immune reconstitution inflammatory syndrome (IRIS)
Cytokine release syndrome (CRS): CAR-T therapy
Inhaled toxic agents
Circulating toxins
Vasoactive substances such as histamine, leukotrienes, and thromboxanes
Diffuse capillary leak syndrome, as in sepsis, SIRS
Immunologic reactions, such as transfusion reactions
Smoke inhalation
Aspiration pneumonia/pneumonitis
Drowning and near drowning
Radiation pneumonia
Uremia
LYMPHATIC INSUFFICIENCY
Congenital and acquired
DECREASED ONCOTIC PRESSURE
Hypoalbuminemia, as in renal and hepatic diseases, protein-losing states, and malnutrition
INCREASED NEGATIVE INTERSTITIAL PRESSURE
Upper airway obstructive lesions, such as croup and epiglottitis
Reexpansion pulmonary edema
MIXED OR UNKNOWN CAUSES
Neurogenic pulmonary edema
High-altitude pulmonary edema
Eclampsia
Pancreatitis
Pulmonary embolism
Heroin (narcotic) pulmonary edema

SIRS, systemic inflammatory response syndrome.
Modified from Robin E, Carroll C, Zelis R. Pulmonary edema. *N Engl J Med.* 1973;288:239, 292; and Desphande J, Wetzel R, Rogers M. In: Rogers M, ed. *Textbook of Pediatric Intensive Care*, 3rd ed. Baltimore: Williams & Wilkins; 1996:432–442.

Increased capillary permeability is usually secondary to endothelial damage. Such damage can occur secondary to direct injury to the alveolar epithelium or indirectly through systemic processes that deliver circulating inflammatory mediators or toxins to the lung. Inflammatory mediators (tumor necrosis factor, leukotrienes, thromboxanes) and vasoactive agents (nitric oxide, histamine) formed during pulmonary and systemic processes potentiate the altered capillary permeability that occurs in many disease processes, with sepsis being a common cause.

Fluid homeostasis in the lung largely depends on drainage via the lymphatics. Experimentally, pulmonary edema occurs with obstruction of the lymphatic system. Increased lymph flow and dilation of lymphatic vessels occur in chronic edematous states.

A decrease in intravascular oncotic pressure leads to pulmonary edema by altering the forces promoting fluid reentry into the vascular space. This occurs in dilutional disorders, such as fluid overload with hypotonic solutions, and in protein-losing states, such as nephrotic syndrome and malnutrition.

The **excessive negative interstitial pressure** seen in upper airway diseases, such as croup and laryngospasm, may promote pulmonary edema. Aside from the physical forces present in these diseases, other mechanisms may also be involved. Theories implicate an increase in CO_2 tension, decreased O_2 tension, and extreme increases in cardiac afterload, leading to transient cardiac insufficiency.

The mechanism causing **neurogenic pulmonary edema** is not clear. A massive sympathetic discharge secondary to a cerebral injury may produce increased pulmonary and systemic vasoconstriction, resulting in a shift of blood to the pulmonary vasculature, an increase in capillary pressure, and edema formation. Inflammatory mechanisms may also play a role by increasing capillary permeability.

The mechanism responsible for **high-altitude pulmonary edema** is unclear, but it may also be related to sympathetic outflow, increased pulmonary vascular pressures, and hypoxia-induced increases in capillary permeability (see Chapter 87).

Active ion transport followed by passive osmotic water movement is important in clearing the alveolar space of fluid. There are some experimental data that β-agonists and growth factors increase alveolar fluid removal. Interindividual genetic differences in the rates of these transport processes may be important in determining which individuals are susceptible to altitude-related pulmonary edema. Although the existence of these mechanisms suggests that therapeutic interventions may be developed to promote resolution of pulmonary edema, no such therapies currently exist.

CLINICAL MANIFESTATIONS

The clinical features depend on the mechanism of edema formation. In general, interstitial edema and alveolar edema prevent the inflation of alveoli, leading to atelectasis and decreased surfactant production. This results in diminished pulmonary compliance and tidal volume. The patient must increase respiratory effort and/or the respiratory rate so as to maintain minute ventilation. The earliest clinical signs of pulmonary edema include increased work of breathing, tachypnea, and dyspnea. As fluid accumulates in the alveolar space, auscultation reveals fine crackles and wheezing, especially in dependent lung fields. In cardiogenic pulmonary edema, a gallop may be present as well as peripheral edema and jugular venous distention.

Chest radiographs can provide useful ancillary data, although findings of initial radiographs may be normal. Early radiographic signs that represent accumulation of interstitial edema include peribronchial and perivascular cuffing. Diffuse streakiness reflects interlobular edema and distended pulmonary lymphatics. Diffuse, patchy densities, the so-called *butterfly pattern,* represent bilateral interstitial or alveolar infiltrates and are a late sign. Cardiomegaly is often seen with cardiogenic causes of pulmonary edema. Heart size is usually normal in noncardiogenic pulmonary edema (Table 445.2). Chest tomography demonstrates edema accumulation in the dependent areas of the lung. As a result, changing the patient's position can alter regional differences in lung compliance, functional residual capacity, and alveolar ventilation.

Measurement of brain natriuretic peptide, often elevated in heart disease, can help to differentiate cardiac from pulmonary causes of pulmonary edema. A brain natriuretic peptide level >500 pg/mL suggests heart disease; a level <100 pg/mL suggests lung disease.

TREATMENT

The treatment of a patient with noncardiogenic pulmonary edema is largely supportive, with the primary goal being to ensure adequate

Table 445.2 Distinguishing Cardiogenic and Noncardiogenic Pulmonary Edema

	HISTORY	EXAMINATION	LABORATORY TESTS	IMAGING

CARDIOGENIC	• Heart disease
	• Renal disease
	• Uncontrolled HTN
	• Edema
	• Orthopnea
	• Recent administration of IV fluids or blood products
		• Heart failure examination findings:
		  • Distended neck veins
		  • S3 heart sound
		  • Dependent edema
		  • Elevated blood pressure
		• Cool extremities
			• ↑ BNP >1200 pg/mL
			• ↑ Creatinine (in setting of volume overload)
			• ↑ Troponin
				• CXR:
				  • CMG pleural effusions
				  • Kerley B lines*
				  • Bedside USG: homogenous B lines and sliding pleura in at least two lung regions
				• TEE:
				  • ↓ LVEF
				  • Diastolic filling defect
				  • Severe mitral or aortic valvular disease
				  • Pericardial effusion with tamponade
				  • VSD

NONCARDIOGENIC	• Sepsis
	• Aspiration event
	• Trauma (long bone fractures)
	• Burn injury
	• Pancreatitis
	• Multiple transfusions
		• Signs of active infection
		• Extensive burn injury
		• Evidence of trauma (absence of heart failure examination findings)
			• ↑ WBC
			• BNP <200 pg/mL
				• CXR:
				  • Diffuse central and peripheral infiltrates
				  • Normal heart size
				  • No or minimal pleural effusions
				• Bedside USG: Presence of nonhomogeneous B lines, limited pleural sliding, and other patterns such as subpleural consolidations in at least two to three lung regions
				• TEE:
				  • Normal LV and valvular function
				  • No evidence of volume overload

*Thin 1–2 cm hyperechoic lines indicating thickened interlobular septae in the lung apices or bases.
BNR, brain natriuretic peptide.
Modified from Pannu SR, Christman JW, Crouser ED: Pulmonary edema. In Vincent JL, Moore FA, Bellomo R, Marini JJ (eds). *Textbook of Critical Care,* 8th ed. Philadelphia: Elsevier, 2024. Table 11.1.

ventilation and oxygenation. Additional therapy is directed toward the underlying cause. Patients should receive supplemental oxygen to increase alveolar oxygen tension and pulmonary vasodilation. Patients with pulmonary edema of cardiogenic causes should be managed with diuretics, inotropic agents, and systemic vasodilators to reduce left ventricular afterload. Diuretics are also valuable in the treatment of pulmonary edema associated with total body fluid overload (sepsis, renal insufficiency). Morphine is often helpful as a vasodilator and a mild sedative.

Positive airway pressure improves gas exchange in patients with pulmonary edema. In tracheally intubated patients, positive end-expiratory pressure can be used to optimize pulmonary mechanics. Noninvasive forms of ventilation, such as mask or nasal prong continuous positive airway pressure, are also effective. The mechanism by which positive airway pressure improves pulmonary edema is not entirely clear but is not associated with decreasing lung water. Rather, continuous positive airway pressure prevents complete closure of alveoli at the low lung volumes present at the end of expiration. It may also recruit already collapsed alveolar units. This leads to increased functional residual capacity and improved pulmonary compliance, improved surfactant function, and decreased pulmonary vascular resistance. The net effect is to decrease the work of breathing, improve oxygenation, and decrease cardiac afterload.

When mechanical ventilation becomes necessary, especially in noncardiogenic pulmonary edema, care must be taken to minimize the risk of development of complications from volutrauma or barotrauma, including pneumothorax, pneumomediastinum, and primary alveolar damage (see Chapter 86.1). Lung protective strategies include setting low tidal volumes, relatively high positive end-expiratory pressure, and allowing for permissive hypercapnia.

High-altitude pulmonary edema should be managed with altitude descent and supplemental oxygen. Portable continuous positive airway pressure or a portable hyperbaric chamber is also helpful. Nifedipine (10 mg initially and then 20-30 mg by slow release every 12-24 hours) in adults is also helpful. If there is a history of high-altitude pulmonary edema, nifedipine and β-adrenergic agonists (inhaled) may prevent recurrence (see Chapter 87).

Chapter 446

Acute Aspiration

Anastassios C. Koumbourlis

ASPIRATION SYNDROMES

Aspiration of material that is foreign to the lower airway produces a varied clinical spectrum ranging from an asymptomatic condition to acute life-threatening events. Except for cases of self-harm, episodes of acute aspiration are almost always unintentional. Whether the aspiration will lead to the development of symptoms and how severe these will be depends on the amount and nature of the aspirated material.

This chapter focuses on aspiration of **biologic liquids** (e.g., gastric contents) and chemical substances such as hydrocarbons or oils. Other chapters discuss the mechanical obstruction of large- or intermediate-size airways from solid foreign bodies (see Chapter 435), drowning (see Chapter 88), and chronic or recurrent (micro)aspiration (see Chapter 447).

GASTRIC CONTENTS

Aspiration of gastric contents may occur in the context of vomiting in persons who are not able to protect their airways. This can be the result of either a chronic neurologic impairment or temporary suppression of the normal protective reflexes. Such circumstances include drowning, seizures, trauma (especially head injury), and cardiopulmonary resuscitation. The most common nonacute condition that may predispose to aspiration is anesthesia that suppresses the protective airway reflexes (e.g., cough, glottic closure) not only during the procedure but even for hours afterward. Fortunately, because of the strict guidelines of fasting before receiving anesthesia, the actual incidence of aspiration during anesthesia is extremely low (<0.4%). It should be noted that in-office sedation/anesthesia for dental procedures also has the potential to cause suppression of the protective airway reflexes. Other conditions that may lead to vomiting and aspiration are alcohol intoxication and use of illicit drugs such as opiates, both of which can cause severe suppression of the level of consciousness.

The consequences of aspiration of gastric contents vary, depending primarily on the pH and volume of the aspirate and on the amount of particulate material it contains. Increased clinical severity is noted with aspirated volumes greater than 0.8 mL/kg and/or pH <2.5, but significant injury may also occur by fluids with alkaline pH such as bile or even with human breast milk.

Acute aspiration may cause **chemical pneumonitis** that may progress to **acute respiratory distress syndrome (ARDS)** consisting of hypoxemia, hemorrhagic pneumonitis, atelectasis, intravascular fluid shifts, and pulmonary edema. These processes occur rapidly (within minutes to 1-2 hours). There is also a marked increase in lung parenchymal neutrophil infiltrations, mucosal sloughing, and alveolar consolidation that often correlates with increasing infiltrates on chest radiographs. These changes tend to occur later (24-72 hours) and are more prolonged after aspiration of particulate material. Aspiration of gastric contents does not cause infection per se, but it predisposes to infection because of impairment of the airway epithelial defenses. If the patient demonstrates clinical worsening, especially with fever and leukocytosis, secondary bacterial pneumonia should be suspected.

HYDROCARBON ASPIRATION

Hydrocarbons are organic compounds that consist entirely of hydrogen and carbon. They are found in abundance in nature in fossil fuels (crude oil, coal, natural gas) and in plants (and some animals). Hydrocarbons are used in numerous common household or industrial products, thus increasing the possibility of accidental (and/or intentional) exposure. The major types of hydrocarbons and their common uses can be found in Table 446.1.

There are thousands of unintentional exposures to hydrocarbons each year, with the vast majority occurring in children under the age of 5, who drink out of curiosity from poorly secured and unlabeled containers. During adolescence, many exposures are intentional for recreational purposes (e.g., glue sniffing). Among adults a common accidental exposure occurs while attempting to siphon gasoline or among performers such as "fire eaters." Aspiration of hydrocarbons can occur while drinking the substance or often in the context of vomiting that follows an ingestion. Hydrocarbons have a noxious, unpleasant taste, and they are highly irritating to mucous membranes, thus preventing ingestion and aspiration of large volumes. One exception is the **mineral seal oil** that has a sweet taste that can lead to the ingestion of fairly large amounts.

The toxicity of the hydrocarbons depends on the specific properties of the compound and the amount that was aspirated. The major properties are:

- **Viscosity:** that is the resistance to flow through an orifice. Low viscosity allows *deeper penetration* into the tracheobronchial tree, and it is the property that primarily determines the aspiration potential for hydrocarbons.
- **Surface tension:** that refers to the cohesiveness of molecules along a liquid surface. Low surface tension allows compounds to *spread over a larger area.*

ventilation and oxygenation. Additional therapy is directed toward the underlying cause. Patients should receive supplemental oxygen to increase alveolar oxygen tension and pulmonary vasodilation. Patients with pulmonary edema of cardiogenic causes should be managed with diuretics, inotropic agents, and systemic vasodilators to reduce left ventricular afterload. Diuretics are also valuable in the treatment of pulmonary edema associated with total body fluid overload (sepsis, renal insufficiency). Morphine is often helpful as a vasodilator and a mild sedative.

Positive airway pressure improves gas exchange in patients with pulmonary edema. In tracheally intubated patients, positive end-expiratory pressure can be used to optimize pulmonary mechanics. Noninvasive forms of ventilation, such as mask or nasal prong continuous positive airway pressure, are also effective. The mechanism by which positive airway pressure improves pulmonary edema is not entirely clear but is not associated with decreasing lung water. Rather, continuous positive airway pressure prevents complete closure of alveoli at the low lung volumes present at the end of expiration. It may also recruit already collapsed alveolar units. This leads to increased functional residual capacity and improved pulmonary compliance, improved surfactant function, and decreased pulmonary vascular resistance. The net effect is to decrease the work of breathing, improve oxygenation, and decrease cardiac afterload.

When mechanical ventilation becomes necessary, especially in noncardiogenic pulmonary edema, care must be taken to minimize the risk of development of complications from volutrauma or barotrauma, including pneumothorax, pneumomediastinum, and primary alveolar damage (see Chapter 86.1). The toxicity of the hydrocarbons depends on the specific properties of the compound and the amount that was aspirated. The major properties are:

- **Viscosity:** that is the resistance to flow through an orifice. Low viscosity allows *deeper penetration* into the tracheobronchial tree, and it is the property that primarily determines the aspiration potential for hydrocarbons.
- **Surface tension:** that refers to the cohesiveness of molecules along a liquid surface. Low surface tension allows compounds to *spread over a larger area.*

Table 446.1 Classes and Uses of Common Hydrocarbons (HC)

CLASS AND CHEMICAL COMPOSITION	SOURCES AND EXAMPLES	USES
Aliphatic HC: Straight-chain compounds	**Source**: crude oil **Examples:** propane, kerosene, mineral seal oil	Furniture polishes, lamp oil, and lighter fluid
Aromatic HC: Cyclic compounds containing a benzene ring	**Source**: fossil fuels **Examples**: benzene, toluene, xylene	Solvents, glues, nail polishes, paints, and paint removers
Halogenated HC: compounds in which at least one hydrogen atom is replaced by a halogen (chlorine, bromine, fluorine)	**Source**: synthetic **Examples:** chloroform, bromopropane, carbon tetrachloride, methylene chloride, tetrachloroethylene	Solvents for dry cleaning, solvents for degreasing of metals, adhesives, refrigeration (Freon); insecticides
Terpene HC: cyclic hydrocarbons that consist of 5-carbon building blocks (isoprene)	**Source**: mostly plants **Examples**: turpentine, pine oil	Paint thinners (turpentine) and cleaning products (pine oil)

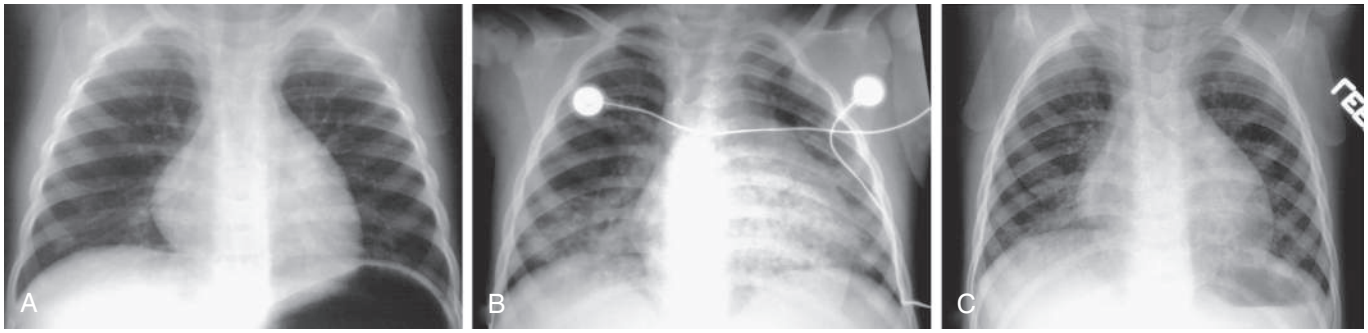

Fig. 446.1 Chest radiographs of a 17-mo-old toddler with hydrocarbon ingestion. **A,** Three hours after ingestion, the lungs are clear. **B,** At 24 hours, there are bibasilar coalescing nodular opacities. **C,** Three days later there is much clearing. *(From Slovis T, ed. Caffey's Pediatric Diagnostic Imaging, 11th ed. Philadelphia: Mosby; 2008:1287.)*

- **Volatility:** that is the *ability to vaporize*. High volatility increases the risk of pulmonary absorption and central nervous system (CNS) depression.

Hydrocarbons with lower surface tensions (gasoline, turpentine, naphthalene) have more potential for aspiration toxicity than heavier mineral or fuel oils. Ingestion of >30 mL of hydrocarbon, the approximate volume of an adult swallow, is associated with an increased risk of severe pneumonitis.

Most patients with hydrocarbon aspiration tend to remain asymptomatic. When symptomatic, patients have cough, choking, gagging, and vomiting. These usually appear within the first 30 minutes after the aspiration, but they may appear as late as 24 hours. Radiographic findings may present within hours and consist of interstitial or alveolar infiltrates in the perihilar regions and/or in the lower lobes (Fig. 446.1). Additional symptoms develop gradually and may include fever and increased work of breathing. Breath sounds may be decreased (or even absent) with wheezing and/or crackles (especially in the lower lobes). Symptomatic patients (especially those with radiographic abnormalities) require hospitalization for prolonged observation and treatment. Most patients require only supportive therapy (e.g., supplemental oxygen and hydration), and they get discharged within 2-3 days. A small number of patients (~5%) may develop ARDS with severe hypoxemia. Because hydrocarbons evaporate, they displace the alveolar gas, thus exacerbating the hypoxemia that is caused by the development of pulmonary edema and atelectasis that characterize ARDS. Necrotizing pneumonia with pneumatoceles, lipoid pneumonia, and hemorrhagic pulmonary edema are typical manifestations of severe cases, and they are often complicated by bacterial superinfection and sepsis, pleural effusions, and air leaks. Fatalities may occur, but most patients are expected to recover. Pneumatoceles can resolve over the course of months.

ASPIRATION OF OTHER SUBSTANCES

Any substance that is not supposed to be found in the airways can cause clinically significant disease. Other substances that can cause significant lung injury when aspirated or inhaled include baby powder (talc), chlorine, shellac, beryllium, and mercury vapors. Repeated exposure to low concentrations of these agents can lead to chronic lung disease, such as interstitial pneumonitis and granuloma formation. Corticosteroids may help reduce fibrosis development and improve pulmonary function, although the evidence for this benefit is limited.

One substance that deserves special mentioning is cinnamon, which achieved "notoriety" during the past decade because of the popularity among teenagers and young adults of the so-called "cinnamon-challenge" in which a person attempts to swallow dry cinnamon. Cinnamon is a caustic substance that causes the person to cough violently while it elicits a severe gag that is apparently the "amusing" part of the challenge for the spectators. Despite the gag, the possibility of aspiration is relatively high. Cinnamon causes significant airway inflammation and a potential hypersensitivity reaction that in rare cases may lead to respiratory distress and failure.

PRINCIPLES OF MANAGEMENT

Suctioning of the aspirated material can be effective only if it is performed during or immediately after the aspiration occurs (e.g., vomiting occurring in a patient who is seizing). Once aspiration occurs, the aspirated fluid will be drawn (or pushed) quickly into the distal airways with every spontaneous or positive pressure breath. Thus gastric emptying is generally contraindicated because the vomiting increases the possibility of aspiration. An exception to this rule is the ingestion of a large volume (>30 mL) of certain hydrocarbons with inherent systemic toxicity, especially if the patient exhibits signs of altered mental status. Such compounds include **c**amphor, **h**alogenated carbons, **a**romatic hydrocarbons, and those containing metals and **p**esticides (mnemonic: CHAMP). *Gastric emptying should be performed after a cuffed endotracheal tube has been inserted for protection from aspiration.* However, because intubating a patient with a full stomach is a high-risk procedure by itself, it should be performed by a specialist with experience in rapid sequence intubation to prevent vomiting and further aspiration.

Bronchoscopy should be considered if there is suspicion of aspiration of significant particulate material that could be potentially removed (see Chapter 435).

Patients in whom large-volume or toxic aspiration is suspected should be observed for several hours (e.g., 6-8 hours) for signs of respiratory distress and/or hypoxemia. A chest radiograph is warranted. A "negative" chest radiograph taken shortly after the event does not rule out the presence, nor does it predict the severity of aspiration, because the radiographic findings usually lag behind the clinical symptoms (see Fig. 447.1).

If the chest radiograph findings and oxygen saturation are normal and the patient remains asymptomatic after several hours of observation, no other treatment is necessary. The caregivers should be instructed to bring the child back to the hospital if respiratory symptoms or fever develop.

Supplemental oxygen is indicated to treat hypoxemia and/or to decrease the work of breathing. High-flow nasal cannula or noninvasive ventilation such as continuous positive airway pressure or bilevel positive airway pressure should be instituted for patients who develop increased work of breathing, progressive hypoxemia, and/or progressive hypercapnia. If these measures fail to control the symptoms, endotracheal intubation and mechanical ventilation are indicated. In rare cases of refractory respiratory failure, extracorporeal membrane oxygenation may become necessary. Exogenous surfactant has been used with success in some reported cases.

There is no specific pharmacologic therapy for aspiration. Bronchodilators may be tried to prevent and/or reverse the bronchospasm triggered by the aspirate (especially if the patient has a history of airway hyperreactivity/asthma). Use of inhaled and especially of systemic corticosteroids may be reasonable considering that severe aspiration triggers a massive inflammatory response, but their actual benefit is rather inconclusive. Animal studies suggest that to be effective corticosteroids should be given nearly simultaneously with the aspiration event. Prophylactic *antibiotics are not generally indicated* because aspiration causes a "chemical" and not an infectious pneumonitis. However, the possibility of a secondary infection is high because of organisms (usually anaerobes) from the oropharynx that enter the lower airways with the aspirate and/or organisms that may already colonize the lower airways (e.g., in patients with artificial airways and/or underlying conditions such as bronchiectasis). Thus the decision to start antibiotics prophylactically should be based on the patient's respiratory status, immune status, and colonization status (if known). Empiric antibiotic therapy is usually targeted against anaerobic organisms. In hospitalized or chronically ill patients (especially those with an artificial airway), coverage of *Pseudomonas, Staphylococcus aureus,* and enteric gram-negative organisms should also be considered. If empiric antibiotics are given, they can be discontinued if the condition improves rapidly and the cultures are negative.

PREVENTION

The best prevention of unintentional aspiration is to keep toxic substances out of reach from young children in containers that are clearly labeled and with safety caps. Prevention of aspiration should always be the goal when airway manipulation is necessary for intubation or other invasive procedures. Feeding with enteral tubes passed beyond the pylorus, elevating the head of the bed 30-45 degrees in mechanically ventilated patients, and oral decontamination reduce the incidence of aspiration complications in the intensive care unit. Acid neutralization is not routinely recommended, but it may be considered if the airway epithelium is damaged and thus unable to neutralize the acid. Minimizing use of sedation, monitoring for gastric residuals, and gastric acid suppression may all help prevent aspiration. *Any patient with altered consciousness, especially one who is receiving nasogastric or gastrostomy tube feedings, is at high risk for aspiration.*

PROGNOSIS

Most patients without any underlying conditions usually recover in 2-3 weeks with minimal or no chronic residual clinical symptoms, abnormal radiographic, or lung function changes. Prolonged lung damage may occur, including scarring, bronchiolitis obliterans, and bronchiectasis. The mortality is relatively low (approximately 5%) and occurs primarily among patients with severe acute or chronic comorbidities. In adults the mortality is much higher (exceeding 20%), but it is difficult to separate the contribution of the aspiration from the effect of the underlying conditions.

Chapter 447

Chronic Recurrent Aspiration

Anastassios C. Koumbourlis

The air that enters the lungs with every breath travels through the same narrow spaces that solid foods and liquids use to enter the esophagus. That aspiration does not occur routinely is the result of several mechanisms that protect the lower airways. The swallowing mechanism is a complex process that starts early in fetal life but fully matures months after birth; its goal is to receive, process, and transfer the food bolus from the mouth to the esophagus while preventing food particles and/or fluids from entering the trachea. When fully developed, the swallow consists of four phases. The first two (oral preparatory and oral) are voluntary and involve the preparation of the food bolus and its transfer to the back of the throat, whereas the last two (pharyngeal and esophageal) are involuntary. Under normal circumstances, by the time the food bolus reaches the pharynx, the respiration transiently stops, the vocal cords close at the midline, the arytenoid cartilages come close to each other, and the epiglottis flexes toward the posterior wall covering the larynx. This allows the food bolus to slide around the epiglottis into the pyriform sinuses and then into the esophagus where peristalsis and gravity help it move to the stomach. If these four phases are not synchronized (e.g., drinking too fast), aspiration may occur. Oropharyngeal incoordination is reportedly the most common underlying problem (with prevalence as high as 48%) associated with recurrent pneumonia in hospitalized children. A wide variety of conditions may impair one or more of the phases of the normal swallow (Table 447.1). Various maxillofacial and oropharyngeal anatomic abnormalities such as micrognathia, macroglossia, and cleft palate affect primarily the first two phases of swallowing, whereas neurologic conditions (affecting the central or the peripheral nervous system and the motor neuron junction) and primary muscle conditions affect the last two. In addition to the mechanisms for airway protection that are part of the normal swallow, there are several reflexes that can prevent aspiration. These include:

1. **The pharyngeal reflex**: Commonly referred to as the "gag" reflex, it can be elicited by touching the posterior pharyngeal wall, the soft palate, the tonsils, and/or the larynx. The gag reflex causes bilateral acute contraction of the pharyngeal muscles and elevation of the soft palate that prevent the bolus from advancing to the glottis. Damage to the glossopharyngeal and/or vagal nerves affects the reflex unilaterally or bilaterally.
2. **The laryngeal spasm**: When the glottis and/or subglottis get irritated, they produce acute contraction of the laryngeal muscles that close the vocal cords. This mechanism is very important when liquid and/or particles reach the larynx from below (gastroesophageal reflux [GER] or regurgitation) without involving the normal swallowing mechanism. Despite its protective role, laryngospasm may have negative consequences, especially in infants, who have normally low breathing reserves and can develop hypoxemia and hypercapnia within seconds. In addition, if during laryngospasm the infant attempts to exhale, the

Table 447.1 Conditions Associated with Chronic Aspiration

DIRECT	IMPAIRED SWALLOWING MECHANISM	PREDISPOSING FACTORS
Anatomic causes • Tracheoesophageal fistula • Bronchoesophageal fistula • Laryngotracheal cleft	Anatomic causes • Cleft lip/cleft palate* • Micrognathia • Macroglossia • Scarring (e.g., burns) • Trauma • Facial rigidity (scleroderma, dermatomyositis)	Anatomic causes • Choanal stenosis • Laryngomalacia • Esophageal stricture • Esophageal foreign body • External compression of the esophagus (e.g., vascular ring, mass)
Functional causes • Vocal cord paralysis in abduction • Central nervous system disorders suppressing the airway-protective reflexes (severe encephalopathy, coma)	Functional causes • Muscle weakness (neuromuscular disorders) • Bulbar dysfunction (motor neuron disorders) • Nonspecific hypotonia (e.g., trisomy 21)	Functional causes • Gastroesophageal reflux • Esophageal achalasia • Immature swallowing (e.g., prematurity) • Severe tachypnea

*Preoperative and postoperative.

Hering-Breuer reflex may cause apnea (this may be a cause of the GER-related apnea often seen among premature infants).

3. **The cough reflex**: The presence of material in the glottis and subglottis will normally elicit a cough to expel the "foreign substance." Thus coughing while eating or drinking is an indication of impaired swallowing and of possible aspiration. However, the absence of cough while eating or drinking does not rule out aspiration because several groups of patients (e.g., premature infants or patients with neuromuscular disorders) may not be able to cough, resulting into the so-called "silent aspiration."

When anatomic abnormalities connect the respiratory and gastrointestinal tracts, the airway protective mechanisms are completely bypassed, and chronic aspiration ensues. Such abnormalities can be found at the level of the larynx (e.g., laryngotracheoesophageal cleft) or at the proximal tracheobronchial tree (e.g., tracheoesophageal and/or bronchoesophageal fistula).

CLINICAL PRESENTATION

Repeated aspiration of even small quantities of gastric, nasal, or oral contents can lead to chronic airway inflammation presenting as recurrent bronchitis, bronchiolitis, and/or pneumonitis. The symptoms vary, but they usually include chronic unexplained cough (especially during or after feeding), gagging, and wheezing. Noisy ("gurgly") breathing caused by accumulation of secretions in the hypopharynx is both a predisposing and a predictive factor of aspiration. Infants (especially those born prematurely) may present with apneic episodes associated with laryngospasm. This can happen while drinking, as a result of oropharyngeal incoordination, or in between feedings due to episodes of GER that reaches the laryngeal area eliciting the laryngeal spasm. Fever is not usually a symptom of aspiration, but it may develop at any point because the chronic airway inflammation caused by the aspiration predisposes to secondary infections.

Pathologic Sequelae

Chronic aspiration can lead to irreversible lung damage in the form of bronchiectasis, granulomatous inflammation, fibrosis, and bronchiolitis obliterans. Recurrent episodes of lipoid pneumonia have been reported after use of oil-based home/folk remedies popular in several parts of the world that are given orally or nasally to children with impaired swallow.

Predisposing Factors

Many of the anatomic and functional abnormalities listed in Table 447.1 predispose the affected patients to aspiration, although technically they do not cause aspiration by themselves. These include but are not limited to the following:

- **Gastroesophageal reflux** (see Chapter 369): GER is a physiologic mechanism that is present from birth and throughout life. When severe, it predisposes to aspiration by bringing gastric contents near the larynx. However, aspiration will not occur unless the protective airway reflexes are defective. In general, GER is less frequently associated with recurrent pneumonia than is dysphagia. Gastroesophageal reflux disease (GERD; see Chapter 369) can cause pharyngeal and laryngeal edema and vocal cord nodules that may interfere with the swallowing mechanism and lead to aspiration. GERD has been associated with chronic microaspiration and bronchiolitis obliterans in lung transplant recipients.
- **Anatomic and functional abnormalities** such as cleft lip/palate, micrognathia, macroglossia, and laryngomalacia can interfere with the mechanism of bolus formation.
- **Nonspecific hypotonia**, seen in conditions such as trisomy 21 and in otherwise healthy infants (especially those born prematurely), may cause oropharyngeal discoordination and lead to recurrent microaspiration.
- **Increased work of breathing**, due to conditions that cause significant nasal obstruction and/or significant tachypnea place otherwise healthy infants at risk for aspiration because they may attempt to breathe and drink at the same time. Thus when a child with an acute respiratory illness who is being fed enterally deteriorates unexpectedly, the possibility of aspiration should be considered.

DIAGNOSIS

A history of unexplained recurrent/persistent respiratory symptoms such as cough and wheezing should always raise suspicions of chronic aspiration. It is then important to determine whether the aspiration occurs from above because of swallowing impairment or from below because of GER. The circumstances around and the timing of the symptoms may offer clues about the exact mechanism. Observation of a feeding is an essential part of the examination when a diagnosis of recurrent aspiration is being considered. Particular attention should be given to nasopharyngeal reflux and difficulty with sucking or swallowing. Symptoms such as choking, cough, stridor, or wheezing occurring during feedings are much more likely the result of impaired swallow. Coughing during or immediately after swallowing points toward anatomic abnormalities (e.g., laryngeal cleft or tracheoesophageal fistula). Symptoms occurring in between feedings, especially in a child with frequent spitting up, vomiting, arching, or complaining of epigastric discomfort, are more likely to be associated with GER.

Voice changes such hoarseness or muffled cry suggest GERD, whereas noisy (wet) breathing suggests pooling of secretions in the hypopharynx. The oral cavity should be inspected for gross abnormalities and

Table 447.2 Diagnostic Modalities for the Detection of Chronic Aspiration

DIAGNOSTIC MODALITY	ADVANTAGES	DISADVANTAGES
Chest radiograph	• Easy to obtain and inexpensive • Low radiation exposure	• Findings are not pathognomonic • Does not distinguish between aspiration from above or from below
Computed tomography of the chest	• Provides details that may be missed in plain chest x-ray (CXR)	• Findings are not pathognomonic • Does not distinguish between aspiration from above or from below • More expensive • Considerably higher radiation exposure
Esophagogram	• Provides information on the anatomy and function of the esophagus (e.g., stricture, hiatal hernia, foreign body, achalasia, decreased motility) • Detects gastroesophageal reflux (GER) • Detects tracheoesophageal fistula and external compression (vascular ring)	• Considerable radiation exposure • Short viewing time • May miss a small H-type tracheoesophageal fistula if the patient is in the supine position
Videofluoroscopic swallowing study (VFSS)	• Gold standard for the detection of aspiration even in patients without obvious respiratory symptoms	• Considerable radiation exposure • Requires the presence of a trained speech pathologist • May lead to aspiration of barium that cannot be cleared by the lung
Milk scintiscan	• More "physiologic" • Provides significantly longer viewing time • High specificity • No radiation exposure	• Low sensitivity • Does not provide any anatomic details
Salivagram	• High sensitivity (similar to VFSS) • No radiation exposure	• Infants may spit out the radionucleotide before it is mixed with the saliva and swallowed • Does not provide information about GER
Fiberoptic endoscopic evaluation of swallowing (FEES)	• Provides direct observation of the swallowing mechanism • Can be performed at the bedside or in the office	• Moderately invasive • Young patients may "fight" the insertion of the laryngoscope in their nose
"Dye" studies	• Simple, easy to perform even at home	• Requires the presence of an artificial airway • Possible toxicity from repeated use
Quantification of lipid-laden macrophages in the bronchoalveolar lavage (BAL) fluid	• High sensitivity	• Requires the performance of a bronchoscopy and BAL • Low specificity • Does not distinguish whether the lipids are the result of aspiration or release from cell damage/death

stimulated to assess the gag reflex. Drooling or excessive accumulation of secretions in the mouth suggests dysphagia. Sudden development of crackles or wheezes, especially in the dependent lung segments after feeding, is highly suggestive of aspiration.

The laboratory diagnosis of recurrent microaspiration is challenging because of the lack of pathognomonic tests. Several diagnostic modalities are currently used for the diagnosis of aspiration (Table 447.2) that can be grouped in the following:

- **Radiographs and computed tomography of the chest**: Aspiration may produce the "typical" segmental or lobar infiltrates in the dependent areas of the lung. However, their presence is not pathognomonic, and their absence does not rule out the diagnosis. Thus any abnormal radiographic finding (e.g., diffuse infiltrates, lobar infiltrates, bronchial wall thickening, and bronchiectasis) that cannot be explained by any other process should raise the possibility of chronic aspiration, especially if the patient has any of the aforementioned predisposing factors (Fig. 447.1).
- **Contrast studies**: Various tests, such as esophagogram, modified barium swallow (MBS), and videofluoroscopic swallowing study (VFSS), are currently considered the "gold standard" for the diagnosis of chronic aspiration. The patient swallows the contrast material (usually barium) under direct fluoroscopic visualization, which provides information on the swallow itself, on the presence of penetration and/or aspiration, and on the anatomy and function of the esophagus.
- **Nuclear scans**: These tests (milk scintigram and salivagram) are based on the oral administration of radionucleotides. Their detection in the lungs is proof of aspiration. A major benefit is that they do not expose the patient to radiation. However, the milk scan has very low sensitivity; the salivagram has much better sensitivity but it does not provide any information on the anatomy or function of the esophagus.
- **Endoscopic studies**: The fiberoptic endoscopic evaluation of swallowing (FEES) allows direct observation of the swallow and documents the aspiration in real time without radiation exposure. However, the child's reaction to placement of the endoscope may alter the assessment of function, depending on the level of comfort and cooperation.

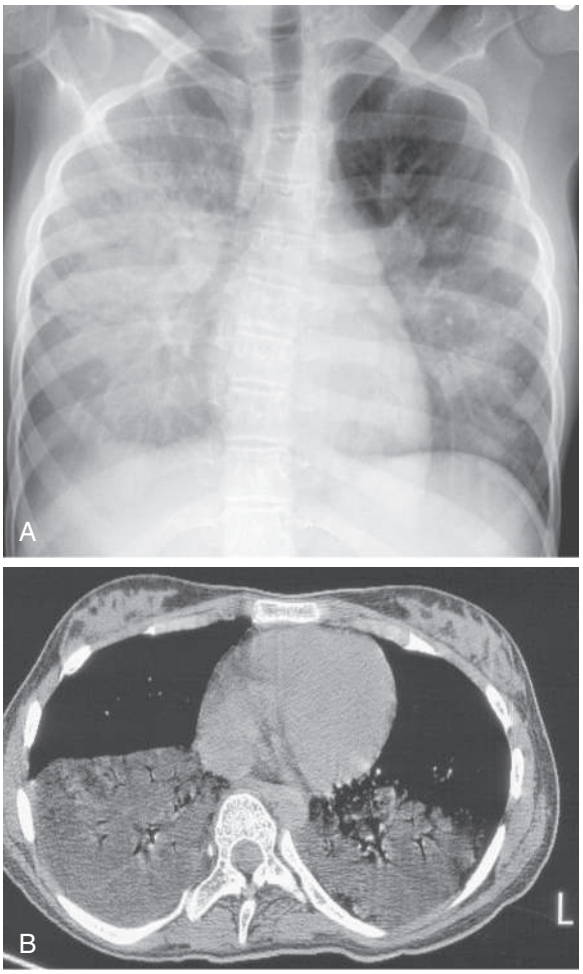

Fig. 447.1 A, Chest radiograph of a developmentally delayed 15-yr-old with chronic aspiration of oral formula. Note posterior (dependent areas) distribution with sparing of heart borders. B, Chest CT scan of same patient. Note lung consolidation in dependent regions is of similar density to subcutaneous fat.

- **Dye studies**: These can be useful tests for patients with artificial airways. A small amount of food coloring (such as methylene blue) is placed in the patient's mouth or into the stomach. If it appears in the tracheobronchial secretions in a few minutes, it confirms aspiration.
- **Analysis of bronchoalveolar lavage (BAL) fluid**: The quantification of lipid-laden alveolar macrophages is a sensitive test for aspiration in children. Its major limitation is that it cannot distinguish between exogenous and endogenous origin of the lipids. The BAF fluid can be also examined for various food substances, including lactose, glucose, food fibers, and milk antigens, as well as pepsin. The specificity and sensitivity of these tests have not been well studied.

MANAGEMENT

There is no specific treatment for aspiration. The focus of its management is the prevention or at least the minimization of the resulting morbidity. The recommended interventions depend largely on the severity of the aspiration and on the nature and prognosis of the underlying condition.

Mild morbidity (e.g., oropharyngeal incoordination due to prematurity):

- **Modifications of the food intake** based on the results of the MBS (e.g., thickening of the liquids, pureed food).
- **Modification of the feeding techniques** (e.g., positioning of the infant in a semierect position, use of special nipples, limiting the amount of food).

These approaches can be used in dysphagia caused by immaturity of the swallowing mechanism (such as that observed in prematurely born and even in term infants) and in impaired swallowing caused by factors that can improve spontaneously (e.g., GER, laryngomalacia) or be corrected surgically (e.g., cleft lip/palate).

Moderate morbidity (e.g., difficulty sucking and swallowing because of chronic lung disease, neuromuscular disorders; presence of tracheostomy):

- **Nasogastric tube feedings**: they can be used temporarily during periods of transient dysphagia. They are minimally invasive but they have several drawbacks such as easy dislodgement and exacerbation of GER (because the lower esophageal sphincter remains open). They can also cause aspiration if placed incorrectly by inexperienced caregivers.
- **Gastrostomy**: should be strongly considered for patients who are not expected to develop or recover the ability to eat by mouth within a relatively short period.
- **Postpyloric feedings**: providing the nutrition into the duodenum or the jejunum is safer because it minimizes (but does not eliminate) GER. Postpyloric feedings can be given either by nasoduodenal or nasojejunal tube or by gastrojejunal (G-J) tube (the latter can be easily threaded through the existing gastrostomy). G-J tubes are recommended for patients with neuromuscular disorders who tend to have significant problems with gastric and intestinal motility.

Severe morbidity:

- **Surgical repair**: Abnormalities such as tracheoesophageal fistula and laryngeal cleft require surgical repair as soon as the infant is stable enough to undergo the operation.
- **Nissen fundoplication** should be reserved for patients whose recurrent aspiration is primarily the result of GER not responding to medical treatment and conservative management. Fundoplication minimizes, but does not eliminate, GER. If tight, it can cause severe retching in patients without muscle weakness.

Management of Oropharyngeal Secretions

The management of nasopharyngeal and oropharyngeal secretions poses a big problem in patients with impaired swallow because the secretions tend to pool in the hypopharynx from where they can easily be aspirated. Saliva can cause inflammation in the tracheobronchial mucosa and introduces organisms from the oropharynx into the lower airways, where they can become pathogenic. The currently available treatments and interventions include the following:

- **Anticholinergic agents**: Medications such as glycopyrrolate and scopolamine are widely used but are of limited effectiveness. When they are given via the gastrostomy tube, they may cause significant dryness in the lower airway, promoting mucus plugging. Nebulization of the intravenous preparation of glycopyrrolate can be effective, but this is not an officially approved use, and the preparation cannot be bought in retail pharmacies.
- **Botox (botulinum toxin type A) injection**: Botox injections in the salivary glands provide a transient decrease in the amount of secretions. To be effective, they need to be repeated every few months under anesthesia.
- **Salivary gland ligation**: This is currently the more definitive intervention for the management of oropharyngeal secretions. Once done, it is irreversible, and therefore it is reserved for very severe cases that are refractory to any other intervention.
- **Tracheostomy**: The role of tracheostomy in the management of chronic aspiration and/or in the management of excessive oropharyngeal secretions is rather controversial. Tracheostomy per se does not prevent aspiration (unless a cuffed tube is used). It actually impairs the swallowing mechanism, and because it is a "foreign body" inside the trachea, it tends to stimulate the production

of more secretions than usual. In addition, it bypasses the natural defenses of the upper airways while it exposes the lower airways directly to the environment, thus increasing the possibility of infection. Its major advantage is that it provides easy access for the suctioning of the lower airways. Most importantly, it provides a secure airway from which positive pressure can be applied, avoiding the risks of emergency endotracheal intubations. It should be considered for patients at high risk for recurrent severe respiratory failure.

Chapter 448

Immune and Inflammatory Lung Disease

448.1 Hypersensitivity Pneumonia

Michelle L. Hernandez and Stephanie D. Davis

Hypersensitivity pneumonia (HP), aptly called *extrinsic allergic alveolitis* because the inciting agent is almost uniformly inhaled from the environment, is a complex immunologic-mediated syndrome of the pulmonary alveoli and interstitium. There are numerous specific disease names based on the origin of the inhaled offending antigen to describe HP. Prompt recognition of the signs and symptoms allows for complete reversal of the disease without long-term adverse consequences if the source of the exposure is recognized and abated. Failure to recognize the disease early may lead to chronic irreversible lung changes with persistent symptoms in the patient.

ETIOLOGY

The most common sources of offending agents that cause HP include agricultural aerosols, inhaled protein antigens from animals, antigens from microorganisms of bacteria, fungi, or protozoan origin, and chemicals of low and high molecular weight (Table 448.1). Many of these inciting agents are associated with *occupational diseases,* which occur in locations where children do not regularly work. However, these same diseases can occur in children because of exposures to many similar antigen sources in nonoccupational environments, or in occupational environments with teenage workers. In addition to HP, the same antigens (i.e., antigens from animal proteins and contaminated metal working fluids or other inhaled antigens) may lead to allergic asthma or chronic bronchitis.

More than 300 antigens have been associated with HP. In children, the primary sources have been the result of exposure to **pet birds** (or feathers in bedding and pillows) such as parakeets, canaries, cockatiels, or cockatoos. Aerosol spread of bird droppings can also occur through the vent of a clothes dryer or through heating vents from a garage where the birds were housed. Humidifiers and hot tubs are notorious for contamination with **thermophilic organisms** (bacteria and mold) as well as *Mycobacterium avium* complex. Buildings with inadequate ventilation and insufficient air turnover present an increased risk of mold exposure from prior flooding or damp condensation. Despite exposures to the same antigen sources, members of the same family may exhibit different presentations of allergic disease. For instance, some family members may have symptoms of asthma or rhinitis, whereas another may have HP.

PATHOGENESIS

The pathogenesis of HP is complex and appears to have a genetic component. Recurrent exposures to environmental agents associated with HP (see Table 448.1) trigger an inflammatory response promoting the development of immune complexes. These immune complexes activate the complement pathway, ultimately resulting in the accumulation of neutrophils in the airway that release enzymes such as neutrophil elastase that damage surrounding lung tissue. Activated macrophages in the lung promote recruitment of lymphocytes into the tissues. Pathology shows alveolitis with a mixed cellular infiltration composed of lymphocytes, macrophage, plasma cells, and neutrophils. Continued exposure to the offending antigen results in the formation of loose, noncaseating granulomas located near the respiratory or terminal bronchioles. Some patients with chronic exposure develop progressive pulmonary fibrosis similar to patients with interstitial pulmonary fibrosis (IPF). Although the mechanisms are not entirely clear, this is thought to occur secondary to recruitment and activation of fibroblasts and uncontrolled production of extracellular matrix cytokines, including transforming growth factor beta (TGF-ß). It is critical when a biopsy is being performed (transbronchial or surgical) that the pathologist knows that HP is being considered because there are other **interstitial lung diseases** that produce similar granulomas with subtle location differences depending on their disease origin. Genetic predisposition also appears to be important, primarily in genes involved with antigen processing and presentation (such as major histocompatibility complex [MHC] I and II), lung homeostasis and wound repair, and telomere-related gene mutations.

Clinical Manifestations and Classification

The prevalence of HP is higher among older individuals but can affect children and young adults. It is estimated that HP accounts for 50% of all childhood idiopathic lung diseases (ILDs). HP had been traditionally classified as acute, subacute, or chronic. However, because of the great variability and overlap in the presentation and course of HP, the American Thoracic Society, Japanese Respiratory Society, and Asociación Latinoamericana de Tórax (ATS/JRS/ALAT) guidelines recategorized HP into two phenotypes based on the predominant presence or absence of fibrosis on imaging or histopathologic examination: (1) **nonfibrotic phenotype** and (2) **fibrotic phenotype**.

Regardless of fibrotic or nonfibrotic phenotype, common symptoms include cough and dyspnea after exposure. The time to symptom presentation after exposure can vary from hours to years and may be recurrent in nature. Acute symptoms can be confused with bacterial or viral disease leading to treatment with antibiotics. For example, as early as 4-8 hours after exposure, patients can present with the abrupt onset of cough, chest tightness, dyspnea, fever, chills, body aches, and fatigue (Table 448.2). Rarely, findings of wheezing are present on the initial examination. Rather, tachypnea with fine crackles may be heard by auscultation in the lung bases and presence of mid-inspiratory squeaks. The duration of symptoms has not been definitively associated with the fibrotic or nonfibrotic phenotype.

The long-term prognosis of HP is quite variable, with some patients developing progressive shortness of breath, cough (productive), weight loss, malaise, loss of appetite, hypoxia, and clubbing of the fingers. Those who have been diagnosed with nonfibrotic HP and are able to avoid exposure to the responsible agent may achieve stabilization or full recovery. In contrast, fibrotic HP is associated with reduced survival secondary to respiratory failure, especially among those with a usual interstitial pneumonia (UIP)–like pattern.

Diagnosis

A diagnosis of HP is certain when the known exposure with the associated immune response to the offending antigen is identified, the medical history and physical examination findings are abnormal on examination, and the pattern of the high-resolution computed tomography (HRCT) of the chest and bronchoalveolar lavage (BAL) findings

Table 448.1 Antigen Sources Associated with Specific Causes of Hypersensitivity Pneumonitis

HYPERSENSITIVITY PNEUMONITIS	ANTIGEN SOURCE
Bagassosis (mold on pressed sugar cane)	*Thermoactinomyces sacchari* *Thermoactinomyces vulgaris*
Bat lung (bat droppings)	Bat serum protein
Bible printer's lung	Moldy typesetting water
Bird fancier's lung (parakeets, budgerigars, pigeons, parrots, cockatiels, geese)	Droppings, feathers, serum proteins
Byssinosis ("brown lung") (unclear if a true cause of hypersensitivity pneumonitis; asthma is common)	Cotton mill dust (carding and spinning areas of cotton, flax, and soft hemp)
Canary fancier's lung	Serum proteins
Cheese washer's lung (moldy cheese)	*Penicillium casei* *Aspergillus clavatus*
Chemical hypersensitivity pneumonitis	Diphenylmethane diisocyanate (MDI) Toluene diisocyanate (TDI)
Coffee worker's lung	Coffee bean dust
Composter's lung	*T. vulgaris* *Aspergillus* species
Contaminated basement (sewage) pneumonitis	*Cephalosporium*
Coptic lung (mummy handler's lung)	Cloth wrappings of mummies
Detergent worker's lung (washing powder lung)	*Bacillus subtilis* enzymes
Dry rot lung	*Merulius lacrymans*
Duck fever	Feathers, serum proteins
Epoxy resin lung	Phthalic anhydride (heated epoxy resin)
Esparto dust (mold in plaster dust)	*Aspergillus fumigatus* Thermophilic actinomycetes
Feather duvet lung (feather bed, pillow, duvet)	Avian proteins on feathers
Fish meal worker's lung	Fish meal
Furrier's lung (sewing furs; animal fur dust)	Animal pelts
Grain measurer's lung	Cereal grain *(Sporobolomyces)* Grain dust (mixture of dust, silica, fungi, insects, and mites)
Hot tub lung (mists; mold on ceiling and around tub)	*Cladosporium* spp. *Mycobacterium avium* complex
Humidifier fever	*Thermoactinomyces (T. vulgaris, T. sacchari, T. candidus)* *Klebsiella oxytoca* *Naegleria gruberi* *Acanthamoeba polyphaga* *Acanthamoeba castellani*
Laboratory worker's lung (rats, gerbils)	Urine, serum, pelts, proteins
Lifeguard lung	Aerosolized endotoxin from pool-water sprays and fountains
Lycoperdonosis (*Lycoperdon* puffballs)	Puffball spores
Machine operator's lung	*Pseudomonas fluorescens* Aerosolized metal working fluid
Malt worker's disease (moldy barley)	*Aspergillus fumigatus, Aspergillus clavatus*
Maple bark disease (moldy maple bark)	*Cryptostroma corticale*
Miller's lung (dust-contaminated grain)	*Sitophilus granarius* (i.e., wheat weevil)
Moldy hay, grain, silage (farmer's lung)	Thermophilic actinomycetes Fungi (e.g., *Aspergillus umbrosus*)
Mollusk shell hypersensitivity pneumonitis	Sea snail shell
Mushroom worker's lung	Mushroom spores Thermophilic actinomycetes
Paprika slicer's lung (moldy paprika pods)	*Mucor stolonifer*
Pauli reagent alveolitis	Sodium diazobenzene sulfate
Pearl oyster shell pneumonitis	Oyster shells
Pituitary snuff taker's disease	Dried, powdered cattle or pig pituitary proteins
Potato riddler's lung (moldy hay around potatoes)	Thermophilic actinomycetes *T. vulgaris* *Faenia rectivirgula* *Aspergillus spp.*
Poultry worker's lung (feather plucker's disease)	Serum proteins (chicken products)
Pyrethrum (pesticide)	Pyrethrum
Sauna taker's lung	*Aureobasidium* spp., other sources
Sequoiosis (moldy wood dust)	*Graphium* *Pullularia* *Trichoderma spp.* *Aureobasidium pullulans*
Suberosis (moldy cork dust)	*Thermoactinomyces viridis* *Penicillium glabrum* *Aspergillus conidia*
Summer-type pneumonitis	*Trichosporon cutaneum*
Tea grower's lung	Tea plants
Thatched-roof lung (huts in New Guinea)	*Saccharomonospora viridis* (dead grasses and leaves)
Tobacco grower's lung	*Aspergillus* spp. *Scopulariopsis brevicaulis*
Turkey handling disease	Serum proteins (turkey products)
Unventilated shower	*Epicoccum nigrum*
Upholstery fabric (nylon filament, cotton/polyester, and latex adhesive)	Aflatoxin-producing fungus, *Fusarium* spp.
Velvet worker's lung	Unknown (? nylon velvet fiber, tannic acid, potato starch)
Vineyard sprayer's lung	Copper sulfate (Bordeaux mixture)
Wine maker's lung (mold on grapes)	*Botrytis cinerea*
Wood dust pneumonitis (oak, cedar, and mahogany dust, pine and spruce pulp)	*Alternaria* spp. *Bacillus subtilis*
Wood pulp worker's disease (oak and maple trees)	*Penicillium* spp.
Wood trimmer's disease (contaminated wood trimmings)	*Rhizopus* spp., *Mucor* spp.

Table 448.2 Clinical History Leading to a Diagnosis of Hypersensitivity Pneumonitis

Recurrent pneumonia
Pneumonia after repeat exposures (week, season, situation)
Cough, fever, and chest symptoms after making a job change or home change
Cough, fever, wheezing after return to school or only at school
Pet exposure (especially birds that shed dust such as pigeons, canaries, cockatiels, cockatoos)
Bird contaminant exposure (e.g., pigeon infestation)
Farm exposure to birds and hay
History of water damage
Use of hot tub, sauna, swimming pool
Other family members or workers with similar recurrent symptoms
Improvement after temporary environment change (e.g., vacation)

are consistent with HP (Table 448.3). These findings must prompt the clinician to identify the exposure in order to secure the diagnosis and eliminate the offending antigen. Without therapy, the progressive inflammatory response leads to air trapping, honeycombing, emphysema, and mild fibrosis in the chronic state. Diagnostic components are reviewed next.

LABORATORY

Most of the abnormal laboratory findings in HP are not specific and represent evidence of activated inflammatory markers or lung injury. For example, nonspecific elevation of immune globulins or the erythrocyte sedimentation rate and C-reactive protein may be found. Circulating immune complexes may be detected. Lactate dehydrogenase may be elevated in the presence of lung inflammation and normalizes with response to therapy.

Serum IgG precipitins to the offending agent are frequently positive and have a poor positive predictive value for disease. For example, among asymptomatic pigeon breeders, precipitating antibodies are nearly universal. False negatives can also be seen as a result of fluctuating serum antibody levels over time and a lack of standardized commercial antigens and reagents available for laboratory testing. It is critical that laboratories familiar with the performance of these tests be used. Those laboratories often recognize the value of processing antigens for precipitation from the environmental source directly as the test substrate with patient serum. Skin testing for immunoglobulin E (IgE)-mediated disease is not warranted unless there is evidence of mixed lung pathology such as asthma and interstitial lung opacities.

Radiology

Chest radiograph almost always precedes the use of HRCT of the chest in children because of the need for sedation and concerns regarding the risk of being exposed to an increased radiation dose from HRCT. The plain radiograph may demonstrate a ground-glass appearance, interstitial prominence, with a predominant location in the upper and middle lung fields. It is common for a chest radiograph to be considered normal by a radiologist early in the disease. Late in the disease, interstitial fibrosis may become prominent in the presence of increasing dyspnea, hypoxemia on room air, and even clubbing of the fingers. Mediastinum widening from lymphadenopathy is not usually present; when present, the lymph nodes are prominent along the airway near the carina, suggesting that the antigen source is inhaled, and this represents the response of the immune system.

HRCT of the chest is important in distinguishing nonfibrotic from fibrotic HP and may reduce the need for a lung biopsy. HRCT of the chest in **nonfibrotic HP** demonstrates (1) at least one abnormality revealing evidence of parenchymal infiltration (such as ground-glass opacities or mosaic attenuation) and (2) at least one abnormality revealing evidence of small airway disease (such as ill-defined, centrilobular nodules or air trapping), both distributed in a diffuse pattern. **Fibrotic HP** is characterized by (1) a lung fibrosis (irregular linear opacities/coarse reticulation; traction bronchiectasis and honeycombing) located in a random or mid-lung zone and (2) at least one abnormality that is consistent with small airway disease.

Table 448.3 Criteria Used in the Diagnosis of Hypersensitivity Pneumonitis

1. Identified exposure to offending antigen(s) by:
- Medical history of exposure to suspected antigen in the patient's living environment
- Investigations of the environment confirm the presence of an inciting antigen
- Identification of specific immune responses (immunoglobulin G serum precipitin antibodies against the identified antigen) are suggestive of the potential etiology but are insufficient in isolation to confirm a diagnosis
- Abnormal response to an inhalation challenge testing to the offending antigen via reexposure to the environment or inhalation challenge to the suspected antigen

2. Clinical, radiographic, or physiologic findings compatible with hypersensitivity pneumonitis:
- Respiratory and often constitutional signs and symptoms
  - Cough
  - Breathlessness
  - Crackles on auscultation of the chest
  - Weight loss
  - Episodic fever
  - Wheezing
  - Fatigue

NOTE: These findings are especially suggestive of hypersensitivity pneumonitis when they appear or worsen several hours after antigen exposure.

- High-resolution chest CT findings typical of HP:
  - Nonfibrotic HP pattern:
    - At least one HRCT abnormality indicative of parenchymal infiltration (such as ground-glass opacities or mosaic attenuation) in a diffuse distribution
    - At least one HRCT abnormality indicative of small airway disease (such as ill-defined, centrilobular nodules or air trapping) in a diffuse distribution
  - Fibrotic HP pattern:
    - Lung fibrosis (irregular linear opacities/coarse reticulation with lung distortion; traction bronchiectasis and honeycombing) in a random or mid-lung zone predominant location
    - At least one abnormality that is indicative of small airway disease

3. Bronchoalveolar lavage with lymphocytosis (>20%, often >50%):
- Usually with low CD4:CD8 ratio (i.e., CD8 is higher than normal)

4. Histopathology showing compatible changes with nonfibrotic or fibrotic hypersensitivity pneumonitis and the absence of features in any biopsy site to suggest an alternative diagnosis
- Nonfibrotic HP (purely inflammatory):
  - Cellular interstitial pneumonia
  - Chronic cellular bronchiolitis with a lymphocytic peribronchial infiltration
  - Poorly formed nonnecrotizing granulomas located near respiratory or terminal bronchioles
- Fibrotic HP (mixed inflammatory plus fibrotic or purely fibrotic):
  - Chronic fibrosing interstitial pneumonia
  - Airway-centered fibrosis
  - Poorly formed nonnecrotizing granulomas

Data from Raghu G, Remy-Jardin M, Ryerson CJ, et al. Diagnosis of hypersensitivity pneumonitis in adults. An official ATS/JRS/ALAT clinical practice guideline [published correction appears in *Am J Respir Crit Care Med.* 2021 Jan 1;203(1):150–151] [published correction appears in *Am J Respir Crit Care Med.* 2022 Aug 15;206(4):518]. *Am J Respir Crit Care Med.* 2020;202(3):e36–e69.

Bronchoalveolar Lavage

BAL is one of the most sensitive tests in supporting the diagnosis of HP. Lymphocytosis frequently exceeding 50% of the recovered cells is seen in the BAL fluid and should alert the clinician to the possibility of HP. Sarcoid, IPF, cryptogenic organizing pneumonia, berylliosis, granite workers lung disease, amiodarone pneumonia, lymphoma, and Langerhans cell histiocytosis may demonstrate lymphocytosis on BAL. All BAL specimens should have *flow cytometry* measurements of T-cell markers (CD3, CD4, and CD8 at a minimum). The predominant phenotype of the lymphocytosis is $CD3^+/CD8^+/CD56^+/CD57^+/CD10^-$. In the normal circulation, lymphocytes with CD4 markers predominate at a ratio of approximately 2:1 compared with CD8 lymphocytes. *In HP, this ratio becomes approximately equal to or less than 1 (CD4:CD8 ≤1) with either an increase in CD8 lymphocytes or a decline in CD4 lymphocytes.* Although this ratio helps the clinician in making a diagnosis of HP, this BAL finding is not 100% diagnostic for HP. Cryptogenic organizing pneumonia, a rare disease in children, also may present with BAL, where the CD4:CD8 is ≤1, and may be confused initially with HP. This is in sharp contrast to other lymphocytic granulomatous diseases, like sarcoidosis, where the CD4:CD8 is ≥2.

Lung Biopsy

Lung biopsy is necessary to confirm a diagnosis of HP when critical elements are not present, including antigen exposure, a medical history classic for HP, characteristic physical exam findings, chest HRCT findings, and $CD8^+$ lymphocytes in the BAL. Open lung biopsy is often the route of choice in young children because of the difficulty in safely obtaining satisfactory amounts of tissue by transbronchial biopsy. Lack of positive serum precipitins to an offending antigen and lack of an exposure history are common reasons for obtaining lung biopsies. It is crucial to inform the pathologist about the suspicion of HP so that the findings can be interpreted appropriately.

Histopathologic examination of **nonfibrotic HP (purely inflammatory)** demonstrates three primary features: (1) cellular interstitial pneumonia, (2) chronic cellular bronchiolitis with a lymphocytic peribronchial infiltration, and (3) nonnecrotizing granulomas near respiratory or terminal bronchioles. **Fibrotic HP (mixed inflammatory plus fibrotic or purely fibrotic)** is histologically characterized by (1) chronic fibrosing interstitial pneumonia, (2) airway-centered fibrosis, and (3) poorly formed nonnecrotizing granulomas. Furthermore, there is an absence of features in any biopsy site to suggest an alternative diagnosis.

Of note, poorly formed noncaseating granulomas and multinucleated giant cells are seen in HP. This is in sharp contrast to the well-formed granulomas seen in sarcoidosis.

Antigen Challenge by Inhalation

Inhalation challenge can support the diagnosis of HP by demonstrating a causal relationship between environmental exposure and symptoms. Inhalation challenge can be performed by two methods: (1) reexposure to the environment where the suspected antigen is present and (2) a direct inhalation challenge at the hospital to material collected from the suspected source of the antigen. As the second method has resulted in severe exacerbation of disease in some individuals, performing this challenge is discouraged.

Two abnormal response patterns may be seen. Most commonly, where there is **HP without asthma**, symptoms occur 8-12 hours after direct challenge in the hospital or after reexposure to the source of the antigen. The challenges replicate some or all of the symptoms observed in the acute syndrome with fever, dyspnea, fatigue, and crackles on lung auscultation. Blood drawn before challenge and then repeated during these symptoms often demonstrates an increased neutrophil count compared to baseline. Pulmonary function tests demonstrate a fall in forced vital capacity (FVC) and often a concurrent fall in the forced expiratory volume at 1 second (FEV_1), with a stable or increasing ratio of FEV_1:FVC reflecting a restrictive defect. Hypoxemia may accompany this decline in pulmonary function along with a fall in the diffusion capacity of carbon monoxide (DLCO). To see the complete effect, exercise during this period may show a considerable fall in oxygenation despite normal arterial blood gas oxygen tension and normal pulse oximetry at rest. This finding denotes the onset of worsening restrictive lung disease.

Where there is **HP with concomitant allergic asthma**, these patients may experience a biphasic response to the inhalation challenge. These patients may develop an early reduction in FEV_1, followed by a second drop in FEV_1 and FVC 4-6 hours later. The patient may also have accompanying fever and leukocytosis.

TREATMENT

The control of environmental exposure to the offending antigen is key to curing HP and remains the ideal method of treatment and prevention of recurrence. The clinical and pathologic manifestations of nonfibrotic (purely inflammatory) HP are reversible with removal of the offending antigen. Counseling parents and children about the risk of exposure to birds and feathered bedding or other environmental antigens, biologic aerosols, or agricultural dusts that are known to induce HP is important. Certainly, the source of the antigen and type of antigen appear to affect the response to treatment and long-term prognosis. Older individuals who contract farmer's lung are likely to recover with minimal permanent residual effect, whereas individuals with bird fancier's lungs from antigens produced by pigeons have a worse prognosis, especially if fibrosis is detected on lung biopsy. The pediatrician should advise—in the strongest terms—removal of the antigen source from the affected child's environment. This may be an extraordinary challenge given various children's living circumstances and lack of independent control of the environment in which they live.

In addition, pediatricians should be familiar with recommendations about the maintenance of heating, ventilation, and air conditioning systems, in addition to humidifiers and vaporizers. Daily drainage, cleansing of residue, and routine cleaning with hydrogen peroxide or bleach help rid humidifiers and vaporizers of harmful pathogens such as thermophiles that cause HP.

Removal of the antigen alone is sufficient to normalize lung function in most patients, but symptoms and pulmonary functions return to normal faster with the use of glucocorticoids. Among those with nonfibrotic HP, glucocorticoids at a dose of 0.5 mg/kg/day of prednisone or equivalent (up to a maximum dose of 30 mg prednisone daily) will reduce the immune inflammatory response in the lungs. Comparative trials in adults demonstrate that the use of 4 weeks of therapy is as effective as 12 weeks of therapy. Because of the rapid reversal of symptoms, successful abatement of the environment is sometimes compromised when the family sees improvement before the antigen source removal.

As with nonfibrotic HP, removal of the offending antigen is also recommended for fibrotic HP. However, there is a paucity of clinical trial data outlining the best immunomodulatory strategies for fibrotic HP. Among those patients with fibrotic HP with inflammatory features present, a trial of glucocorticoids may be pursued at a dose of 0.5 mg/kg per day (up to 30 mg per day) for 4-8 weeks, followed by tapering for 3 months. For patients who have not responded to both antigen removal and corticosteroid treatment, azathioprine and mycophenolate mofetil have been used, but their efficacy has not been tested in clinical trials. Case reports have also reported the use of rituximab for HP treatment because of its ability to reduce immune cell complexes. Results have reported mixed clinical efficacy. Antifibrotic drugs that are used for IPF such as nintedanib or pirfenidone are being tested in clinical trials.

448.2 Occupational and Environmental Lung Disease

Michelle L. Hernandez and Stephanie D. Davis

Although occupational and environmental lung diseases include **occupational asthma**, **irritant-induced asthma**, HP, hard metal inhalation lung disease, berylliosis, and air pollution, this chapter focuses on occupational asthma and irritant-induced asthma. Berylliosis has a propensity to form granulomas (see Chapter 448.3). Although some diseases will be seen with regularity, the important role that a workplace, school, daycare, neighbors' housing, multiple family housing, and indoor and outdoor environments may have in the causation of signs and symptoms in the patient is often not considered by the clinician.

Occupational asthma *differs* from work-exacerbated asthma. Individuals with occupational asthma develop asthma after exposure to immunologic or nonimmunologic stimuli found in the workplace, whereas those with work-exacerbated asthma already have asthma that worsens in the workplace because of a myriad of exposures.

The vast array of exposures that may cause disease of the lungs is daunting, such as the inhalation of baking flour or household cleaning fluids causing asthma, microwave popcorn that uses diacetyl flavoring resulting in bronchiolitis obliterans, and exposure to thermophilic organisms or mold resulting in HP. The acute eosinophilic pneumonias associated with the new onset of smoking and chemical inhalation of 1,1,1-trichloroethane (Scotchgard) require a high index of suspicion and unique lines of questioning. The same antigen encountered in a work, school, home, or outdoor environment may result in different disease presentations among patients because of host factors, dose exposure, and genetic susceptibility. One of the most prominent examples is an investigation of workers who inhaled metal working fluid. Despite similar exposures, some developed HP, others developed asthma, and some displayed no symptoms at all. Immunologic evaluation in some exposures has shown similar immune responses in different individuals, but a wide range of disease provocation. When high molecular weight proteins cause asthma, symptoms of rhinoconjunctivitis frequently precede the onset of pulmonary symptoms. The medical history in occupational and environmental lung diseases has used an expanded construct with a simple acronym, **WHACOS** (Table 448.4).

CLASSIFICATION AND PATHOGENESIS

Occupational and environmental lung diseases include numerous syndromes of human lung disease such as **occupational asthma**, **irritant-induced asthma**, reactive upper airway disease syndrome, HP (see Chapter 448.1), air pollution–induced disease, hard metal inhalation lung disease, berylliosis, occupation-induced lung cancer (e.g., mesothelioma from asbestosis), and chronic obstructive pulmonary disease. Most of these diseases are not problematic for children, but adolescents may be at risk to develop lung disease through exposure through part-or full-time work or by single exposures, as seen in some types of irritant-induced asthma.

Table 448.4 A Construct (WHACOS) that Has Been Used in Medical Interviewing of Patients, Coworkers, and Family Members when Environmental or Occupational Lung Disease Is Being Considered

W	***W**hat* do you do?
H	***H**ow* do you do what you do?
A	Are symptoms ***A**cute* or are they *Chronic*?
C	Do any ***C**oworkers*, family, classmates, or friends have the same symptoms?
O	Do you have any hobbies, travel, or animal/pet exposures ***O**utside* of school or work?
S	Are you ***S**atisfied* with work or school?

Occupational and Environmental Asthma

It is important to remember that in patients with occupational- or environmental-induced disease, the onset of symptoms has a lag time between exposure and symptoms. In **occupational asthma**, there may be an immediate response within 30 minutes to 2 hours of exposure, demonstrated as a decline in pulmonary function, specifically the FEV_1. Usually, lung function returns to normal spontaneously unless persistent exposure occurs. Some patients demonstrate no immediate reduction in lung function, but rather experience a delayed response of 4-6 hours after the exposure. Treating physicians can take advantage of this physiology by using spirometry before and after work or school or using peak flow measurements hourly during exposure and after leaving the exposure. Because workers and school children have prolonged periods of exposure followed by a number of days without exposure, the use of pulmonary function plus nonspecific bronchial responsiveness (e.g., methacholine) testing is helpful. For example, pulmonary function tests before starting work or school on a Monday of a typical week may be normal. By Friday of this typical work or school week, the baseline pulmonary function indices may have fallen, and nonspecific bronchial responsiveness may have become more sensitive to a lower concentration of histamine, methacholine, or mannitol. By Monday, the tests may have returned to normal or near normal with no change other than reduced exposure.

High molecular weight causes of occupational and environmental asthma can be characterized as allergens, which are normally proteins and enzymes, inhaled from multiple sources (Table 448.5). These include various animals, shellfish, fish, enzymes (e.g., *Bacillus subtilis* in laundry detergent), and flour or cereals. Occupational and environmental asthma is also caused by a number of low molecular weight agents, including reactive chemicals, transition metals, and wood dusts (Table 448.6). These **low molecular weight agents** are sufficient to induce an immune response, but often *not by an IgE-mediated mechanism.* These low molecular weight chemicals appear to act as haptens that bind directly to human proteins, causing an immune response in the human host.

The pathogenesis of asthma in patients exposed to **high molecular weight** antigens follows the experience of nonoccupational asthma in patients where atopy, sex, genetics, concentration of antigen, duration of exposure, and other individual factors all contribute to the development of disease. Most individuals require a concentration and duration of exposure sufficient to cause IgE antibody sensitization to the offending allergen with development of bronchial hyperresponsiveness and airway inflammatory disease upon reexposure. If the allergen exposure is sufficient, these proteins can drive the immune response to a T-lymphocyte type 2 phenotype (Th2), even in patients without prior atopic disposition. This occurred in the case of latex allergy, where many nonatopic individuals and patients exposed to allergen in their personal healthcare environment developed occupational allergy to multiple proteins from natural rubber latex. Atopic individuals are at the highest risk of developing latex allergy. A longitudinal study demonstrated that powdered latex gloves with high allergen content were the reason for the epidemic of latex allergy and occupational asthma. Unfortunately, despite primary removal of the offending sensitizing agent, symptoms caused by asthma and bronchial hyperresponsiveness continue in roughly 70% of individuals.

Diagnosis of Occupational Asthma

Occupational asthma should be assessed with a full history, physical examination and objective confirmation of an asthma diagnosis using spirometry, and nonspecific bronchial responsiveness. The negative predictive value of methacholine challenge while the patient is still in the workplace is high (98%): a negative methacholine challenge makes the diagnosis of occupational asthma very unlikely in a patient who is continuously exposed to the suspected causative agent. In addition to comparing measures of nonspecific bronchial responsiveness while on and off work, induced sputum and fractional exhaled nitric oxide (FeNO) can increase the diagnostic sensitivity to 94% through identifying the presence of eosinophilic inflammation. Specific IgE testing

Table 448.5 High Molecular Weight Antigens Known to Induce Occupational or Environmental Asthma

OCCUPATION OR ENVIRONMENT	SOURCE
ANIMAL-DERIVED ANTIGENS	
Agricultural worker	Cow dander
Bakery	Lactalbumin
Butcher	Cow bone dust, pig, goat dander
Cook	Raw beef
Dairy industry	Lactoserum, lactalbumin
Egg producer	Egg protein
Farmer	Deer dander, mink urine
Frog catcher	Frog
Hairdresser	Sericin
Ivory worker	Ivory dust
Laboratory technician	Bovine serum albumin, laboratory animal, monkey dander
Nacre buttons	Nacre dust
Pharmacist	Endocrine glands
Pork producer	Pig gut (vapor from soaking water)
Poultry worker	Chicken
Tanner	Casein (cow's milk)
Various	Bat guano
Veterinarian	Goat dander
Zookeeper	Birds
CRUSTACEANS, SEAFOOD, FISH	
Canning factory	Octopus
Diet product	Shark cartilage
Fish food factory	Gammarus shrimp
Fish processor	Clam, shrimp, crab, prawn, salmon, trout, lobster, turbot, various fishes
Fisherman	Red soft coral, cuttlefish
Jewelry polisher	Cuttlefish bone
Laboratory grinder	Marine sponge
Oyster farm	Hoya (oyster farm prawn or sea-squirt)
Restaurant seafood handler	Scallop and shrimp
Scallop plant processor	King scallop and queen scallop
Technician	Shrimp meal *(Artemia salina)*
ARTHROPODS	
Agronomist	Bruchus lentis
Bottling	Ground bug
Chicken breeder	Herring worm *(Anisakis simplex)*
Engineer at electric power plant	Caddis flies *(Phryganeidae)*
Entomologist	Lesser mealworm (*Alphitobius diaperinus* Panzer), moth, butterfly
Farmer	Grain pests (*Eurygaster* and *Pyrale*)
Fish bait handler	Insect larvae *(Galleria mellonella)*, mealworm larvae *(Tenebrio molitor)*, green bottle fly larvae *(Lucila caesar)*, daphnia, fish-feed Echinodorus larva *(Echinodorus plasmosus)*, Chiromids midge *(Chironomus thummi thummi)*
Fish processing	Herring worm *(Anisakis simplex)*
Flight crew	Screw worm fly *(Cochliomyia hominivorax)*
Honey processors	Honeybee
Laboratory worker	Cricket, fruit fly, grasshopper *(Locusta migratoria)*, locust
Mechanic in a rye plant	Confused flour beetle *(Tribolium confusum)*
Museum curator	Beetles (Coleoptera)
Seed house	Mexican bean weevil *(Zabrotes subfasciatus)*
Sericulture	Silkworm, larva of silkworm
Sewage plant worker	Sewer fly *(Psychoda alternata)*
Technician	Arthropods *(Chrysoperla carnea, Leptinotarsa decemlineata, Ostrinia nubilalis,* and *Ephestia kuehniella)*, sheep blowfly *(Lucilia cuprina)*
Wool worker	*Dermestidae* spp.
ACARIANS	
Apple grower	Fruit tree red spider mite *(Panonychus ulmi)*
Citrus farmer	Citrus red mite *(Panonychus citri)*
Farmer	Barn mite, two-spotted spider mite *(Tetranychus urticae)*, grain mite
Flour handler	Mites and parasites
Grain-store worker	Grain mite
Horticulturist	*Amblyseius cucumeris*
Poultry worker	Fowl mite
Vine grower	McDaniel spider mite *(Tetranychus mcdanieli)*
MOLDS	
Agriculture	*Plasmopara viticola*
Baker	*Alternaria, Aspergillus* (unspecified)
Beet sugar worker	*Aspergillus* (unspecified)
Coal miner	*Rhizopus nigricans*
Coffee maker	*Chrysonilia sitophila*
Laborer	*Sooty molds (Ascomycetes,* deuteromycetes)
Logging worker	*Chrysonilia sitophila*
Plywood factory worker	*Neurospora*
Sausage processing	*Penicillium nalgiovense*
Sawmill worker	*Trichoderma koningii*
Stucco worker	*Mucor* spp. (contaminating esparto fibers)
Technician	*Dictyostelium* discoideum (mold), *Aspergillus niger*
MUSHROOMS	
Agriculture	*Agaricus bisporus* (white mushroom)
Baker	Baker's yeast *(Saccharomyces cerevisiae), Boletus edulis*
Greenhouse worker	Sweet pea *(Lathyrus odoratus)*
Hotel manager	*Boletus edulis*
Mushroom producer	*Pleurotus cornucopiae*

Table 448.5 High Molecular Weight Antigens Known to Induce Occupational or Environmental Asthma—cont'd

OCCUPATION OR ENVIRONMENT	SOURCE
Mushroom soup processor	Mushroom unspecified
Office worker	Boletus edulis
Seller	*Pleurotus ostreatus* (spores of white spongy rot)
ALGAE	
Pharmacist	Chlorella
Thalassotherapist	Algae (species unspecified)
FLOURS	
Animal fodder	Marigold flour *(Tagetes erecta)*
Baker	Wheat, rye, soya, and buckwheat flour; Konjac flour; white pea flour *(Lathyrus sativus)*
Food processing	White Lupin flour *(Lupinus albus)*
POLLENS	
Florist	Cyclamen, rose
Gardener	Canary island date palm *(Phoenix canariensis)*, bell of Ireland *(Moluccella laevis)*, bell pepper, chrysanthemum, eggplant *(Solanum melongena)*, *Brassica oleracea* (cauliflower and broccoli)
Laboratory worker	Sunflower (*Helianthus* spp.), thale cress *(Arabidopsis thaliana)*
Olive farmers	White mustard *(Sinapis alba)*
Processing worker	*Helianthus annuus*
PLANTS	
Brewery chemist	Hops
Brush-makers	Tampico fiber in agave leaves
Butcher	Aromatic herb
Chemist	Linseed oilcake, *Voacanga africana* seed dust
Cosmetics	Dusts from seeds of sacha inchi *(Plukenetia volubilis)*, chamomile (unspecified)
Decorator	Cacoon seed (Entage gigas)
Floral worker	Decorative flower, safflower *(Carthamus tinctorius)* and yarrow *(Achillea millefolium)*, spathe flower, statice *(Limonium tataricum)*, baby's breath *(Gypsophila paniculata)*, ivy *(Hedera helix)*, flower (various), sea lavender *(Limonium sinuatum)*
Food industry	Aniseed, fenugreek, peach, garlic dust, asparagus, coffee bean, sesame seed, grain dust, carrot *(Daucus carota L.)*, green bean *(Phaseolus multiflorus)*, lima bean *(Phaseolus lunatus)*, onion, potato, Swiss chard *(Beta vulgaris L.)*, courgette, carob bean, spinach powder, cauliflower, cabbage, chicory, fennel seed, onion seeds (*Allium cepa*, red onion), rice, saffron *(Crocus sativus)*, spices, grain dust
Gardener	Copperleaf *(Acalypha wilkesiana)*, grass juice, weeping fig *(Ficus benjamina)*, umbrella tree (*Schefflera* spp.), amaryllis (*Hippeastrum* spp.), Madagascar jasmine sap *(Stephanotis floribunda)*, vetch *(Vicia sativa)*
Hairdresser	Henna (unspecified)
Herbal tea processor	Herbal tea, sarsaparilla root, sanyak *(Dioscorea batatas)*, Korean ginseng *(Panax ginseng)*, tea plant dust *(Camellia sinensis)*, chamomile (unspecified)
Herbalist	Licorice roots (*Glycyrrhiza* spp.), wonji *(Polygala tenuifolia)*, herb material
Horticulture	Freesia (Freesia hybrida), paprika *(Capsicum annuum)*, Brazil ginseng *(Pfaffia paniculata)*
Laborer	Citrus food handling (*dl*-limonene, *l*-citronellol, and dichlorophen)
Oil industry	Castor bean, olive oil cake
Pharmaceutical	Rose hip, passion flower *(Passiflora alata)*, cascara sagrada *(Rhamnus purshiana)*
Powder	Lycopodium powder
Sewer	Kapok
Sheller	Almond shell dust
Stucco handler	Esparto (*Stipa tenacissima* and *Lygeum spartum*)
Tobacco manufacturer	Tobacco leaf
PLANT-DERIVED NATURAL PRODUCTS	
Baker	Gluten, soybean lecithin
Candy maker	Pectin
Glove manufacturer	Latex
Health professional	Latex
Rose extraction	Rose oil
BIOLOGIC ENZYMES	
Baker	Fungal amylase, fungal amyloglucosidase and hemicellulase
Cheese producer	Various enzymes in rennet production (proteases, pepsine, chymosins)
Detergent industry	Esterase, *Bacillus subtilis*
Factory worker	*Bacillus subtilis*
Fruit processor	Pectinase and glucanase
Hospital personnel	Empynase (pronase B)
Laboratory worker	Xylanase, phytase from *Aspergillus niger*
Pharmaceutical	Bromelin, flaviastase, lactase, pancreatin, papain, pepsin, serratia peptidase, and lysozyme chloride; egg lysozyme, trypsin
Plastic	Trypsin
VEGETABLE GUMS	
Carpet manufacturing	Guar
Dental hygienist	*Gutta-percha*
Gum importer	Tragacanth
Hairdresser	Karaya
Printer	Acacia

Table 448.6 Low Molecular Weight Chemicals Known to Induce Occupational or Environmental Asthma

CHEMICALS	OCCUPATION OR ENVIRONMENT SOURCE
Diisocyanates	
• Diphenylmethane • Hexamethylene • Naphthalene • Toluene	• Polyurethane • Roofing materials • Insulations • Paint
Anhydrides	Manufacturers or users
• Trimellitic • Phthalic	• Paint • Plastics • Epoxy resins
Dyes	Personal or business use of dyes
• Anthraquinone • Carmine • Henna • Persulfate	• Hair dye • Fur dye • Fabric dye
Glue or resin	Plastic
• Methacrylate • Acrylates • Epoxy	• Manufacturers • Healthcare professionals • Orthopedic specialists
Metals	Metal work
• Chromic acid • Potassium dichromate • Nickel sulfate • Vanadium • Platinum salts	• Plating • Welding
Drugs	Exposure to drugs in environment
• β-Lactams • Opioids • Other	• Pharmaceutical workers • Farmers • Healthcare workers
Chemicals	Exposure in the healthcare field
• Formaldehyde • Glutaraldehyde • Ethylene oxide	• Laboratory work • Healthcare professionals
Wood dust	Workers/hobbyists

(via percutaneous skin testing or serum IgE) to the causative agent is often impractical given the lack of commercial extracts to the over 300 known causative agents for occupational asthma (see Table 448.5).

Treatment of Occupational Asthma

The management of occupational asthma is centered on exposure reduction and optimized pharmacotherapy with inhaled corticosteroids (ICS) following the National Asthma Education and Prevention Program (NAEPP) and the Global Initiative for Asthma (GINA) guidelines (reviewed in Chapter 185). Ideally, patients would be completely removed from the exposure for the best outcomes. However, in cases where this is not feasible, respiratory protection devices and work accommodations to reduce the exposure should be pursued under the guidance of an occupational hygienist. Because of a lack of commercially available extracts for the causative agent, allergen-specific immunotherapy has limited applicability for the treatment of occupational asthma for patients who cannot avoid the exposure. For these reasons, omalizumab therapy has been successfully used in small case series to attenuate the IgE response, resulting in reduced exacerbations and systemic and/or inhaled corticosteroid requirements.

Irritant-Induced Asthma and Reactive Airways Disease Syndrome

Irritant-induced asthma is also a form of work-related asthma and has both **acute and subacute** phenotypes. As opposed to occupational asthma, irritant-induced asthma results from **nonimmunologic** provocation of bronchial hyperresponsiveness with airflow obstruction.

The most well-characterized presentation of **acute irritant-induced asthma** is **reactive airways dysfunction syndrome (RADS)**, where patients present with acute respiratory symptoms within minutes or hours after a single inhalation of an *elevated concentration* of irritant aerosol, gas, or smoke. Many of these exposures are accidental in nature. The clinical manifestations and pathophysiology of RADS have been studied through experimental design or epidemiology studies involving exposure to chlorine gas, acetic acid, dimethylaminoethanol, chlorofluorocarbons, epichlorohydrin, and diisocyanates. Patients with RADS typically can pinpoint the exact time of onset of symptoms and the exact number of hours post exposure. The symptoms are so severe that nearly 80% of subjects in one study presented to an emergency department for care. The lower airway symptoms of cough, dyspnea, chest tightness, and wheezing are prominent features in RADS, with cough being most prevalent. Because of the toxic nature of the inhaled chemical, it is predictable that an upper airway syndrome of throat and nose burning will often accompany the lower airway symptoms. This part of the complex has been referred to as **respiratory upper airway dysfunction syndrome**.

Predisposing factors for the development of RADS are not well characterized. Cigarette smoking may increase the risk of developing RADS when exposure through inhalation of irritant chemicals occurs. In addition to host factors, the type of chemical appears to be important. Higher concentrations of chemicals, the type of chemical (vapor or wet aerosols), and bleaching agents are the most offending agents to cause RADS. Dry particle aerosols are less likely to cause RADS. Analysis of the World Trade Center firefighters indicates that the presence of bronchial hyperresponsiveness before this catastrophe did not increase the risk for an individual to develop RADS.

The pathogenesis of RADS follows a typical pattern, driven by the initial injury to the airway epithelium. Initial histology demonstrates rapid mucosal denudation accompanied by a submucosal fibrinous, hemorrhagic exudate. Subepithelial edema subsequently occurs with epithelial layer regeneration, basal and parabasal cells increase, and eventually areas of fibrosis form. The desquamation, fibrosis, basement membrane thickening, and basal cell regeneration are more characteristic of RADS than occupational asthma. This may explain the limited response to bronchodilator therapy in this syndrome compared to asthma.

In contrast to the acute onset of symptoms after exposure seen with RADS, individuals with **subacute irritant-induced asthma** present with a more insidious onset of symptoms. Because of the recurrent nature of the low concentration of the chemical exposure, patients may initially not be able to identify the underlying trigger. **Subacute irritant-induced asthma** has been described through epidemiologic studies and characterized by (1) the insidious onset of symptoms occurring after *multiple high exposures to irritants* (such as what occurred among some rescue workers at the World Trade Center) or (2) single or multiple exposures to irritant chemicals in *low concentrations*. Similar to allergic rhinitis, patients may describe nasal congestion, rhinorrhea, sneezing, postnasal drip, ocular irritation, and conjunctival injection. Pulmonary symptoms include those typically seen with asthma exacerbations.

Table 448.7 Criteria for Reactive Airways Disease (Dysfunction) Syndrome

- Documented absence of preceding respiratory symptoms
- Onset after single specific high-level exposure incident
- Exposure to very high concentration of gas, smoke, fumes, or vapors with *irritant* properties
- Onset of symptoms within 24 hours after exposure with persistence for ≥3 months
- Symptoms similar to asthma with cough, wheeze, and dyspnea
- Presence of airflow obstruction on pulmonary function ± nonspecific bronchial (methacholine) hyper-responsiveness
- Other pulmonary disease excluded

Data from Varney VA, Evans J, Bansal. Successful treatment of reactive airways dysfunction syndrome by high-dose vitamin D. *J Asthma Allergy*. 2011;4:87–91.

Diagnosis of Irritant-Induced Asthma

Initial evaluation of the patient with acute (RADS) or subacute irritant-induced asthma usually includes the medical history, physical examination, and pulse oximetry. Because of the acute nature of RADS, a chest radiograph is obtained in order to rule out other acute causes of dyspnea, including pneumonia or pulmonary edema. In patients with both acute and subacute irritant-induced asthma, the chest radiograph is frequently normal or may reveal hyperinflation. Ideally, if the patient is not in significant distress, complete pulmonary function testing with spirometry, assessment of bronchodilator reversibility, and nonspecific bronchial provocation with methacholine are helpful in the initial evaluation.

Table 448.7 lists the criteria for a diagnosis of **RADS**. Asthma-like symptoms and airway hyperresponsiveness occur and often persist for prolonged periods. Unlike typical asthma, *RADS is often not reversible after administration of a bronchodilator*. This is probably a consequence of the direct injury to the epithelium and subsequent submucosal fibrosis.

Treatment of RADS and Irritant-Induced Asthma

Treatment of acute (RADS) and subacute irritant-induced asthma focuses on prevention of exposure. Because the exposure in RADS is often associated with a single known exposure, this task is readily accomplished. The low, persistent exposures associated with subacute irritant-induced asthma are more challenging to identify and remove.

Implementing treatment guidelines for asthma is recommended when intervention is required beyond antigen removal. Managing an acute presentation of RADS is exactly the same as managing an acute asthma exacerbation. Short-acting β-agonist treatment may not be effective; a trial of inhaled ipratropium may add benefit in the short term. For moderate to severe symptoms and FEV_1 values that are less than 70% of predicted, administration of systemic glucocorticoids (2 mg/kg prednisone equivalent, up to 60 mg daily) can be beneficial based on some clinical case studies and animal studies. Unlike the typical 5-day courses of systemic glucocorticoids for asthma exacerbations, many patients remain symptomatic beyond 5 days as a result of the extent of the airway epithelial injury. Steroid treatment may be prolonged up to 10-15 days after the onset of symptoms; a slow taper of corticosteroids may be implemented after the 10-15 days. High-dose ICS therapy with or without long-acting β-agonists may be added while the systemic steroids are being tapered. The initial high-dose ICS regimens are based on the NAEPP and the GINA guidelines. For patients whose initial symptoms are not as severe and/or spirometry demonstrates milder airway obstruction (FEV_1 greater than or equal to 70% of predicted), high-dose ICS therapy alone can be started without requiring systemic corticosteroid treatment. Once patients' asthma symptoms are improved, ICS doses can be tapered by increments of 25–50% over a period of up to 6 months in some case series based on patient symptoms. However, prolonged ICS treatment beyond 6 months has also been noted.

448.3 Granulomatous Lung Disease

Timothy J. Vece, Eveline Y. Wu, and Stephanie D. Davis

GRANULOMATOSIS WITH POLYANGIITIS

Granulomatosis with polyangiitis (GPA), formerly *Wegener granulomatosis,* is a disease that involves both the lower and upper respiratory tracts with granulomatous inflammation of small- to medium-sized vessels (see Chapter 210). Pulmonary disease is frequently associated with glomerulonephritis. The simultaneous presence of pulmonary and renal disease should immediately raise the suspicion for GPA, microscopic polyangiitis, or anti–glomerular basement membrane (anti-GBM) disease (see Chapter 448.5).

Epidemiology

The prevalence of GPA during childhood is rare, but epidemiologic data suggest an increase in cases in the last 2 decades. The median age at diagnosis is 10-14 years, and there is a female predominance of 3-4:1. Improved clinical recognition, disease classification, and tests, such as antineutrophil cytoplasmic antibodies (ANCAs), have helped in the diagnosis of this rare disorder.

Etiology and Pathogenesis

In GPA, the development of both upper and lower airway disease with granulomas implies that exposure to antigens in the airways of an endogenous or exogenous source is involved with aberrant innate and adaptive immune responses. Neutrophils are a key effector cell. There is also a predominantly T-lymphocyte type 1 response with overexpression of interferon-γ (IFN-γ) and tumor necrosis factor (TNF). In vitro studies demonstrate a skewed T-lymphocyte type 17 response by blood $CD4^+$ T cells in GPA, suggesting there is an immune regulatory defect that leads to excessive production of T-lymphocyte type 1 and type 17 cytokines (interleukin [IL]-17, TNF, and IFN-γ). Such an inflammatory response may be sufficient to induce and sustain granuloma formation.

ANCAs are autoantibodies reactive against proteins in the cytoplasmic granules of neutrophils and monocytes and are found in 90% of patients with GPA. The most common ANCAs in GPA have a cytoplasmic fluorescence pattern (c-ANCA) and usually indicate antibodies against proteinase-3 (PR3-ANCA). Perinuclear fluorescence (p-ANCA) usually indicate antibodies directed toward myeloperoxidase (MPO-ANCA), which are less common in GPA. Approximately 5–10% of children develop the clinical phenotype of GPA in the absence of detectable ANCA.

Clinical Manifestations

Children with GPA present with respiratory complaints accompanied by fever, loss of energy, and vague joint symptoms. Some may present with severe nasal disease manifested as ulceration, septal perforation, pain, sinusitis, and/or epistaxis. The septal perforation may lead to deformation of the nasal bridge from erosion of the underlying cartilage, but this is more common in adults. Sinusitis may be present, and pulmonary disease occurs in the majority of patients. Symptoms range from cough, hemoptysis (seen in less than 50% of pediatric patients), dyspnea, and chest discomfort to asymptomatic infiltrates on chest radiography. Occasionally, patients with GPA will present with hemoptysis or recurrent fleeting infiltrates from *pulmonary hemorrhage*. The pathology is confusing because granulomatous disease may be difficult to demonstrate, and *pulmonary capillaritis,* the other main component seen on histology, can be seen in other disorders, including anti-GBM disease, microscopic polyangiitis, idiopathic pulmonary capillaritis, and IgA vasculitis (Henoch-Schönlein purpura). Distinguishing GPA from other pulmonary-renal syndromes is easiest when there are classical symptoms of upper airway disease (nasal/sinus), lower airway disease with necrosis and granulomas on lung biopsy along with vasculitis, and renal disease consistent with glomerulonephritis.

As many as 20% of patients with GPA will present with subglottic or endobronchial stenosis from scarring and inflammatory changes.

Although it may be the presenting symptom, it often occurs in conjunction with other disease manifestations. Dyspnea and voice changes are common complaints from patients.

Skin, ocular (uveitis), and joint symptoms are common in GPA and have been found to accompany the lung and renal disease up to 50% of the time. Biopsy of the skin may show nonspecific leukocytoclastic vasculitis, venulitis, or capillaritis.

Laboratory and Pathology

PR3-ANCA are found in 70–90% of children with GPA, and in the correct clinical situation are sufficient for the diagnosis of ANCA-associated vasculitis, although it may be difficult to differentiate GPA from MPA. In unusual or uncertain cases, tissue diagnosis is required. In lung tissue, the usual pathology demonstrates multiple parenchymal nodules that may be located in either the bronchial, vascular, or interstitial tissues (Fig. 448.1). The granulomatous inflammation is often found in areas of necrosis and/or vasculitis.

Renal biopsy rarely demonstrates granulomas or vasculitis. Rather, kidney tissues may show focal, segmental, or necrotizing glomerulonephritis without deposits of immune complexes. Kidney biopsy is preferred when a histopathologic diagnosis is required, as kidney biopsy has a lower morbidity and mortality than lung biopsy. When the tissues fail to demonstrate classical findings, a variety of diseases (e.g., tuberculosis, sarcoid, microscopic polyangiitis, malignancy, and other autoimmune disorders) must be considered in the evaluation.

Radiology

Chest imaging findings are quite variable in GPA. Chest radiography may reveal multiple infiltrates, nodules, cavitary lesions, or ILD. Fleeting infiltrates may be seen when recurrent hemorrhage is a clinical manifestation. HRCT of the chest often demonstrates more extensive lung disease and the cavitation associated with the necrotizing nature of the disease (Fig. 448.2).

Treatment

Rapidly progressive, debilitating disease may occur if there is a failure to diagnose GPA. One early series of patients reported that death occurred in 90% of patients within 2 years of diagnosis. Glucocorticoid therapy alone resulted in relapses and inadequate control of disease in many subjects.

Therapy is divided into *induction* and *maintenance* phases. Systemic corticosteroids, while ineffective as monotherapy, are a mainstay of therapy in conjunction with other immune-suppressive agents. Prednisone can be given orally. Alternatively, intravenous methylprednisolone may be used at a dosage of 10-30 mg/kg (max 1 g) administered weekly or for 3 consecutive days monthly. Combination therapy traditionally includes cyclophosphamide given either orally at 2 mg/kg/day or intravenous dosing at 15 mg/kg monthly. Rituximab, an anti-CD20 antibody, is as effective as cyclophosphamide in inducing remission of GPA. Rituximab dosing is either 350 mg/m^2 given weekly for the first 4 weeks or 750 mg/m^2 given on initiation of therapy and 2 weeks after initiation. A second dose of 500 mg/m^2 is often given 6 months after the first course of rituximab. Induction therapy should be continued for 3-6 months.

Continued therapy is required past the initial induction phase to maintain remission. Because of the toxicity of cyclophosphamide, other immune-suppressive agents are preferred. Methotrexate and azathioprine have been shown to be noninferior to cyclophosphamide in maintaining remission, whereas mycophenolate mofetil has higher relapse rates than azathioprine. Rituximab is also used for maintenance remission and is associated with lower risk of major relapse compared with azathioprine, particularly for patients with GPA and PR3-ANCA. Systemic steroid dosages should be progressively weaned at the beginning of the maintenance phase of therapy to a dosage of 5-10 mg/day. Maintenance therapy should be continued for an additional 1.5-2 years.

Adjuvant therapy with plasma exchange may be considered when life-threatening GPA disease presents. This is advocated on the premise that ANCAs are inducing disease and will be removed from the circulation with this intervention; its use has been favorably evaluated in GPA-induced renal disease. Adjuvant plasma exchange has been studied mainly in patients with severe renal vasculitis, but there are also reports of success in severe pulmonary hemorrhage. The results

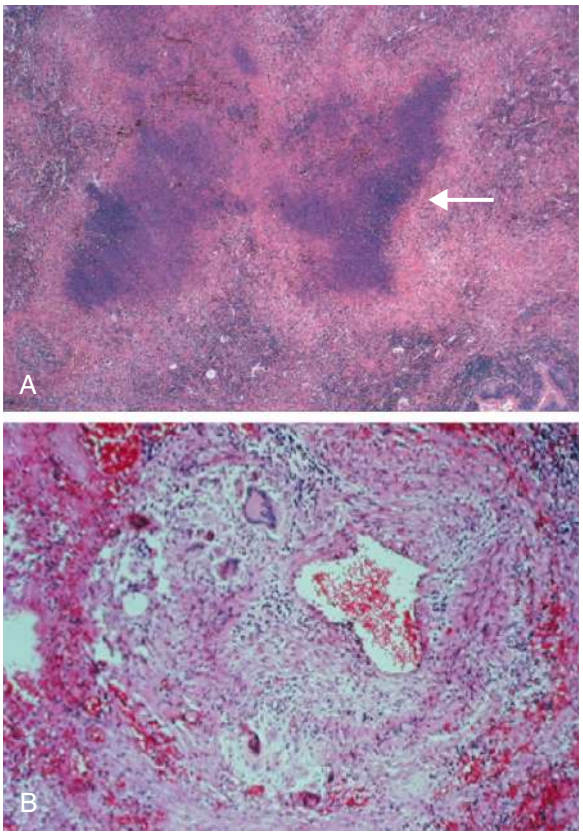

Fig. 448.1 **A,** Low-power view of granulomatous inflammation and geographic necrosis *(arrow)* in a lung biopsy from a patient with GPA. **B,** Granulomatous vasculitis involving a small pulmonary artery in the lung of a patient with GPA. The vessel wall is markedly thickened with an inflammatory infiltrate that includes multinucleated giant cells. *(From Sneller MC, Fontana JR, Shelhamer JH. Immunologic nonasthmatic diseases of the lung. In Adkinson NF Jr, Bochner BS, Burks AW, et al., eds. Middleton's Allergy Principles and Practice, 8th ed. Philadelphia: Elsevier; 2014: Fig. 62.1B and C.)*

Fig. 448.2 Chest CT scan of a patient with granulomatosis with polyangiitis shows typical nodular lung infiltrate with cavitation. *(From Sneller MC, Fontana JR, Shelhamer JH. Immunologic nonasthmatic diseases of the lung. In Adkinson NF Jr, Bochner BS, Burks AW, et al., eds. Middleton's Allergy Principles and Practice, 8th ed. Philadelphia: Elsevier; 2014: Fig. 62.1A.)*

of a meta-analysis of patients with renal vasculitis in nine trials suggest that adjuvant plasma exchange may be associated with improved renal outcome. Other adjuvant therapy includes high-dose intravenous immunoglobulin (IVIG) in recalcitrant disease, which acts to cross-link IgG and likely decrease circulating ANCA antibodies.

Recurrent disease remains a major problem, with relapse rates of up to 50% reported in most studies. ANCA levels do not always correlate with disease activity or severity. Patients with isolated disease of the sinuses and nose may not require such toxic therapy. Therapy with topical corticosteroid and antibiotics for infection appear to be warranted. If unsuccessful, steroids with methotrexate appear to be an effective therapy.

The development of subglottic stenosis requires specific treatment. Use of cyclophosphamide with oral corticosteroid may only partially treat the airway disease or not treat the airway disease at all. Local injection of a prolonged-acting corticosteroid may reduce the inflammation and prevent further scarring. If this complication is found at presentation, simultaneous airway intervention with induction of corticosteroid and cyclophosphamide is warranted and encouraged.

SARCOIDOSIS

Sarcoidosis is an idiopathic multisystem inflammatory disease with a characteristic histology of *noncaseating granulomas* (see Chapter 209). It has been postulated that sarcoidosis represents an exaggerated immune response to a yet-to-be-identified agent from the environment that is likely inhaled in a susceptible host. Sarcoidosis remains a diagnosis of exclusion from other diseases, with granuloma formation noted on histology, such as chronic granulomatous disease (CGD), granulomatous lymphocytic interstitial lung disease (GLILD) associated with common variable immune deficiency (CVID), HP associated with some drugs and inhalation agents, GPA, typical and atypical *Mycobacterium, Pneumocystis jiroveci,* and malignancy.

Epidemiology and Pathogenesis

The Black population is disproportionately affected by sarcoidosis; however, it can present in any group. Because an asymptomatic sarcoid-like distribution of noncaseating granulomas may be found at autopsy, the contribution of the granulomas to the disease is not clear. In countries that perform chest radiograph screening, up to 50% of people diagnosed with sarcoidosis are asymptomatic. The mortality and severity of sarcoidosis are poorer among Black patients; this is likely multifactorial, with racism and healthcare inequities playing a significant role. Sarcoidosis is more endemic in the Southeastern and South Central United States. There have been clusters of disease in families, and genetic testing suggests that the MHC linkage on the short arm of chromosome 6 is most likely to be observed.

Unrecognized infection or inhalation of an immune response–inducing antigen continues to be at the forefront of consideration as a cause of the disease. Clusters of sarcoidosis in small populations, variable prevalence by geography and race, the transfer of disease by organ transplant, and the reproducible noncaseating granuloma formation only noted in patients with sarcoidosis in the skin when homogenized lymph node tissue from patients with sarcoid is injected intradermally (Kveim-Siltzbach test) have supported this hypothesis.

Clinical Manifestations

Sarcoidosis is rarely found in young children. Skin rash, uveitis, and arthritis are seen most often in younger children without pulmonary symptoms. In older children, the presentation is similar to adults, with multisystem disease being the most common. In Northern Europe, erythema nodosum with the ocular involvement of iridocyclitis is seen most frequently. Despite the lack of symptoms, chest radiography may be abnormal in approximately 90% of children. The pulmonary disease can be less progressive compared with adults, and patients can recover spontaneously without corticosteroids. Rarely, pulmonary disease may progress to fibrosis. Ocular disease is more likely to be progressive and warrant intervention, as the inflammatory response may lead to blindness from complications of iritis.

Patients may present with malaise, fever, and weight loss. Those with lung disease are more likely to be asymptomatic as the presentation. When symptomatic, patients demonstrate shortness of breath, cough, and dyspnea. Younger children are more likely to manifest the disease as iridocyclitis, skin rash, and arthritis. Black children appear to have more frequent lymph node involvement, nonspecific elevations of gamma globulin, erythema nodosum, and hypercalcemia.

Physical exam may reveal only an elevated respiratory rate without crackles or rales by auscultation. Pleural involvement has been seen but is uncommon. When present, a lymphocytic predominant exudate may be observed in the pleural fluid. Unusual but reported findings include cases of pneumothorax, hemothorax, and chylothorax. One specific syndrome, **Lofgren syndrome**, with hilar lymphadenopathy, erythema nodosum, and migratory polyarthralgias, is almost exclusively seen in females. This syndrome has a strong association with HLA-DQB1*0201 and polymorphisms in the C-C chemokine receptor 2 (CCR2); these genetic markers are a predictor of a good outcome.

Although almost 90% of patients with sarcoidosis demonstrate parenchymal or mediastinal disease on chest radiography, there are many who have minimal to no symptoms. Approximately 40% of adults with stage 1 disease have endobronchial involvement found at bronchoscopy. The higher the staging level of the disease, the more likely patients are to have airway involvement.

Diagnostic Laboratory Testing

The most common but nonspecific findings are hypergammaglobulinemia, elevated acute-phase reactants, hypercalciuria, hypercalcemia, elevated alkaline phosphatase when liver disease is present, and, occasionally, anemia of chronic disease. Serum angiotensin-converting enzyme may be elevated in 75% of patients with untreated sarcoidosis. False-positive tests occur from other diseases, so it is not considered a diagnostic test but may be used for monitoring disease activity.

Pulmonary function tests can be performed accurately in most children older than the age of 4 years. There are no specific diagnostic findings of spirometry, lung volumes, or diffusion capacity in sarcoidosis. Restrictive lung disease has been reported, but obstruction may be present because of an airway granuloma or lymph node compression. A decline in diffusion capacity when alveolitis is present in hypersensitivity pneumonitis could help diagnostically when attempting to differentiate sarcoidosis from HP before biopsy.

BAL is of great help when differentiating other diseases from sarcoidosis. BAL in sarcoidosis shows a marked predominance of $CD4^+$ T cells. *A lymphocyte percentage >16% on BAL, a CD4:CD8 ratio >4:1, and noncaseating granulomas on bronchial biopsy in the presence of abnormal angiotensin-converting enzyme levels are nearly completely diagnostic for sarcoidosis.* In addition, T cells are activated on BAL in sarcoidosis. BAL in HP shows a significant change in the balance of $CD4^+$ to $CD8^+$ T cells, with the two cell types being nearly equal compared with the normal mild predominance of $CD4^+$ T cells in the circulation. A ratio of CD4:CD8 of <1 predicts 100% of patients with BAL lymphocytosis to *not* have sarcoidosis. Neutrophil counts >2% and/or eosinophil counts >1% exclude the diagnosis of sarcoidosis.

The analysis of D-dimers in BAL fluid from subjects with sarcoidosis demonstrates an elevation in 80% of patients compared with no detectable D-dimers in unaffected controls.

Histopathology

The characteristic feature of sarcoidosis is the noncaseating granuloma formation in the lung (Fig. 448.3). These granulomas are found in the bronchial walls, alveolar septa, and vascular walls of pulmonary arteries and veins. The formation of noncaseating granulomas is likely preceded by alveolitis involving the interstitium more than the alveolar spaces. There is an accumulation of inflammatory cells, including monocytes, macrophages, and lymphocytes, that accompanies the granulomas. Multinucleated giant cells are frequently found among the epithelioid cells within the granuloma follicle. These may show cytoplasmic inclusions (e.g., asteroid bodies and Schaumann bodies) and some birefringent crystalline particles made of calcium oxalate and other calcium salts. These are most often identified in the upper lobes of the lungs, which may lead to confusion with diseases such as HP, eosinophilic granuloma, collagen vascular disease, pneumoconiosis, and infectious disease such as tuberculosis or histoplasmosis.

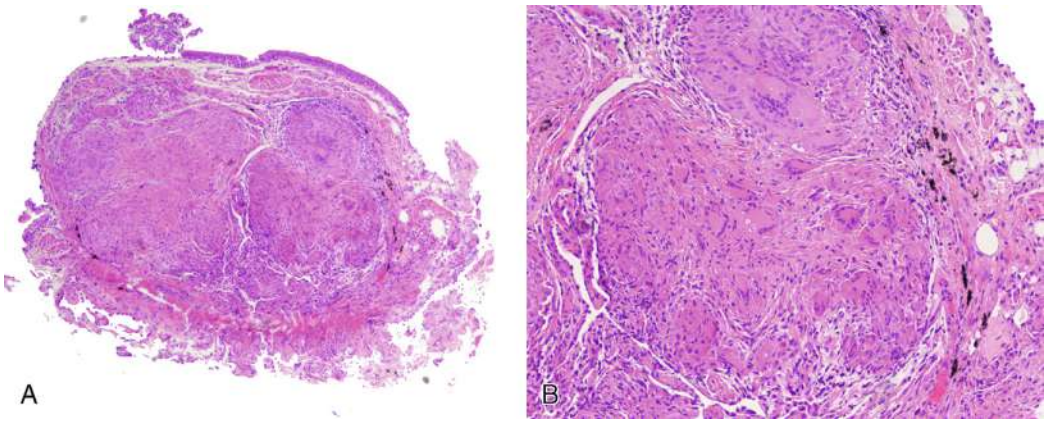

Fig. 448.3 Transbronchial biopsy specimen showing a sarcoid granuloma. **A,** The granulomas are located below the bronchiolar epithelial layer that appears at the top of the frame. **B,** A higher-power view of the same biopsy specimen. The epithelioid granuloma is tightly packed and contains multiple multinucleated giant cells. There is no caseous necrosis. Special stains for acid-fast bacilli and fungi were negative. *(From Sneller MC, Fontana JR, Shelhamer JH. Immunologic nonasthmatic diseases of the lung. In Adkinson NF Jr, Bochner BS, Burks AW, et al., eds. Middleton's Allergy Principles and Practice, 8th ed. Philadelphia: Elsevier; 2014: Fig. 62.6.)*

Radiology

Pulmonary imaging in sarcoidosis has included plain chest radiography, HRCT of the chest, positron emission tomography using fluorine-18-fluorodeoxyglucose, or radiotracer using gallium-67. The staging of sarcoidosis is performed using plain radiography and is outlined as follows:

- Stage I—Bilateral hilar lymphadenopathy accompanied by right paratracheal lymphadenopathy.
- Stage II—Bilateral hilar lymphadenopathy accompanied by reticular opacities. If symptomatic, patients have cough and dyspnea. Occasional fever and fatigue accompany the respiratory symptoms.
- Stage III—Reticular opacities are found predominantly in the upper lobes with regression of hilar lymphadenopathy.
- Stage IV—Reticular opacities start to coalesce and lead to volume loss in the lung fields and traction bronchiectasis from conglomeration of the inflamed tissues. Extensive calcium deposits may be seen at this stage.

HRCT of the chest may be helpful in further staging of the disease and in revealing abnormalities not appreciated on chest radiography. Findings in patients with sarcoidosis by HRCT of the chest include hilar lymphadenopathy, paratracheal nodules, middle to upper lung parenchymal ground-glass appearance, bronchial wall thickening, bronchiectasis, cystic changes, and fibrosis. The ground-glass appearance suggests that alveolitis, as seen in hypersensitivity pneumonitis, may be present. Biopsy has usually shown granuloma formation as the predominant histologic finding.

Treatment

Because pulmonary sarcoidosis spontaneously resolves without therapy in almost 75% of patients, clear guidelines for treatment focused on minimizing therapeutic side effects is imperative. Glucocorticosteroids (GCSs) have long been the mainstay of therapy in sarcoidosis and are often used because of extrapulmonary disease. When pulmonary disease is progressive, GCS therapy is aimed at the prevention of fibrosis, honeycombing, and irreversible lung disease. Assuring that disseminated infections, heart failure, thromboembolism, or pulmonary hypertension are not present is important. In addition to HRCT of the chest, performance of pulmonary function tests, electrocardiogram, and echocardiogram should be considered before starting GCS therapy.

GCS therapy is often not started in the asymptomatic patient with stage I or II disease. This scrutiny of the benefit of therapy was highlighted when a prospective evaluation of GCS therapy for pulmonary disease found that nearly 50% of patients receiving GCSs had active or relapsing disease 2 years later. In contrast, 90% of patients who did not receive GCSs had spontaneous remission of disease, with the other 10% needing intervention 2 years later. Absolute indications include progressive stage III disease with symptoms of shortness of breath, cough, or other chest symptoms such as pain. Progressive restriction shown on pulmonary function testing is an indication for therapy. Specific pulmonary function changes where lung capacity declines a total of 10% or greater, FVC declines 15% or more, or diffusion capacity degradation is noted to be ≥20% are all indications for GCS intervention.

Initially, patients are treated with oral prednisone depending on the severity of symptoms. Stability is usually achieved within 6-8 weeks, after which slow, progressive tapering of GCS may occur every 4-8 weeks. Many favor the use of alternate-day steroids to reduce the side effects of GCSs, but little data exist to show efficacy.

For patients who do not tolerate GCSs or develop progressive disease, alternative immunosuppressive agents may add benefit to the regimen. Progressive disease also is a reminder for the clinician to reassess the diagnosis of sarcoidosis and review the possibility that beryllium or an infection may be the underlying reason for the progressive disease.

BERYLLIOSIS

Chronic berylliosis disease (CBD), a rare disease, is caused almost exclusively by environmental, and specifically occupational, exposure to beryllium. Examples of these high-risk industries include beryllium and beryllium alloy production, nuclear weapon development, the dental industry, and aircraft/automotive manufacturing. CBD is similar in appearance and pathogenesis to sarcoidosis; however, patients have had a previous exposure to beryllium. Although uncommon in pediatrics, CBD is important to consider in adolescents who work in high-risk industries.

Diagnosis

The most important step in the diagnosis of CBD is establishing a beryllium exposure by performing a thorough history. Special attention should be given to the patient's work history, and in younger children, the work history of the parents, as there are reports of secondary exposure to beryllium causing CBD in at-risk patients. Symptom history is nonspecific, with the most common being dry cough, shortness of breath particularly on exertion, and weight loss. Workplace screening for beryllium sensitization is now implemented in high-risk professions. Given this, the majority of patients are often asymptomatic at the time of diagnosis. The physical exam is also nonspecific in CBD, with most patients having a normal examination; however, crackles and digital clubbing may develop as the disease progresses.

Laboratory testing is a critical step in establishing a diagnosis. Beryllium sensitization is established by performing a beryllium lymphocyte proliferation test (BeLPT). This test is performed by isolating mononuclear cells from patients (either through blood or bronchoalveolar lavage fluid [BALF]) and culturing these cells in different concentrations of beryllium salts. Results are reported as a ratio of stimulated lymphocytes in the beryllium culture versus a control. A BeLPT is considered positive if two or more of the six stimulation indices exceed normal. A diagnosis of beryllium sensitization is confirmed by two positive blood BeLPT tests or one positive BALF BeLPT test. BeLPT screening is performed for employees in high-risk occupations.

Radiography is often obtained but may be nonspecific. Chest x-rays are often not sensitive enough to diagnose CBD. Computed tomography (CT) of the chest reveals a pattern similar to sarcoidosis, with nodules following a bronchovascular distribution. Hilar lymphadenopathy is less common in CBD compared to sarcoidosis. In later stages of the disease, evidence of fibrosis may be seen on the CT scan of the chest.

Pulmonary function testing (PFT) is also commonly performed in the evaluation of CBD. As a result of increased screening with BeLPT, most patients with CBD are now diagnosed before PFT abnormalities become apparent. If PFT abnormalities are noted, these changes are variable, demonstrating an obstructive, restrictive, or mixed pattern. Diffusion capacity for carbon monoxide is often low, especially in advanced disease. Finally, exercise stress testing is also abnormal in advanced CBD.

Bronchoscopy and BAL are important in the evaluation of CBD. BALF often reveals lymphocyte counts above 20%. Furthermore, BeLPT can be performed on BALF, which can confirm beryllium sensitivity. In conjunction with a positive BeLPT and a history of beryllium exposure, lung biopsy is needed to establish a definitive diagnosis of CBD. Biopsy can be obtained either through transbronchial biopsies or surgical lung biopsy. Unlike most pediatric ILDs, transbronchial biopsies are acceptable because of the bronchovascular distribution of CBD. Biopsies reveal noncaseating granulomas with a core of epithelial histiocytes surrounded by a rim of $CD4^+$ lymphocytes. Although lung biopsy is essential for diagnosis, a presumptive diagnosis of CBD can be made with a combination of a history of symptoms consistent with CBD, beryllium exposure, beryllium sensitization, PFT abnormalities, radiography changes, and BALF abnormalities.

Treatment

Treatment is not well studied in CBD. Most physicians do not treat asymptomatic patients with normal lung function indices. If lung function declines, first-line therapy is often systemic corticosteroids. Although some patients can stop corticosteroids over time, many will continue to progress without systemic treatment. In patients with persistent disease despite corticosteroids or in those patients who require ongoing treatment and would benefit from steroid-sparing therapy, other medications have been used such as azathioprine, methotrexate, mycophenolate, infliximab, or cyclophosphamide.

GRANULOMATOUS LUNG DISEASE IN PRIMARY IMMUNE DEFICIENCY

Primary immune deficiency (PID) often presents with recurrent or persistent pulmonary symptoms. Patients may experience recurrent infections, pneumonia, bronchiectasis, and ILD with or without fibrosis. Immune dysregulation occurs in many of the PIDs and may manifest with development of granulomatous lung disease and an autoimmune response. Most effort is focused on identifying the infectious pathogens in the PID that may be leading to the pulmonary symptoms; however, immune dysregulation may be the primary problem. This requires counterintuitive therapies with suppression of the immune system concurrently with immune deficiency therapy such as IVIG. The two most prominent PIDs associated with granulomatous lung disease are **chronic granulomatous disease** (see Chapter 170) and **common variable immune deficiency** (see Chapter 166.2).

The classic organism causing granuloma formation in the lung is *Mycobacterium tuberculosis*. Nontuberculous mycobacterial infections also can cause granulomas in the presence of a specific PID. These infections have been seen in patients with defective IL-12, IL-23, and IFN-γ signaling or when there are autoantibodies to IFN-γ. Defective regulation of nuclear factor-kappa B (nuclear factor-kappa B essential modifier defects) have also been reported in patients with nontuberculous mycobacteria. The clinician must be certain that this low-virulence organism is not causing disease before therapy for immune dysregulation is considered. Another PID associated with granulomatous disease involves defects in the INF-γ pathway. These disorders are grouped under the name **Mendelian susceptibility to mycobacterial disease**.

Pathogenesis

In CGD, there are defects in the phagocytic nicotinamide adenine dinucleotide phosphate oxidase system. These defects lead to impairment in the respiratory burst capacity to generate reactive oxygen species (see Chapter 170).

Patients with CVID have abnormalities in B lymphocytes and hypogammaglobulinemia. Pulmonary manifestations of CVID include organizing pneumonia, ILD, mucosa-associated lymphoid tissue lymphoma, and noncaseating granulomas in **granulomatous and lymphocytic interstitial lung disease (GLILD)** (see Chapter 166.2). Elevated levels of TNF from polymorphisms have been implicated as a possible mechanism. GLILD is becoming recognized more frequently in CVID and other immune disorders. It is defined by the presence of a granulomatous and a lymphocytic proliferative pattern in the lung. Granulomas may be found in other organs, including the bone marrow, spleen, gastrointestinal tract, skin, and liver in GLILD.

The etiology of GLILD is unknown. In a case cohort study, a majority of subjects with pathology diagnostic of GLILD were found to have human herpesvirus-8 infection of the lung. These findings in this subgroup of patients with GLILD may point to a mechanism underlying the development of pulmonary granulomas.

GLILD is sometimes misdiagnosed as sarcoidosis initially because both involve pulmonary granuloma, often accompanied by hilar and/or mediastinal lymphadenopathy. Sarcoidosis has several features that distinguish it from GLILD, such as normal or elevated serum immunoglobulin levels and frequent spontaneous remissions.

Clinical Manifestations of Granulomatous Lung Disease in Primary Immune Deficiency

Chronic respiratory disease as a result of recurrent infections is common in CGD. This is accompanied by clubbing in some patients and additional organ manifestations in the skin, liver, and genitourinary and gastrointestinal tracts. Granulomas are especially problematic in the gastrointestinal and genitourinary tracts. The inhalation of fungal spores and hyphae has led to acute pneumonia in CGD with rapid progression to respiratory failure, with hypoxemia, dyspnea, and fever. This entity, characterized as *mulch pneumonia,* appears to be best treated with antifungal medications and corticosteroids. Patients with GLILD present with progressive exercise intolerance and hypoxemia.

Radiography

Hilar and/or mediastinal lymphadenopathy occur with granulomatous lung involvement. These may manifest as parenchymal nodules and/or ground-glass abnormalities and can be seen commonly in CVID and CGD. Differentiating infectious causes of pulmonary infiltration in PID is often difficult on chest radiography; HRCT of the chest is often mandatory in the initial evaluation of the patients with CVID as a result of nonspecific findings on chest radiograph.

Laboratory and Pulmonary Function Testing

A definitive diagnosis of GLILD is made by lung biopsy with granulomatous disease. Transbronchial biopsy in children is often insufficient, and lung biopsy by video-assisted thoracoscopy or open biopsy is preferred. Unless the patient's underlying immune deficiency is unknown, other laboratory testing (except testing for infectious organisms) does not contribute significantly to the diagnosis of GLILD. When the child is old enough, complete PFT with spirometry, lung volumes, and diffusion capacity should be obtained at baseline and then followed serially to assess therapeutic response or progression of disease.

Therapy

The presence of GLILD in CVID can be associated with significant morbidity and possibly death. Without therapy, progressive pulmonary fibrosis and respiratory failure may occur in GLILD. The parenchymal disease may not always be controlled or relieved by glucocorticoid treatment. Other treatments include TNF antagonists, cyclosporine, or a combination therapy with rituximab and azathioprine. Response to therapy is monitored clinically and by interval HRCT of the chest and PFT, including spirometry, lung volumes, and diffusing capacity.

448.4 Eosinophilic Lung Disease

Timothy J. Vece and Stephanie D. Davis

The eosinophilic lung diseases are a group of heterogeneous pulmonary disorders with a predominant diffuse infiltration of eosinophils in the alveolar spaces or interstitial pulmonary spaces. Collectively, the disorders are often referred to as *pulmonary infiltrates with eosinophilia* and include acute eosinophilic pneumonia, chronic eosinophilic pneumonia, simple eosinophilic pneumonia (also known as *Loeffler eosinophilic pneumonia*), and eosinophilic granulomatosis with polyangiitis (previously Churg-Strauss). The lung architecture is well preserved throughout the inflammatory response, often with complete reversal of the inflammation without long-term sequelae in the majority of cases. The peripheral white blood cell count often (but not always) reveals elevated eosinophils, and BALF shows an elevation in eosinophils. Prompt recognition of these diseases allows for lifesaving interventions in idiopathic **acute eosinophilic pneumonia (AEP) syndrome** or resolution of persistent symptoms in patients with chronic disease.

ETIOLOGY

Eosinophilic lung diseases are often classified under two subheadings: idiopathic disease and known causation (Tables 448.8-448.10). They are frequently further subdivided into acute and chronic or infectious and noninfectious. The division of acute or chronic is arbitrary based on the length of symptoms present but is relevant to the clinician in determining the etiology of the symptoms (Table 448.11). Loeffler eosinophilic pneumonia, induced by *Ascaris lumbricoides, Strongyloides,* and other ascarids, produces transient symptoms that self-resolve and is classified as neither acute nor chronic.

PATHOLOGY AND PATHOGENESIS

Eosinophilic lung disease, regardless of the stage of disease or etiology, shows mixed cellular infiltration of the alveoli and interstitial spaces with a predominance of eosinophils when open lung biopsy is performed. This may be accompanied by a fibrinous exudate with intact lung architecture. Other findings include eosinophilic microabscesses, a nonnecrotizing nongranulomatous vasculitis, and occasional multinucleated giant cells, again without granuloma formation. BAL is the diagnostic procedure of choice, especially with the acute types of eosinophilic pneumonia, where peripheral eosinophilia is often absent; the differential cell count on the BAL is ≥20% eosinophils and is often more than 40%. This highly sensitive and specific test has allowed clinicians to forego lung biopsy.

Eosinophils are filled with numerous toxic granules. Evidence of eosinophil degranulation may be found by electron microscopy, biopsy, urine excretion, and BALF. Most commonly, eosinophil-derived neurotoxin, leukotriene E_4, and other granule proteins, such as major basic protein, Charcot Leyden crystals, or proinflammatory cytokines, are identified and support the evidence that eosinophils are not only present but contributing to the disease process.

CLINICAL MANIFESTATIONS

Specific eosinophilic lung diseases present with a variable clinical picture; however, there are some common findings across many of the eosinophilic diseases. Dyspnea is the most common and prevalent symptom in patients with acute or chronic eosinophilic pneumonia and is accompanied by cough in the majority of patients (90%). Rhinitis and sinusitis symptoms are of lower prevalence with wide variability in children with eosinophilic pulmonary disease. **Acute eosinophilic pneumonia** often presents with respiratory failure and the requirement for mechanical ventilation at high levels of positive end expiratory pressure and high concentrations of oxygen, whereas chronic eosinophilic pneumonia has a more indolent presentation (see Table 448.11). Although malignancy (e.g., eosinophilic leukemia) and organizing pneumonia may present with a need for mechanical ventilation, this is uncommon. A history of asthma is common in the chronic eosinophilic pneumonias and in **allergic bronchopulmonary aspergillosis (ABPA)**; it often precedes the diagnosis of these two conditions.

Table 448.8 Key Elements in the Medical History, Laboratory Findings, and Physical Exam to Raise Clinical Suspicion for Diagnostic Testing to Confirm Eosinophilic Lung Disease

MEDICAL HISTORY AND EXAMINATION
- Drug exposure (especially antibiotics, NSAIDs, antiepileptics, antileukotriene modifiers in EGPA)
- Environmental inhalation exposures to dust or inhaled chemicals
- New onset of smoking cigarettes
- Travel or immigration status from areas endemic with various parasites or coccidioidomycosis
- Asthma (may be severe or poorly controlled with ABPA, CSS, or is relatively new in onset with IAEP)
- ABPA concurrent in 7–15% of patients with cystic fibrosis
- Extrapulmonary symptoms suggestive of vasculitis, neuropathy, heart failure, or neoplasm
- Rash (creeping eruption in visceral larval migrans disease or ulceration in EGPA)

DIAGNOSTIC IMAGING AND TESTING
- Radiography helpful in AEP, CEP, and ABPA
  - Radiography not diagnostic in EGPA or drug-induced eosinophilic disease of the lung
- Simple chest radiography findings
  - Nonlobar infiltrate
  - Classic description as mirror image of pulmonary edema with peripheral infiltrates
  - Bilateral pleural effusion in AEP
  - Central bronchiectasis in ABPA
- High-resolution computed tomography of the chest
  - Middle and upper lobe nonlobar infiltrates with areas of ground-glass appearance
  - Mucus plugging in ABPA
  - Central bronchiectasis in ABPA (confused with cystic fibrosis)
- Blood eosinophil count
  - Elevated in many eosinophilic lung diseases
  - Magnitude of eosinophil blood count does not distinguish different pulmonary diseases
  - Not elevated in AEP
  - May occasionally not be elevated in CEP or after use of corticosteroids
- Total serum IgE elevated in ABPA but not always in patients with cystic fibrosis with ABPA
- Serology for helminthic infections or parasites may be diagnostic but are usually not available acutely
- P-ANCA (MPO ANCA) is positive in 40–70% of EGPA (CSS)
- BAL eosinophil percentage
  - ≥25% eosinophils diagnostic in AEP
  - ≥40% eosinophils diagnostic in CEP or tropical pulmonary eosinophilia
  - Eosinophil percentages below these criteria may require lung biopsy
  - <25% eosinophils seen in connective tissue disease, sarcoid, drug-induced disease, histiocytosis X of pulmonary Langerhans cells, and interstitial pulmonary fibrosis

ABPA, Allergic bronchopulmonary aspergillosis; AEP, acute eosinophilic pneumonia; BAL, bronchoalveolar lavage; CEP, chronic eosinophilic pneumonia; CSS, Churg-Strauss syndrome; EGPA, eosinophilic granulomatosis with polyangiitis; IAEP, idiopathic acute eosinophilic pneumonia; MPO ANCA, myeloperoxidase antineutrophil cytoplasmic antibody; NSAID, nonsteroidal antiinflammatory drug; P-ANCA, perinuclear antineutrophil cytoplasmic antibody.

Other symptoms of fever, myalgia, fatigue, weight loss, poor appetite, and night sweats may accompany the acute or chronic eosinophilic pneumonias. When abnormalities of the liver are detected, or if arthralgia, skin changes, pericardial effusion, or peripheral neuropathy accompany the disease presentation, a diagnosis of **eosinophilic granulomatosis with polyangiitis (EGPA)** (formerly known as *Churg-Strauss syndrome*) or **hypereosinophilic syndrome (HES)** should be aggressively investigated.

Chest Imaging

The chest radiograph is one of the most helpful tests for evaluating the child with dyspnea. The characteristic feature of fluffy alveolar

Table 448.9 Classification of the Eosinophilic Pneumonias in Clinical Practice

Eosinophilic Pneumonias of Unknown Cause
Solitary idiopathic eosinophilic pneumonias
Idiopathic chronic eosinophilic pneumonia
Idiopathic acute eosinophilic pneumonia
Eosinophilic pneumonia in systemic syndromes
Eosinophilic granulomatosis with polyangiitis
Idiopathic hypereosinophilic syndromes (lymphocytic or myeloproliferative variant)
Eosinophilic Pneumonias of Known Cause
Allergic bronchopulmonary aspergillosis and related syndromes (including bronchocentric granulomatosis)
Eosinophilic pneumonias of parasitic origin
Eosinophilic pneumonias of other infectious causes
Drug-induced eosinophilic pneumonias
Eosinophilic Airways Diseases
Idiopathic hypereosinophilic constrictive bronchitis
Other Pulmonary Syndromes with Possible (Usually Mild) Eosinophilia
Organizing pneumonia, asthma, idiopathic pulmonary fibrosis, Langerhans cell histiocytosis, malignancies, and so forth

Table 448.11 Diagnostic Criteria for Idiopathic Chronic Eosinophilic Pneumonia and for Idiopathic Acute Eosinophilic Pneumonia

IDIOPATHIC CHRONIC EOSINOPHILIC PNEUMONIA
1. Diffuse pulmonary alveolar consolidation with air bronchogram and/or ground-glass opacities at chest imaging, especially with peripheral predominance.
2. Eosinophilia at bronchoalveolar lavage differential cell count ≥40% (or peripheral blood eosinophils ≥1,000/mm^3).
3. Respiratory symptoms present for at least 2-4 wk.
4. Absence of other known causes of eosinophilic lung disease (especially exposure to drug susceptible to induce pulmonary eosinophilia).
IDIOPATHIC ACUTE EOSINOPHILIC PNEUMONIA
1. Acute onset with febrile respiratory manifestations (≤1 mo, and especially ≤7 days duration before medical examination).
2. Bilateral diffuse infiltrates on imaging.
3. Pa_{O_2} on room air ≤60 mm Hg (8 kPa), or Pa_{O_2}/F_{IO_2} ≤300 mm Hg (40 kPa), or oxygen saturation on room air <90%.
4. Lung eosinophilia, with ≥25% eosinophils at BAL differential cell count (or eosinophilic pneumonia at lung biopsy when done).
5. Absence of determined cause of acute eosinophilic pneumonia (including infection or exposure to drugs known to induce pulmonary eosinophilia). Recent onset of tobacco smoking or exposure to inhaled dusts may be present.

BAL, Bronchoalveolar lavage.
From Cottin V. Eosinophilic lung diseases. *Clin Chest Med.* 2016;37:535–556, Box 2, p. 538.

infiltrates in the peripheral lung field is classic (Fig. 448.4). The images may be easily recognizable by astute clinicians who have identified the etiology of the disease without elevated blood eosinophil counts or BAL.

HRCT of the chest is the best advanced imaging modality for eosinophilic lung disease. Spontaneous migration of lung opacities is commonly seen in the chronic pneumonias. Most often HRCT of the chest shows simultaneous evidence of bilateral alveolar infiltrates with both confluent consolidations and ground-glass appearance. The most prominent areas of abnormality are visualized in the upper lobes and subpleural regions. Specific diseases have unique findings, such as *proximal bronchiectasis* in **ABPA** and pleural effusion in acute eosinophilic pneumonia. HRCT of the chest is most sensitive in identifying the correct etiology of the disease when chest radiographic findings are nonspecific.

LOEFFLER SYNDROME

The **transient pulmonary infiltrates with eosinophilia syndrome** that is most often seen in children (formerly known as Loeffler syndrome) is characterized by migrating pulmonary infiltrates with peripheral blood eosinophilia. This syndrome is caused by helminthic infections. *A. lumbricoides* or roundworm is the most common parasite causing this disease in the United States. When a fertilized egg is ingested from contaminated food from areas with poor sanitation, it becomes a larval worm that can penetrate the duodenum of the small intestine and migrate in the circulation to the liver, heart, and lungs. In the pulmonary venous circulation, the larvae can break through the interstitial space to the alveoli. The juvenile larva may subsequently migrate to the trachea, where they are expectorated and swallowed. Other nematodes cannot mature in the intestinal tract, so their disease is limited to a single passage into the lungs.

Visceral larva migrans from multiple nematodes may cause eosinophilic lung disease. The most common etiologies are the dog roundworm, *Toxocara canis,* but *Toxocara cati, Strongyloides stercoralis, Baylisascaris procyonis,* and *Lagochilascaris minor* can all produce visceral larva migrans. Outside the United States, the common lung fluke, *Paragonimus westermani,* may cause a similar pulmonary disease in older children and adolescents. Western Africa, Central and South America, and East Asia are regions where paragonimiasis may be found, especially in those who eat raw crabs or crawfish. Many other parasites may have a transient pulmonary syndrome, but their manifestations are most commonly in other organs.

The pulmonary syndrome is classic with cough, dyspnea, migratory peripheral pulmonary infiltrates, and blood eosinophilia that is self-limited. Young children most often have a history of pica and eating dirt that is contaminated with the eggs. Because the larva can migrate to other organs and multiply in the intestinal and biliary tract, symptoms of abdominal pain, vomiting, rarely obstruction, cholecystitis, and pancreatitis may be found. Diagnosis is frequently made by examination of the stool, where the eggs may be detected microscopically. Treatment is aimed at the intestinal disease and not the pulmonary disease per se. It is possible that anthelminthic treatment of other organ disease during the pulmonary phase will increase the inflammatory response in the lung, leading to the need for treatment with corticosteroids.

ACUTE EOSINOPHILIC PNEUMONIA

A unique and dramatic presentation of the eosinophilic pneumonias is **AEP** (see Table 448.11). AEP mimics infectious pneumonia or acute respiratory distress syndrome with its rapid onset and marked hypoxemia. This disease most frequently occurs in the teenage and young adult populations. Essentially all patients present within 7 days of symptom onset with dyspnea, fever, and cough, and more than 50% have chest pain. Myalgia and abdominal pain also frequently accompany this disease. Rarely, patients have presented up to 4-5 weeks after the onset of symptoms. Physical exam demonstrates tachypnea, tachycardia, and crackles in the lung fields. Many patients rapidly deteriorate and require mechanical ventilation.

There is an *absence* of circulating eosinophilia, which contrasts with the dramatic number of eosinophils seen in the BAL representing at

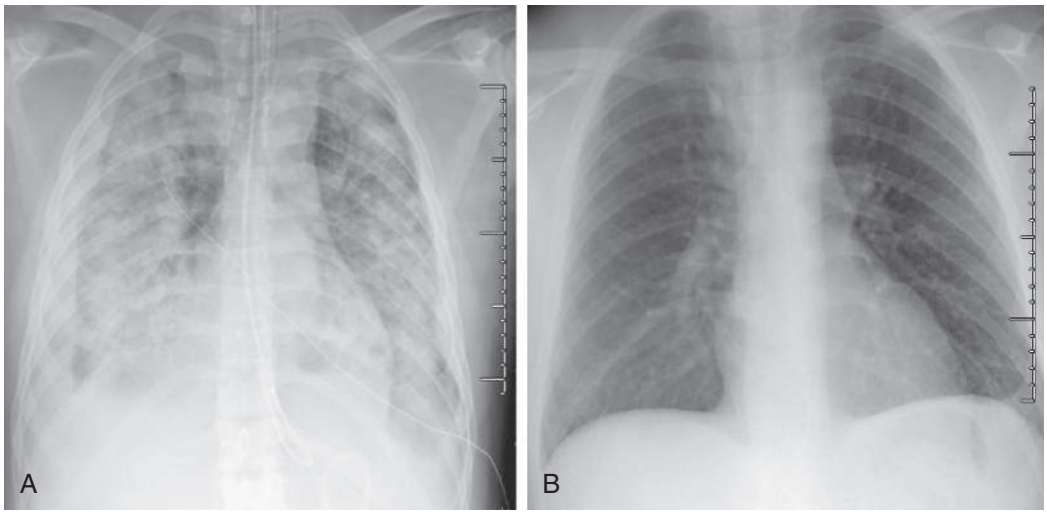

Fig. 448.4 A, Acute eosinophilic pneumonia demonstrating the mirror image pulmonary edema with a right pleural effusion on admission. B, Complete clearing upon discharge from the hospital after corticosteroid usage.

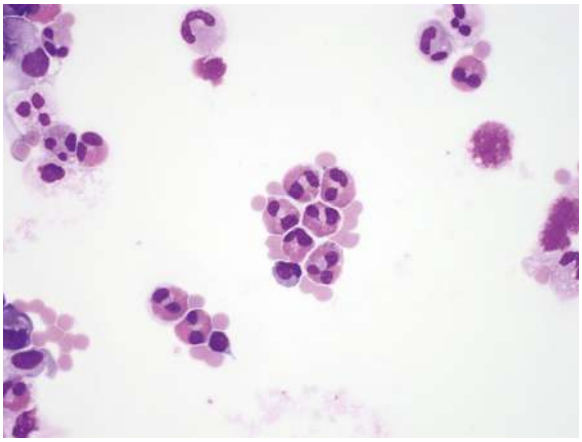

Fig. 448.5 Light microscopy of eosinophils in bronchoalveolar lavage fluid.

least 20% of the inflammatory cells (often 40–55%) (Fig. 448.5). This feature helps distinguish it from the chronic pulmonary disease of eosinophilic origin.

Although this disease has been labeled as idiopathic, there have been identifiable exposures (e.g., 1,1,1-trichloroethane or Scotchgard). Numerous reports link the onset of smoking tobacco, change in smoking frequency, reinitiation of smoking in young male adolescents or adults, and even massive secondary smoke exposure as critical associations with the onset of AEP. World Trade Center dust is associated with development of AEP. A single smoke challenge study is associated with recurrence. Some medications are also linked to the onset of AEP. The most complete and current resource for medications linked to pulmonary disease is "The Drug-Induced Respiratory Disease Website" (http://www.pneumotox.com). When AEP is identified in a patient, the pediatrician should educate the patient and family about the link to smoking exposure and the risk of AEP upon reexposure.

In addition to smoke exposure, AEP has been reported after smoking cocaine; typically, within hours to days after use. Whether this is a unique eosinophilic response to cocaine that represents one manifestation of *crack lung* or is a separate disease is unknown. Crack lung refers to diffuse alveolitis with pulmonary hemorrhage from an unknown mechanism that occurs within 48 hours of cocaine smoke inhalation.

Lung function has not been measured frequently in the disease because the patients have proceeded rapidly to the intensive care unit (ICU) for mechanical ventilation. When measured, a restrictive pattern of lung disease and reduced diffusion capacity are the usual findings. Arterial blood gases will also show a significant increase in the alveolar-arterial gradient.

The criteria for diagnosis include the acute onset of disease, bilateral pulmonary infiltrates, reduced oxygen saturation or Pao_2 ≤60 mm Hg, BAL of ≥25% eosinophils, and absence of a determined cause of eosinophilia (see Table 448.11). The recent onset of tobacco exposure, dust, or chemical inhalation are supporting factors in confirming a diagnosis.

Treatment has uniformly been the use of a corticosteroid (e.g., methylprednisolone 1-2 mg/kg/day) either intravenously or orally. A minimum or maximum treatment time has not been determined. Rare fatalities have been reported. Complete recovery has been seen in days, with resolution of pleural effusions within 4 weeks of treatment. Most important, relapse and persistent symptoms are rare, which sharply contrasts with the idiopathic chronic eosinophilic pneumonias. Follow-up testing of pulmonary function is usually normal, which supports the contention that lung parenchyma heals without evidence of compromise or fibrosis.

CHRONIC EOSINOPHILIC PNEUMONIA

Chronic eosinophilic pneumonia is another idiopathic pulmonary condition without a known exposure to toxin, dust, or chemical inhalation. Eosinophils infiltrate the lung parenchyma resulting in dyspnea, cough, fever, and weight loss. It is primarily a problem for adults, with a female predominance (2:1 female:male) and usually in patients who are nonsmokers. Chest examination reveals tachypnea, crackles, and wheezing; a diagnosis of asthma is a common finding. The classic finding on chest x-ray of the *radiographic negative of pulmonary edema* is found in these patients: central clear lung fields but fluffy, patchy peripheral infiltrates; however, this is not seen in all cases.

When compared to AEP, the onset of disease is indolent and subtle, but the accompanying fever and weight loss may lead the clinician toward a concern for an underlying malignancy before the chest radiograph and laboratory investigation. *Peripheral* blood eosinophilia is commonly as high as 5,000/mm^3 or greater, accompanied by BAL eosinophilia >40% on the differential count (see Table 448.11). The peripheral eosinophilia sharply contrasts with the lack of eosinophils seen in the blood in AEP. HRCT scan of the chest contrasts with the AEP, with pleural effusion as a rare finding, as well as rare cavitation.

In contrast to AEP, PFT shows a mixed obstructive and restrictive pattern, especially given that asthma often occurs concurrently with this disease.

Inflammatory markers associated with migration and activation of eosinophils are predictably found in BAL and the urine. These include the T-lymphocyte type 2 cytokines of IL-4, IL-5, IL-6, IL-10, IL-13, and IL-18. However, T-lymphocyte type 1 cytokines of IL-2 and IL-12 are also present with many of the potent eosinophilic chemoattractants such as CCL5 (RANTES [regulated upon activation, normal T-cell expressed and secreted]) and CCL11 (eotaxin-1).

Toxic granule proteins of major basic protein, eosinophil-derived neurotoxin, and eosinophil cationic protein are frequently present. Unfortunately, these important molecules help confirm the eosinophilic nature of the disease, but their presence adds no additional sensitivity or specificity over the presence of eosinophils on BAL.

Treatment is similar to most eosinophilic lung syndromes, where corticosteroids (oral) are the mainstay of treatment. The minimum dose of steroid needed to induce remission is not known, but most clinicians recommend prednisone (or equivalent) at 0.5 mg/kg/day for 2 weeks. The dose is reduced to half (0.025 mg/kg/day) for an additional 2 weeks if symptoms have abated. The remaining dose of steroid may need to be weaned over 6 months. Alternatively, IV methylprednisolone is used, starting with 10-30 mg/kg/dose (maximum 1 g) given either 3 consecutive days per month or 1 day per week. Symptoms and pulmonary infiltrates rapidly disappear after initiation of this treatment but frequently recur with tapering of the steroid. Asthma that occurs concurrently in patients with chronic eosinophilic pneumonia represents a phenotype of the disease that appears to have lower relapse risk, yet up to 50% of all identified patients with chronic eosinophilic pneumonia relapse during or after corticosteroid taper.

Many believe that this disease is a precursor to the development of EGPA (formerly Churg-Strauss syndrome). The utility of ICS in chronic eosinophilic pneumonia is unknown but is warranted for the persistent asthma phenotype of the disease. A subset of patients develops permanent lower airway obstruction without reversibility, which requires patients with this disease to have close follow-up and monitoring of pulmonary function tests.

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS (CHURG-STRAUSS SYNDROME)

EGPA syndrome is a systemic disease involving multiple organs but most prominently the lung. Patients present with difficult-to-control asthma, allergic rhinitis, and peripheral eosinophilia (>10% or >1,500 cells/μL) in the blood. Evidence of vasculitis must be present in at least two organs. The polyangiitis appears later in the disease process, with asthma being the precursor symptom in more than 90% of the cases reported. EGPA affects multiple organs, including the skin, heart, gastrointestinal tract, kidneys, and central nervous system (Table 448.12). Rhinitis and upper airway disease are present in 75% of the patients but are not specific. Symptoms of fever, weight loss, fatigue, arthralgia, and myalgia may be seen in approximately two thirds of patients. Cardiac and renal involvement is insidious in onset, and screening should occur for these manifestations. The multiple organ involvement results in the morbidity and mortality of this disease. The typical progression of the disease is in three phases: rhinitis and asthma first, tissue eosinophilia second, and, finally, systemic vasculitis of small and medium vessels.

The pathogenesis of EGPA is still unknown but several factors are suspected to contribute to the development of the disease. The possible link between leukotriene-receptor antagonists (zafirlukast, montelukast, or pranlukast) is controversial but still considered possible. It is suspected that use of this class of adjunctive medications in severe asthma allows for the reduction in the use of corticosteroids leading to the full-blown (unmasking) manifestation of EGPA. Many refrain from use of leukotriene-receptor antagonists when EGPA syndrome has been diagnosed.

Clinical and laboratory findings pinpoint the diagnosis with high specificity (99.7%) and sensitivity (85%) when at least four of six criteria developed by the American College of Rheumatology are met (asthma, eosinophilia >10%, mononeuropathy or polyneuropathy, nonfixed pulmonary infiltrates, paranasal sinus abnormalities, and biopsy findings of extravascular eosinophil infiltrates). In contrast to GPA, the rhinitis is not destructive, and nasal septal perforation does not occur in EGPA.

Radiography of the chest or HRCT of the chest demonstrates migratory, peripheral predominant opacities, ground-glass appearance, nodules, bronchiectasis, and bronchial wall thickening. Pleural effusion should raise suspicion for the presence of heart failure from cardiomyopathy.

Laboratory findings include striking eosinophilia, with values generally between 5,000 and 20,000/mm^3 at the time of diagnosis. These counts often parallel vasculitis activity. The BAL shows striking eosinophilia with differential counts often >60%. Biopsies of other organ systems reflect the activity of eosinophils and are not specific for the EGPA diagnosis.

ANCAs may be present in EGPA syndrome. The perinuclear-ANCA targeting myeloperoxidase is specifically found in EGPA in approximately 40% of the patients; the absence of myeloperoxidase-ANCA does not exclude the diagnosis. Those patients with eosinophilic pneumonia, fever, and cardiac involvement are less likely to have myeloperoxidase-ANCA detected. Those with peripheral neuropathy, renal glomerular disease, and skin purpura usually have detectable myeloperoxidase-ANCAs (see Table 448.12).

Pulmonary function tests show an obstructive pattern caused by the asthma component. The pulmonary obstruction is responsive to oral corticosteroid use, but often mild obstruction persists.

Treatment of EGPA with systemic oral corticosteroids remains the mainstay of therapy at a starting dose of 0.5 to 1 mg/kg/day. This therapy is often required for up to 12 months or longer, with a steady taper in dosage over that time. EGPA resistant to corticosteroids has responded to cyclophosphamide, IFN-α, cyclosporine, IVIG, and plasmapheresis. The use of anti–IL-5 (mepolizumab) has been encouraging and may be used as a steroid-sparing agent in the future.

Table 448.12 Eosinophilic Granulomatosis with Polyangiitis

	VASCULITIC PHENOTYPE	EOSINOPHILIC TISSULAR DISEASE PHENOTYPE
Respective frequency	~40%	~60%
ANCA	Present (mostly perinuclear-ANCA with anti-MPO specificity)	Absent
Predominant manifestations	Glomerular renal disease Peripheral neuropathy Purpura Biopsy-proven vasculitis	Cardiac involvement (eosinophilic myocarditis) Eosinophilic pneumonia Fever

ANCA, Antineutrophil cytoplasmic antibody; MPO, myeloperoxidase.

Data from Sablé-Fourtassou R, Cohen P, Mahr A, et al. Antineutrophil cytoplasmic antibodies and the Churg-Strauss syndrome. *Ann Intern Med.* 2005;143:632–638; and Sinico RA, Di Toma L, Maggiore U, et al. Prevalence and clinical significance of antineutrophil cytoplasmic antibodies in Churg-Strauss syndrome. *Arthritis Rheum.* 2005;52:2926–2935.

From Cottin V, Cordier JF. Eosinophilic lung diseases. *Immunol Allergy Clin North Am.* 2012;32(4):557–586, Table 2, p. 569.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

ABPA is a complex hypersensitivity reaction that occurs in the lungs and bronchi in response to exposure and colonization of *Aspergillus* species (usually *Aspergillus fumigatus*; see Chapter 283). This disease occurs in patients with preexisting asthma and up to 15% of patients with cystic fibrosis (see Chapter 454). The quantity of *Aspergillus* exposure does not correlate with the severity of disease.

The clinical pattern of disease (Table 448.13) is remarkably similar with a presentation of difficult-to-treat asthma. The patient suffers from periods of acute obstructive lung disease with bronchial mucous plugs, elevated total IgE antibody, elevated specific IgE and IgG anti-*Aspergillus* antibodies, skin prick test reactions to *Aspergillus* species, precipitating antibodies to *Aspergillus* species, and proximal bronchiectasis. Other clinical manifestations include dyspnea, cough, shortness of breath, and peripheral eosinophilia, along with pulmonary eosinophilia seen on BAL with infiltration of the parenchyma. The use of systemic corticosteroids may lower the total IgE antibody levels such that a diagnosis may be in question when the initial tests are conducted.

ABPA should be considered in patients with cystic fibrosis when clinical deterioration occurs without evidence of an identifiable cause. Symptoms heralding such deterioration include increasing cough, wheezing, loss of exercise tolerance, worsening exercise-induced asthma, reduction of pulmonary function, or increased sputum production without another discernible reason. Clinical findings of elevated total IgE antibody, anti-*Aspergillus* IgE antibodies, precipitating antibodies to *A. fumigatus,* and/or new abnormalities on chest radiography that fail to clear with antibiotics should alert the clinician to the possibility of ABPA.

Table 448.13 Criteria for the Diagnosis of Allergic Bronchopulmonary Aspergillosis

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS–CENTRAL BRONCHIECTASIS
• Medical history of asthma*
• Immediate skin prick test reaction to *Aspergillus* antigens*
• Precipitating (IgG) serum antibodies to *Aspergillus fumigatus**
• Total IgE concentration >500 IU/mL (>1,000 ng/mL)*
• Central bronchiectasis on chest CT*
• Peripheral blood eosinophilia >500/mm^3
• Lung infiltrates on chest x-ray or chest HRCT
• Elevated specific serum IgE and IgG to *A. fumigatus*
ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS SEROPOSITIVE†
• Medical history of asthma†
• Immediate skin prick test reaction to *A. fumigatus* antigens†
• Precipitating (IgG) serum antibodies to *A. fumigatus*†
• Total IgE concentration >417 IU/mL (>1,000 ng/mL)†

*The criteria required for a diagnosis of ABPA with central bronchiectasis.
†The first four criteria are required for a diagnosis of seropositive ABPA.
ABPA, Allergic bronchopulmonary aspergillosis; CSD, corticosteroid dependent; HRCT, high-resolution computed tomography.

When evaluating a child with asthma symptoms, the clinician must distinguish asthma from ABPA. If the diagnosis is suspected, skin prick test for evidence of IgE-specific antibody directed against *A. fumigatus* is essential. Intradermal skin testing, when the skin prick test is negative, although not routinely performed because of poor specificity, may be conducted. The absence of a positive skin prick test and intradermal test to *A. fumigatus* excludes the diagnosis of ABPA. The prevalence of ABPA in patients with an existing diagnosis of asthma and an abnormal immediate skin prick test response to *A. fumigatus* has been evaluated. Between 2% and 32% of patients with asthma with concurrent skin prick test–positive reactions to *Aspergillus* have evidence of ABPA.

Patients with cystic fibrosis who are less than 6 years of age rarely develop ABPA. When the total IgE antibody in patients with cystic fibrosis exceeds 500 IU/mL (1,200 ng/mL), a strong clinical suspicion of ABPA is necessary.

ABPA pathology has characteristic findings of mucoid bronchi impaction, eosinophilic pneumonia, and granulomas. Histologic features characteristic of asthma are also present. Septated hyphae are often found in the mucus-impacted bronchial tree. However, the fungi are not invasive in this unique disease. *Aspergillus* may be cultured from sputum in more than 60% of patients. Interestingly, hyphae may not be detected on microscopy.

Staging of the disease (Table 448.14) represents distinct phases; however, progression does not necessary occur in sequence from stage 1 to stage 5. Staging of ABPA is important for treatment considerations. In many hypersensitivity diseases where IgE antibody contributes to the pathogenesis (e.g., asthma), total IgE is often used to screen for an atopic state but is not a test that helps the clinician with serial measures. In sharp contrast, the measurement of IgE during acute exacerbations, remission, and recurrent ABPA disease is helpful in identifying the activity of disease and may herald the recurrence. During stage 1 disease, the level of IgE antibody is often very high. During stage 2 remission, a fall in the levels may be as much as 35% or more. Recurrence of activity may result in a marked rise of total IgE with a doubling of the baseline level seen during remission. During the use of glucocorticoid therapy, monthly or bimonthly levels of IgE are followed serially to assist the clinician in tapering therapy. Because exacerbations of ABPA are not accompanied by changes in symptoms in approximately 25% of the recurrences, serial IgE accompanied by chest radiography is helpful to the clinician to guide therapy.

Radiography

Plain chest x-ray shows evidence of infiltrates, especially in the upper lobes and the classic findings of bronchiectasis (Fig. 448.6). HRCT of the chest demonstrates central bronchiectasis (Fig. 448.7) and mucus impaction of the airways (finger-in-glove appearance). HRCT may add value for the patient with a positive skin prick test and normal chest radiograph to detect characteristic abnormalities of ABPA.

Treatment

The mainstay of therapy for ABPA has been systemic glucocorticoids with adjunct therapy including antifungal medications and anti-IgE therapy with omalizumab. Exacerbations in stages 1 and 3

Table 448.14 Staging of Allergic Bronchopulmonary Aspergillosis

Stage 1	Acute	Upper and middle lobe infiltration	High IgE
Stage 2	Remission	No infiltrate off steroids >6 mo	Normal to high IgE
Stage 3	Exacerbation	Upper and middle lobe infiltration	High IgE
Stage 4	CSD asthma	Minimal infiltrate	Normal to high IgE
Stage 5	End stage	Fibrosis and/or bullae	Normal

CSD, Corticosteroid dependent.

may be treated for 14 days with 0.5-1 mg/kg of glucocorticoids followed by every-other-day usage and tapering over 3 months or as long as 6 months. Stage 2 remission phase and stage 5 where fibrosis has occurred do not require glucocorticoid therapy. Stage 4 denotes a state where glucocorticoid weaning has not been successful and continued long-term therapy is required.

Antifungal therapy with a 16-week course of itraconazole improves the response rate during exacerbations, allowing the reduction of glucocorticoid dosage by 50% and resulting in a reduction of total serum IgE of 25% or more. The proposed mechanisms of action have been to either reduce the antigen load driving the immune response or possibly raising the corticosteroid serum levels by slowing the metabolism of the steroid. This latter mechanism would be true for prednisone, which is methylated in the liver, but not for methylprednisolone, which does not require methylation.

The adult dosage recommendation for itraconazole is 200 mg 3 times per day for 3 days followed by 200 mg twice daily for the remainder of the 16 weeks. Children should receive 5 mg/kg/day in a single dose. If the proper calculated dose exceeds 200 mg, then the total dose should be divided equally and given twice daily. Serum levels of itraconazole are necessary to ensure proper drug absorption when in capsule form.

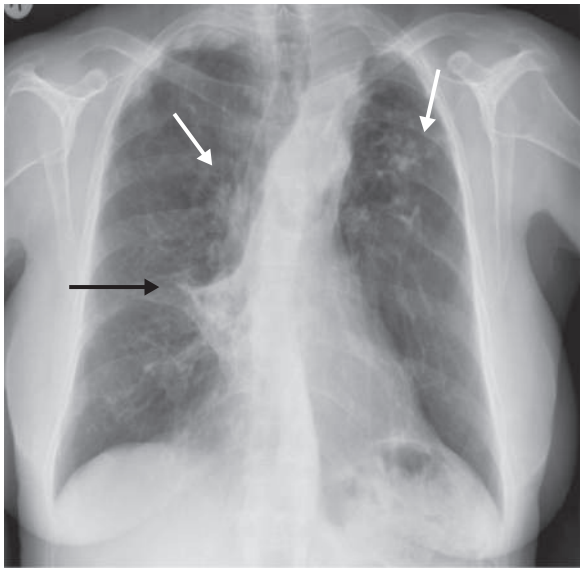

Fig. 448.6 Transitory opacities *(white arrows)* and lobar collapse *(black arrow)* in patient with allergic bronchopulmonary aspergillosis. *(From Douglass JA, Sandrini A, Holgate ST, O'Hehir RE. Allergic bronchopulmonary aspergillosis and hypersensitivity pneumonitis. In Adkinson NF Jr, Bochner BS, Burks AW, et al., eds. Middleton's Allergy Principles and Practice, 8th ed. Philadelphia: Elsevier; 2014: Fig. 61.2.)*

The liquid form is more readily absorbed and has achieved substantially higher levels. The use of proton pump inhibitors and histamine 2 antagonists may reduce absorption of itraconazole. Voriconazole has been used as a substitute antifungal medication. Proper dosing has been established for invasive *Aspergillus* disease but not for ABPA. Hepatotoxicity may occur with these drugs so liver function must be monitored.

Omalizumab, an anti-IgE humanized monoclonal antibody, has been used in a case series of patients with cystic fibrosis and ABPA and in a small cohort of adults without cystic fibrosis but with ABPA. Both case series demonstrated significant reductions in asthma exacerbations, ABPA exacerbations, and glucocorticoid usage. The dose prescribed has been 300-375 mg every 2 weeks by subcutaneous injection.

HYPEREOSINOPHILIC SYNDROME

See Chapter 169.

HES is a descriptive name of a group of disorders that are characterized by the persistent overproduction of eosinophils accompanied by eosinophil infiltration in multiple organs with end-organ damage from mediator release. The term *HES* should only be used when there is eosinophilia with end-organ damage from the eosinophils and not from another cause. The discovery of underlying genetic, biochemical, or neoplastic reasons for HES has led to the classification of primary, secondary, and idiopathic HES (Table 448.15). Specific

Table 448.15 Hypereosinophilic Syndrome Variants

Myeloproliferative	Nonclonal Clonal–F1P1L1/PDGFRA-positive chronic eosinophilic leukemia
Lymphocytic	Nonclonal T cells Clonal T-cell expansion with T-cell activation
Overlap	Organ restricted
Familial	Family history of eosinophilia without known cause
Associated	Eosinophilia in chronic disease like inflammatory bowel disease or EGPA (Churg-Strauss syndrome)
Undefined	Asymptomatic Cyclic angioedema with eosinophilia (Gleich syndrome) Symptomatic without myeloproliferation or lymphocytic form

EGPA, Eosinophilic granulomatosis with polyangiitis; PDGFRA, platelet-derived growth factor receptor-α.

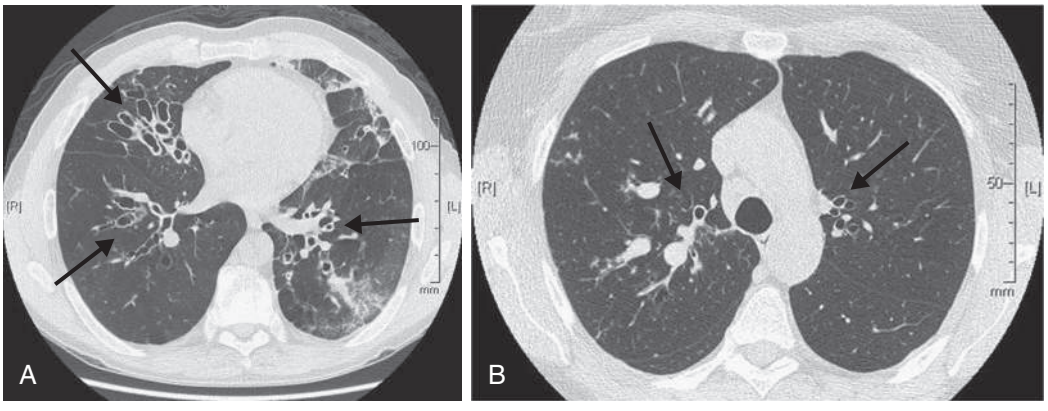

Fig. 448.7 A, Central bronchiectasis in patient with ABPA *(arrows)*. B, Central bronchiectasis in the upper lobes *(arrows)*. *(From Douglass JA, Sandrini A, Holgate ST, O'Hehir RE. Allergic bronchopulmonary aspergillosis and hypersensitivity pneumonitis. In Adkinson NF Jr, Bochner BS, Burks AW, et al., eds. Middleton's Allergy Principles and Practice, 8th ed. Philadelphia: Elsevier; 2014: Fig. 61.3.)*

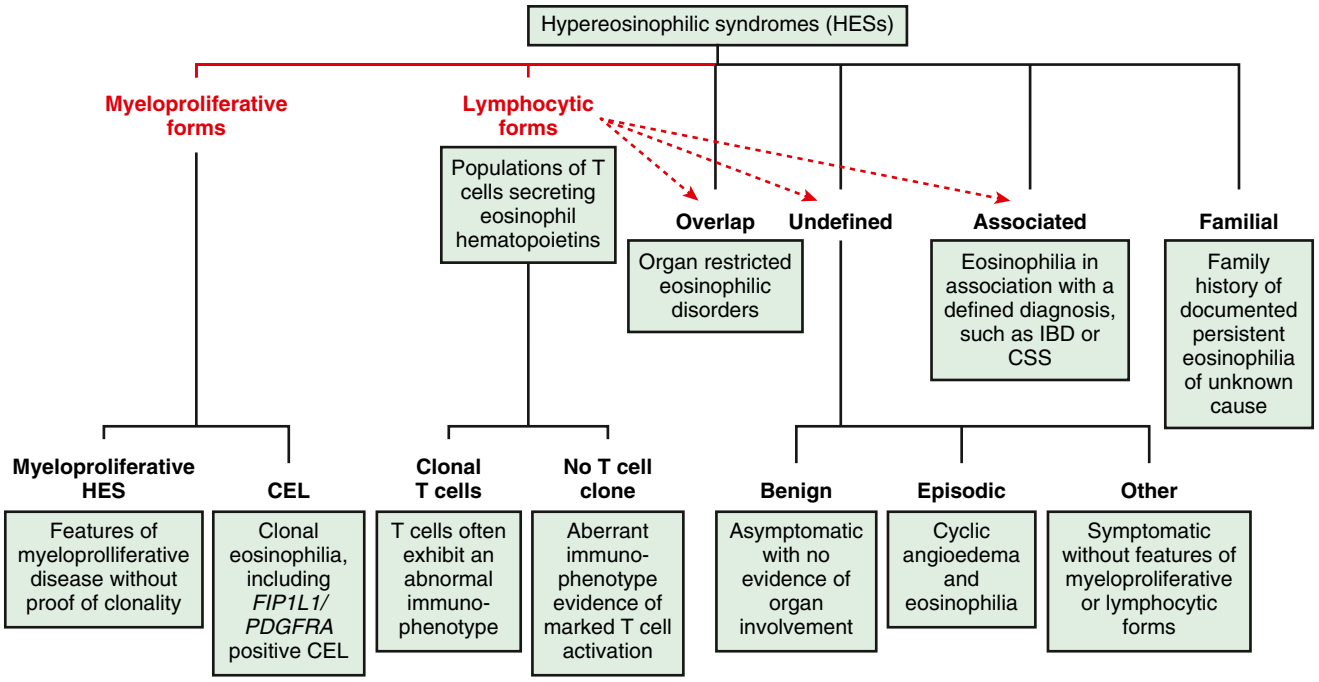

Fig. 448.8 A revised classification of hypereosinophilic syndrome (HES). Changes from the previous classification are indicated in *red type*. *Dashed arrows* identify HES forms in some patients who have T-cell–driven disease. Classification of myeloproliferative forms has been simplified, and patients with HES and eosinophil hematopoietin-producing T cells in the absence of a T-cell clone are included in the lymphocytic forms of HES. CSS, Churg-Strauss syndrome; IBD, inflammatory bowel disease. *(From Simon H, Rothenberg ME, Bochner BS, et al. Refining the definition of hypereosinophilic syndrome. J Allergy Clin Immunol. 2010;126:45–49, Fig. 1.)*

syndromes such as EGPA have eosinophilia, but the contribution of eosinophils to the organ damage is incompletely understood.

Some variants of HES have pathogenic variants in tyrosine kinase receptor platelet-derived growth factor receptor-α (*PDGFRA)*; males are almost exclusively affected. *PDGFRA* can also form a fusion gene with *FIP1L1* in some patients with HES. Patients with *PDGFRA-PIP1L1* are more likely to be responsive to imatinib, a tyrosine kinase inhibitor. Otherwise, HES appears to be distributed equally among females and males.

Hypereosinophilia is defined as an absolute eosinophil number in the blood that exceeds 1.5×10^9 eosinophils on two separate occasions separated by at least 1 month and/or a tissue diagnosis of hypereosinophilia. Tissues are abnormal when more than 20% of nucleated cells in the bone marrow are of eosinophil origin, a pathologist determines the presence of eosinophilia, or the presence of extensive eosinophilic granule proteins are determined on biopsy to be deposited in large quantities. These disorders can be subclassified into primary (neoplastic), secondary (reactive), and idiopathic (Fig. 448.8).

Clinical manifestations of HES include organ involvement of the heart (5%), gastrointestinal tract (14%), skin (37%), and respiratory system (25–63%). HES is complicated by thrombosis and/or neurologic disease in many patients, although the exact prevalence of this problem is incompletely categorized. Peripheral neuropathy, encephalopathy, transverse sinus thrombosis, or cerebral emboli are the most common neurologic complications. The exact mechanism of the manifestations is unclear, especially in major artery thrombosis such as the femoral artery.

The most frequent pulmonary symptoms include cough and dyspnea. Many patients have obstructive lung disease with clinical wheezing. Evidence of pulmonary fibrosis and pulmonary emboli are seen with regularity. Because biopsy shows eosinophilic infiltrates similar to other pulmonary eosinophilic diseases of the lung, it is the constellation of other organ involvement or thromboembolic phenomena that leads the clinician to a high index of suspicion for HES.

Laboratory evaluation should include evaluation of liver enzymes, kidney function tests, creatine kinase, and troponin. The extent of cardiac involvement should be evaluated by electrocardiogram and echocardiogram. Some unique biomarkers may be tested when evaluating the myeloproliferative and T-lymphocyte HES diagnoses. Vitamin B_{12} and serum tryptase may be elevated, especially the latter, when the myeloproliferative disease is accompanied by mastocytosis. These two biomarkers are most frequently elevated when the *FIP1L1-PDGFRA* fusion pathogenic variant is present.

Because of the extensive pulmonary disease that is seen in HES, pulmonary function tests (spirometry, lung volumes) should be performed at diagnosis. Dead space ventilation may be significantly elevated in patients with pulmonary emboli. Pulse oximetry may be helpful in the evaluation as well.

Chest radiography and CT of the chest are helpful in the evaluation. Spiral chest CT should also be performed when pulmonary emboli are being considered. In one series of patients, nearly half of the patients with HES had evidence of pulmonary abnormalities, including ground-glass–appearing infiltrates, pulmonary emboli, mediastinal lymphadenopathy, and/or pleural effusion.

Treatment of HES depends on the type of variant (myeloproliferative, lymphocytic forms, undefined, associated with systemic diseases such as EGPA, or familial). Rarely, some patients present with marked eosinophilia, where the total count exceeds 100,000 cells/μL, and vascular insufficiency symptoms. Prednisone is indicated to acutely reduce the eosinophil count after diagnostic tests are performed and when safe. If the patient is unstable, the glucocorticoid should be administered to prevent progression of symptoms. Other acute therapies aimed at reduction of eosinophil counts include vincristine, imatinib mesylate, or even leukapheresis. Imatinib is especially used in patients found to have the *FIP1L1-PDGFRA* fusion variant.

When eosinophil counts are not as dramatically elevated, therapy begins with glucocorticoids at 1 mg/kg for patients who do not have the *FIP1L1-PDGFRA* variant. Patients with this variant are resistant

to glucocorticoids, and initial treatment should begin with imatinib, a tyrosine kinase inhibitor. In cases where genetic testing for *FIP1L1-PDGFRA* is not readily available, surrogate markers for the presence of this variant are vitamin B_{12} levels >2,000 pg/mL or serum tryptase >11.5 ng/mL. These findings denote the presence of resistant disease that should initially be treated with imatinib. The goal of therapy is to reduce and maintain eosinophil counts below 1.5×10^9 at the lowest dose of prednisone possible to reduce or avoid corticosteroid-related side effects. If corticosteroid doses cannot be lowered below 10 mg/day, then imatinib can be added as combination therapy in order to spare the dose of steroid. Caution must be used in the presence of cardiac disease, as introduction of imatinib has precipitated left ventricular failure.

Additional or alternative adjunct therapies that have shown promise include hydroxyurea, IFN-α, anti–IL-5 monoclonal antibody therapy, and a monoclonal antibody directed against CD52. Failure of these modalities may signal a need for hematopoietic stem cell transplantation. This therapy has been successful in some patients.

448.5 Interstitial Lung Disease

Timothy J. Vece and Stephanie D. Davis

Interstitial lung disease in children (chILD) is caused by a large group of rare, heterogeneous, familial, or sporadic diseases that involve the pulmonary parenchyma and cause significant impairment of gas exchange (Tables 448.16-448.18). Although there are some shared diseases, childhood ILD is often different from ILD in adults, especially notable for the absence of IPF in children. Furthermore, certain ILDs only occur in children (e.g., neuroendocrine cell hyperplasia of infancy, pulmonary interstitial glycogenosis). Despite wide variations in cause, these disorders are classified together because of the similar clinical, physiologic, radiographic, and pathologic processes involving disruption of the alveolar interstitium and/or airways. Prevalence estimates vary widely with a range of 0.13-16.2 cases/100,000 children. This large range in prevalence is likely a result of the lack of standardization of the diseases that are included in the definition of ILD in children. The pathophysiology is more complex than that of adult disease because pulmonary injury occurs during the process of lung growth and differentiation. In ILD, the initial injury causes damage to the alveolar epithelium and capillary endothelium. Genetic causes of ILD are becoming increasingly important, especially the disorders of surfactant metabolism (DSM) and immune dysregulatory disorders.

CLASSIFICATION AND PATHOLOGY

Through the work of the children's ILD research network in the United States and the children's ILD-European Union group, consensus on a classification scheme has been reached. The classification is broken down based on histologic pattern and by age, with 2 years of age serving as a cutoff. The classification scheme was first applied to biopsies from children less than 2 years of age and was later extended to children greater than 2 years of age (see Tables 448.16 and 448.17). Growth disorders such as alveolar simplification, unique diseases of infancy such as neuroendocrine cell hyperplasia of infancy **(NEHI)**, and disorders of surfactant metabolism **(DSM)** are common in children less than 2 years of age. In contrast, disorders of the immunocompromised host, such as ILD related to immune deficiency, and disorders of systemic diseases such as the collagen vascular disorders, are much more common in older children.

Neuroendocrine Cell Hyperplasia of Infancy

See Chapter 448.6.

Table 448.16 The Pediatric Interstitial Lung Diseases in Children Under 2 Years of Age

AGE-RELATED INTERSTITIAL LUNG DISEASES IN INFANCY AND EARLY CHILDHOOD
Diffuse developmental disorders
Acinar dysplasia
Congenital alveolar dysplasia
Alveolar capillary dysplasia with misalignment of pulmonary veins (some caused by *FOXF1* pathogenic variants)
Growth abnormalities reflecting deficient alveolarization
Pulmonary hypoplasia
Chronic neonatal lung disease
Chromosomal disorders
Congenital heart disease
Neuroendocrine cell hyperplasia of infancy
Pulmonary interstitial glycogenosis (infantile cellular interstitial pneumonia)
Surfactant dysfunction disorders (pulmonary alveolar proteinosis)
Surfactant protein B variant
Surfactant protein C variant
ABCA3 variant
Granulocyte-macrophage colony-stimulating factor receptor *(CSF2RA)* variant
NKX2.1 (transcription factor for SP-B, SPC, ABCA3)
INTERSTITIAL LUNG DISEASE DISORDERS WITH KNOWN CAUSES
Infectious/postinfectious processes
Adenovirus viruses
Influenza viruses
Chlamydia pneumoniae
Mycoplasma pneumoniae
Environmental agents
Hypersensitivity pneumonitis
Toxic inhalation
Aspiration syndromes
PULMONARY DISEASES ASSOCIATED WITH PRIMARY AND SECONDARY IMMUNE DEFICIENCY
Opportunistic infections
Granulomatous lymphocytic interstitial lung disease associated with common variable immunodeficiency syndrome
Lymphoid intestinal pneumonia (HIV infection)
Therapeutic interventions: chemotherapy, radiation, transplantation, and rejection
IDIOPATHIC INTERSTITIAL LUNG DISEASES
Desquamative interstitial pneumonitis
Lymphocytic interstitial pneumonitis and related disorders
Nonspecific interstitial pneumonitis (cellular/fibrotic)
Eosinophilic pneumonia
Bronchiolitis obliterans syndrome
Pulmonary hemosiderosis and acute idiopathic pulmonary hemorrhage of infancy
Pulmonary vascular disorders
Pulmonary lymphatic disorders
Pulmonary microlithiasis
SYSTEMIC DISORDERS WITH PULMONARY MANIFESTATIONS
Anti-GBM disease
Granulomatosis with polyangiitis
Microscopic polyangiitis
Idiopathic pulmonary capillaritis
Gaucher disease and other storage diseases
Malignant infiltrates
Hemophagocytic lymphohistiocytosis
Langerhans cell histiocytosis
Sarcoidosis
Systemic sclerosis
Polymyositis/dermatomyositis
Systemic lupus erythematosus
Rheumatoid arthritis
Lymphangioleiomyomatosis
Pulmonary hemangiomatosis
Neurocutaneous syndromes
Hermansky-Pudlak syndrome

Disorders of Surfactant Metabolism

One of the more important groups of disorders in childhood ILD is the **DSM** (Table 448.19). These disorders likely account for previously unknown cases of neonatal respiratory distress in full-term infants. Surfactant protein B deficiency, caused by pathogenic variants in the surfactant protein B gene, leads to severe neonatal respiratory distress. Chest CT imaging often reveals a pattern of diffuse ground-glass opacities with septal thickening. Histopathology reveals alveolar proteinosis with interstitial widening, and electron microscopy shows disorganized lamellar bodies. Most children die within the first 2 months of life without a lung transplant. Surfactant protein C deficiency can cause disease in older infants, children, or adults. Chest CT imaging reveals diffuse ground-glass opacities with septal thickening early in the disease or significant fibrosis and honeycombing with cyst formation in more advanced disease. Histopathologic findings vary with age, with alveolar proteinosis and interstitial widening seen in young children, and fibrosis seen in older children and adults. Electron microscopy reveals normal lamellar bodies. *ABCA3* variants cause variable lung disease in children, with some having severe disease similar to surfactant protein B deficiency, whereas others have less severe disease similar to surfactant protein C. Chest CT imaging most often reveals diffuse ground-glass opacities with septal thickening early in the disease (Fig. 448.9). Histopathology depends on the age of the child; however, electron microscopy shows characteristic changes in the lamellar bodies with an eccentric electron dense body without the characteristic concentric circles, the so-called *fried egg appearance*. **DSM** caused by pathogenic variants in the gene *NKX2.1* has also been described. *NKX2.1* encodes for thyroid transcription factor 1 (TTF-1), which is a major regulator of surfactant protein transcription. Pathogenic variants in *NKX2.1* cause variable disease in the lungs, brain, and thyroid **(brain-lung-thyroid syndrome)** (see Table 448.19). Lung disease is variable and can present similar to surfactant protein B deficiency, similar to surfactant protein C deficiency, or as recurrent pulmonary infections. Finally, variants in the α and β subunits of the granulocyte-macrophage colony-stimulating factor (GM-CSF) receptor leads to alterations in surfactant catabolism. Alveolar macrophages are critical for surfactant recycling and are unable to perform this function effectively in patients with these variants. The inability to recycle surfactant leads to subsequent accumulation of proteinaceous material and pulmonary alveolar proteinosis.

Interstitial Lung Disease Due to Systemic Disease

ILD due to systemic disease is more common in older children with diffuse lung disease. The most common lung disease seen on biopsy is nonspecific interstitial pneumonia; however, other patterns are seen depending on the underlying disorder. For example, lymphocytic interstitial pneumonia may be seen in Sjögren syndrome or cryptogenic organizing pneumonia in dermatomyositis. Findings on chest CT scans depend on the underlying ILD, with nonspecific interstitial pneumonia revealing areas of ground-glass opacities and septal thickening in the early cellular phase of the disease (Fig. 448.10) and progressing to diffuse fibrosis with traction bronchiectasis and peripheral cysts in the later fibrotic stage of the disease. The exact mechanism for disease is unknown but likely is caused by autoantibodies to respiratory tissue.

Pulmonary vasculitis, either caused by granulomatosis with polyangiitis, microscopic polyangiitis, idiopathic pulmonary capillaritis, or anti-GBM syndrome (formerly Goodpasture disease), is another common manifestation of systemic diseases. The disease is likely the result of autoantibody stimulation of lymphocytes with resultant inflammation of pulmonary endothelium causing interstitial changes and pulmonary hemorrhage. Histopathology reveals diffuse alveolar hemorrhage, interstitial widening, and with the exception of anti-GBM disease, neutrophilic inflammation of the pulmonary vasculature.

Genetic causes of immune dysregulation may also be responsible for ILD in children. Pathogenic variants in both *STAT3b* and *LRBA* have been shown to cause lymphocytic interstitial pneumonia and lymphoproliferative disease. Pathogenic variants in coatomer-associated protein-alpha *(COPA)*, a protein involved in endoplasmic reticulum to Golgi transport, cause familial pulmonary hemorrhage and/or ILD.

Persistent pulmonary symptoms can occur after respiratory infections caused by adenoviruses, influenza viruses, *Chlamydia pneumoniae,* and *Mycoplasma pneumoniae*. The resultant pulmonary disease is called **bronchiolitis obliterans** and is characterized by obstructive lung disease and obliteration or constriction of the bronchioles on lung biopsy. There is a characteristic appearance on HRCT of the chest with mosaicism, vascular attenuation, and central bronchiectasis, which if present, can obviate the need for lung biopsy (Fig. 448.11). Aspiration is a frequent cause of chronic lung disease in childhood and can mimic ILD. Children with developmental delay or neuromuscular weakness are at an increased risk for aspiration of food, saliva, or foreign matter secondary to swallowing dysfunction and/or gastroesophageal reflux (GER). An undiagnosed tracheoesophageal fistula can also result in pulmonary complications related to aspiration of gastric contents leading to interstitial pneumonia.

Children experiencing an exaggerated immunologic response to organic dust, molds, or bird antigens may demonstrate hypersensitivity pneumonitis. Children with malignancies may have ILD related to the primary malignancy, an opportunistic infection, or related to chemotherapy or radiation treatment.

CLINICAL MANIFESTATIONS

A detailed history is needed to assess the severity of symptoms and the possibility of an underlying systemic disease in a patient with suspected ILD. One should also ask about any family history of lung disease. Identification of precipitating factors, such as exposure to

Table 448.18 Pathogenic Variants Associated with Children's Interstitial and Diffuse Lung Disease

DISORDER (GENE)	INHERITANCE	CLINICAL PRESENTATION	TREATMENT APPROACH
ABCA3 deficiency *(ABCA3)*	Autosomal recessive	Loss of functional protein causes severe respiratory failure in newborn babies or gradual development of respiratory symptoms in older children and adults	Reported responses to immune suppression with hydroxychloroquine; azithromycin; lung transplantation considered
COPA syndrome *(COPA)*	Autosomal dominant	Autoimmune interstitial lung, joint, and kidney disease arising in the first 2 decades of life	Janus kinase inhibitors; lung transplantation considered
Pulmonary alveolar proteinosis (colony stimulating factor 2 receptor α *[CSF2RA]*)	X-linked	Primary PAP; dyspnea and cough in early childhood	Whole lung lavage
Pulmonary alveolar proteinosis (colony-stimulating factor 2 receptor β *[CSF2RB]*)	Autosomal recessive	Primary PAP; dyspnea and cough in early childhood	Whole lung lavage
Filamin A syndrome *(FLNA)*	X-linked recessive	Dyspnea in infancy	Symptomatic; lung transplantation considered
Alveolar capillary dysplasia with misalignment of the pulmonary veins *(FOXF1)*	Autosomal dominant (usually with paternal imprinting)	Acute respiratory distress within first few hr of birth; without transplant few survive to 1 yr	Lung transplantation considered
Immunodeficiency 21: profound deficiency with pulmonary alveolar proteinosis *(GATA2)*	PAP form is autosomal dominant	Profound B-cell loss with normal T-cell numbers leads to opportunistic infection and PAP	Hematopoietic stem cell transplantation
Interstitial lung and liver disease (*MARS*[methionyl-tRNA synthetase])	Autosomal recessive	Failure to thrive, hypotonia, intermittent lactic acidosis, severe cirrhosis, respiratory failure (PAP), and interstitial lung disease in infancy or early childhood	Symptomatic; whole lung lavage considered
Brain-lung-thyroid syndrome *(NKX2-1)*	Autosomal dominant	Infant respiratory distress and recurrent pulmonary infection with associated hypothyroidism and neurologic impairment	Symptomatic; lung transplantation considered
Lung disease, immunodeficiency, and chromosome breakage syndrome *(NSMCE3)*	Autosomal recessive	Failure to thrive in infancy with immunodeficiency and viral-induced fatal lung disease	Hematopoietic stem cell transplantation
Infantile-onset pulmonary alveolar proteinosis *(OAS1)*	Autosomal dominant	Onset of dyspnea and respiratory distress often associated with a viral infection; hypogammaglobulinemia and splenomegaly	Hematopoietic stem cell transplantation
Surfactant protein B deficiency *(SFTPB)*	Autosomal recessive	Acute neonatal fatal respiratory distress; some reports of dyspnea in older children	Symptomatic; lung transplantation considered
Surfactant protein C mutation *(SFTPC)*	Autosomal dominant	Acute neonatal respiratory distress, but also presents in older children and adults	Consider corticosteroids and hydroxychloroquine; lung transplantation considered in severe or progressive cases
Lysinuric protein intolerance *(SLC7A7)*	Autosomal recessive	Short stature, hepatosplenomegaly; recurrent infection; early childhood respiratory failure in some (PAP); pulmonary fibrosis in a third in later life	Poor response to GMCSF; low-protein diet and citrulline supplementation
Acinar dysplasia *(TBX4)*	Autosomal dominant	Acute fatal neonatal respiratory insufficiency; patellar aplasia or hypoplasia syndrome; pulmonary arterial hypertension	Lung transplantation considered
STING associated vasculopathy with onset in infancy *(TMEM173)*	Autosomal dominant	Infant-onset systemic inflammation with skin lesions, vasculopathy, and pulmonary fibrosis	Janus kinase inhibitors

molds or birds and a severe lower respiratory infection, is important in establishing the diagnosis and instituting potential avoidance measures. Patients may develop hypoxia and hypercarbia. Tachypnea, crackles on auscultation, retractions, and digital clubbing may be noted on physical examination in children with ILD. However, chest physical examination findings can be normal. Failure to thrive, likely because of increased work of breathing leading to high caloric needs, is also common in ILD. Wheeze and fever are less common but have been noted in childhood ILD, especially in bronchiolitis obliterans. Cyanosis accompanied by a prominent P_2 heart sound is indicative of severe disease with the development of secondary pulmonary hypertension. Anemia or hemoptysis suggests a pulmonary vascular disease or pulmonary hemosiderosis. Rashes or joint complaints are consistent with an underlying connective tissue disease.

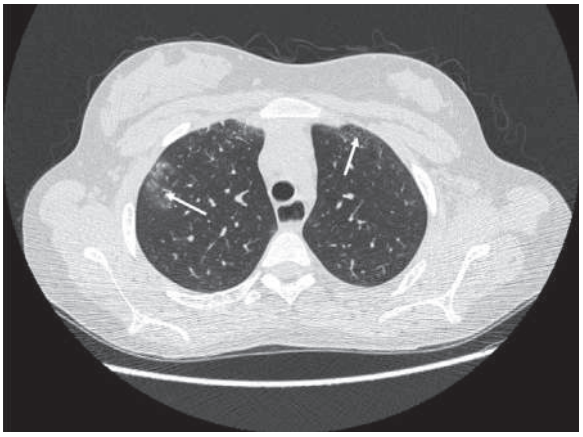

Fig. 448.10 Chest CT from an 11-yr-old patient with systemic sclerosis and cellular nonspecific interstitial pneumonia. Note the areas of ground-glass opacities in the periphery *(arrows)*. *(Courtesy R. Paul Guillerman, MD.)*

DIAGNOSIS

Radiography

Chest radiographic abnormalities can be classified as interstitial, reticular, nodular, reticulonodular, or honeycombed. The chest radiographic appearance may also be normal despite significant clinical impairment and may correlate poorly with the extent of disease. HRCT of the chest better defines the extent and distribution of disease and can provide specific information for selection of a biopsy site. Chest CT imaging may reveal air trapping, ground-glass patterns, mosaic patterns of attenuation, hyperinflation, bronchiectasis, cysts, and/or nodular opacities. Serial HRCT scans have been beneficial in monitoring disease progression and severity.

Pulmonary Function Tests

Pulmonary function tests are important in defining the degree of respiratory dysfunction and in following the response to treatment. In ILD, pulmonary function abnormalities demonstrate a restrictive ventilatory deficit with decreased lung volumes and reduced

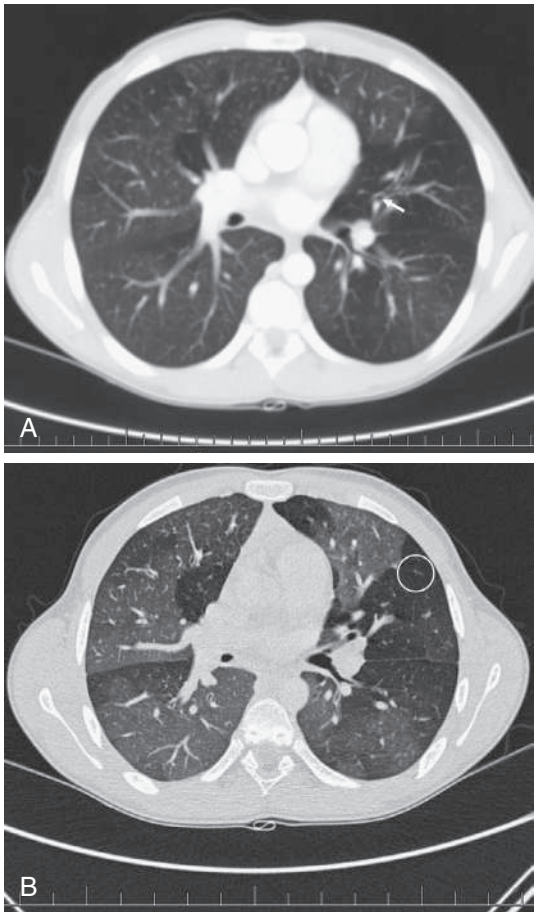

Fig. 448.11 Chest CT from an 11-yr-old patient with bronchiolitis obliterans after Stevens-Johnson syndrome. **A,** Volumetric scan at full inspiration shows central bronchiectasis *(arrow)* and mosaic attenuation. **B,** High-resolution image taken in exhalation better highlights the mosaic attenuation and vascular attenuation *(circle)*.

lung compliance. However, obstructive impairment may be seen in some forms of ILD such as bronchiolitis obliterans. The functional residual capacity is often reduced but is usually less affected than vital capacity and total lung capacity (TLC). The residual volume (RV) is usually maintained; therefore ratios of functional residual capacity:total lung capacity and RV:TLC are increased. Diffusion capacity of the lung is often reduced. Exercise testing may detect pulmonary dysfunction, even in the early stage of ILD, with a decline in oxygen saturation.

Bronchoalveolar Lavage

BAL may provide helpful information regarding secondary infection, bleeding, and aspiration and allows cytology and molecular analyses. Evaluation of cell counts, differential, and lymphocyte markers may be helpful in determining the presence of hypersensitivity pneumonitis or sarcoid. Although BAL does not usually determine the exact diagnosis, it can be diagnostic for disorders such as pulmonary alveolar proteinosis.

Lung Biopsy

Lung biopsy for histopathology by conventional thoracotomy or video-assisted thoracoscopy *is sometimes the final step and is often necessary for a diagnosis*. Biopsy yields a diagnosis in greater than 80% of patients. Because of the low diagnostic yield, transbronchial biopsies are not recommended for the evaluation of ILD in children. Evaluation for possible systemic disease may also be necessary.

Molecular Diagnosis

For those genetic-based disorders, gene panels or whole exome sequencing may yield a rapid diagnosis (see Table 448.18).

TREATMENT

Supportive care of patients with ILD is essential and includes supplemental oxygen for hypoxia and adequate nutrition for growth failure. Antimicrobial treatment may be necessary for secondary infections. Some children may receive symptomatic relief from the use of bronchodilators. Antiinflammatory treatment with corticosteroids remains the initial treatment of choice for many forms of childhood ILD. Controlled trials in children are lacking, however, and the clinical responses reported in case studies are variable. The usual dose of prednisone is 1-2 mg/kg/24 hr or 10-30 mg/kg of IV methylprednisolone given either weekly or for 3 consecutive days per month. Treatment length varies but is often initially given for 3-6 months with tapering of dosage dictated by clinical response. Alternative but not adequately evaluated agents include hydroxychloroquine, azathioprine, cyclophosphamide, cyclosporine, methotrexate, and IVIG. Investigational approaches involve specific agents directed against the action of cytokines, growth factors, or oxidants. In severe, progressive, or end-stage ILD, lung transplantation is an option, and outcomes are similar to other end-stage lung diseases in children. Appropriate treatment for underlying systemic disease or aspiration syndrome is indicated. Preventive measures include avoidance of all inhalation irritants, such as tobacco smoke and, when appropriate, molds and bird antigens. Supervised pulmonary rehabilitation programs may be helpful.

For those disorders with fibrotic ILD, antifibrotic therapy may be another option. The greatest experience with antifibrotic therapy has been in adults with IPF. Other indications for antifibrotic therapy include fibrosing ILD, autoimmune ILD, hypersensitivity pneumonitis, and nonspecific ILD. Nintedanib and pirfenidone have been approved for patients ≥18 years; both have demonstrated efficacy in slowing the decline in pulmonary function.

Genetic Counseling

A high incidence of ILD in some families suggests a genetic predisposition to either development of the disease or severity of the disorder. Genetic counseling may be beneficial if a positive familial history is obtained.

PROGNOSIS

The overall mortality of ILD is variable and depends on the specific diagnosis. Some children recover spontaneously without treatment, but other children steadily progress to death. Pulmonary hypertension and severe fibrosis are considered poor prognostic indicators.

ANTI–GLOMERULAR BASEMENT MEMBRANE DISEASE (ANTI-GBM DISEASE)

Anti-GBM disease, formerly known as Goodpasture disease, is the prototypical immunologic-mediated ILD (see Chapter 560.4). Because of the concurrent presentation of renal (glomerulonephritis) and pulmonary (alveolar hemorrhage) disease, the differential diagnosis focuses on distinguishing anti-GBM disease from vasculitis, infection, and other syndromes such as GPA, microscopic polyangiitis, Henoch-Schönlein purpura, and idiopathic pulmonary hemorrhage syndromes.

Pathophysiology

Immunology Factors

The development of anti-GBM antibodies against antigens that are present on the basement membranes of the glomerulus and alveolar directly correlates with the development of pulmonary and renal

disease. Removal of such antibodies by plasmapheresis results in improvement of the disease process in some patients but not in all.

Genetic Factors

Genetics appears to contribute strongly to the development of this disease, with the presence of MHC class II alleles DR15, DR4, DRB1*1501, DRB1*04, and DRB1*03 predisposing to disease. The disease is triggered by environmental factors in those with a genetic predisposition. There may be other genetic factors as well, and our understanding of the genetics involved in anti-GBM disease is evolving.

Environmental Factors

Exposure to cigarette smoke appears to be a strong factor in the development anti-GBM disease. Whether smoking alters the ultrastructure of the basement membrane or exogenous particles or noxious substances in smoke alter the type IV collagen is unknown. Smokers are more likely to develop pulmonary hemorrhage than nonsmokers who have anti-GBM disease. Other injuries to the alveoli from infection, hydrocarbon inhalation, or cocaine inhalation have been reported as associated events before the development of anti-GBM disease.

Clinical Manifestations

The majority of patients present with many days or weeks of cough, dyspnea, and fatigue, and up to 60% present with hemoptysis. Young children tend to swallow small amounts of blood from hemoptysis and may present with vomiting blood. Occasionally, the hemoptysis is large and resultant anemia is a consequence of large quantities of blood loss. Younger patients tend to present with both the pulmonary and renal syndrome concurrently. Adults are less likely to develop pulmonary disease.

Laboratory

Serologic detection of anti-GBM antibodies is positive in more than 90% of patients with anti-GBM disease. A complete blood count may show anemia that is normocytic and normochromic, as seen in chronic inflammatory disease. Urinalysis may reveal hematuria and proteinuria, and blood tests demonstrate renal compromise with elevated blood urea nitrogen and creatinine. Studies for ANCAs should also be performed and are positive in approximately 25–30% of patients concurrently with anti-GBM antibodies. The ANCA that is often positive is anti–myeloperoxidase ANCA.

Chest Radiography

Chest radiography in anti-GBM disease will often show widely scattered patches of pulmonary infiltrates. If these infiltrates are in the periphery of the lung, they may be difficult to distinguish from the eosinophilic lung diseases. Interstitial patterns of thickening may be found as well. HRCT of the chest reveals a diffuse ground-glass pattern or opacities.

Pulmonary Function Testing

Spirometry may be suggestive of a restrictive defect with reduction in FVC and FEV_1. DLCO is a valuable test when pulmonary hemorrhage is a strong consideration. The intent of this test is to measure the ability of the lung to transfer inhaled gas to the red blood cell in the pulmonary capillary bed. This test takes advantage of hemoglobin's high affinity to bind carbon monoxide. Current data suggest that DLCO directly correlates with the volume of blood in the pulmonary capillary bed. In pulmonary hemorrhage syndromes, blood in the alveoli plus the blood in the capillary bed increase the DLCO significantly and should alert the clinician to the possibility of pulmonary hemorrhage.

Bronchoscopy and Bronchoalveolar Lavage

Defining pulmonary hemorrhage can often be best assessed through bronchoscopy with BAL. The visual presence of blood during bronchoscopy will be obvious. Infections must be ruled out in many cases. The cytology from the BAL may reveal hemosiderin-laden macrophages through Prussian blue staining. These macrophages would have engulfed and broken down the red blood cells, leaving iron in these cells.

Tissue Histopathology

The most common tissue obtained for diagnosis is a kidney biopsy. Kidney biopsies most commonly reveal crescentic glomerulonephritis with positive anti-GBM. Staining for IgG and complement is found by immunofluorescence along the basement membrane in a linear pattern. This antibody deposition pattern led to the investigation of endogenous antigens in the basement membrane. Although less likely to be performed in anti-GBM disease, lung biopsy in patients with active disease reveals capillaritis from neutrophils, hemosiderin-laden macrophages, type II pneumocyte hyperplasia, and interstitial thickening at the level of the alveolus.

Treatment

More than half of patients with anti-GBM disease who forego treatment die within 2 years from either respiratory failure, renal failure, or both. After a diagnosis is made, therapy with corticosteroids coupled with oral cyclophosphamide is initiated. The addition of daily plasmapheresis may accelerate improvement. Alternative therapies are rituximab or mycophenolate. Anti-GBM antibodies are monitored during treatment. Survival is affected by the need for ongoing dialysis. Kidney transplant is an option for those with significant renal impairment. Patients who do not require persistent dialysis have a survival rate at 1 year of 80% or more.

448.6 Neuroendocrine Cell Hyperplasia of Infancy

W. Adam Gower

NEHI is an idiopathic form of diffuse lung disease that typically presents during the first year of life with persistent tachypnea, retractions, hypoxemia, crackles, and failure to thrive. Initial descriptions of NEHI used the term *persistent tachypnea of infancy*; some authors now use this to refer to both NEHI and pulmonary interstitial glycogenosis. Characteristic findings are seen on chest imaging studies and lung histopathology. Pulmonary function studies typically demonstrate an obstructive pattern with air trapping. *There are no effective specific therapies for NEHI, and the usual approach is supportive care.* The natural course is typically one of gradual improvement of symptoms, although exacerbations may occur throughout childhood, and potentially into adulthood. The long-term consequences of this disorder are not well-delineated.

EPIDEMIOLOGY

The prevalence of NEHI is not known, but it is generally considered to be a rare lung disease. Some studies have noted a slight male predominance. Otherwise, no other clear maternal or patient-level risk factors have been identified. Cases of NEHI have been reported in the literature from North and South America, Europe, Asia, and Australia.

PATHOPHYSIOLOGY

The primary clue to the pathophysiology of NEHI is increased numbers of neuroendocrine cells (NECs) in the airways of affected children. NECs are normally found in the airways, where they exist as both as individual cells and innervated clusters known as *neuroendocrine bodies* (NEBs), and secrete factors such as gastrin releasing peptide (GRP) and serotonin (5-HT). They are thought to be involved in local oxygen sensing and may transmit signals to other cells. Increases in NECs are seen in several respiratory disorders

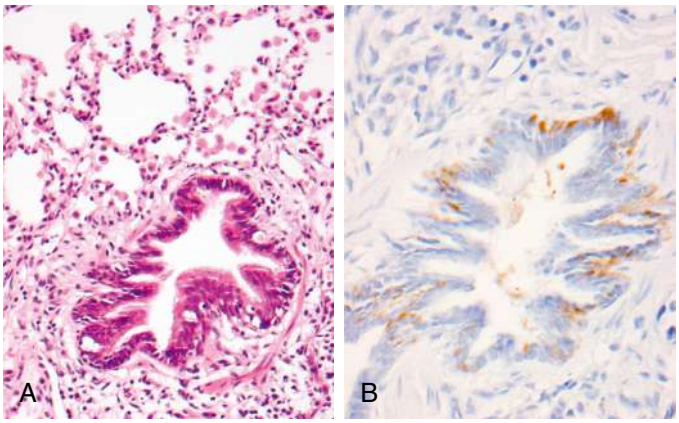

Fig. 448.12 Neuroendocrine cell hyperplasia of infancy. **A,** A small airway showing only minimal chronic inflammation on routine staining. **B,** Staining for bombesin shows increased numbers of neuroendocrine cells within the surface epithelium. *(From Corrin B, Nicholson AG. Pathology of the Lungs, 3rd ed. Philadelphia: Churchill Livingstone; 2011: Fig. 2.19.)*

of childhood, usually with other additional findings, where they are thought to be reactive to other primary pathology. It is unclear whether their presence in increased numbers in NEHI causes the clinical picture or is the result of abnormal pulmonary physiology secondary to some other primary factor. Increased numbers of NECs seem to be associated with increased small airway obstruction in those with NEHI.

Although most cases appear to be sporadic, familial NEHI has been described, suggesting a possible inherited mechanism and/or shared environmental factors between affected siblings. The association of NEHI with heterozygosity for a variant in the gene *Nkx2.1* has been described in one kindred. Variants in this gene are also known to cause a wide spectrum of disorders, including more severe forms of diffuse lung disease (see Chapter 448.5).

CLINICAL PRESENTATION

The symptoms of NEHI characteristically appear during infancy, although the diagnosis may be delayed until after the first year of life. The typical presentation includes persistent tachypnea, hypoxemia, retractions, and poor weight gain in an otherwise healthy infant. The exam reveals crackles or clear lung sounds, and cough, wheezing, and digital clubbing are not typical.

DIAGNOSIS

The diagnosis of NEHI requires that other more common causes of the presenting symptoms be ruled out. Strong consideration should be given to consultation with a pediatric pulmonologist when possible. Although children with NEHI may have comorbid GER and/or swallowing dysfunction, this is thought to be secondary to tachypnea and increased work of breathing rather than the cause of respiratory symptoms. Plain chest films may show hyperinflation. When biopsy material from the lung is stained with immunohistochemical reagents highlighting bombesin, increased numbers of positive-staining cells are noted in the airways. In general, biopsies from children with NEHI are remarkably void of fibrosis, inflammation, or signs of injury (Fig. 448.12).

Although the pattern of NEC hyperplasia seen in histopathology has classically been the gold standard for diagnosis of NEHI, HRCT of the chest has a high specificity, such that biopsy may be avoided in most cases. The classic pattern seen on chest CT is ground-glass opacities

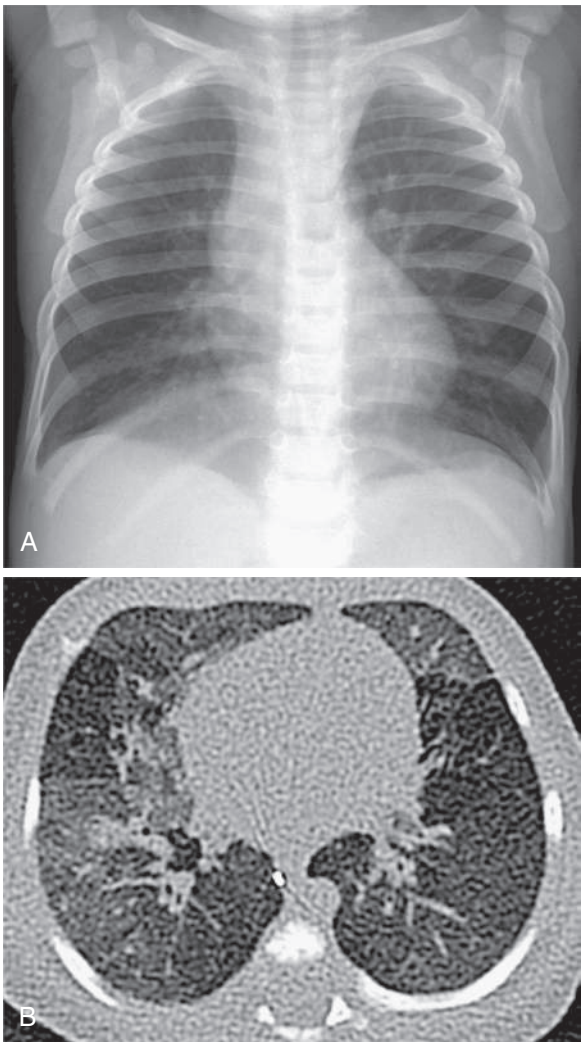

Fig. 448.13 **A,** Neuroendocrine cell hyperplasia of infancy in a 15-mo-old. Chest radiograph demonstrates pulmonary hyperinflation and parahilar opacities resembling reactive airways disease or bronchiolitis. **B,** Neuroendocrine cell hyperplasia of infancy. Axial expiratory CT image shows characteristic geographic ground-glass opacities involving the paramediastinal right middle lobe and lingula and the right lower lobe. *(From Zucker EJ, Lee EY. Diffuse lung disease. In Coley BD, ed. Caffey's Pediatric Diagnostic Imaging, 13th ed. Philadelphia: Elsevier; 2019: Figs. 56.7 and 56.8, p. 541.)*

in the lingula, right middle lobe, and perihilar regions, with air trapping on expiratory images. The lungs otherwise appear normal (Fig. 448.13). If a patient with clinically diagnosed NEHI has a more severe clinical course than expected, biopsy may be helpful to rule out other pathology.

The diagnosis of NEHI is supported by an obstructive pattern that does not reverse with bronchodilators, on either infant pulmonary function testing (iPFT) or standard spirometry. Static lung volumes may show air trapping with increased RV relative to the TLC. BAL findings are notable for lack of inflammatory markers, as compared to other pulmonary diseases of infancy.

Genetic testing may be useful to rule out disorders of surfactant metabolism and other causes of infant diffuse lung disease. Targeted testing for variants in *Nkx2.1* can be considered, but as this association has been found in only one kindred thus far, the diagnostic value of such testing is limited.

NATURAL COURSE AND TREATMENT

Because the symptoms of NEHI typically improve and eventually largely resolve over the first few years of life, the standard approach to treatment of NEHI is supportive. The time frame for clinical improvement in NEHI is variable. Symptoms with rest may improve, whereas those on exertion or with sleep persist. Affected children may require supplemental oxygen to maintain normal saturations, sometimes only with sleep or illnesses, but often at all times. Clinicians should have a low threshold to evaluate for sleep-related breathing disorders, and these should be treated accordingly. Inhaled or systemic corticosteroids are generally not thought to be helpful in treating the primary manifestations of NEHI.

Because they may expend more energy to breathe, children with NEHI may have difficulty gaining weight and often require supplemental nutrition. This may be delivered by gastrostomy tube. Management of GER and/or dysfunctional swallowing, when present, may be helpful. Mild abnormalities of the immune system may be seen in some patients with NEHI and, when present, may be addressed with specific therapy such as prophylactic antibiotics and/or immunoglobulin replacement.

When clinical symptoms improve, the need for supplemental oxygen and/or nutritional support typically decreases, and patients may be weaned as tolerated. Children with NEHI whose symptoms have improved may experience exacerbations later in childhood. These episodes may be associated with increased air trapping.

Although the symptoms of NEHI typically resolve during childhood, limited data suggest that some may persist into the adult years. This may manifest as exercise intolerance or an asthma-like picture. Obstruction with air trapping may be seen on PFT, and persistent abnormalities may be identified on chest imaging. No cases of respiratory failure, need for lung transplantation, or death caused by NEHI have been reported.

448.7 Fibrotic Lung Disease

Deborah R. Liptzin, Jason P. Weinman, and Robin R. Deterding

Pulmonary fibrosis is scarring in the lung parenchyma (as opposed to bronchiectasis, which is scarring of the airways). Idiopathic pulmonary fibrosis is a common form of fibrotic lung disease in adults. This presents with usual interstitial pneumonia (a pathologic finding with patchy interstitial fibrosis, fibroblastic foci, and honeycomb change) (see Chapter 448.5). Additional adult fibrotic lung diseases include sarcoidosis, silicosis, coal worker's pneumoconiosis, and hypersensitivity pneumonitis (e.g., farmer's lung). In children, fibrotic lung disease is rare, and *idiopathic* pulmonary fibrosis has not been described. The differential diagnosis of *fibrotic* lung disease includes surfactant dysfunction pathogenic variants (see Chapter 444); immunocompromised patients with opportunistic infections, radiation-induced fibrosis, or status-post hematopoietic stem cell transplantation; patients with systemic disease processes that can lead to pulmonary fibrosis (systemic vasculitis, collagen vascular disease, juvenile idiopathic arthritis, storage diseases, Langerhans cell histiocytosis, sarcoidosis, systemic lupus erythematosus, systemic sclerosis, and nonspecific interstitial pneumonia); and pleuropulmonary fibroelastosis. Airway fibrosis can be seen in bronchiolitis obliterans (see Chapter 443.1) and aspiration (see Chapter 446) (Tables 448.20-448.22).

CLINICAL PRESENTATION

Pulmonary fibrosis classically presents with nonspecific respiratory symptoms such as cough, crackles, wheezes, prolonged expiratory phase, exercise intolerance, and hypoxemia, especially at nighttime.

Table 448.20 Diseases Associated with Pulmonary Fibrosis

- Idiopathic pulmonary fibrosis/nonspecific interstitial pneumonia
- Familial pulmonary fibrosis/familial interstitial pneumonia
- Hypersensitivity pneumonitis (many agents)
- Cryptogenic organizing pneumonia
- Adverse reaction to therapy (drugs, radiation)
- Pleuroparenchymal fibroelastosis
- Hermansky-Pudlak syndrome
- Sarcoidosis
- Eosinophilic pneumonia (primary or parasitic)
- Langerhans cell histiocytosis
- Dyskeratosis congenita
- Tuberous sclerosis
- Neurofibromatosis
- Erdheim-Chester disease
- Gaucher disease
- Niemann-Pick disease
- Familial hypocalciuric hypercalcemia
- Lysinuric protein intolerance
- IgG4-mediated immune disorder
- Myelodysplastic syndrome
- Progressive systemic sclerosis
- Other connective tissue diseases (SLE, dermatomyositis)
- Granulomatosis with polyangiitis
- Eosinophilic granulomatosis with polyangiitis

Symptom onset can be insidious or rapid. In children, oxygen desaturation with activity may be the earliest sign of fibrotic lung disease, and cough, crackles, and wheezes may be later findings. Children with surfactant dysfunction pathogenic variants can present with respiratory failure in the neonatal period.

EVALUATION

Pulmonary function tests typically show restriction and reduced diffusion capacity. Air trapping can also be seen. Patients may desaturate with exercise challenges such as 6-minute walks, and this may be the first indication of disease in children.

There are a variety of findings on CT scan that suggest pulmonary fibrosis, and these findings can evolve over time. In surfactant dysfunction variants, ground-glass opacities are prominent early on with subsequent evolution to more typical findings of fibrosis such as reticular abnormalities, honeycombing, architectural distortion, and/or traction bronchiectasis. Typical findings in pediatric nonspecific interstitial pneumonia include subpleural sparing, ground-glass opacities, cystic change, reticular abnormalities, and bronchiectasis (Fig. 448.14). Novel measures of quantifying fibrosis have been described in the literature, and CT findings consistent with fibrosis are being used as criteria for study enrollment. Of note, CT findings and pulmonary function tests can be discrepant with stable pulmonary function tests over time, whereas the CT scan can evolve over the same period.

In certain disease processes such as surfactant deficiency (positive genetic testing) or genetic disorders of surfactant metabolism, biopsy is not necessary for diagnosis of fibrosis. Cryobiopsy is becoming popular in the adult pulmonary landscape but is in its infancy in the pediatric pulmonary field. In the absence of a definitive diagnosis, a thoracoscopic wedge biopsy is necessary for diagnosis and to guide treatment. Transbronchial biopsies in pediatrics are of limited utility because the small instruments typically obtain inadequate tissue specimens; transbronchial biopsies in pediatrics are limited to monitoring post–lung transplantation and for diagnosis of sarcoidosis. Pathologic findings in pulmonary fibrosis are variable, depending on the duration and etiology of disease (see Table 448.21), but typically include a component of interstitial inflammation, interstitial expansion by dense collagen, and lobular

Table 448.21 Pediatric Fibrotic Lung Diseases

DISEASES	CT FINDINGS	PATHOLOGY FINDINGS	ADDITIONAL EVALUATION	TREATMENT
Surfactant dysfunction	**Early:** Diffuse ground-glass opacities, septal thickening (crazy paving) **Chronic:** Decreased ground-glass opacities with reticulation and cystic lucencies	Variable: fibrosis, honeycomb cysts at end stage, NSIP, CPI, few globules of pulmonary alveolar proteinosis, foamy macrophages and cholesterol clefts (endogenous lipoid pneumonia)	Genetic testing	Supportive care (nutrition, respiratory support, vaccinations), antifibrotic therapy *plus* hydroxychloroquine, azithromycin, high-dose intravenous steroids; genetic counseling
Aspiration	**Acute:** Consolidation and centrilobular (tree in bud) nodules with a dependent distribution **Chronic:** bronchiectasis, architectural distortion	Airway-centered lesions/ bronchiolitis, food particles with or without granulomas, foamy macrophages (endogenous lipoid pneumonia), organizing pneumonia	Video fluoroscopic or fiberoptic endoscopic swallow evaluation	Stop aspiration through thickening feeds, gastric feeds, cleft repair
Radiation fibrosis	Architectural distortion, volume loss, traction bronchiectasis; often with geometric distribution related to radiation field	Pleural, septal, and paraseptal fibrosis; reactive atypia of alveolar epithelium and endothelium		Steroids may help
Bronchopulmonary dysplasia	Hyperlucent regions, cystic lucencies, architectural distortion (linear and subpleural triangular opacities)	Alveolar simplification and enlargement; patchy hyperinflation; interstitial fibrosis, with or without interlobular septal fibrosis	Consider evaluation for pulmonary hypertension and/or aspiration	Consider inhaled corticosteroids, inhaled steroids, diuretics
Nonspecific interstitial pneumonia (NSIP)	Basilar predominant findings of ground-glass opacities (often with subpleural sparing), reticulation, architectural distortion, and traction bronchiectasis	Interstitial lymphocytic inflammation and fibrosis with homogenous distribution		Consider steroids
Hypersensitivity pneumonitis (chronic)	Patchy and often parahilar reticulation, ground-glass opacities, centrilobular nodules; honeycombing (rare)	Airway-centered small noncaseating granulomas, multinucleated giant cells, lymphocytic bronchiolitis and peribronchiolitis, airway fibrosis, organizing pneumonia	Lymphocytosis in bronchoalveolar lavage, precipitins to specific antigen	Remove trigger, intravenous steroids
Autoimmune connective tissue disorders (collagen vascular disease)	See NSIP; honeycombing (rare)	NSIP; lymphoid hyperplasia; fibrosis and cystic change; pleuritis and pleural fibrosis (variable); chronic vasculopathy (variable); airway fibrosis (variable)	Serologic studies	Disease-specific immune modulation
Drug reactions	Peripheral predominant consolidation or ground glass opacities; reverse halo sign; see NSIP; honeycombing (rare)	Variable: organizing pneumonia, NSIP, UIP, DAD, pulmonary hemorrhage, eosinophilic pneumonia		Drug avoidance
Infection	**Acute:** Consolidation and centrilobular (tree in bud) nodules; appearance and distribution vary with type of infection **Chronic:** May progress to IPF/UIP with honeycombing	**Acute:** Neutrophilic alveolitis (bacterial) or lymphocytic bronchiolitis (viral) **Chronic:** Variable airway fibrosis (constrictive/obliterative bronchiolitis) and interstitial fibrosis		Antimicrobials
Immunodeficiency	Bronchiectasis, consolidation, centrilobular nodules	Follicular bronchiolitis or diffuse lymphoid hyperplasia; NSIP; LIP; GLILD	Immunologic and genetic testing	Treat underlying immunodeficiency
Usual interstitial pneumonia (UIP)	Honeycombing, reticulation, traction bronchiectasis, ground-glass opacities (less prominent than NSIP)	Fibroblast foci; interstitial, septal, and pleural fibrosis with heterogenous distribution; minimal to absent inflammation	Genetic testing	

Table 448.22 Genes Associated with Familial* or Idiopathic Pulmonary Fibrosis

GENE	GENE FUNCTION
IL1RN	Inhibitor of proinflammatory effect of IL-1α and IL-1β
IL8	Proinflammatory cytokine
FAM13A	Signal transduction
TLR3	Pathogen recognition and activation of innate immunity
TERT	Enzyme in telomerase complex maintaining telomere length
HLA-DRB1	Major histocompatibility complex—immune system
DSP	Tightly links adjacent cells
OBFC1	Stimulates the activity of DNA polymerase-α-primase
MUC5B	Influence on rheological properties of airway mucus, mucociliary transport, and airway defense
MUC2	Mucin production
TOLLIP	Regulator of innate immune responses mediated by toll-like receptor and the transforming growth factor β signaling pathway
ATP11A	Phospholipid translocation
MDGA2	Cell-cell interaction
MAPT	Promotes microtubule assembly and stability
SPPL2C	Protein cleavage
DPP9	Cell-cell adhesion
TGFB1	Set of peptides that controls proliferation, differentiation, and other functions in many cell types
SFTPC†	Component of surfactant fluid
SFTPA2†	To modulate innate and adaptive immunity
ABCA3†	Transport of lipids across plasma membrane
TERC†	Template in telomerase complex
DKC1†	Stabilization of the template in telomerase complex
TINF2†	Telomere maintenance
RTELI†	DNA helicase
PARN†	mRNA stability

*Also called familial interstitial pneumonia.
†Rarer variant.

remodeling (parenchymal architectural distortion and honeycomb cysts). Interlobular septal fibrosis, pleural fibrosis, and chronic pulmonary arteriopathy are common associated findings. Dense

Fig. 448.14 Chest CT demonstrates typical CT findings in a pediatric patient with nonspecific interstitial pneumonia, including basilar-predominant ground-glass opacities *(blue arrows)*, reticulation *(yellow arrows)*, mild cystic change *(green arrows)*, and bronchiectasis *(orange arrow)*.

globules of pulmonary alveolar proteinosis material in infancy may indicate a genetic disorder of surfactant metabolism. Reactive lymphoid follicles suggest an immunologic process, such as autoimmune disease or immunodeficiency. Organizing pneumonia (polypoid aggregates of fibroblasts, *Masson bodies*) is a common feature in hypersensitivity pneumonitis and autoimmune diseases. The usual interstitial pneumonia pattern signaled by fibroblast foci arising within a background of dense interstitial fibrosis is almost never seen in children. Connective tissue stains, such as Masson trichrome, elastic Verhoff von Giesen, and Movat pentachrome, aid in determining the severity and distribution of collagen deposition.

TREATMENT

Treatment varies based on disease process (see Tables 448.20-448.22). Because of the nature of rare disease, treatment regimens are largely based on expert opinion, as controlled clinical trials are challenging to perform. *Antifibrotic agents approved in adults with fibrotic lung disease include pirfenidone and nintedanib, and weight-based dosing of nintedanib has been shown to have an acceptable safety profile in children.*

Monitoring may include evaluation of pulmonary function (spirometry, lung volumes, and diffusion capacity); functional evaluation of exercise (6-minute walk); and screening for comorbidities such as pulmonary hypertension, aspiration, poor weight gain, and sleep-associated breathing disorders. Respiratory support varies depending on each patient's needs, from no support to oxygen via nasal cannula and with ventilation (noninvasive or invasive); treatments may occur only with exercise and/or sleep or may be all the time. Comorbidities such as pulmonary hypertension or aspiration should be treated appropriately. Genetic counseling and recurrence risk should be provided with genetic forms of fibrotic lung disease. Patients should be counseled about preventing further lung damage from infection (up-to-date on vaccines, including pneumococcus, influenza, SARS-CoV-2, and respiratory syncytial virus) or particulate matter (air pollution, wildfires, wood-burning stoves, and environmental exposure to tobacco or marijuana).

Chapter 449

Community-Acquired Pneumonia

Matthew S. Kelly and Thomas J. Sandora

Pneumonia, defined as inflammation of the lung parenchyma, is the leading infectious cause of death globally among children younger than 5 years, accounting for an estimated 880,000 deaths in 2015 (Fig. 449.1). Pneumonia mortality is closely linked to poverty; more than 99% of child pneumonia deaths are in low- and middle-income countries, with the highest pneumonia mortality rate occurring in Africa and South Asia.

In the United States, mortality from pneumonia in children declined by 97% between 1939 and 1996. This decline can largely be attributed to the development of antibiotics and vaccines and the expansion of medical insurance coverage for children. Effective vaccines against measles (see Chapter 293) and pertussis (see Chapter 243) contributed to the decline in child pneumonia mortality during the 20th century. *Haemophilus influenzae* type b (see Chapter 240) was also an important cause of bacterial pneumonia in young children but became uncommon after licensure of a conjugate vaccine in 1987. The introduction of pneumococcal conjugate vaccines (PCVs) (see Chapter 228) has been an important contributor to the further reductions in pneumonia mortality achieved over the past 2 decades. Epidemics (influenza, severe acute respiratory system coronavirus, Middle East respiratory syndrome, respiratory syncytial virus [RSV]) and pandemics (COVID-19) contribute to the incidence, morbidity, and mortality in pediatric patients with pneumonia. In addition, unexpected global increases in group A streptococcus (GAS) infections have contributed to both morbidity and mortality in children with pneumonia.

ETIOLOGY

Although most cases of pneumonia are caused by microorganisms, noninfectious causes include aspiration (of food or gastric acid, foreign bodies, hydrocarbons, and lipoid substances), hypersensitivity reactions, and drug- or radiation-induced pneumonitis (see Chapter 448). The cause of pneumonia in an individual patient is often difficult to determine because direct sampling of lung tissue is invasive and rarely performed. Bacterial cultures of sputum or upper respiratory tract samples typically do not accurately reflect the cause of lower respiratory tract infection in children. *Streptococcus pneumoniae* (pneumococcus) is the most common bacterial pathogen in children 3 weeks to 5 years of age, whereas *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae* are the most frequent bacterial pathogens in children 5 years and older. In addition to pneumococcus, other bacterial causes of pneumonia in previously healthy children in the United States include GAS (*Streptococcus pyogenes*; see Chapter 229) and *Staphylococcus aureus* (see Chapter 227.1) (Tables 449.1-449.3). *S. pneumoniae* or *S. aureus* pneumonia often complicates an illness caused by influenza viruses.

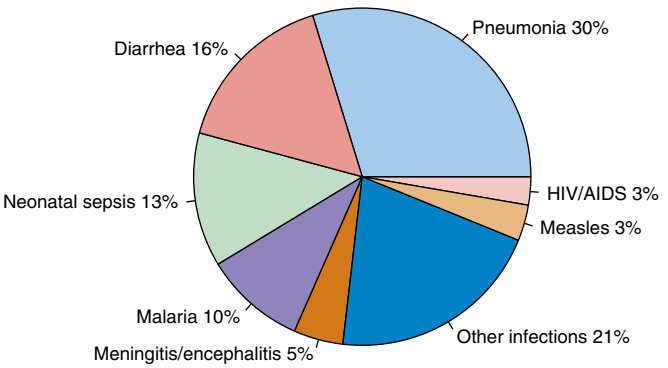

Fig. 449.1 Pneumonia is the leading infectious killer of children worldwide, as shown by this illustration of global distribution of cause-specific infectious mortality among children younger than age 5 yr in 2017. Pneumonia causes nearly one third of all under-5 deaths from infection. *(From World Health Organization Global Health Observatory Data Repository, 2017 estimates.)*

S. pneumoniae, H. influenzae, GAS, and *S. aureus* are the major causes of hospitalization and death from bacterial pneumonia among children in developing countries, although in children with HIV infection, *Mycobacterium tuberculosis* (see Chapter 261), nontuberculous mycobacteria (see Chapter 263), *Salmonella* (see Chapter 244), *Escherichia coli* (see Chapter 246), *Pneumocystis jirovecii* (see Chapter 290), and cytomegalovirus (see Chapter 302) should also be considered. The incidence of pneumonia caused by *H. influenzae* or *S. pneumoniae* has been significantly reduced in areas where routine immunization has been implemented.

Viral pathogens are the most common causes of lower respiratory tract infections in infants and children older than 1 month but younger than 5 years of age (see Table 449.2). Viruses can be detected in 40–80% of children with pneumonia using molecular diagnostic methods (e.g., polymerase chain reaction [PCR]), with more than one respiratory virus identified in up to 20% of cases. Of the respiratory viruses, RSV (see Chapter 307) and rhinoviruses (see Chapter 310) are the most commonly identified pathogens, especially in children younger than 2 years of age. However, the role of rhinoviruses in severe lower respiratory tract infection remains unclear, as these viruses are frequently detected with co-infecting pathogens and among asymptomatic children. Other common viruses causing pneumonia include influenza viruses (see Chapter 305), human metapneumovirus (see Chapter 308), parainfluenza viruses (see Chapter 306), adenoviruses (see Chapter 309), enteroviruses (see Chapter 297), and coronaviruses (see Chapter 311), including severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the cause of coronavirus disease 2019 (COVID-19; see Chapter 449.1).

Lower respiratory tract viral infections are much more common in the fall and winter in both the Northern and Southern Hemispheres in relation to the seasonal epidemics of respiratory viruses that occur each year. The typical pattern of these epidemics usually begins in the fall, when parainfluenza virus infections appear and most often manifest as croup. Later in winter, RSV, human metapneumovirus, and influenza viruses cause widespread infection, including upper respiratory tract infections, bronchiolitis, and pneumonia. RSV is particularly severe among infants and young children, whereas influenza viruses cause disease and excess hospitalization in all age groups. Knowledge of the prevailing viruses circulating in the community may lead to a presumptive initial diagnosis for children with acute respiratory illnesses.

Immunization status is relevant because children fully immunized against *H. influenzae* type b and *S. pneumoniae* are less likely to have pneumonia caused by these pathogens. Children who are immunocompromised or who have certain medical comorbidities may be at risk for specific pathogens, such as *Pseudomonas* spp. in patients with cystic fibrosis (see Chapter 454).

PATHOGENESIS

The lower respiratory tract possesses a number of defense mechanisms against infection, including mucociliary clearance, macrophages and secretory immunoglobulin A, and clearing of the airways by coughing. Previously, it was believed that the lower respiratory tract was—in the absence of infection—kept sterile by these mechanisms, supported primarily by culture-based studies. However, recent use of culture-independent techniques, including high-throughput sequencing methods, suggests that the lower respiratory tract contains diverse microbial communities. These data have challenged the traditional model of pneumonia pathogenesis that maintained that pneumonia was the result of invasion of the sterile lower respiratory tract by a single pathogen. More recent conceptual models postulate that pneumonia results from disruption of a complex lower respiratory ecosystem that is the

Table 449.1 Causes of Infectious Pneumonia

BACTERIAL	
Common	
Streptococcus pneumoniae	Consolidation, empyema
Group B streptococcus	Neonates
Group A streptococcus	Empyema
Staphylococcus aureus	Pneumatoceles, empyema; infants; nosocomial pneumonia
*Mycoplasma pneumoniae**	Adolescents; summer to fall epidemics
*Chlamydophila pneumonie**	Adolescents
Chlamydia trachomatis	Infants
Mixed anaerobes	Aspiration pneumonia
Gram-negative enterics	Nosocomial pneumonia
Uncommon	
Haemophilus influenzae type b	Unimmunized
Moraxella catarrhalis	
Neisseria meningitidis	
Francisella tularensis	Animal, tick, fly contact; bioterrorism
Nocardia species	Immunocompromised patients
*Chlamydophila psittaci**	Bird contact (especially parakeets)
Yersinia pestis (plague)	Rat contact; bioterrorism
Legionella species*	Exposure to contaminated water; nosocomial
*Coxiella burnetii** (Q fever)	Animal (goat, sheep, cattle) exposure
VIRAL	
Common	
Respiratory syncytial virus	Bronchiolitis
Parainfluenza types 1-4	Croup
Influenza A, B	High fever; winter months
Adenovirus	Can be severe; often occurs between January and April
Human metapneumovirus	Similar to respiratory syncytial virus
Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2):COVID-19	Global pandemic
Uncommon	
Rhinovirus	Rhinorrhea
Enterovirus D68, others	Neonates
VIRAL	
Uncommon	
Herpes simplex	Neonates, immunocompromised persons
Cytomegalovirus	Infants; immunocompromised persons (particularly HIV-infected infants)
Measles	Rash, coryza, conjunctivitis
Varicella	Unimmunized; immunocompromised persons
Hantavirus	Southwestern United States, rodents
Coronaviruses (SARS-CoV-1, Middle East respiratory syndrome [MERS])	Asia, Arabian Peninsula
FUNGAL	
Histoplasma capsulatum	Ohio/Mississippi River valley; bird, bat contact
Blastomyces dermatitidis	Ohio/Mississippi River valley, upper Midwest states
Coccidioides immitis	Southwestern United States, Great Lakes states
Cryptococcus neoformans and *C. gattii*	Bird contact; immunocompromised; Northwestern United States (*C. gattii*)
Aspergillus species	Immunocompromised persons; nodular lung infection
Mucormycosis	Immunocompromised persons
Pneumocystis jirovecii	Immunocompromised persons (particularly HIV-infected infants); steroids
RICKETTSIAL	
Rickettsia rickettsiae	Tick bite
MYCOBACTERIAL	
Mycobacterium tuberculosis	Travel to endemic region; exposure to high-risk persons
Mycobacterium avium complex	Immunocompromised (particularly HIV-infected) persons
Other nontuberculous mycobacteria	Immunocompromised persons; cystic fibrosis
PARASITIC	
Various parasites (e.g., *Ascaris*, *Strongyloides* species)	Eosinophilic pneumonia

*Atypical pneumonia syndrome; may have extrapulmonary manifestations, low-grade fever, patchy diffuse infiltrates, and poor response to β-lactam antibiotics.
Adapted from Kliegman RM, Greenbaum LA, Lye PS, eds. *Practical Strategies in Pediatric Diagnosis and Therapy,* 2nd ed. Philadelphia: Elsevier; 2004: p. 29.

Table 449.2 Pneumonia Etiologies Grouped by Age of the Patient

AGE GROUP	FREQUENT PATHOGENS (IN ORDER OF FREQUENCY)
Neonates (<3 wk)	Group B streptococcus, *Escherichia coli,* other gram-negative bacilli, *Streptococcus pneumoniae, Haemophilus influenzae* (type b,* nontypeable)
3 wk-3 mo	Respiratory syncytial virus, other respiratory viruses (rhinoviruses, parainfluenza viruses, influenza viruses, human metapneumovirus, adenovirus), enterovirus D68, *S. pneumoniae, H. influenzae* (type b,* nontypeable); if patient is afebrile, consider *Chlamydia trachomatis*
4 mo-4 yr	Respiratory syncytial virus, other respiratory viruses (rhinoviruses, parainfluenza viruses, influenza viruses, human metapneumovirus, adenovirus), enterovirus D68, *S. pneumoniae, H. influenzae* (type b,* nontypeable), *Mycoplasma pneumoniae,* group A streptococcus
≥5 yr	*M. pneumoniae, S. pneumoniae, Chlamydophila pneumoniae, H. influenzae* (type b,* nontypeable), influenza viruses, adenovirus, COVID-19, other respiratory viruses, *Legionella pneumophila*

**H. influenzae* type b is uncommon with routine immunization.
Adapted from Kliegman RM, Marcdante KJ, Jenson HJ, et al., eds. *Nelson Essentials of Pediatrics,* 5th ed. Philadelphia: Elsevier; 2006: p. 507.

site of dynamic interactions between potential pneumonia pathogens, resident microbial communities, and host immune defenses.

Viral pneumonia usually results from spread of infection along the airways, accompanied by direct injury of the respiratory epithelium, which results in airway obstruction from swelling, abnormal secretions, and cellular debris. The small caliber of airways in young infants makes such patients particularly susceptible to severe infection. Atelectasis, interstitial edema, and hypoxemia from ventilation-perfusion

Table 449.3 Pneumonia: Etiology Suggested by Exposure History

EXPOSURE HISTORY	INFECTIOUS AGENT
Exposure to concurrent illness in school dormitory or household setting	*Neisseria meningitidis, Mycoplasma pneumoniae*
Exposure to persons with known or suspected COVID-19	SARS-CoV-2
ENVIRONMENTAL EXPOSURES	
Exposure to contaminated aerosols (e.g., air coolers, hospital water supply)	Legionnaires' disease
Exposure to goat hair, raw wool, animal hides	Anthrax
Ingestion of unpasteurized milk	Brucellosis
Exposure to bat droppings (caving) or dust from soil enriched with bird droppings	Histoplasmosis
Exposure to water contaminated with animal urine	Leptospirosis
Exposure to rodent droppings, urine, saliva	Hantavirus
Potential bioterrorism exposure	Anthrax, plague, tularemia
ZOONOTIC EXPOSURES	
Employment as abattoir work or veterinarian	Brucellosis
Exposure to cattle, goats, pigs	Anthrax, brucellosis
Exposure to ground squirrels, chipmunks, rabbits, prairie dogs, rats in Africa or southwestern United States	Plague
Hunting or exposure to rabbits, foxes, squirrels	Tularemia
Bites from flies or ticks	Tularemia
Exposure to birds (parrots, budgerigars, cockatoos, pigeons, turkeys)	Psittacosis
Exposure to infected dogs and cats	*Pasteurella multocida*, Q fever *(Coxiella burnetii)*
Exposure to infected goats, cattle, sheep, domestic animals, and their secretions (milk, amniotic fluid, placenta, feces)	Q fever *(C. burnetii)*
TRAVEL EXPOSURES	
Residence in or travel to San Joaquin Valley, southern California, southwestern Texas, southern Arizona, New Mexico	Coccidioidomycosis
Residence in or travel to Mississippi or Ohio river valleys, Great Lakes States, Caribbean, Central America, or Africa	Histoplasmosis, blastomycosis
Residence in or travel to southern China	Avian influenza
Residence in or travel to Arabian Peninsula	MERS-CoV
Residence in or travel to Southeast Asia	Paragonimiasis, melioidosis
Residence in or travel to West Indies, Australia, or Guam	Melioidosis

MERS-CoV, Middle East respiratory syndrome coronavirus; COVID-19, coronavirus disease 2019; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2.
From Ellison RT III, Donowitz GR. Acute pneumonia. In: Bennett JE, Blaser MJ, Dolin R, et al., eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, 8th ed. Philadelphia: Saunders; 2015: Table 69.3, p. 828.

mismatch often accompany airway obstruction. Viral infection of the respiratory tract can also predispose to secondary bacterial infection by disturbing normal host defense mechanisms, altering secretions, and disrupting the microbial communities that reside in the respiratory tract.

Bacterial pneumonia most often occurs when respiratory tract organisms colonize the upper respiratory tract and subsequently gain access to the lungs, but pneumonia may also result from direct seeding of lung tissue in the setting of bacteremia. When bacterial infection is established in the lung parenchyma, the pathologic process varies according to the invading organism. *M. pneumoniae* (see Chapter 269) attaches to the respiratory epithelium, inhibits ciliary action, and leads to cellular destruction and an inflammatory response in the submucosa. When the infection progresses, sloughed cellular debris, inflammatory cells, and mucus cause airway obstruction, with spread of infection occurring along the bronchial tree, as is seen in viral pneumonia. *S. pneumoniae* produces local edema that aids in the proliferation of organisms and their spread into adjacent portions of the lung, often resulting in the characteristic lobar consolidation. Lower respiratory tract infection caused by GAS typically results in more diffuse lung involvement with interstitial pneumonia. The pathology includes necrosis of tracheobronchial mucosa; formation of large amounts of exudate, edema, and local hemorrhage, with extension into the interalveolar septa; and involvement of lymphatic vessels with frequent pleural involvement. *S. aureus* pneumonia manifests as confluent bronchopneumonia, which is often bilateral and characterized by the presence of extensive areas of hemorrhagic necrosis and irregular areas of cavitation of the lung parenchyma, resulting in pneumatoceles, empyema, and, at times, bronchopulmonary fistulas.

Recurrent pneumonia is defined *as two or more* episodes in a single year *or three or more* episodes ever, with radiographic clearing between occurrences. An underlying disorder should be considered if a child experiences recurrent pneumonia (Table 449.4).

CLINICAL MANIFESTATIONS

Pneumonia is frequently preceded by several days of symptoms of an upper respiratory tract infection, typically rhinitis and cough. In viral pneumonia, fever is usually present but temperatures are generally lower than in bacterial pneumonia. Tachypnea is the most consistent clinical manifestation of pneumonia. Increased work of breathing manifested by intercostal, subcostal, and suprasternal retractions; nasal flaring; and use of accessory muscles is also common. Severe infection may be accompanied by cyanosis and lethargy, especially in infants. Auscultation of the chest may reveal crackles and wheezing, but it is often difficult to localize the source of these adventitious sounds in young children with hyperresonant chests. It is often not possible to distinguish viral pneumonia clinically from disease caused by *Mycoplasma* and other bacterial pathogens.

Bacterial pneumonia in adults and older children typically begins suddenly with high fever, cough, and chest pain. Other symptoms that may be seen include drowsiness with intermittent periods of restlessness; rapid respirations; anxiety; and, occasionally, delirium. In many children, splinting on the affected side to minimize pleuritic pain and improve ventilation is noted; such children may lie on one side with the knees drawn up to the chest. Lower lobe pneumonia may cause abdominal pain (but no tenderness), or the pain may be referred to the ipsilateral shoulder.

Physical findings depend on the stage of pneumonia. Early in the course of illness, diminished breath sounds, scattered crackles, and rhonchi are commonly heard over the affected lung field. With the development of increasing consolidation or complications of pneumonia such as pleural effusion or empyema, dullness on percussion is noted and breath sounds may be diminished. A lag in respiratory excursion often occurs on the affected side. Abdominal distention may be prominent because of gastric dilation from swallowed air or ileus. The liver may seem enlarged because of downward displacement of the diaphragm secondary to hyperinflation of the lungs or superimposed congestive heart failure.

Table 449.4 Differential Diagnosis of Recurrent Pneumonia

HEREDITARY DISORDERS

Symptoms described in adults with pneumococcal pneumonia may be noted in older children but are rarely observed in infants and young children, in whom the clinical pattern is considerably more variable. In infants, there may be a prodrome of upper respiratory tract infection and poor feeding, leading to the abrupt onset of fever, restlessness, apprehension, and respiratory distress. These infants typically appear ill, with respiratory distress manifested as grunting; nasal flaring; retractions of the supraclavicular, intercostal, and subcostal areas; tachypnea; tachycardia; air hunger; and often cyanosis. Auscultation may be misleading, particularly in young infants, with meager findings disproportionate to the degree of tachypnea. Some infants with bacterial pneumonia may have associated gastrointestinal disturbances characterized by vomiting, anorexia, diarrhea, and abdominal distention secondary to a paralytic ileus. Rapid progression of symptoms is characteristic in the most severe cases of bacterial pneumonia. Cyanosis often predicts multilobular involvement. Risk factors for severe pneumonia include temperature >38.5°C, tachypnea, retractions, nasal flaring, grunting, capillary refill >2 seconds, cyanosis, tachycardia, and poor feeding.

DIAGNOSIS

In 2011, the Pediatric Infectious Diseases Society (PIDS) and the Infectious Diseases Society of America (IDSA) published clinical practice guidelines for community-acquired pneumonia in children older than 3 months of age. These evidence-based guidelines provide recommendations for diagnostic testing and treatment of previously healthy children with pneumonia in both outpatient and inpatient settings. With the advent of advanced technologies and changing epidemiologic pathogens, these guidelines have required modifications.

An infiltrate on chest radiograph (posteroanterior and lateral views) supports the diagnosis of pneumonia; images may also identify a complication such as a pleural effusion or empyema. Viral pneumonia is usually characterized by hyperinflation with bilateral interstitial infiltrates and peribronchial cuffing (Fig. 449.2). Confluent lobar consolidation is typically seen with pneumococcal pneumonia (Fig. 449.3). The radiographic appearance alone does not accurately identify

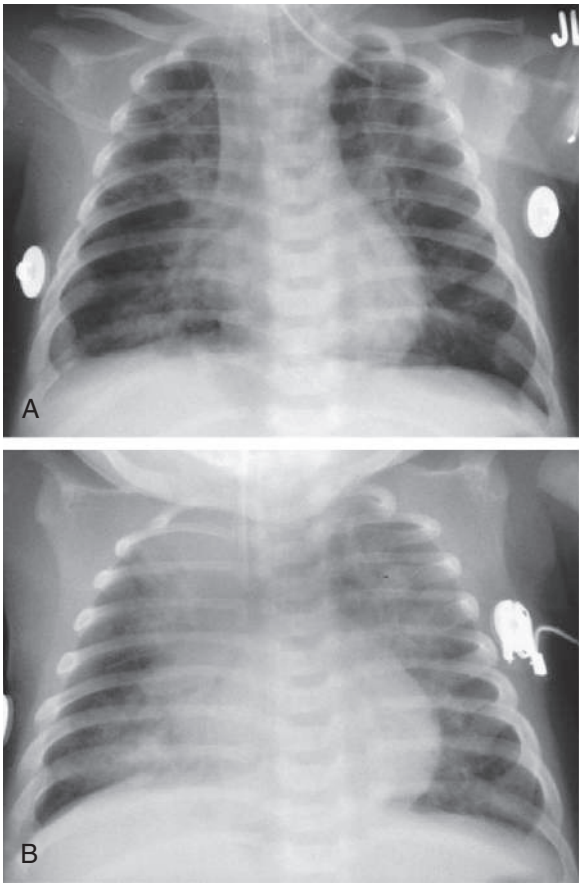

Fig. 449.2 A, Radiographic findings characteristic of respiratory syncytial virus pneumonia in a 6-mo-old infant with rapid respirations and fever. Anteroposterior radiograph of the chest shows hyperexpansion of the lungs with bilateral fine air space disease and streaks of density, indicating the presence of both pneumonia and atelectasis. An endotracheal tube is in place. B, One day later, the anteroposterior radiograph of the chest shows increased bilateral pneumonia.

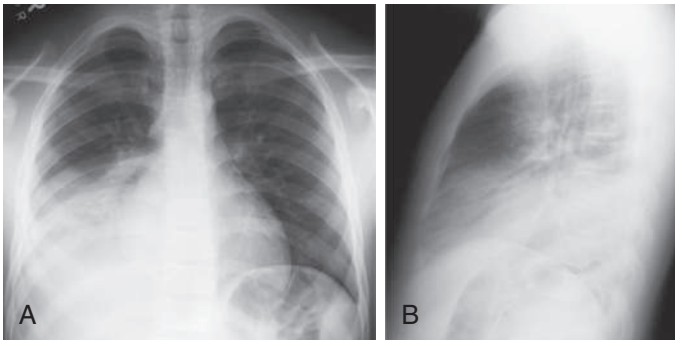

Fig. 449.3 Radiographic findings characteristic of pneumococcal pneumonia in a 14-yr-old male with cough and fever. Posteroanterior (A) and lateral (B) chest radiographs reveal consolidation in the right lower lobe, strongly suggesting bacterial pneumonia.

pneumonia etiology, and other clinical features of the illness must be considered. Repeat chest radiographs are not required for proof of cure for patients with uncomplicated pneumonia. Moreover, current PIDS-IDSA guidelines do not recommend that a chest radiograph be performed for children with suspected pneumonia (tachypnea, cough, fever, localized crackles, or decreased breath sounds) who are well enough to be managed as outpatients because imaging in this context only rarely changes management.

Point-of-care use of portable or handheld ultrasonography is highly sensitive and specific in diagnosing pneumonia in children by

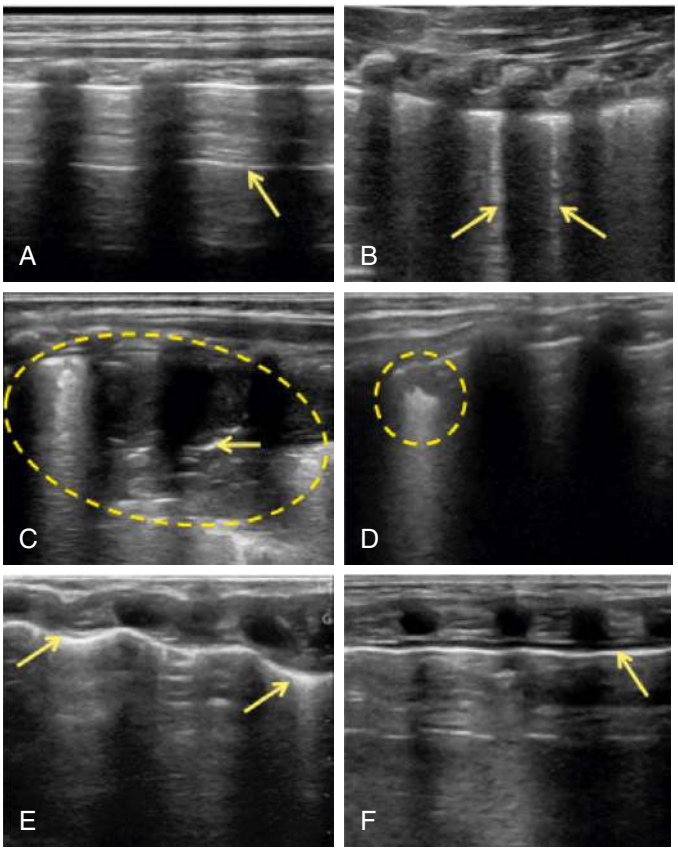

Fig. 449.4 Lung ultrasound patterns. **A,** Negative lung ultrasound pattern with A-line *(arrow)* and no other findings. Positive lung ultrasound patterns with **(B)** B-lines *(arrows)*; **(C)** large consolidation (>1 cm) with tissue-like echo-texture *(circle)* and ultrasonographic bronchograms *(arrow)*; **(D)** small consolidation (<1 cm; *circle*); **(E)** pleural line abnormality with thickening and irregularity *(arrows)*; and **(F)** pleural effusion *(arrow). (From Varshney T, Mok E, Shapiro AJ, et al. Point-of-care lung ultrasound in young children with respiratory tract infections and wheeze. Emerg Med J. 2016;33:603–610, Fig. 1.)*

determining lung consolidations and air bronchograms or effusions (Fig. 449.4). However, the reliability of this imaging modality for pneumonia diagnosis is highly user-dependent, which has limited its widespread use.

The peripheral white blood cell (WBC) count can be useful in differentiating viral from bacterial pneumonia. In viral pneumonia, the WBC count can be normal or elevated but is usually not higher than 20,000/mm^3, with a lymphocyte predominance. Bacterial pneumonia is often associated with an elevated WBC count, in the range of 15,000-40,000/mm^3, and a predominance of polymorphonuclear leukocytes. A large pleural effusion, lobar consolidation, and a high fever at the onset of the illness are also suggestive of a bacterial etiology. Atypical pneumonia caused by *C. pneumoniae* or *M. pneumoniae* is difficult to distinguish from pneumococcal pneumonia on the basis of radiographic and laboratory findings; although pneumococcal pneumonia is associated with a higher WBC count, erythrocyte sedimentation rate, procalcitonin, and C-reactive protein level, there is considerable overlap.

The definitive diagnosis of a viral infection rests on the detection of the viral genome or antigen in respiratory tract secretions. Reliable PCR assays are widely available for the rapid detection of many respiratory viruses, including RSV, parainfluenza, influenza, human metapneumovirus, adenovirus, enterovirus, rhinovirus, and SARS-CoV-2. Serologic techniques can also be used to diagnose a recent respiratory viral infection but generally require testing of acute and convalescent serum samples for a rise in antibodies to a specific virus. This diagnostic technique is laborious, slow, and not generally clinically useful because the infection usually has resolved by the time it is confirmed serologically. Serologic testing may be valuable as an epidemiologic tool to define the incidence and prevalence of various respiratory viral pathogens.

Table 449.5 Factors Suggesting Need for Hospitalization of Children with Pneumonia

Age <6 mo
Immunocompromised state
Toxic appearance
Moderate to severe respiratory distress (retractions, nasal flaring, grunting)
Cyanosis/hypoxemia (oxygen saturation <90% breathing room air, sea level)
Shock (tachycardia, hypotension, prolonged capillary refill time)
Complicated pneumonia*
Sickle cell anemia with acute chest syndrome
Vomiting or inability to tolerate oral fluids or medications
Severe dehydration
No response to appropriate oral antibiotic therapy
Social factors (e.g., inability of caregivers to administer medications at home or follow up appropriately)
High-risk pathogen

*Pleural effusion, empyema, abscess, bronchopleural fistula, necrotizing pneumonia, acute respiratory distress syndrome, extrapulmonary infection (meningitis, arthritis, pericarditis, osteomyelitis, endocarditis), hemolytic uremic syndrome, or sepsis.
Adapted from Baltimore RS. Pneumonia. In: Jenson HB, Baltimore RS, eds. *Pediatric Infectious Diseases: Principles and Practice.* Philadelphia: WB Saunders; 2002: p. 801.

The definitive diagnosis of a typical bacterial infection requires isolation of an organism from the blood, pleural fluid, or lung. Culture of sputum is of little value in the diagnosis of pneumonia in young children, and percutaneous lung aspiration is invasive and not routinely performed. Blood culture is positive in only 10% of children with pneumococcal pneumonia (bacteremia is more common in GAS and *H. influenzae* pneumonias) and is not recommended for nontoxic-appearing children treated as outpatients. Blood cultures are recommended for children who fail to improve or have clinical deterioration, have complicated pneumonia (Table 449.5), or require hospitalization. Pertussis infection can be diagnosed by PCR or culture of a nasopharyngeal specimen; although culture is considered the gold standard for pertussis diagnosis, it is less sensitive than the available PCR assays. Acute infection caused by *M. pneumoniae* can be diagnosed on the basis of a PCR test result from a respiratory specimen or seroconversion in an immunoglobulin G assay. Cold agglutinins at titers >1:64 are also found in the blood of roughly half of patients with *M. pneumoniae* infections; however, cold agglutinins are nonspecific because other pathogens such as influenza viruses may also cause increases. Serologic evidence, such as antistreptolysin O and anti-DNase B titers, may also be useful in the diagnosis of GAS pneumonia.

Noninvasive diagnostic tests *may* help differentiate children with bacterial versus viral causes of pneumonia. Various biomarkers, including C-reactive protein, procalcitonin, and ESR, have been evaluated for their ability to differentiate these pneumonia etiologies. For many of these biomarkers, values differ in children with bacterial compared with viral causes of pneumonia (except adenovirus and influenza), but the reliability of these tests is not sufficiently high to justify routine clinical use. Cell-free next-generation sequencing of plasma or blood has been helpful in identifying pathogens in patients suspected of having bacterial pneumonia; identified pathogens include *S. pneumoniae, S. aureus,* and *Fusobacterium nucleatum* (blood cultures were negative in most of these patients). In addition, culture and PCR analysis of pleural fluid may also yield an organism.

TREATMENT

Treatment of suspected bacterial pneumonia is based on the presumptive cause and the age and clinical appearance of the child. For mildly ill children who do not require hospitalization, amoxicillin is recommended. With the emergence of penicillin-resistant pneumococci, high doses of amoxicillin (90 mg/kg/day orally divided twice daily) should be prescribed unless local data indicate a low prevalence of resistance.

Therapeutic alternatives include cefuroxime and amoxicillin/clavulanate. For school-age children and adolescents or when infection with *M. pneumoniae* or *C. pneumoniae* is suspected, a macrolide antibiotic is an appropriate choice for outpatient management. Azithromycin is generally preferred, but clarithromycin or doxycycline (for children 8 years or older) are alternatives. For adolescents, a respiratory fluoroquinolone (levofloxacin, moxifloxacin) may also be considered as an alternative if there are contraindications to other agents.

The empiric treatment of suspected bacterial pneumonia in a hospitalized child requires an approach based on local epidemiology, the immunization status of the child, and the clinical manifestations at the time of presentation. In areas without substantial high-level penicillin resistance among *S. pneumoniae,* children who are fully immunized against *H. influenzae* type b and *S. pneumoniae* and are not severely ill should receive ampicillin or penicillin G. For children who do not meet these criteria, ceftriaxone or cefotaxime may be used. If infection with *M. pneumoniae* or *C. pneumoniae* is suspected, a macrolide antibiotic should be included in the treatment regimen. If clinical features suggest staphylococcal pneumonia (pneumatoceles, empyema), initial antimicrobial therapy should also include vancomycin or clindamycin. For children with respiratory failure in the setting of influenza–methicillin-resistant *S. aureus* (MRSA) co-infection, data from a multicenter study support combination therapy with vancomycin and a second antibiotic with MRSA activity (e.g., clindamycin).

If viral pneumonia is suspected, it is reasonable to withhold antibiotic therapy, especially for preschool-age patients who are mildly ill, have clinical evidence suggesting viral infection, and are in no respiratory distress. However, up to 30% of patients with known viral infection, particularly influenza viruses, may have coexisting bacterial pathogens. Therefore if the decision is made to withhold antibiotic therapy on the basis of presumptive diagnosis of a viral infection, deterioration in clinical status should signal the possibility of superimposed bacterial infection, and antibiotic therapy should be initiated.

Table 449.5 notes the indications for admission to a hospital. Hospitalized children should receive supportive care and may require intravenous fluids; respiratory support, including supplemental oxygen, continuous positive airway pressure (CPAP), or mechanical ventilation; or vasoactive medications for hypotension or sepsis physiology.

The optimal duration of antibiotic treatment for pneumonia has not been well-established in controlled studies. However, antibiotics should generally be continued until the patient has been afebrile for 72 hours. Several studies suggest that shorter courses (5-7 days) may also be effective, particularly for children managed on an outpatient basis. Available data do not support prolonged courses of treatment for uncomplicated pneumonia. Some studies suggest that a reduction of previously elevated serum procalcitonin levels to an absolute level (0.1-0.25 μg/L) may help determine when to stop treatment.

Despite substantial gains over the past 15 years, less than two thirds of children with symptoms of pneumonia are taken to an appropriate caregiver in low- and middle-income countries, and fewer than half receive antibiotics. The World Health Organization and other international groups have developed systems to train mothers and local healthcare providers in the recognition and appropriate antibiotic treatment of pneumonia. In addition to antibiotics, oral zinc (10 mg/day for <12 months, 20 mg/day for ≥12 months given for 7 days) may reduce mortality among children in low- and middle-income countries with clinically defined severe pneumonia. Bubble CPAP improves mortality from pneumonia with hypoxemia compared with standard oxygen therapy in settings without access to ventilator-derived CPAP or mechanical ventilation.

PROGNOSIS

Typically, patients with uncomplicated community-acquired bacterial pneumonia show response to therapy, with improvement in clinical symptoms (fever, cough, tachypnea, chest pain), within 48-72 hours of initiation of antibiotics. Radiographic evidence of improvement lags substantially behind clinical improvement. A number of possibilities must be considered when a patient does not improve with appropriate antibiotic therapy: (1) complications, such as pleural effusion or empyema (see Table 449.5); (2) bacterial resistance; (3) nonbacterial etiologies such as viruses or fungi and aspiration of foreign bodies or food; (4) bronchial obstruction from endobronchial lesions, foreign body, or mucous plugs; (5) preexisting diseases such as immunodeficiencies, ciliary dyskinesia, cystic fibrosis, pulmonary sequestration, or congenital pulmonary airway malformation; and (6) other noninfectious causes (including bronchiolitis obliterans, hypersensitivity pneumonitis, eosinophilic pneumonia, and granulomatosis with polyangiitis, formerly called *Wegener granulomatosis*). A chest radiograph is the first step in determining the reason for a lack of response to initial treatment. Bronchoalveolar lavage may be indicated in children with respiratory failure. High-resolution CT scans may better identify complications or an anatomic reason for a poor response to therapy.

Mortality from community-acquired pneumonia in developed countries is rare, and most children with pneumonia do not experience long-term pulmonary sequelae. Some data suggest that up to 45% of children have symptoms of asthma 5 years after hospitalization for pneumonia; this finding may reflect either undiagnosed asthma at the time of presentation or a propensity for development of asthma after pneumonia.

COMPLICATIONS

Complications of pneumonia (see Table 449.5) are usually the result of direct spread of bacterial infection within the thoracic cavity (pleural effusion, empyema, and pericarditis) or bacteremia and hematologic spread (Figs. 449.5-449.7). Meningitis, endocarditis, suppurative arthritis, and osteomyelitis are rare complications of hematologic spread of pneumococcal or *H. influenzae* type b infection.

S. aureus, S. pneumoniae, and *S. pyogenes* (GAS) are the most common causes of parapneumonic effusions and empyema. Nonetheless many effusions that complicate bacterial pneumonia are sterile. Analysis of pleural fluid parameters, including pH, glucose, protein, and lactate dehydrogenase, can differentiate transudative from exudative effusions (Table 449.6). However, current PIDS-IDSA guidelines do not recommend that these tests be performed because this distinction rarely changes management. Pleural fluid should be sent for Gram stain and bacterial culture, as this may identify the bacterial cause of pneumonia. Molecular methods, including bacterial species–specific PCR

Fig. 449.5 Chest radiograph of large right-sided pleural effusion complicating community-acquired pneumonia. *(From de Benedictis FM, Kerem E, Chang AB, et al. Complicated pneumonia in children. Lancet. 2010;396:786–798, Fig. 1, p. 789.)*

assays, detect pathogens and can often determine the bacterial etiology of the effusion if the culture is negative, particularly if the pleural fluid sample was obtained after initiation of antibiotics. A pleural fluid WBC count with differential may be helpful if there is suspicion for pulmonary tuberculosis or a noninfectious etiology for the pleural effusion, such as malignancy.

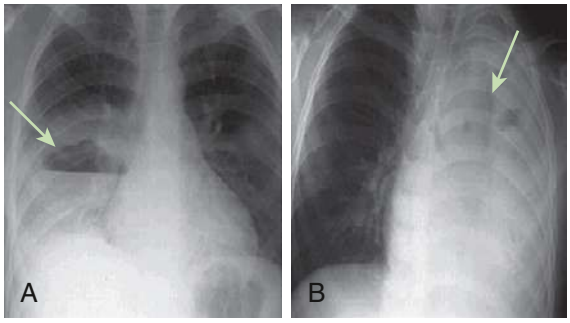

Fig. 449.6 Chest radiographs of lung abscess and necrotizing pneumonia. **A,** Lung abscess. A single thick walled, irregular cavity containing an air-fluid level can be seen *(arrow)*. **B,** Necrotizing pneumonia. A completely opacified left hemithorax with multiple necrotic areas can be seen *(arrow)*. *(From de Benedictis FM, Kerem E, Chang AB, et al. Complicated pneumonia in children. Lancet. 2010;396:786–798, Fig. 2, p. 789.)*

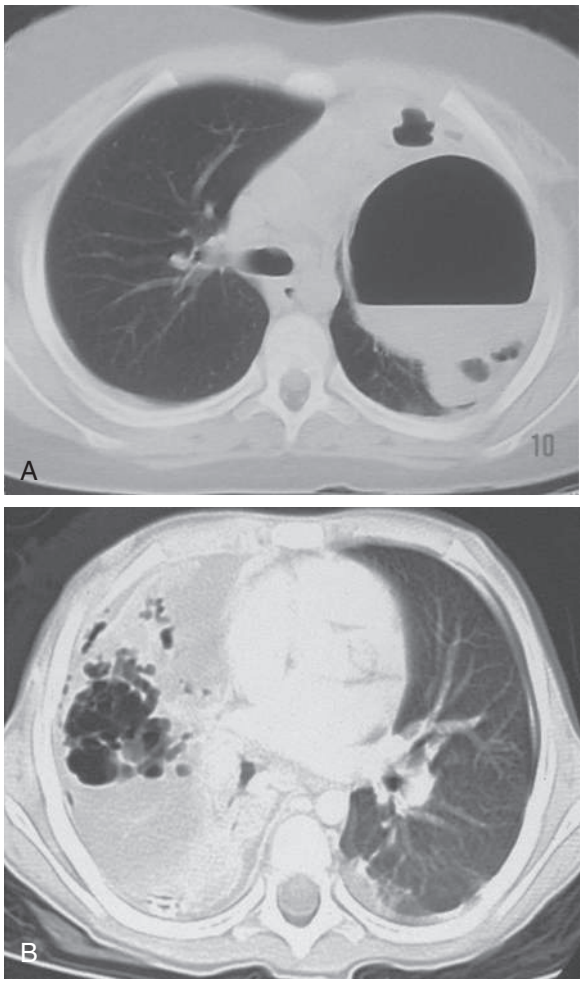

Fig. 449.7 Chest CT in complicated community-acquired pneumonia. **A,** Lung abscess. A large cavity containing an air-fluid level can be seen. **B,** Necrotizing pneumonia with cavitation. *(From de Benedictis FM, Kerem E, Chang AB, et al. Complicated pneumonia in children. Lancet. 2010;396:786–798, Fig. 4, p. 790.)*

Small (<1 cm on lateral decubitus radiograph), free-flowing parapneumonic effusions often do not require drainage but respond to appropriate antibiotic therapy. Larger effusions should typically be drained, particularly if the effusion is purulent or associated with respiratory distress. Chest ultrasound, or alternatively CT, may be helpful in determining whether loculations are present. The mainstays of therapy include antibiotic therapy and drainage by tube thoracostomy with the instillation of fibrinolytic agents (tissue plasminogen activator). Video-assisted thoracoscopy is a less often employed alternative that enables debridement or lysis of adhesions and drainage of loculated areas of pus. Early diagnosis and intervention, particularly with fibrinolysis or, less often, video-assisted thoracoscopy, may obviate the need for thoracotomy and open debridement.

PREVENTION

The introduction of PCVs resulted in a substantial reduction in the incidence of pneumonia hospitalizations among children. The annual rate of all-cause pneumonia hospitalization among children younger than 2 years of age in the United States was 12.5 per 1,000 children during the period from 1997 to 1999. In 2000, seven-valent pneumococcal conjugate vaccine (PCV7) was licensed and recommended. In 2006, the pneumonia hospitalization rate in this age-group was 8.1 per 1,000 children, a 35% decrease from the prevaccine rate. In 2010, 13-valent pneumococcal conjugate vaccine (PCV13) was licensed in the United States; data indicate that introduction of this vaccine resulted in a 16–27% further reduction in pneumonia hospitalizations among children relative to the post-PCV7 era.

Influenza vaccine may also prevent pneumonia hospitalizations among children and should be administered to all children >6 months of age. For infants <6 months of age, household contacts and other primary caregivers should receive the influenza vaccine. Maintaining high rates of vaccination for *H. influenzae* type b, pertussis, and measles remains important for the prevention of pneumonia from these causes. Several RSV vaccines are currently under development; introduction of an effective vaccine against RSV would be anticipated to substantially reduce pneumonia incidence among children, particularly young infants. Several vaccines that are highly effective in preventing COVID-19 have received Emergency Use Authorization by the U.S. Food and Drug Administration for use in children 6 months of age or older (see Chapter 449.1); such vaccines are often updated to cover emergence of new variants.

449.1 COVID-19

Matthew S. Kelly and Thomas J. Sandora

See also Chapter 311.

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the etiologic agent of coronavirus disease 2019 (COVID-19), has created a global pandemic. As of July 2023, SARS-CoV-2 caused more than 767 million cases and 6.9 million deaths worldwide. SARS-CoV-2 is spread primarily through person-to-person respiratory transmission; viral particles in respiratory secretions that are released when an infected individual coughs, sneezes, or talks can infect another person when inhaled or through contact with mucous membranes. Direct person-to-person contact and fomites are believed to play minor roles in SARS-CoV-2 transmission. The incubation period for the virus can be up to 14 days after exposure, with most cases occurring within 4-5 days. Public health measures such as face masks, physical distancing, stay-at-home orders, and restrictions on public gatherings are highly effective in interrupting SARS-CoV-2 transmission (see Chapter 214). Several vaccines have been developed that are effective in preventing SARS-CoV-2 infection and severe COVID-19. SARS-CoV-2 has undergone substantial genetic evolution since it was first identified; several viral variants have emerged that are associated with different clinical symptoms along with increased transmissibility and reduced vaccine effectiveness.

Table 449.6 Features Differentiating Exudative from Transudative Pleural Effusion

FEATURE	TRANSUDATE	EXUDATE
Appearance	Serous	Cloudy
Leukocyte count	<10,000/mm^3	>50,000/mm^3
pH	>7.2	<7.2
Protein	<3.0 g/dL	>3.0 g/dL
Ratio of pleural fluid protein to serum	<0.5	>0.5
LDH	<200 IU/L	>200 IU/L
Ratio of pleural fluid LDH to serum	<0.6	>0.6
Glucose	≥60 mg/dL	<60 mg/dL

LDH, Lactate dehydrogenase.
From Septimus EJ. Pleural effusion and empyema. In: Bennett JE, Blaser MJ, Dolin R, et al. eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, 8th ed. Philadelphia: Saunders; 2015: Table 70-1, p. 851.

Some data suggest that children and adolescents may be less susceptible to SARS-CoV-2 infection than adults. In a meta-analysis that included data from 18 contact-tracing studies, children and adolescents less than 20 years of age had a 44% lower odds of being an infected contact compared to adults 20 years of age or older. However, widespread transmission of SARS-CoV-2 has occurred among children in schools and other congregate childcare settings, typically when face masks and other mitigation measures have not been in place.

CLINICAL MANIFESTATIONS

In children, COVID-19 is generally a mild illness, characterized most frequently by low-grade fever (30–50%) and cough (30–50%). Other commonly reported symptoms include nasal congestion or rhinorrhea, myalgias, and pharyngitis. Older children and adolescents often report headache, loss of smell (anosmia), or loss of taste (dysgeusia). Gastrointestinal symptoms such as abdominal pain, diarrhea, and vomiting occur less frequently but may be the presenting complaints in some children. Skin findings occur infrequently with SARS-CoV-2 infection, although maculopapular rash, urticarial lesions, and reddish-purple nodules on the toes (sometimes referred to as "COVID toes") have been described. Tachypnea and signs of increased work of breathing should raise suspicion for pneumonia, the most common serious clinical manifestation of COVID-19. Severe neurologic symptoms such as seizures and encephalopathy have been reported among children hospitalized for severe COVID-19. *There are no signs or symptoms that can reliably distinguish COVID-19 from other illnesses caused by respiratory viruses or bacteria.* Up to 20–30% of children and adolescents with COVID-19 have asymptomatic infections; these individuals can still effectively transmit the virus to others.

Children and adolescents with SARS-CoV-2 infection are at a lower risk of severe COVID-19 than adults. Despite accounting for 10–20% of SARS-CoV-2 infections in the United States as of August 2021, children and adolescents represented less than 3% of hospitalizations and less than 0.5% of deaths from COVID-19. Children with underlying medical conditions are at higher risk of developing severe COVID-19. Data on risks associated with specific conditions in children are currently lacking, but the Centers for Disease Control and Prevention suggests that children with obesity, medical complexity, neurodevelopmental disorders, congenital heart disease, asthma or chronic lung disease, diabetes, or sickle cell disease may be at higher risk of progression to severe illness (Table 449.7). Children are also at higher risk of **multisystem inflammatory syndrome in children** (MIS-C; see Chapter 207), a postinfectious inflammatory condition that typically occurs in the 4-6 weeks after SARS-CoV-2 infection.

DIAGNOSIS

The IDSA recommends that children who have symptoms compatible with COVID-19, or asymptomatic individuals with known or suspected exposure to an individual diagnosed with COVID-19, be tested for SARS-CoV-2 using a nucleic acid amplification test (NAAT). In symptomatic individuals with a low clinical suspicion of COVID-19, a single NAAT test is considered sufficient, and testing should not be repeated if the result is negative. If the clinical suspicion for COVID-19 is considered intermediate or high but the initial test is negative, a repeat test should be performed 24-48 hours after initial testing. When available, standard laboratory-based NAATs or rapid reverse transcriptase (RT)-PCR tests are recommended over rapid isothermal NAATs because of higher sensitivity (98% for both standard laboratory-based NAATs and rapid RT-PCR vs 81% for rapid isothermal NAATs), despite comparable specificity. Rapid antigen tests are widely available and have high specificity but low to modest sensitivity compared with NAAT. Antigen test sensitivity is highly dependent on viral load, and therefore is influenced by the presence of symptoms and the timing of the test. For these reasons, IDSA does not recommend antigen tests as the preferred testing strategy, but rather maintains that antigen testing can identify some individuals infected with SARS-CoV-2 when molecular testing is not available.

A variety of specimen types can be tested for the presence of SARS-CoV-2, including nasopharyngeal (NP) swab, NP wash/aspirate, nasal wash/aspirate, oropharyngeal (OP) swab, nasal mid-turbinate (MT) swab, anterior nares (AN) swab, or saliva. Assay performance is highly dependent on collection procedure. IDSA recommends collecting an NP swab, MT swab, AN swab, saliva, or a combined AN/OP swab rather than an OP swab alone for symptomatic individuals suspected of having COVID-19. For hospitalized patients with suspected pneumonia and clinical suspicion for COVID-19, IDSA suggests a strategy of initially obtaining an upper respiratory specimen (e.g., NP swab) rather than a lower respiratory sample. However, if the initial specimen is negative and suspicion for disease remains high, a lower respiratory specimen (e.g., sputum, bronchoalveolar lavage fluid, or tracheal aspirate) should be collected rather than repeating the test from an upper respiratory sample.

Common laboratory abnormalities among children hospitalized for severe COVID-19 include lymphopenia, elevated aminotransaminases, and elevated markers of inflammation (e.g., C-reactive protein). Although imaging findings are neither sensitive nor specific for COVID-19, the most common abnormalities on chest radiography in children are perihilar bronchial wall thickening and/or air space consolidation. CT scans may show ground-glass opacities (mainly in the lower lobes) and/or air space consolidation. Chest radiography should be used as the first imaging modality to assess for pneumonia in symptomatic children, whereas CT should be reserved for assessing

Table 449.7 Framework for Assessing the Risk of Progression to Severe COVID-19 Based on Patient Conditions and COVID-19 Vaccination Status

CONDITIONS	RISK LEVEL BY VACCINATION STATUS[a]		
	UNVACCINATED	PRIMARY SERIES	UP TO DATE
STRONG OR CONSISTENT ASSOCIATION WITH PROGRESSION TO SEVERE COVID-19			
• Moderately or severely immunocompromised	High	High	High
• Obesity (BMI ≥95th percentile for age), especially severe obesity (BMI ≥120% of 95th percentile for age)[b] • Medical complexity with dependence on respiratory technology[c] • Severe neurologic, genetic, metabolic, or other disability that results in impaired airway clearance or limitations in self-care or activities of daily living • Severe asthma or other severe chronic lung disease requiring ≥2 inhaled or ≥1 systemic medications daily • Severe congenital or acquired cardiac disease • Multiple moderate to severe chronic diseases	High	Intermediate	Intermediate
MODERATE OR INCONSISTENT ASSOCIATION WITH PROGRESSION TO SEVERE COVID-19			
• Age <1 yr • Prematurity in children age ≤2 yr • Sickle cell disease • Diabetes mellitus (poorly controlled) • Nonsevere cardiac, neurologic, or metabolic disease[d]	Intermediate	Intermediate	Intermediate
WEAK OR UNKNOWN ASSOCIATION WITH PROGRESSION TO SEVERE COVID-19			
• Mild asthma • Overweight • Diabetes mellitus (well controlled)	Low	Low	Low

[a]**Unvaccinated** = individuals who are not eligible for COVID-19 vaccination or are <2 wk from the final dose of the primary series. **Vaccinated with primary series** = individuals who completed the primary series of two or three doses (the current CDC term is *fully vaccinated*) and are >2 wk after the final dose of the primary series but have not received a booster if they are eligible for a booster. **Vaccinated and up to date** = individuals who received the recommended primary series and booster doses.
[b]The degree of risk conferred by obesity in younger children is less clear than it is in older adolescents.
[c]This includes patients with a tracheostomy and those who require NIV.
[d]The data for this group are particularly limited.
BMI, Body mass index; CDC, Centers for Disease Control and Prevention; NIV, noninvasive ventilation; the Panel, the COVID-19 Treatment Guidelines Panel
From NIH COVID-19 Treatment Guidelines (Table 3b). https://www.covid19treatmentguidelines.nih.gov/tables/assessing-risk/

for complications, particularly in children with coexisting medical conditions.

TREATMENT

For ambulatory patients with mild to moderate COVID-19 at high risk for progression to severe disease (e.g., obesity or overweight, immunosuppression, medical-related technologic dependence, or a chronic medical condition such as kidney disease, diabetes, cardiovascular disease, sickle cell disease, or neurodevelopmental disorders), current treatment options include nirmatrelvir/ritonavir (≥12 years of age) or a 3-day course of remdesivir. Nirmatrelvir is an inhibitor of the main protease of SARS-CoV-2; coadministration with ritonavir results in higher concentrations and a longer half-life. Remdesivir is an antiviral agent that works by interfering with viral RNA transcription (see Table 449.8). As of July 2023, no monoclonal antibodies have been authorized for COVID-19 treatment or prophylaxis because of reduced susceptibility of circulating Omicron subvariants to these products.

For hospitalized children with severe illness (SpO_2 ≤94% on room air, including patients on supplemental oxygen) or critical illness (mechanical ventilation or extracorporeal membrane oxygenation [ECMO]), dexamethasone treatment is recommended (Table 449.8). Inflammatory injury from the host immune response is thought to play a role in patients with severe or critical illness.

The IDSA recommends remdesivir for hospitalized patients with SpO_2 ≤94% on room air, including patients on supplemental oxygen, but suggests against routine administration to patients on mechanical ventilation and/or ECMO. A panel of pediatric infectious diseases physicians and pharmacists recommended that remdesivir could be considered on a case-by-case basis for children with severe or critical COVID-19. Children receiving remdesivir should have daily measurements of creatinine and transaminases.

Tocilizumab is a monoclonal anti–interleukin (IL)-6-receptor blocking antibody. The IDSA suggests tocilizumab in addition to standard of care for hospitalized adults with progressive severe or critical COVID-19 who have elevated markers of systemic

inflammation. Baricitinib is a selective Janus kinase 1 and 2 inhibitor that has been studied as a substitute for dexamethasone in patients who cannot receive corticosteroids because of a contraindication (see Table 449.8).

PREVENTION

Vaccination is the most effective intervention to prevent COVID-19 infection and is highly protective against severe illness, hospitalization, and death. COVID-19 vaccination is available for use in children ≥6 months of age. Vaccine modifications are necessary when new variants emerge.

Because the emergence of viral variants with the potential to escape vaccine-induced immunity remains a threat, nonpharmaceutical interventions to mitigate transmission of SARS-CoV-2 still play an important role in the public health response. Face mask use, eye protection, and physical distancing have all been demonstrated to reduce the risk of infection. A cross-sectional study conducted in the United States found an increase in reported mask-wearing was associated with an increased odds of transmission control. A modeling study by the Centers for Disease Control and Prevention demonstrated that high vaccination coverage and compliance with nonpharmaceutical interventions are essential to control COVID-19.

Table 449.8 Therapeutic Management of Hospitalized Children with COVID-19

DISEASE SEVERITY	PANEL'S RECOMMENDATIONS
Hospitalized for COVID-19	For children age ≥12 yr admitted for COVID-19, use prophylactic anticoagulation unless contraindicated.
Does Not Require Supplemental Oxygen	For children admitted for COVID-19 who are at the highest risk of progression to severe COVID-19,[a] consider using remdesivir[b] for children age 12-17 yr. There is insufficient evidence for using remdesivir in children age 28 days to <12 yr. For children admitted for reasons other than COVID-19 who have mild to moderate COVID-19 and are at the highest risk of progression, see footnote *a*.
Requires Conventional Oxygen	Use one of the following options: • Remdesivir[b] • Dexamethasone plus remdesivir[b] for children with increasing oxygen needs, particularly adolescents
Requires Oxygen Through High-Flow Device or NIV[d]	Use one of the following options: • Dexamethasone • Dexamethasone plus remdesivir[b] For children who do not have rapid (e.g., within 24 hr) improvement in oxygenation after initiation of dexamethasone, baricitinib[e] or tocilizumab can be considered for children aged 12-17 yr (BIII) and for children age 2-11 yr, respectively.
Requires MV or ECMO[f]	Dexamethasone[f] For children who do not have rapid (e.g., within 24 hr) improvement in oxygenation after initiation of dexamethasone, baricitinib[e] or tocilizumab may be considered for children age 12-17 yr and for children age 2-11 yr, respectively.

[a] For example, for children who are severely immunocompromised regardless of COVID-19 vaccination status and those who are unvaccinated and have additional risk factors for progression.
[b] The clinical benefit of remdesivir is greatest if it is initiated within 10 days of symptom onset. Remdesivir should be given for 5 days or until hospital discharge, whichever comes first.
[c] Conventional oxygen refers to oxygen supplementation that is not high-flow oxygen, NIV, MV, or ECMO.
[d] Patients who are receiving NIV or MV at baseline and require a substantial increase in baseline support should be treated per the recommendations for patients requiring new NIV or MV.
[e] Tofacitinib is an alternative if baricitinib is not available.
[f] For children who started receiving remdesivir before admission to the ICU, remdesivir should be continued to complete the treatment course.
ECMO, Extracorporeal membrane oxygenation; ICU, intensive care unit; MV, mechanical ventilation; NIV, noninvasive ventilation.

Chapter 450

E-Cigarette or Vaping Product Use–Associated Lung Injury (EVALI)

Lynn A. D'Andrea and Louella B. Amos

Beginning in 2019, there was a nationwide outbreak of patients who presented with acute lung injury believed to be related to vaping, designated as *E-cigarette or vaping product use–associated lung injury* (EVALI).

EPIDEMIOLOGY

As of January 2020, there were >2,500 hospitalized EVALI patients reported by all 50 states (approximately two thirds of patients were male). The median patient age was 21 years (range 13-85 years). The Centers for Disease Control and Prevention (CDC) stopped collecting data on EVALI cases in early 2020 because of the COVID-19 pandemic; although the number of cases may have decreased, EVALI must be considered in patients with features associated with the condition (Fig. 450.1).

Among hospitalized patients with information on substances used, ~90% reported using any tetrahydrocannabinol (THC)-containing product and ~70% reported using any nicotine-containing product; 40–60% reported both THC and nicotine use. The THC products were often flavored, prefilled THC cartridges obtained from black market sources.

PATHOPHYSIOLOGY

Carrier solvents or humectants such as propylene glycol and glycerin, as well as nicotine vapor itself, can cause airway inflammation

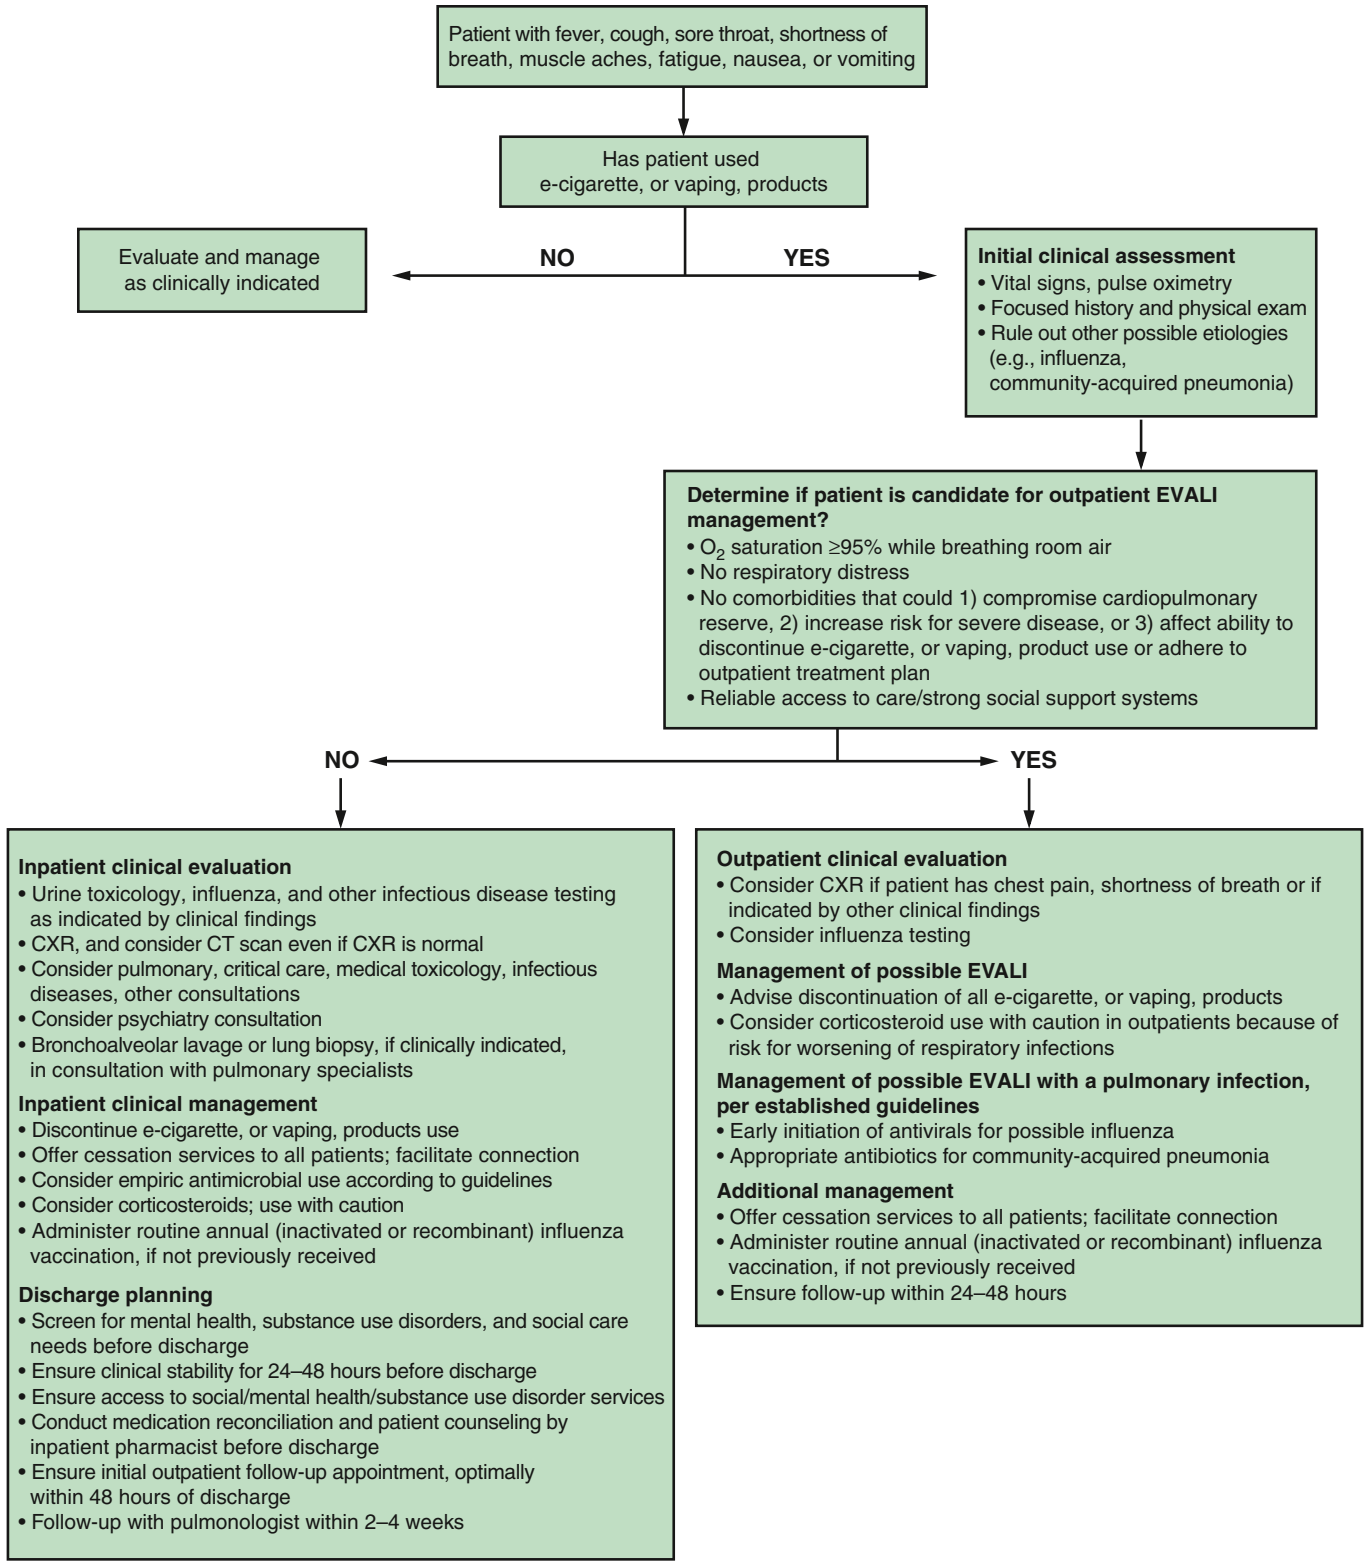

Fig. 450.1 Updated algorithm for management of patients with suspected e-cigarette, or vaping, product use–associated lung injury (EVALI), December 2019. CT, Computed tomography; CXR, chest x-ray.* Influenza vaccination recommendations: https://www.cdc.gov/mmwr/volumes/68/rr/rr6803a1.htm?s_cid=rr6803a1_w. *(From Evans ME, Twentyman E, Click ES, et al. Update: interim guidance for health care professionals evaluating and caring for patients with suspected E-cigarette, or vaping, product use-associated lung injury and for reducing the risk of rehospitalization and death following hospital discharge – United States, December 2019. MMWR. 2020;68:1189-1194, Fig. p. 1191.)*

that can induce airway remodeling and disrupt alveolar macrophage function. Flavoring additives generate by-products that directly injure airway epithelium. Vitamin E acetate that was used as a diluent in the THC-containing products disrupts alveolar macrophage function and surfactant homeostasis. EVALI is best considered an airway-centered chemical pneumonitis rather than an exogenous lipoid pneumonia. Thermal injury can also be a factor in acute lung injury.

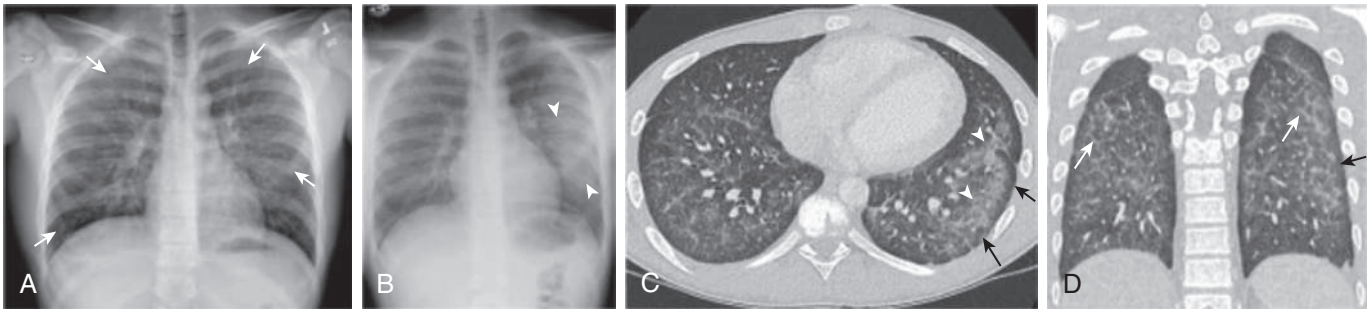

Fig. 450.2 E-cigarette, or vaping, product use–associated lung injury in a 16-yr-old male who presented with chest pain, shortness of breath, and cough for 1 month. **A,** Posteroanterior (PA) radiograph of the chest demonstrates faint nodular opacities in both lungs *(arrows)* with diffusely increased interstitial markings. **B,** PA radiograph of the chest obtained 2 days later demonstrates progression of the nodular opacities into confluent opacities in the left mid-lung *(arrowheads).* Axial **(C)** and coronal **(D)** chest CT images in lung windows (slice thickness 0.63 mm, kVp 100, mAs 61-106) obtained 4 days after the initial chest radiograph demonstrate centrilobular ground-glass nodules in both lungs and confluent ground-glass opacities in the left lower lobe *(arrowheads)* with subpleural sparing *(black arrows)* and interstitial septal thickening *(white arrows). (From Thakrar PD, Boyd KP, Swanson CP, et al. E-cigarette, or vaping, product use-associated lung injury in adolescents: a review of imaging features. Pediatr Radiol. 2020;50:338–344, Fig. 1, p. 340.)*

CLINICAL MANIFESTATIONS

Acutely, patients often present with a combination of respiratory distress, gastrointestinal (GI), and constitutional symptoms. Respiratory symptoms include shortness of breath, cough, hemoptysis, and chest or pleuritic pain. On physical examination, patients have tachypnea with hypoxemia and tachycardia. GI symptoms include nausea, vomiting, diarrhea, and abdominal pain.

Subacute constitutional and GI symptoms can occur day to weeks before the acute presentation. Constitutional symptoms include weight loss, fatigue, fever, myalgias, and chills.

DIAGNOSIS

There is no specific test for lung injury associated with EVALI; rather, evaluation should primarily focus on excluding infectious causes. It is important to evaluate for other possible causes (rheumatologic, neoplastic, cardiac) as appropriate (see Fig. 450.1).

Imaging

Chest radiographic evaluation is key in the diagnosis of EVALI, although findings are generally nonspecific (Fig. 450.2). Chest CT imaging is most consistent with acute lung injury from toxic inhalation, with centrilobular ground-glass opacities with subpleural sparing. The most common radiologic findings reported on chest x-ray are bilateral infiltrates, and ground-glass opacities predominantly at the bases. The most common radiologic findings reported on chest CT are bilateral infiltrates, bilateral ground-glass opacities, and subpleural sparing, followed by small pleural effusions and centrilobular nodularity. Pneumothorax and pneumomediastinum are less common.

Laboratory

Laboratory evaluation is suggestive of inflammation with neutrophilic leukocytosis, elevated C-reactive protein (CRP), and erythrocyte sedimentation rate (ESR). Elevated transaminases (AST/ALT) and lactate dehydrogenase (LDH) have been reported in some patients. Urine drug screening is useful to confirm the presence of THC or nicotine.

Other Testing

Pulmonary Function Testing

The acute effects of EVALI on lung function are variable. In a case series of adolescents hospitalized with EVALI, predischarge testing demonstrated that >50% had an abnormality on spirometry, with a restrictive pattern occurring twice as often as obstruction; ~60% of patients had a decreased diffusion capacity, and ~50% had an abnormal 6-minute walk test. Patients continued to have abnormal testing at follow-up, including abnormal spirometry (both obstructive and restrictive patterns), decreased diffusion capacity, and rarely, 6-minute walk test. One follow-up study also identified abnormal 6-minute walk tests as a marker of lung injury and submaximal exercise capacity. However, another follow-up study showed ~85% of previously hospitalized pediatric patients had normal spirometry.

Bronchoscopy

Bronchoscopy with bronchoalveolar lavage is used to evaluate for possible infectious processes. Gross pathologic abnormalities can include mucosal hypervascularity, diffuse mucosal erythema, punctate mucosal hemorrhage, and frank airway bleeding consistent with a pulmonary hemorrhage. Cytopathologic findings commonly include lipid-laden macrophages on oil-red-O staining and elevated neutrophil counts more than 10% of total cell differential. Hemosiderin-laden macrophages are absent. Bacterial cultures are negative.

Caution is required when performing bronchoscopy with lavage, as it may worsen the patient's respiratory status. Many patients develop significant airway reactivity (bronchospasm) that requires intraprocedure management.

TREATMENT

Treatment focuses on supportive care. Supplemental oxygen may be required to maintain oxygen saturations in an appropriate range. Bronchodilators should be considered if there is an element of bronchospasm. Some patients have been treated with systemic corticosteroids with good improvement of their symptoms, but this should be considered on a case-by-case basis (see Fig. 450.1). Antibiotics should *only* be used for secondary infection.

Less often, patients have required more invasive respiratory support, including high-flow nasal cannula, mechanical ventilation, and rarely, extracorporeal membrane oxygenation (ECMO). There are rare case reports of patients requiring lung transplantation.

Follow-up should include recommendations regarding vaping cessation; some patients will require assistance with nicotine replacement therapy (see Chapter 157.2). Many adolescents require support from a mental health provider (see Fig. 450.1).

Advocacy and Prevention

In December 2019, the federal government passed legislation raising the age for purchasing tobacco products, including e-cigarettes, from 18 to 21 years. The FDA set the deadline for e-cigarette manufacturers to submit their marketing applications or risk having their products taken off the market. As of September 2021, the FDA ordered over 90% of e-cigarette products off the market; however, many products appealing to youth, including disposable flavored e-cigarettes, remain available, and the black market continues to thrive.

The initial EVALI outbreak primarily affected young adults, was driven by the use of THC-containing products from black market sources, and was strongly linked to vitamin E acetate. However, 15–20% of reported EVALI cases describe the exclusive use of nicotine-containing products. It is recommended that the term *EVALI* refer to all e-cigarette-related lung injuries, including other chronic respiratory symptoms of vaping (e.g., chronic wheeze, recurrent bronchitis, asthma exacerbations, emphysema).

Chapter 451

Pleurisy, Pleural Effusions, and Empyema

Aarthi P. Vemana and Suraiya K. Haider

Pleurisy is the inflammation of the pleura; it may be accompanied by an effusion. The most common cause of pleural effusion in children is bacterial pneumonia (see Chapter 449); other common causes include heart failure (see Chapter 491), rheumatologic and immune causes, and metastatic or intrathoracic malignancy. A variety of other diseases account for the remaining cases, including tuberculosis (see Chapter 261), lupus erythematosus (see Chapter 199), aspiration pneumonitis (see Chapter 446), uremia, pancreatitis, subdiaphragmatic abscess, and rheumatoid arthritis.

Inflammatory processes in the pleura are usually divided into three types: dry pleurisy, serofibrinous or serosanguineous, and purulent pleurisy or empyema.

451.1 Dry Pleurisy

Aarthi P. Vemana and Suraiya K. Haider

Dry pleurisy, formerly called *plastic pleurisy,* may be associated with acute bacterial or viral pulmonary infections or may develop during the course of an acute upper respiratory tract illness. The condition is also associated with tuberculosis and autoimmune and systemic inflammatory diseases such as systemic lupus erythematosus.

PATHOLOGY AND PATHOGENESIS

The process is usually limited to the visceral pleura, with small amounts of yellow serous fluid and adhesions between the pleural surfaces. In tuberculosis, pleurisy can be caused by a severe delayed-type hypersensitivity reaction to *Mycobacterium tuberculosis*; the adhesions develop rapidly, and the pleura are often thickened. Occasionally, fibrin deposition and adhesions are severe enough to produce a fibrothorax that markedly inhibits the excursions of the lung.

CLINICAL MANIFESTATIONS

The primary disease often overshadows signs and symptoms of pleurisy. Pain, the principal symptom, is exaggerated by deep breathing, coughing, and straining. Occasionally, pleural pain is described as a dull ache, which is less likely to vary with breathing. The pain is often localized over the chest wall and is referred to the shoulder or the back. Pain with breathing is responsible for grunting and guarding of respirations, and the child often lies on the affected side in an attempt to decrease respiratory excursions. Early in the illness, a leathery, rough, inspiratory, and expiratory friction rub may be audible, but it usually disappears rapidly. If the layer of exudate is thick, increased dullness to percussion and decreased breath sounds may be heard. Pleurisy may be asymptomatic. Chronic pleurisy is occasionally encountered with conditions such as atelectasis, pulmonary abscess, connective tissue diseases, and tuberculosis.

LABORATORY FINDINGS

Dry pleurisy may be detected on radiographs as a diffuse haziness at the pleural surface or a dense, sharply demarcated shadow (Figs. 451.1 and 451.2). The latter finding may be indistinguishable from small amounts of pleural exudate. Chest radiographic findings may be normal, but ultrasonography or CT findings will be positive.

DIFFERENTIAL DIAGNOSIS

Pleurisy pain must be distinguished from other diseases, such as epidemic pleurodynia, trauma to the rib cage (rib fracture), lesions of the dorsal root ganglia, tumors of the spinal cord, herpes zoster, gallbladder disease, and trichinosis. Even if evidence of pleural fluid is not found on physical or radiographic examination, a CT- or ultrasound-guided pleural tap in suspected cases often results in the recovery of a small amount of exudate, which, when cultured, may reveal the underlying bacterial cause in patients with an acute pneumonia. Patients with pleurisy and pneumonia should always be screened for tuberculosis.

TREATMENT

Therapy should be aimed at the underlying disease. When pneumonia is present, neither immobilization of the chest with adhesive plaster nor therapy with drugs capable of suppressing the cough reflex is indicated. If pneumonia is not present or is under good therapeutic control, strapping of the chest to restrict expansion may afford relief from pain. Analgesia with nonsteroidal antiinflammatory agents may be helpful.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

451.2 Serofibrinous or Serosanguineous Pleurisy with Pleural Effusion

Aarthi P. Vemana and Suraiya K. Haider

Serofibrinous pleurisy is defined by a fibrinous exudate on the pleural surface and an exudative effusion of serous fluid into the pleural cavity. In general, it is associated with infections of the lung or with inflammatory conditions of the abdomen or mediastinum; occasionally, it is found with connective tissue diseases such as lupus erythematosus, periarteritis, and rheumatoid arthritis, and it may be seen with primary or metastatic neoplasms of the lung, pleura, or mediastinum. Tumors are commonly associated with a hemorrhagic fluid. Infectious etiologies include *Streptococcus pneumonia, Staphylococcus aureus* including methicillin-resistant *S. aureus* (MRSA), group A streptococcus, and viral infections, including COVID-19 (although pleural disease is seen in approximately 10%).

PATHOGENESIS

Pleural fluid originates from the capillaries of the parietal pleura and is absorbed from the pleural space via pleural stomas and the lymphatics of the parietal pleura. The rate of fluid formation is dictated by the Starling law, by which fluid movement is determined by the balance of hydrostatic and osmotic pressures in the pleural space and pulmonary capillary bed and the permeability of the pleural membrane. Normally, approximately 10 mL of fluid is present in the pleural space, but if formation exceeds clearance, fluid accumulates. Pleural inflammation increases the permeability of the plural surface, with increased proteinaceous fluid formation; there may also be some obstruction to lymphatic absorption.

CLINICAL MANIFESTATIONS

Because serofibrinous pleurisy is often preceded by the dry type, early signs and symptoms may be those of dry pleurisy. As fluid accumulates, pleuritic pain may disappear. The patient may become asymptomatic if the effusion remains small, or there may be only signs and symptoms of the underlying disease. Large fluid collections can produce cough, dyspnea, retractions, tachypnea, orthopnea, or cyanosis. In children with bacterial pneumonia, pleural effusion should be suspected when symptoms do not improve after 48 hours of appropriate therapy.

Physical findings depend on the amount of effusion. Dullness to flatness may be found on percussion. Breath sounds are decreased or absent, and there is a diminution in tactile fremitus, a shift of the mediastinum away from the affected side, and, occasionally, fullness of the intercostal spaces. If the fluid is not loculated, these signs may shift with changes in position. If extensive pneumonia is present, crackles and

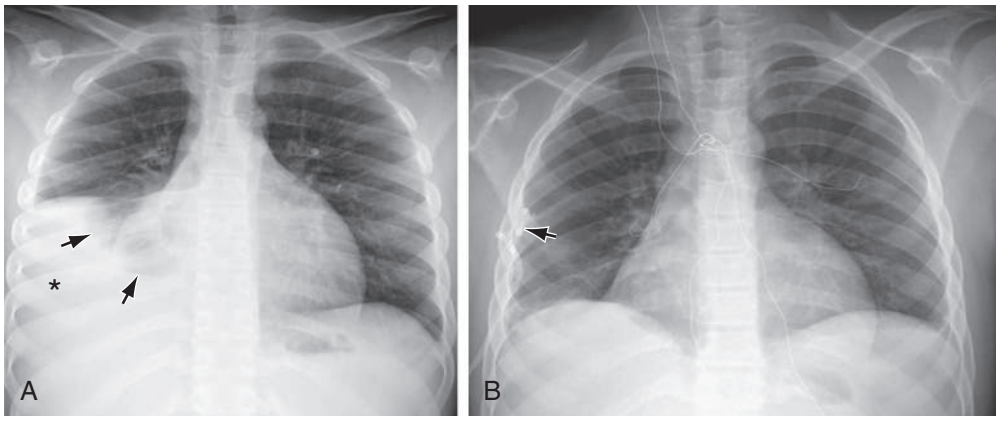

Fig. 451.1 A, Right pleural effusion *(asterisk)* caused by lupus erythematosus in a 12-yr-old child. Note compressed middle and lower lobes of the right lung *(arrows)*. B, The effusion was evacuated, and the right lung was completely reexpanded after insertion of the pigtail chest tube *(arrow)*.

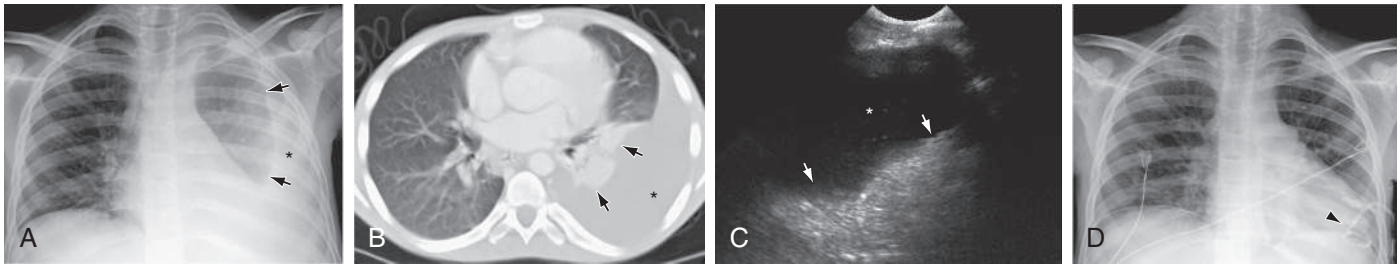

Fig. 451.2 Left pleural effusion in a teenager with AIDS and *Mycobacterium avium-intracellulare* infection. The pleural effusion *(asterisk)* is clearly seen on the chest radiograph (A), CT scan (B), and ultrasonogram (C) of the left chest. *Arrows* point to the compressed and atelectatic left lung. D, A pigtail chest tube *(arrowhead)* was inserted, resulting in reexpansion of the left lung.

rhonchi may also be audible. Friction rubs are usually detected only during the early or late plastic stage. In infants, physical signs are less definite, and bronchial breathing may be heard instead of decreased breath sounds.

LABORATORY FINDINGS

Radiographic examination shows a homogeneous density obscuring the normal markings of the underlying lung, obliterating the costophrenic or cardiophrenic angles. Radiographs should be performed with the patient both supine and upright to demonstrate a shift of the effusion with a change in position; the decubitus position may be helpful. Especially with large effusions, ultrasonography can identify the presence of septations, the lack of free movement of the fluid with gravity, and guide placement of a chest tube or site of thoracentesis loculated. Examination of the fluid is essential to differentiate **exudates** from **transudates** and to determine the type of exudate (see Table 449.6). Depending on the clinical scenario, pleural fluid is sent for culture for bacterial, fungal, and mycobacterial cultures; microbial analysis (quantitative polymerase chain reaction [qPCR], rapid antigen testing, and immunochromatography); Gram staining; and chemical evaluation of content, including protein, lactic dehydrogenase and glucose, amylase, specific gravity, total cell count and differential, cytologic examination for malignancy, and pH. Complete blood count and serum chemistry analysis should be obtained; hypoalbuminemia is often present. **Exudates** usually have at least one of the following features: protein level >3.0 g/dL, with pleural fluid:serum protein ratio >0.5; pleural fluid lactic dehydrogenase values >200 IU/L; or fluid:serum lactic dehydrogenase ratio >0.6. Although systemic acidosis reduces the usefulness of pleural fluid pH measurements, pH <7.20 suggests an exudate. Glucose is usually <60 mg/dL in malignancy, rheumatoid disease, and tuberculosis; the finding of many small lymphocytes and a pH <7.20 suggest tuberculosis. The fluid of serofibrinous pleurisy is clear or slightly cloudy and contains relatively few leukocytes and, occasionally, some erythrocytes. Gram staining may occasionally show bacteria; however, acid-fast staining rarely demonstrates tubercle bacilli. Cytologic examination may reveal malignant cells, if present.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Unless the patient has a classic-appearing lobar pneumonia and the effusion is small, thoracentesis should be performed when pleural fluid is present or is suggested. Thoracentesis can differentiate serofibrinous pleurisy, empyema, hydrothorax, hemothorax, and chylothorax. Exudates are usually associated with an infectious process. In hydrothorax, the fluid has a specific gravity <1.015, and evaluation reveals only a few mesothelial cells rather than leukocytes. Chylothorax and hemothorax usually have fluid with a distinctive appearance, but differentiating serofibrinous from purulent pleurisy is impossible without microscopic examination of the fluid. Serofibrinous fluid may rapidly become purulent.

COMPLICATIONS

Unless the fluid becomes purulent, it usually disappears relatively rapidly, particularly with appropriate treatment of bacterial pneumonia. It persists somewhat longer if a result of tuberculosis or a connective tissue disease and may recur or remain for a long time if caused by a neoplasm. When the effusion is absorbed, adhesions often develop between the two layers of the pleura, but usually little or no functional impairment results. Pleural thickening may develop and is occasionally mistaken for small quantities of fluid or for persistent pulmonary infiltrates. Pleural thickening may persist for months, but the process usually disappears, leaving no residua.

TREATMENT

Treatment of the underlying pneumonia with antibiotics should be continued. If the effusion is less than 10 mm in size on a chest x-ray, there is no need for drainage. Drainage of large effusions can shorten the course of treatment and provide symptomatic relief. When a diagnostic thoracentesis is performed, as much fluid as possible should be removed for therapeutic purposes. Rapid removal of ≥1 L of pleural fluid may be associated with the development of **reexpansion pulmonary edema**. If sufficient fluid reaccumulates to cause tachypnea, chest tube drainage should be performed. In older children, tube thoracostomy is considered necessary if the pleural fluid pH is <7.20

or the pleural fluid glucose level is <50 mg/dL. If the fluid is thick, loculated, or clearly purulent, chest tube drainage with fibrinolytic therapy or, less often, video-assisted thoracoscopic surgery (VATS) is indicated. Patients with pleural effusions may need analgesia, particularly after thoracentesis or insertion of a chest tube. Those with acute pneumonia may need supplemental oxygen in addition to specific antibiotic treatment. Monitoring with serial chest x-ray should be considered in children who have had complications or needed fibrinolytic treatment.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

451.3 Empyema

Aarthi P. Vemana and Suraiya K. Haider

Empyema is an accumulation of pus in the pleural space. It is most often associated with pneumonia (see Chapter 449) caused by gram-positive organisms such as *S. pneumoniae* (see Chapter 228), group A streptococcus, and *S. aureus* (see Chapter 227.1). The relative incidence of *Haemophilus influenzae* (see Chapter 240) empyema has decreased since the introduction of the *H. influenzae* type b vaccination. Gram-negative organisms, tuberculosis, fungi, viruses, and malignancy are less common causes. The disease can also be produced by rupture of a lung abscess into the pleural space, contamination introduced from trauma or thoracic surgery, or, rarely, mediastinitis or the extension of intraabdominal abscesses.

EPIDEMIOLOGY

Empyema is most frequently encountered in infants and preschool children. Although rates of bacterial pneumonia have decreased, the incidence of parapneumonic effusions has increased. This may be related to a shift toward more virulent organisms after the introduction of the 13-valent pneumococcal conjugate vaccine, with a trend toward serotypes not covered by the vaccine. Empyema occurs in 5–10% of children with bacterial pneumonia and in up to 86% of children with necrotizing pneumonia.

PATHOLOGY

Empyema has three stages: exudative, fibrinopurulent, and organizational. During the exudative stage, fibrinous exudate forms on the pleural surfaces. In the fibrinopurulent stage, fibrinous septa form, causing loculation of the fluid and thickening of the parietal pleura. If the pus is not drained, it may dissect through the pleura into lung parenchyma, producing bronchopleural fistulas and pyopneumothorax, or into the abdominal cavity. Rarely, the pus dissects through the chest wall (i.e., empyema necessitatis). During the organizational stage, there is fibroblast proliferation; pockets of loculated pus may develop into thick-walled abscess cavities, or the lung may collapse and become surrounded by a thick, inelastic envelope (peel).

CLINICAL MANIFESTATIONS

The initial signs and symptoms are primarily those of bacterial pneumonia. Children treated with antibiotic agents may have an interval of a few days between the clinical pneumonia phase and the evidence of empyema. Most patients are febrile, develop increased work of breathing or respiratory distress, and often appear more ill. Physical findings are identical to those described for serofibrinous pleurisy, and the two conditions are differentiated only by thoracentesis, which should always be performed when empyema is suspected.

LABORATORY FINDINGS

Radiographically, all pleural effusions appear similar, but the absence of a shift of the fluid with a change of position indicates a loculated empyema (Figs. 451.3-451.5 and see Fig. 449.5). Ultrasonography, CT, and, less frequently, magnetic resonance imaging can all be used to further define the size of the effusion, identify septations, and assess loculations. The maximal amount of fluid obtainable should be withdrawn by thoracentesis and studied (see Chapter 451.2). The effusion is an empyema if bacteria are present on Gram staining, the pH is <7.20, and there are >100,000 neutrophils/μL (see Chapter 449). Cultures of the fluid must always be performed to help identify the causal organism. Using standard culture methods, the organism can be identified in up to 60% of cases. The yield improves significantly with concomitant use of nucleic acid amplification techniques. Blood cultures may be positive and have a higher yield than cultures of the pleural fluid. Laboratory analysis shows leukocytosis and elevated erythrocyte sedimentation rate and elevated C-reactive protein.

COMPLICATIONS

With staphylococcal infections, bronchopleural fistulas and pyopneumothorax commonly develop. Other local complications include purulent pericarditis, pulmonary abscesses, peritonitis from extension through the diaphragm, and osteomyelitis of the ribs. Septic complications such as meningitis, arthritis, and osteomyelitis may also occur. Septicemia is often encountered in *H. influenzae* and pneumococcal infections. The effusion may organize into a thick "peel," which may restrict lung expansion and may be associated with persistent fever and temporary scoliosis.

TREATMENT

The aim of empyema treatment is to sterilize pleural fluid and restore normal lung function. Treatment includes systemic antibiotics, thoracentesis, chest tube drainage, and use of a fibrinolytic agent; VATS and open decortication are used if there is poor resolution with the preceding therapies (see Chapter 461).

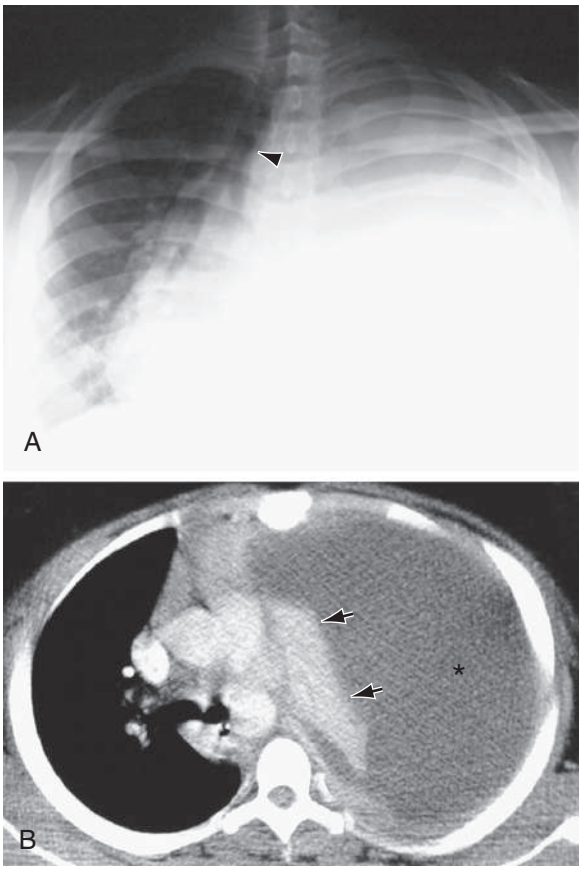

Fig. 451.3 Empyema and pneumonia in a teenager. **A,** Chest radiograph shows opacification of the left thorax. Note shift of mediastinum and trachea *(arrowhead)* to the right. **B,** Thoracic CT scan shows massive left pleural effusion *(asterisk)*. Note the compression and atelectasis of the left lung *(arrows)* and shift of the mediastinum to the right.

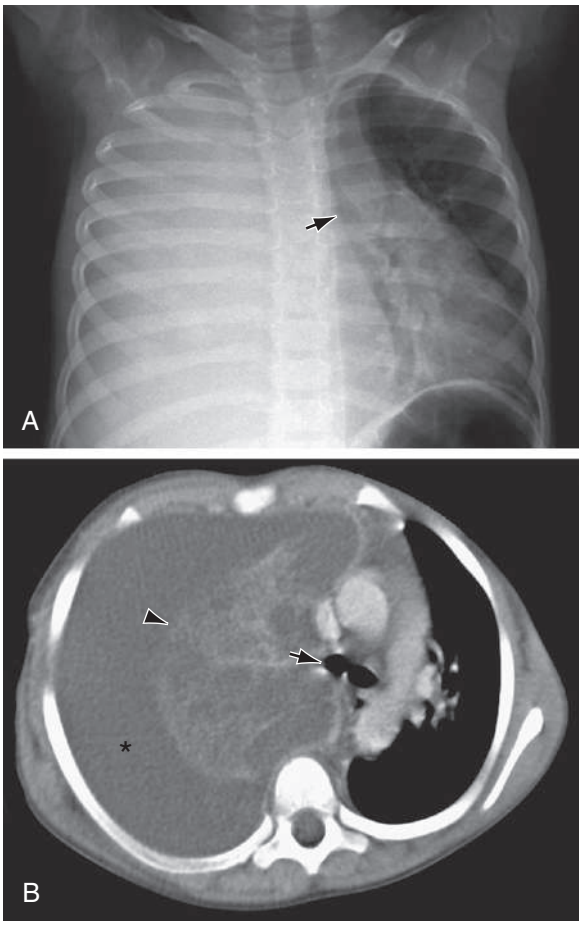

Fig. 451.4 Pneumonia and parapneumonic effusion in a 4-yr-old child. **A,** Chest radiograph shows complete opacification of the right thorax as a result of a large pleural effusion. Note the shift of the mediastinum and trachea *(arrow)* to the left. **B,** Thoracic CT scan shows a large right pleural effusion *(asterisk)* surrounding and compressing the consolidated right lung *(arrowhead)*. Note the shift of the mediastinum and tracheal carina *(arrow)* to the left.

If empyema is diagnosed early, antibiotic treatment plus thoracentesis achieves a complete cure. The selection of antibiotic should be based on the in vitro sensitivities of the responsible organism. See Chapters 227, 228, and 240 for treatment of infections by *Staphylococcus, S. pneumoniae*, and *H. influenzae*, respectively. Treatment with systemic antibiotics is usually needed for 2-4 weeks, with the duration being guided by individual clinical response to treatment. Instillation of antibiotics into the pleural cavity does not improve results.

After empyema has been confirmed, interventions include closed chest tube drainage with fibrinolytics, decortication with VATS (video-assisted thoracoscopic surgery), and, less often, open thoracotomy. Multiple aspirations of the pleural cavity should not be attempted. Closed-chest tube drainage is controlled by an underwater seal or continuous suction; sometimes more than one tube is required to drain loculated areas. Closed drainage is usually continued for 5-7 days. Chest tubes that are no longer draining are removed.

Instillation of fibrinolytic agents into the pleural cavity via the chest tube often promotes drainage, decreases the length of time a chest tube is in place, decreases fever, lessens the need for surgical intervention, and shortens hospitalization. The optimal fibrinolytic drug and dosages have not been determined. Streptokinase 15,000 units/kg in 50 mL of 0.9% saline, urokinase 40,000 units in 40 mL saline, and tissue plasminogen activator (tPA) 4 mg in 20-40 mL of saline have been used in the pediatric population. Although the combination of fibrinolytic therapy with dornase alfa (DNAse) improves outcomes in adults with empyema, it has not been shown to consistently improve outcomes in pediatric patients with empyema. There is a risk of anaphylaxis with streptokinase, and all three drugs can be associated with hemorrhage and other complications.

If pneumatoceles form, no attempt should be made to treat them surgically or by aspiration, unless they reach sufficient size to cause respiratory compromise or become secondarily infected. Pneumatoceles usually resolve spontaneously with time. Extensive fibrinous changes may take place over the surface of the lungs owing to empyema, but they eventually resolve. The long-term clinical prognosis for adequately treated empyema is excellent, and follow-up pulmonary function studies suggest that residual restrictive disease is uncommon, with or without surgical intervention.

Chapter 452

Bronchiectasis

Oren J. Lakser

Bronchiectasis is characterized by irreversible abnormal dilation and anatomic distortion of the bronchial tree and represents the common end stage of many nonspecific and unrelated antecedent events. Its incidence has been decreasing overall in industrialized countries, but it persists as a problem in lower- and middle-income countries and among some ethnic groups in industrialized nations (particularly in aboriginal children). Females are afflicted more frequently than males.

PATHOPHYSIOLOGY AND PATHOGENESIS

In industrialized nations, cystic fibrosis (see Chapter 454) is the most common cause of clinically significant bronchiectasis. Other conditions associated with bronchiectasis include primary ciliary dyskinesia (see Chapter 455), postinfectious conditions, especially pertussis, measles, and tuberculosis, immune deficiency syndromes (especially humoral immunity), foreign body aspiration, and aspiration of gastric contents (Table 452.1). Bronchiectasis has also been associated with severe asthma in children. It can also be congenital, as in **Williams-Campbell syndrome**, in which there is an absence of annular bronchial cartilage, and **Marnier-Kuhn syndrome** (congenital tracheobronchomegaly), in which there is a connective tissue disorder. Other disease entities associated with bronchiectasis are **yellow nail syndrome** (pleural effusion, lymphedema, discolored nails) and **right middle lobe syndrome**. Right middle lobe syndrome is mostly associated with other generalized causes of bronchiectasis, including asthma, cystic fibrosis, primary ciliary dyskinesia, severe pneumonia, aspiration pneumonia, foreign bodies, and immune-deficient states.

Three basic mechanisms are involved in the pathogenesis of bronchiectasis. **Obstruction** can occur because of tumor, foreign body, impacted mucus because of poor mucociliary clearance, external compression, bronchial webs, and atresia. **Infections** caused by *Bordetella pertussis,* measles, rubella, togavirus, respiratory syncytial virus, adenovirus, and *Mycobacterium tuberculosis* induce chronic inflammation, progressive bronchial wall damage, and dilation. More recently, nontypeable *Haemophilus influenzae* seems to be a common cause of infection in adults and children with bronchiectasis. *Streptococcus pneumoniae* and *Moraxella catarrhalis* are more common in children with bronchiectasis than in adult patients. **Chronic inflammation** similarly contributes to the mechanism by which obstruction leads to bronchiectasis. Both inadequate and exaggerated/dysregulated immune responses may play a role in the development of bronchiectasis. Activation of toll-like receptors results in the activation of nuclear factor κB and the release of proinflammatory cytokines interleukin (IL)-1β, IL-8, and tumor necrosis factor-α. IL-8 is a chemoattractant for neutrophils, which are the main inflammatory cell involved in the pathogenesis of bronchiectasis. Once activated, neutrophils produce neutrophil elastase and matrix metalloproteinase (MMP)-8 and MMP-9. IL-6, IL-8, and tumor necrosis factor-α are elevated in the airways of patients with bronchiectasis. Eosinophils are also elevated in the airways of indigenous children with bronchiectasis, which promotes neutrophil recruitment, goblet cell hyperplasia, and airway destruction. There is an increase in proinflammatory cytotoxic T lymphocytes in the peripheral blood of children with bronchiectasis. The mechanism by which bronchiectasis occurs in congenital forms is likely related to abnormal cartilage formation. The common thread in the pathogenesis of bronchiectasis consists of difficulty clearing secretions and recurrent infections with a "vicious cycle" of infection and inflammation resulting in airway injury and remodeling. This cycle results in a spectrum of pediatric suppurative lung disorders: protracted bacterial bronchitis (PBB), chronic suppurative lung disease (CSLD), and bronchiectasis. CSLD patients suffer from symptoms of bronchiectasis without its radiographic features. In early stages, bronchiectasis consists primarily of bronchiolar wall thickening and destruction of elastin resulting in bronchial dilatation. In later stages, the bronchial walls develop cartilage destruction with associated pulmonary artery/arteriole vascular remodeling, resulting in pulmonary hypertension.

Bronchiectasis can manifest in any combination of three pathologic forms, best defined by high-resolution CT (HRCT) scan (Fig. 452.1). In **cylindrical** bronchiectasis, the bronchial outlines are regular, but there is diffuse dilation of the bronchial unit. The bronchial lumen ends abruptly because of mucous plugging. In **varicose** bronchiectasis, the degree of dilation is greater, and local constrictions cause an irregularity of outline resembling that of varicose veins. There may also be small sacculations. In **saccular** (cystic) bronchiectasis, bronchial dilation progresses and results in ballooning of bronchi that end in fluid- or mucus-filled sacs. This is the most severe form of bronchiectasis. The following definitions have been proposed: **prebronchiectasis** (chronic or recurrent endobronchial infection with nonspecific HRCT changes; may be reversible), **HRCT bronchiectasis** (clinical symptoms with HRCT evidence of bronchial dilation; may persist, progress, or improve and resolve), and **established bronchiectasis** (like the previous but with no resolution within 2 years). Early diagnosis and aggressive therapy are important to prevent the development of established bronchiectasis.

CLINICAL MANIFESTATIONS

The most common complaints in patients with bronchiectasis are chronic wet cough and/or production of copious purulent sputum. Younger children may swallow the sputum. In particular, wet or productive cough failing to respond to 4 weeks of oral antibiotics is predictive of the presence of chest CT–defined bronchiectasis. Hemoptysis is seen with some frequency. Fever can occur with infectious exacerbations. Anorexia and poor weight gain may occur as time passes. Physical examination typically reveals crackles localized to the affected area, but wheezing and digital clubbing may also occur. In severe cases, dyspnea and hypoxemia can occur. Pulmonary function studies may demonstrate an obstructive, restrictive, or mixed pattern. Typically, impaired diffusion capacity is a late finding.

Table 452.1 Conditions That Predispose to Bronchiectasis in Children

PROXIMAL AIRWAY NARROWING
Airway wall compression (i.e., vascular ring, adenopathy impinging on airways)
Airway intraluminal obstruction (e.g., inhaled foreign body, granulation tissue)`
Airway stenosis and malacia (tracheal, bronchial)
AIRWAY INJURY
Bronchiolitis obliterans (e.g., postviral, after lung transplantation)
Recurrent pneumonitis or pneumonia (e.g., pneumococcal pneumonia, aspiration pneumonia, tuberculosis, *B. pertussis*)
ALTERED PULMONARY HOST DEFENSES
Cystic fibrosis
Primary ciliary dyskinesia
Impaired cough (e.g., neuromuscular weakness conditions)
ALTERED IMMUNE STATES
Primary abnormalities (e.g., agammaglobulinemia, hypogammaglobulinemia, common variable immune deficiency, hyper IgE, hyper IgM, neutrophil dysfunction, gain-of-function *STAT1* variants)
Secondary abnormalities (e.g., HIV infection, immunosuppressive agents)
OTHER
Systemic pseudohypoaldosteronism
Epithelial sodium channel variants *(SCNN1A, SCNN1B)*
Allergic bronchopulmonary aspergillosis
Plastic bronchitis
Right middle lobe syndrome

From Redding GJ. Bronchiectasis in children. *Pediatr Clin North Am.* 2009;56:157–171, Box 1.

DIAGNOSIS

Conditions that can be associated with bronchiectasis should be ruled out by appropriate investigations (e.g., sweat test, immunologic workup). Chest radiographs of patients with bronchiectasis tend to be nonspecific. Typical findings can include increase in size and loss of definition of bronchovascular markings, crowding of bronchi, and loss of lung volume. In more severe forms, cystic spaces, occasionally with air-fluid levels and honeycombing, may occur. Compensatory overinflation of the unaffected lung may be seen. Thin-section HRCT scanning and multidetector CT scanning are the gold standards because they have excellent sensitivity and specificity. CT provides further information on disease location, presence of mediastinal lesions, and the extent of segmental involvement. The main features of bronchiectasis in CT scans include (1) increased bronchoarterial ratio and *signet-ring* appearance; (2) bronchial wall thickening; (3) mucous plugging; (4) lack of bronchial tapering to the lung periphery—"tramlines"; (5) bronchial structures in the lung periphery; and (6) air trapping (mosaic perfusion), most obvious on expiration. The lower lobes (left > right) are more commonly affected. Early in the course, tree-in-bud appearance can also be seen. These CT findings are used to define the bronchiectasis as *cylindrical* ("tram lines," "signet ring appearance"), *varicose* (bronchi with "beaded contour"), *cystic* (cysts in "strings and clusters"), or mixed forms (Fig. 452.2).

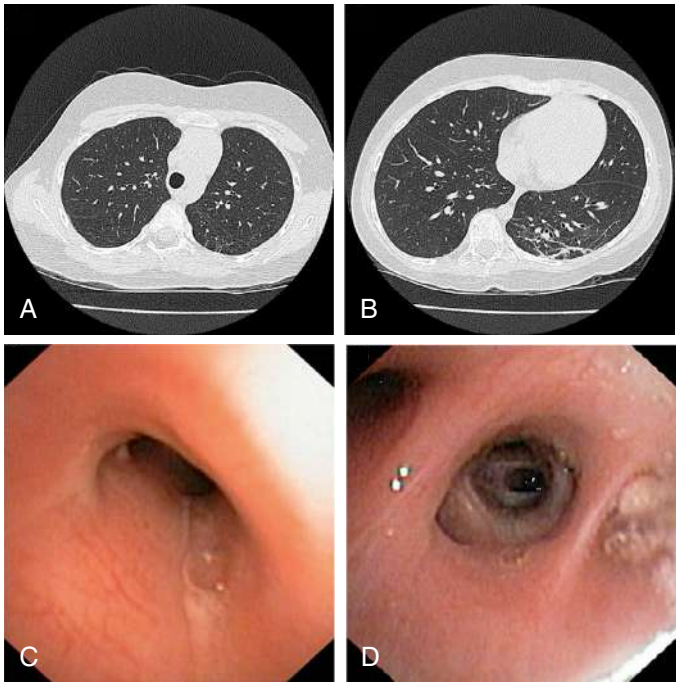

Fig. 452.1 High-resolution chest CT scans (**A** and **B**) and bronchoscopy images (**C** and **D**) in a child with bronchiectasis. (**C** and **D**) Bronchoscopy findings. Images from a chest high-resolution computed tomography (cHRCT) scan (**A** and **B**) in a 10-yr-old girl who presented with a chronic wet cough. The child was treated with a 2-wk course of IV antibiotics (after failing oral antibiotic treatment). The scan was reported as having no evidence of bronchiectasis by pediatric radiologists. At bronchoscopy thick mucus was seen in the trachea (**C**) and the right lower lobe (**D**). The case highlights the need to consider the diagnosis of bronchiectasis on the basis of history, examination findings, and using the pediatric cutoff (bronchoarterial ratio >0.8) for defining bronchiectasis on the cHRCT scan. *(From Goyal V, Grimwood K, Marchant J, et al. Pediatric bronchiectasis: no longer an orphan disease. Pediatr Pulmonol. 2016;51:450–469.)*

TREATMENT

The initial therapy for patients with bronchiectasis is medical and aims at decreasing airway obstruction and controlling infection. Airway clearance techniques (e.g., gravity-assisted drainage, active cycle of breathing, positive expiratory pressure [PEP], acapella, high-frequency chest wall oscillation), antibiotics, and bronchodilators are essential. Two to four weeks of parenteral antibiotics (in hospital or at home) is often necessary to manage more severe acute exacerbations adequately. Exacerbations can be defined as the presence of one major criteria (wet cough enduring longer than 72 hours, increased cough frequency over 72 hours) *plus* one laboratory criteria (C-reactive protein >3 mg/L, serum IL-6 >2 ng/L, serum amyloid A >5 mg/L, elevated neutrophil percentage), two major criteria, or one major criterion *plus* two minor criteria (change in sputum color, breathlessness, chest pain, crackles/crepitations, wheeze). The presence of dyspnea (increased work of breathing) and/or hypoxemia should be considered a severe exacerbation, irrespective of duration.

Antibiotic choice is dictated by the identification and sensitivity of organisms found on deep throat, sputum (induced or spontaneous), or bronchoalveolar lavage fluid cultures. The most common organisms found in children with bronchiectasis include *H. influenzae* non–type b, *S. pneumoniae*, *M. catarrhalis*, *Mycoplasma pneumoniae, Pseudomonas aeruginosa,* and *Staphylococcus aureus*. Viruses (most commonly human rhinovirus) are often found in children with bronchiectasis suffering from an exacerbation. A 14-day course of amoxicillin/clavulanic acid (22.5 mg/kg/dose twice daily) has been particularly successful at treating most pulmonary exacerbations. Azithromycin (5 mg/kg/day) is a reasonable alternative in those with penicillin allergy. For those experiencing frequent exacerbations of more than three per year, long-term prophylactic macrolide antibiotics (which also have immunomodulatory and antiinflammatory properties) or nebulized antibiotics (e.g., tobramycin, colistin, aztreonam, ciprofloxacin) may be beneficial (reduced exacerbations and hospitalizations, improved lung function) but may also increase antibiotic

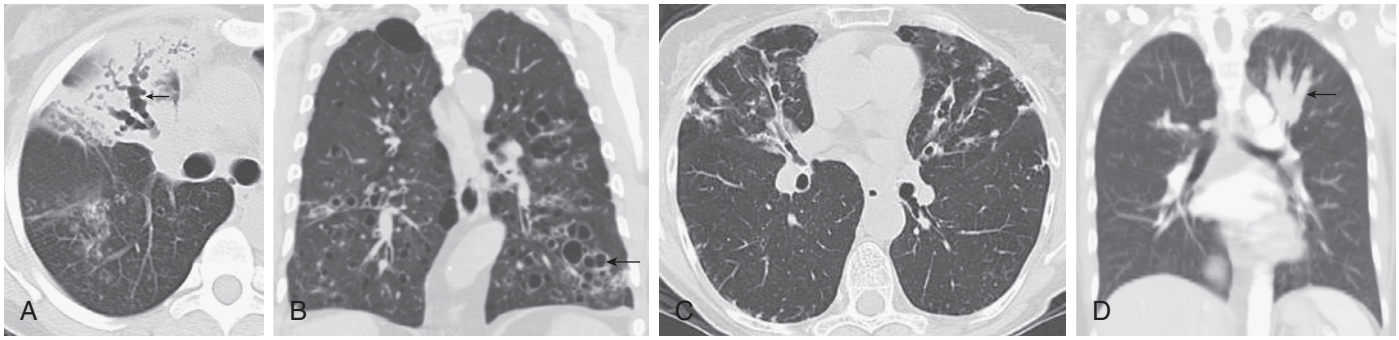

Fig. 452.2 Bronchiectasis. **A,** Axial CT image demonstrates a beaded appearance of dilated bronchi *(arrow)* in the right upper lobe, consistent with varicoid bronchiectasis. **B,** Coronal reformation CT image shows multiple foci of cystic bronchiectasis, with a few air-fluid levels *(arrow)*. Also note paraseptal emphysema, most marked at the right apex. **C,** Bronchiectatic form of chronic atypical mycobacterial infection. Axial CT scan shows extensive bronchiectasis, bronchial wall thickening, and centrilobular nodules, most severe in the middle lobe and lingula. **D,** Allergic bronchopulmonary aspergillosis. Coronal reformation CT image demonstrates impacted bronchi in the left upper lobe *(arrow)* producing a "gloved finger" appearance. *(From Boiselle PM. Airway. In: Haaga JR, Boll DT, eds. CT and MRI of the Whole Body, 6th ed. Philadelphia: Elsevier; 2017: Figs 40-30, 32-34.)*

resistance. Airway hydration (inhaled hypertonic saline or mannitol) also improves quality of life in adults with bronchiectasis, but there are few studies in children. Any underlying disorder (immunodeficiency, aspiration) that may be contributing must be addressed. When localized bronchiectasis becomes more severe or resistant to medical management, segmental or lobar resection may be warranted and may improve growth and reduce the need for intravenous antibiotics. Lung transplantation can also be performed in patients with bronchiectasis. There is no strong evidence to support the routine use of inhaled corticosteroids, although some studies demonstrate improved quality of life and reduced exacerbations in patients with bronchiectasis treated with inhaled corticosteroids. Preventive strategies, including immunization against typical respiratory pathogens (influenza, pneumococci), are generally recommended.

Development of novel treatments is ongoing and centered around targeting three components of the vicious cycle of bronchiectasis: bacterial infection (vitamin D supplementation, exogenous granulocyte-macrophage stimulating factor, phosphodiesterase 4 inhibitors, statins), neutrophilic inflammation (e.g., neutrophil elastase inhibitors, cathepsin C inhibitors, CXCR2 receptor antagonists), and mucociliary clearance (epithelial sodium channel inhibitors).

PROGNOSIS

Children with bronchiectasis often suffer from recurrent pulmonary illnesses, resulting in missed school days, stunted growth, osteopenia, and osteoporosis. The prognosis for patients with bronchiectasis has improved considerably in the past few decades. In some children and adolescents, their bronchiectasis is reversible and/or preventable. Factors important for reversibility and/or prevention of bronchiectasis include early identification and treatment of inhaled foreign bodies, preventing early and severe pneumonia, preventing recurrent protracted bacterial bronchitis, treating primary immunodeficiency disorders causing bronchiectasis, promoting breastfeeding and immunization, and avoiding tobacco smoke and other pollutants.

Thus earlier recognition or prevention of predisposing conditions, specialist multidisciplinary management, more powerful and broad-spectrum antibiotics, and improved surgical outcomes will further improve the prognosis for children with bronchiectasis.

Chapter 453

Pulmonary Abscess

Oren J. Lakser

Lung infection that destroys the lung parenchyma, resulting in cavitations and central necrosis, can result in localized areas composed of thick-walled purulent material called *lung abscesses. Primary* lung abscesses occur in previously healthy patients with no underlying medical disorders and are usually solitary. *Secondary* lung abscesses occur in patients with underlying or predisposing conditions and may be multiple. Lung abscesses are much less common in children (estimated at 0.7 per 100,000 admissions per year) and result in less morbidity than in adults.

PATHOLOGY AND PATHOGENESIS

Multiple conditions predispose children to the development of pulmonary abscesses, including aspiration, pneumonia, cystic fibrosis (see Chapter 454), gastroesophageal reflux (see Chapter 369), tracheoesophageal fistula (see Chapter 365.1), immunodeficiencies, postoperative complications of tonsillectomy and adenoidectomy, seizures, a variety of neurologic diseases, and other conditions associated with impaired mucociliary defense. Lung abscesses have been associated with e-cigarette or vaping product use–associated lung injury (EVALI; see Chapter 450). In children, aspiration of infected materials or a foreign body is the predominant source of the organisms causing abscesses. Initially, pneumonitis impairs drainage of fluid or the aspirated material. Inflammatory vascular obstruction occurs, leading to tissue necrosis, liquefaction, and abscess formation. Abscess can also occur as a result of pneumonia and hematogenous seeding from another site.

If the aspiration event occurred while the child was recumbent, the right and left upper lobes and apical segment of the right lower lobes are the dependent areas most likely to be affected. In a child who was upright, the posterior segments of the upper lobes were dependent and therefore are most likely to be affected. Primary abscesses are found most often on the right side, whereas secondary lung abscesses, particularly in immunocompromised patients, have a predilection for the left side.

Both anaerobic and aerobic organisms can cause lung abscesses. Common anaerobic bacteria that can cause a pulmonary abscess include *Bacteroides* spp., *Fusobacterium* spp., and *Peptostreptococcus* spp. Abscesses can be caused by aerobic organisms such as *Streptococcus angiosus*, group A streptococcus, *Staphylococcus aureus, Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa,* and very rarely, *Mycoplasma pneumoniae.* Aerobic and anaerobic cultures should be part of the workup for all patients with lung abscess. Occasionally, concomitant viral-bacterial infection can be detected. Fungi can also cause lung abscesses, particularly in immunocompromised patients.

CLINICAL MANIFESTATIONS

The most common symptoms of pulmonary abscess in the pediatric population are fever, cough, and emesis. Other common symptoms include tachypnea, dyspnea, chest pain, sputum production, weight loss, and hemoptysis. Physical examination typically reveals tachypnea, dyspnea, retractions with accessory muscle use, decreased breath sounds, and dullness to percussion in the affected area. Crackles and, occasionally, a prolonged expiratory phase may be heard on lung examination.

DIAGNOSIS

Diagnosis is most commonly made on the basis of chest radiography. Classically, the chest radiograph shows a parenchymal inflammation with a cavity containing an air-fluid level (Fig. 453.1). A chest CT scan can provide better anatomic definition of an abscess, including location and size (Fig. 453.2). Ultrasound can also help provide rapid diagnosis and procedural guidance.

An abscess is usually a thick-walled lesion with a low-density center progressing to an air-fluid level. Abscesses should be distinguished from **pneumatoceles**, which often complicate severe bacterial pneumonias and are characterized by thin- and smooth-walled, localized air collections with or without air-fluid level (Fig. 453.3). Pneumatoceles often resolve spontaneously with the treatment of the specific cause of the pneumonia. The differential diagnosis of a cavitary lung lesion is noted in Table 453.1.

The determination of the etiologic bacteria in a lung abscess can be helpful in guiding antibiotic choice. Although Gram stain of sputum can provide an early clue as to the class of bacteria involved, sputum cultures typically yield mixed bacteria and therefore are not always reliable. Attempts to avoid contamination from oral flora include direct lung puncture, percutaneous (aided by CT guidance) or transtracheal aspiration, and bronchoalveolar lavage specimens obtained bronchoscopically. Bronchoscopic aspiration should be avoided, as it can be complicated by massive intrabronchial aspiration, and great care should therefore be taken during the procedure. To avoid invasive procedures in previously normal hosts, empiric therapy can be initiated in the absence of culturable material.

TREATMENT

Conservative management is recommended for pulmonary abscess. Most experts advocate a 2- to 3-week course of parenteral antibiotics

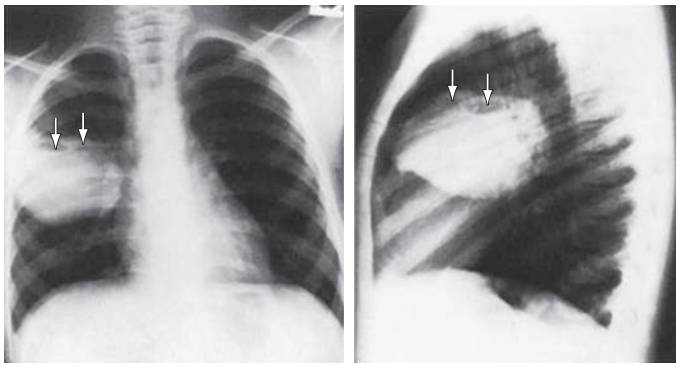

Fig. 453.1 Multiloculated lung abscess *(arrows). (From Brook I. Lung abscess and pulmonary infections due to anaerobic bacteria. In Chernick V, Boat TF, Wilmott RW, et al., eds. Kendig's Disorders of the Respiratory Tract in Children, 7th ed. Philadelphia: WB Saunders; 2006:482.)*

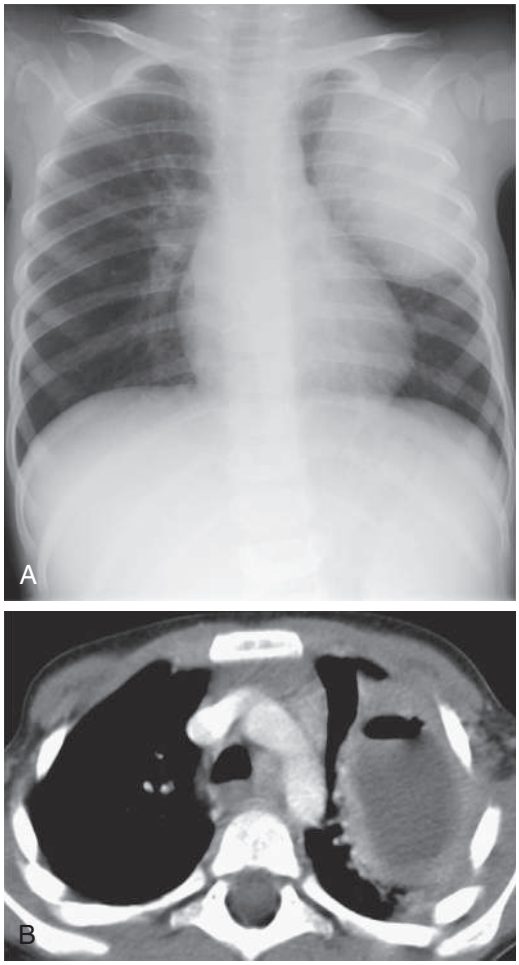

Fig. 453.2 Pulmonary abscess in a 2-yr-old male with persistent cough. **A,** Chest radiograph shows large oval mass in the left upper lobe. **B,** CT scan demonstrates an abscess with a thick enhancing wall that contains both air and fluid. *(From Slovis T, ed. Caffey's Pediatric Diagnostic Imaging, 11th ed. Philadelphia: Mosby; 2008, Fig. 78-3, p. 1297.)*

for uncomplicated cases, followed by a course of oral antibiotics to complete a total of 3-4 weeks. Antibiotic choice should be guided by results of Gram stain and culture but initially should include agents with aerobic and anaerobic coverage. Treatment regimens should include a penicillinase-resistant agent active against *S. aureus* and anaerobic coverage, typically with clindamycin or ampicillin-sulbactam. If gram-negative

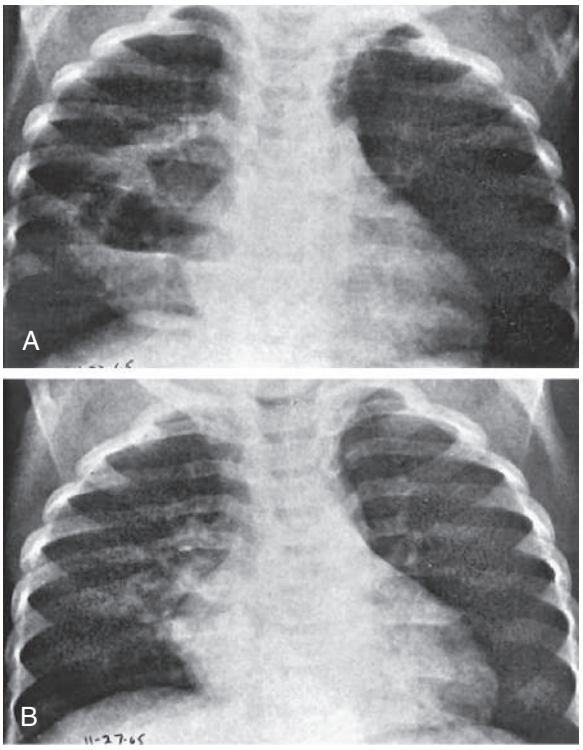

Fig. 453.3 Appearance over a period of 5 days of a large, multiloculated pneumatocele in a segment of alveolar consolidation. **A,** There is a large cavity with two air-fluid levels in a segment of alveolar pneumonia in the right upper lobe. **B,** Five days later, the cavity and most of the pneumonic consolidation have disappeared. *(From Silverman FN, Kuhn JP. Essentials of Caffey's Pediatric X-ray Diagnosis. Chicago: Year Book; 1990:303.)*

bacteria are suspected or isolated, piperacillin-tazobactam or a carbapenem should be added. With improvement, oral antibiotics (clindamycin or amoxicillin-clavulanate) can be used to finish the 4 weeks of total therapy. Early CT-guided percutaneous aspiration or drainage has been advocated by some; it may hasten the recovery and shorten the course of parenteral antibiotic therapy. Nonetheless, antibiotic therapy is successful in ~85% of patients with uncomplicated lung abscesses.

For severely ill patients, patients with larger abscess, or those whose status fails to improve after 7-10 days of appropriate antimicrobial therapy, surgical intervention should be considered. Minimally invasive percutaneous aspiration techniques, often with CT guidance, are the initial and, often, only intervention required. Thoracoscopic drainage has also been successfully used with minimal complications. In rare, complicated cases, thoracotomy (e.g., video-assisted thoracoscopic surgery [VATS] with or without bronchoscopic occlusion) with surgical drainage or lobectomy and/or decortication may be necessary. Abscess drainage is reportedly required in ~20% of cases of pulmonary abscess in children.

PROGNOSIS

Overall, the prognosis for children with primary pulmonary abscesses is excellent. The presence of aerobic organisms may be a negative prognostic indicator, particularly in those with secondary lung abscesses. Most children become asymptomatic within 7-10 days, although the fever can persist for as long as 3 weeks. Radiologic abnormalities usually resolve in 1-3 months but can persist for years (e.g., B-line artifacts on lung ultrasound). Long-term sequalae can also include air trapping/hyperinflation on lung function testing. With treatment, mortality is typically less than 5%.

Table 453.1 Differential Diagnosis of a Cavitary Lesion on Chest Radiograph

INFECTIOUS CAUSES
Bacteria
Oral anaerobes
Less commonly: *Staphylococcus aureus, Klebsiella pneumoniae, Pseudomonas aeruginosa,* enteric gram-negative rods, *Pasteurella multocida, Burkholderia cepacia, Burkholderia pseudomallei, Haemophilus influenzae* types b and c, *Legionella,* group A streptococcus, *Streptococcus pneumoniae, Streptococcus anginosus, Nocardia, Rhodococcus equi, Actinomyces, Clostridium, Capnocytophaga*
Septic Pulmonary Embolism
Originating in septic phlebitis, including Lemierre syndrome and vegetations from tricuspid endocarditis
Mycobacteria
Tuberculosis and nontuberculous pathogens
Fungi
Endemic mycoses (*Histoplasma, Coccidioides,* blastomycosis), *Cryptococcus, Aspergillus,* Zygomycetes
Parasites
Paragonimus westermani, Entamoeba histolytica, Echinococcus
NONINFECTIOUS CAUSES
Neoplasm
Primary lung cancer, metastatic carcinoma (particularly squamous cell)
Pulmonary infarction caused by bland embolus
Vasculitis
Wegener granulomatosis, rheumatoid lung nodule
Airway Disease
Bullae, blebs, or cystic bronchiectasis
Developmental cause
Pulmonary sequestration
Other
Sarcoidosis, achalasia, or transdiaphragmatic bowel herniation giving appearance of cavity with air-fluid level

Modified from Lorber B. Bacterial lung abscess. In: Bennett JE, Dolin R, Blaser M, eds. *Principles and Practice of Infectious Diseases,* 8th ed. Philadelphia: Elsevier; 2014:855–859.

Table 454.1 Complications of Cystic Fibrosis

RESPIRATORY
Bronchiectasis, bronchitis, bronchiolitis, pneumonia
Atelectasis
Hemoptysis
Pneumothorax
Nasal polyps
Sinusitis
Reactive airway disease
Mucoid impaction of the bronchi
Allergic bronchopulmonary aspergillosis
Cor pulmonale
Respiratory failure
GASTROINTESTINAL
Meconium ileus, meconium plug (neonate)
Meconium peritonitis (neonate)
Distal intestinal obstruction syndrome (non-neonatal obstruction)
Rectal prolapse
Intussusception
Volvulus
Fibrosing colonopathy (strictures)
Appendicitis
Intestinal atresia
Pancreatitis (recurrent)
Biliary cirrhosis (portal hypertension: esophageal varices, hypersplenism)
Neonatal obstructive jaundice
Hepatic steatosis
Gastroesophageal reflux
Cholelithiasis
Inguinal hernia
Growth failure (malabsorption)
Vitamin deficiency states (vitamins A, K, E, D)
Insulin deficiency, symptomatic hyperglycemia, diabetes
Malignancy (rare)

Chapter 454

Cystic Fibrosis

Marie E. Egan, Michael S. Schechter, and Judith A. Voynow

Cystic fibrosis (CF) is an inherited multisystem disorder of children and adults; it is the most common life-limiting recessive genetic trait among Whites. Dysfunction of the cystic fibrosis transmembrane conductance regulator (CFTR) protein, the primary defect, leads to a wide and variable array of presenting manifestations and complications.

CF is responsible for most cases of exocrine pancreatic insufficiency in early life and is the major cause of severe chronic lung disease in children. It is also responsible for many cases of hyponatremic salt depletion, nasal polyposis, pansinusitis, rectal prolapse, pancreatitis, cholelithiasis, and nonautoimmune insulin-dependent hyperglycemia. Because CF may manifest as failure to thrive and hepatic dysfunction, including cirrhosis, this disorder enters into the differential diagnosis of many pediatric conditions (Table 454.1).

GENETICS

CF occurs most frequently in White populations of Northern Europe, North America, and Australia/New Zealand. The prevalence in these populations varies but approximates 1 in 3,500 live births (compared with 1 in 9,200 individuals of Hispanic descent and 1 in 15,000 African Americans). Although less frequent in African, Hispanic, Middle Eastern, South Asian, and Eastern Asian populations, the disorder does exist in these populations as well (Fig. 454.1).

CF is inherited as an autosomal recessive trait. The *CF* gene codes for the CFTR protein, which is 1,480 amino acids. CFTR is expressed largely in epithelial cells of airways, the gastrointestinal tract (including the pancreas and biliary system), the sweat glands, and the genitourinary system, but is expressed in other cell types at lower levels. CFTR is a member of

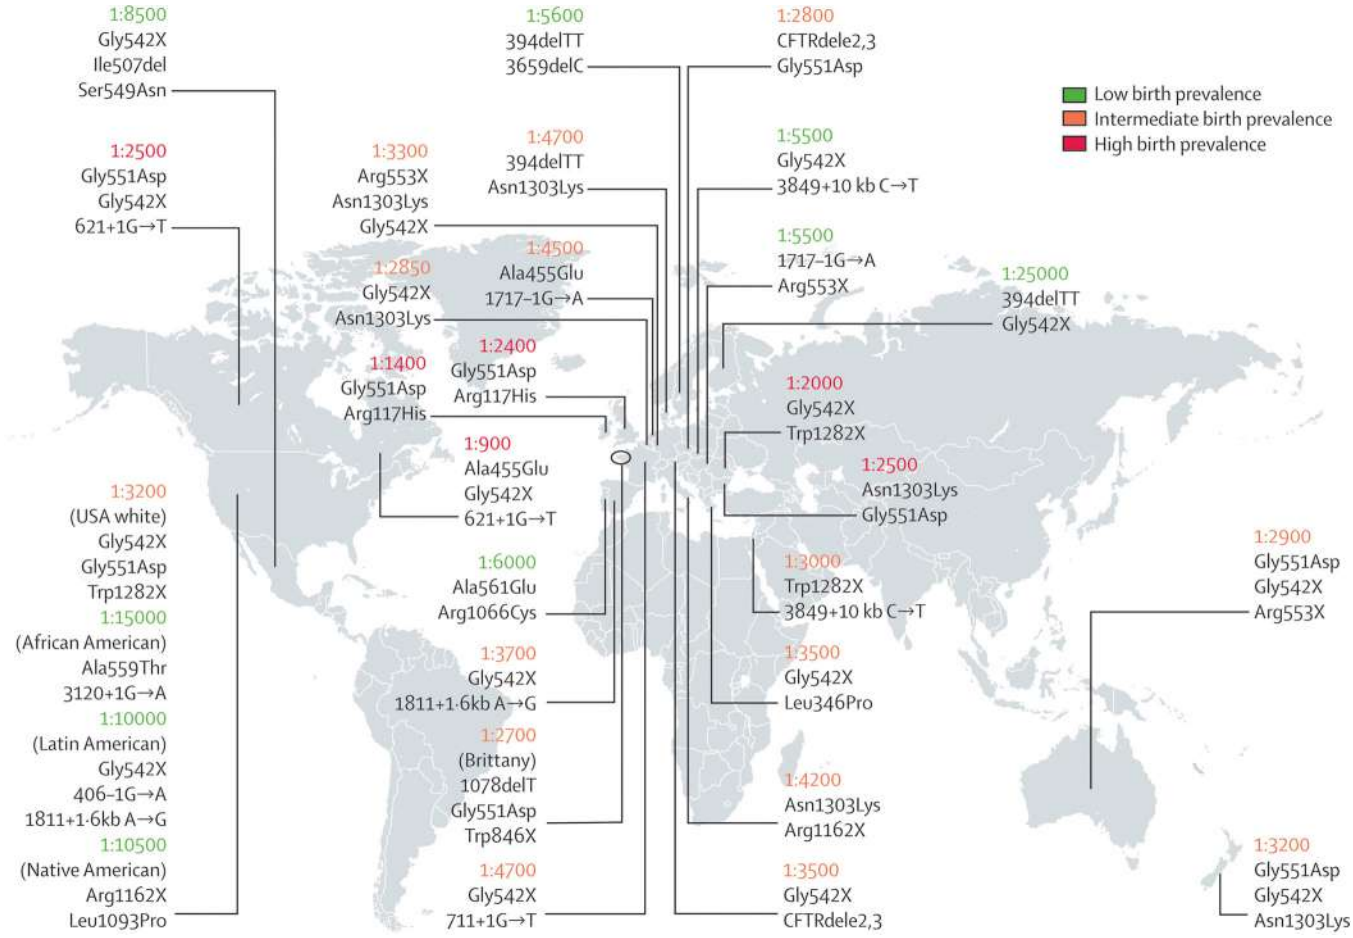

Fig. 454.1 Approximate cystic fibrosis birth prevalence and common pathogenic variants for selected countries. Birth prevalence is reported as the number of live births per case of cystic fibrosis. Common/important pathogenic variants in each region are listed below the prevalence figures. The birth prevalence can vary greatly among ethnic groups in a country. *(From O'Sullivan BP, Freedman SD. Cystic fibrosis. Lancet. 2009;373:1891–1902.)*

the adenosine triphosphate (ATP)–binding cassette superfamily of proteins. It functions as an anion channel and is essential for proper chloride and bicarbonate transport across epithelia. More than 1,900 *CFTR* polymorphisms have been described, many of which are not clearly of clinical significance. Those that are associated with clinical manifestations may be grouped into six main classes based on how they affect protein structure and function (Fig. 454.2). Class I-III pathogenic variants are generally considered to be *severe* pathogenic variants in that they lead to a complete or nearly complete absence of CFTR function, whereas class IV-VI pathogenic variants are associated with some residual functional protein. The most prevalent pathogenic variant of *CFTR* is the deletion of a single phenylalanine residue at amino acid 508 (F508del). This pathogenic variant is responsible for the high incidence of CF in northern European populations and is considerably less frequent in other populations, such as those of southern Europe and Israel. Nearly 50% of individuals with CF in the United States Cystic Fibrosis Foundation (CFF) Patient Registry are homozygous for F508del, and approximately 87% carry at least one F508del gene. The remaining patients have an extensive array of pathogenic variants, none of which has a prevalence of more than several percentage points, except in certain populations; for example, the W1282X pathogenic variant occurs in 60% of Ashkenazi Jews with CF. Through the use of probes for 40 of the most common pathogenic variants, the genotype of 80–90% of Americans with CF can be ascertained. Genotyping using a discrete panel of pathogenic variant probes is quick and less costly than more comprehensive sequencing and is the approach typically used in state newborn screening (NBS) programs. In remaining patients, sequencing the entire *CFTR* gene and looking for deletions and duplications are necessary to establish the genotype.

The relationship between CFTR genotype and clinical phenotype is highly complex. The CFTR pathogenic variant class is strongly associated with pancreatic dysfunction and will usually predict this manifestation in any given patient. Respiratory complications and lung function decline are also correlated with pathogenic variant class severity but with greater variation because of the influence of non-CFTR modifier gene polymorphisms and environmental influences on the manifestations of lung disease in any one individual. Studies have identified specific non-CFTR modifier genes of importance; genome-wide association studies identified a polymorphism on chromosome 11 in the intergenic region between EHF (an epithelial transcription factor) and APIP (an inhibitor of apoptosis) that is associated with lung disease severity and may influence the expression of *EHF* and *APIP,* as well as other genes in the region, including *PDHX, CD44,* and *ELF5*. A region on chromosome 20 may also be found to relate to lung disease severity. This region encompasses several genes *(MC3R, CASS4, AURKA)* that may play a role in lung host defense involving neutrophil function, apoptosis, and phagocytosis. Genome-wide association studies analysis also identified genetic regions that predispose to risk for liver disease, CF-related diabetes, and meconium ileus.

The high frequency of *CFTR* pathogenic variants has been ascribed to resistance to the morbidity and mortality associated with infectious dysenteries through the ages. Cultured CF intestinal epithelial cells homozygous for the F508del pathogenic variant are unresponsive to the secretory effects of cholera toxin. CFTR heterozygous mice experience less mortality when treated with cholera toxin than their unaffected wild-type littermates.

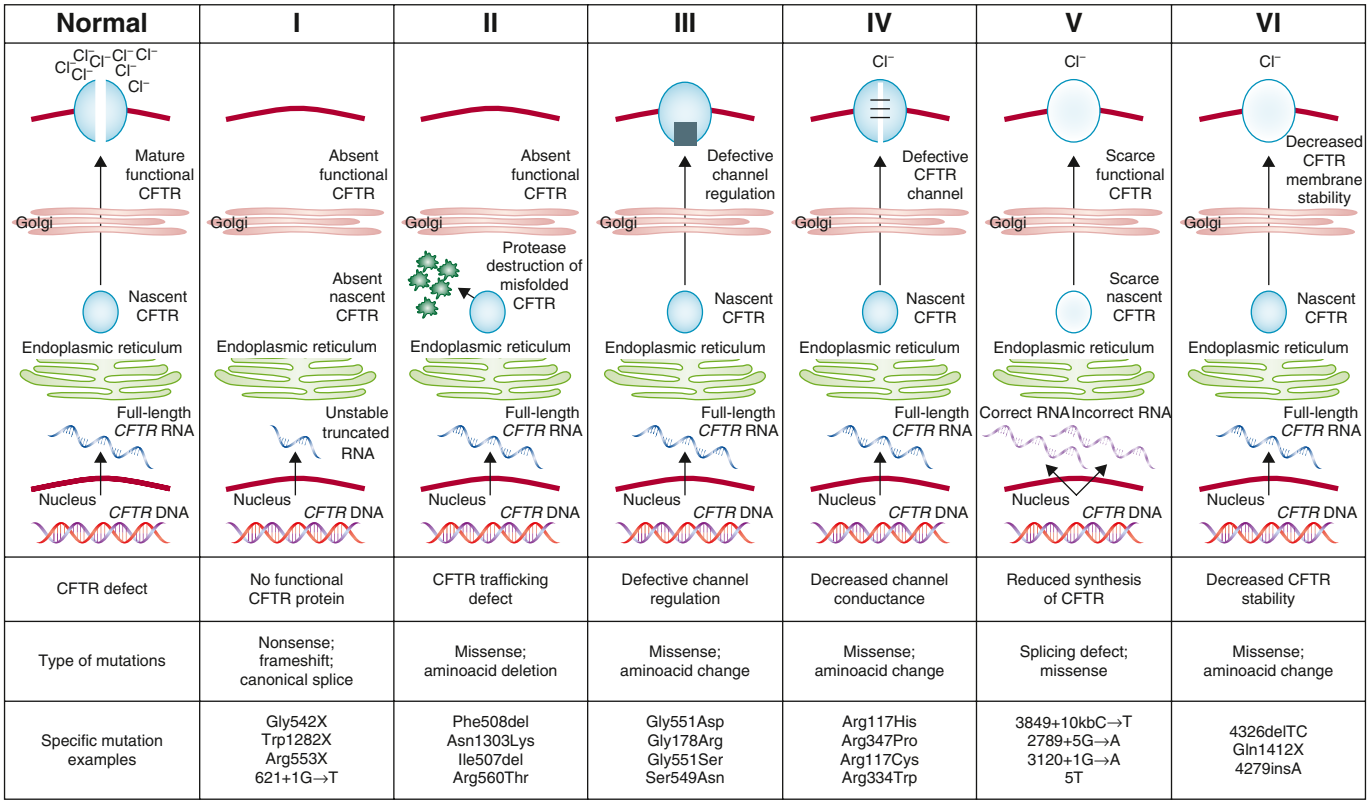

Fig. 454.2 Classes of cystic fibrosis transmembrane conductance regulator *(CFTR)* pathogenic variants. Pathogenic variants in the *CFTR* gene can be divided into six classes. Class I pathogenic variants result in no protein production. Class II pathogenic variants (including the most prevalent, Phe508del) cause retention of a misfolded protein at the endoplasmic reticulum and subsequent degradation in the proteasome. Class III pathogenic variants affect channel regulation, impairing channel opening (e.g., Gly551Asp). Class IV pathogenic variants show reduced conduction—that is, decreased flow of ions (e.g., Arg117His). Class V pathogenic variants cause substantial reduction in mRNA or protein, or both. Class VI pathogenic variants cause substantial plasma membrane instability and include Phe508del when rescued by most correctors (rPhe508del). *(From Boyle MP, De Boeck K. A new era in the treatment of cystic fibrosis: correction of the underlying CFTR defect. Lancet Respir Med. 2013;1:158–163.)*

PATHOGENESIS

A number of long-standing observations of CF are of fundamental pathophysiologic importance; they include failure to clear mucous secretions, a paucity of water in mucous secretions, an elevated salt content of sweat and other serous secretions, and chronic infection limited to the respiratory tract. In addition, there is a greater negative potential difference across the respiratory epithelia of patients with CF than across the respiratory epithelia of control subjects. Aberrant electrical properties are also demonstrated for CF sweat gland duct and rectal epithelia. The membranes of CF epithelial cells are unable to secrete chloride or bicarbonate in response to cyclic adenosine monophosphate–mediated signals, and at least in the respiratory epithelial cells, excessive amounts of sodium are absorbed through these membranes. These defects can be traced to a dysfunction of CFTR. CFTR function is highly regulated and energy dependent; it requires both cyclic adenosine monophosphate–stimulated protein kinase A phosphorylation of the regulatory domain and ATP binding and hydrolysis at the nucleotide binding domains. CFTR also interacts with other ion channels, signal transduction proteins, and the cytoskeleton (Fig. 454.3 and see Fig. 454.2).

Many hypotheses have been postulated to explain how CFTR dysfunction results in the clinical phenotype (Fig. 454.4). It is likely that no one hypothesis explains the full spectrum of disease. One model is that airway hydration homeostasis requires both CFTR and $P2Y_2$-regulated calcium-activated chloride secretion. When extracellular ATP is depleted, such as after viral infections, calcium-activated chloride secretion is not activated, and the failure of CFTR chloride secretion results in dehydrated airway secretions, increased concentration of mucin solids, and more viscoelastic mucus that is not cleared by normal mucociliary transport. Another mechanism that is supported by both primary human airway studies and investigations in the CF pig is that variant CFTR causes failure of HCO_3^- secretion and a more acidic airway surface liquid, which increases mucous viscoelasticity, resulting in poor mucociliary clearance. Mucous secretions are tethered to submucosal gland ducts and are retained and obstruct airways, starting with those of the smallest caliber, the bronchioles. Airflow obstruction at the level of small airways is the earliest observable physiologic abnormality of the respiratory system. CFTR dysfunction in airway smooth muscle has been implicated in tracheal and airway abnormalities in humans and in animal models of the disease (pig and mice). These data suggest that CFTR expression in this nonepithelial tissue contributes to airway constriction.

It is plausible that similar pathophysiologic events take place in the pancreatic and biliary ducts (and in the vas deferens), leading to desiccation of proteinaceous secretions and obstruction. Because the function of sweat gland duct cells is to absorb rather than secrete chloride, salt is not retrieved from the isotonic primary sweat as it is transported to the skin surface; chloride and sodium levels are consequently elevated.

Chronic infection in CF is limited to the airways. One explanation for infection is a sequence of events starting with failure to clear inhaled bacteria promptly and then proceeding to persistent infection and an inflammatory response in airway walls. Another explanation for early infection is the failure of innate immune proteins to kill bacteria in an abnormally acidic airway milieu. In addition, it has been proposed that abnormal CFTR creates a proinflammatory state or amplifies the inflammatory response to initial infections (viral or bacterial). Some investigators have identified primary differences in CF-affected immune cells (including macrophage, neutrophils, lymphocytes, and

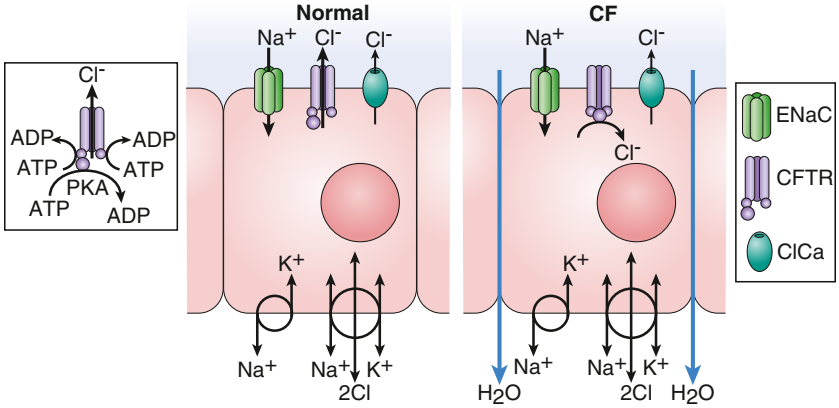

Fig. 454.3 Schematic diagram depicting cystic fibrosis *(CF)* epithelial channel defects, characterized by impaired chloride secretion, massive sodium absorption, and movement of water through the epithelium, leading to a dehydrated airway surface. ADP, Adenosine diphosphate; ATP, adenosine triphosphate; CFTR, cystic fibrosis transmembrane conductance regulator; ClCa, alternative chloride channel; ENaC, epithelium sodium channel; PKA, protein kinase A. *(From Michelson P, Faro A, Ferkol T. Pulmonary disease in cystic fibrosis. In Wilmott RW, Deterding RR, Li A et al., eds. Kendig's Disorders of the Respiratory Tract in Children, 9th ed. Philadelphia: Elsevier; 2019: Fig. 51.1, p. 778.)*

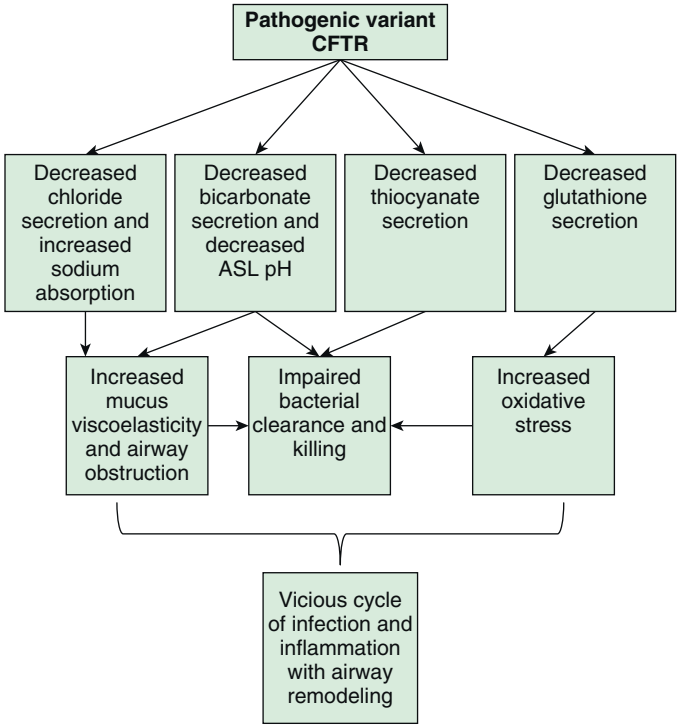

Fig. 454.4 Schema of variant cystic fibrosis transmembrane conductance regulator *(CFTR)* mechanisms of chronic airway disease. CFTR conducts several anions, including chloride, bicarbonate, thiocyanate, and glutathione. The loss of CFTR function affects critical airway epithelial functions: (1) It increases the risk for dehydration of airway surface liquid *(ASL)* with loss of chloride efflux and associated increased sodium channel activity. (2) The loss of secreted bicarbonate and/or acidic pH of the ASL increases mucous viscoelasticity resulting in failure of mucociliary transport. (3) Acidic pH in the ASL impairs normal innate immune clearance of bacteria. (4) Loss of thiocyanate impairs lactoperoxidase bacterial killing. (5) Loss of glutathione secretion depletes the antioxidant capacity of the airway resulting in increased inflammation, increased mucous secretion, and increased mucous viscoelasticity. These factors lead to a vicious cycle of infection and inflammation that is progressive.

dendritic cells) and have suggested that these alterations contribute to this proinflammatory state and to a dysregulated immune response. It appears that inflammatory events occur first in small airways, perhaps because it is more difficult to clear altered secretions and microorganisms from these regions. The agents of airway injury include neutrophil products, such as oxidative radicals and proteases, and immune reaction products. These inflammatory products further aggravate airway obstruction by increasing mucin secretion and altering mucin structure to promote both intramolecular and intermolecular interactions. Excessive inflammatory cell polymers in CF sputum, including DNA, filamentous actin, and glycosaminoglycans, further contribute to abnormal mucous viscoelastic properties and airway obstruction. Chronic bronchiolitis and bronchitis are the initial lung manifestations (see Chapter 439), but after months to years, structural changes in airway walls produce bronchiolectasis and **bronchiectasis**. With advanced lung disease, infection may extend to peribronchial lung parenchyma.

A central feature of lung disease in patients with CF is the high prevalence of airway infection with *Staphylococcus aureus* (see Chapter 227.1), *Pseudomonas aeruginosa* (see Chapter 251.1), and *Burkholderia cepacia* complex (see Chapter 251.2), organisms that rarely infect the lungs of other individuals. It has been postulated that the CF airway epithelial cells or surface liquids may provide a favorable environment for harboring these organisms. CF airway epithelium may be compromised in its innate defenses against these organisms, through either acquired or genetic alterations. Antimicrobial activity is diminished in CF secretions; this diminution may be related to hyperacidic surface liquids or other effects on innate immunity. Another puzzle is the propensity for *P. aeruginosa* to undergo mucoid transformation in the CF airways. The complex polysaccharide produced by these organisms generates a biofilm that provides a hypoxic environment and thereby protects *Pseudomonas* against antimicrobial agents.

Altered lipid homeostasis has been implicated as a predisposing factor for respiratory tract infection and inflammation. Concentrations of lipoxins—molecules that suppress neutrophilic inflammation—are suppressed in CF airways. There is an imbalance of lipids with increased arachidonic acid and decreased docosahexaenoic acid, which promotes inflammation. There is also an imbalance of ceramide in the CF airway that is proinflammatory. Supporting the idea that altered lipid uptake affects infection and inflammation is the observation that the 10–15% of individuals with CF who retain substantial exocrine pancreatic function have delayed acquisition of *P. aeruginosa* and slower deterioration of lung function. However, it appears that nutritional factors are contributory only because preservation of pancreatic function does not preclude development of typical lung disease.

The variation in progression of lung disease seen in patients with CF is also influenced by social and physical environment factors, whose impact matches that of the CFTR genotype. Exposure to environmental tobacco smoke and outdoor air pollutants and early acquisition of respiratory virus infections, as well as pathogenic organisms like *P. aeruginosa* and methicillin-resistant *S. aureus* (MRSA), have been implicated as causes of worsening disease. Sex/gender disparities also seem to exist, with females having a poorer prognosis. Although studies have suggested that estrogen may influence disease exacerbations, the gap seems to be narrowing.

Although most CF care is delivered at specialty centers and is broadly influenced by current clinical guidelines, there is enough variability in treatment approaches to cause large variation in respiratory and

nutritional outcomes across the care networks in both North America and Europe. Social determinants of health are associated with significant disparities in outcome; socioeconomic status has been shown to be a strong predictor of mortality, as well as both nutritional status and lung function on both sides of the Atlantic. The specific mechanism of effect is unclear, but evidence suggests a role for socioeconomic status–related differences in health behaviors and disease self-management practices, stress and mental health issues, and environmental tobacco smoke exposure. Differential access to specialty care and medications are also known to affect clinical outcomes.

PATHOLOGY

The earliest pathologic lesion in the lung is that of bronchiolitis (mucous plugging and an inflammatory response in the walls of the small airways); with time, mucous accumulation and inflammation extend to the larger airways *(bronchitis)* (see Chapter 439.2). Goblet cell hyperplasia and submucosal gland hypertrophy become prominent pathologic findings, which is most likely a response to chronic airway infection. Organisms appear to be confined to the endobronchial space; invasive bacterial infection is not characteristic. With long-standing disease, evidence of airway destruction such as **bronchiolar obliteration**, **bronchiolectasis**, and **bronchiectasis** (see Chapter 452) becomes prominent. Imaging modalities demonstrate both increased airway wall thickness and luminal cross-sectional area relatively early in lung disease evaluation. Bronchiectatic cysts and emphysematous bullae or subpleural blebs are frequent with advanced lung disease, with the upper lobes being most commonly involved. These enlarged air spaces may rupture and cause pneumothorax. Interstitial disease is not a prominent feature, although areas of fibrosis appear eventually. Bronchial arteries are enlarged and tortuous, contributing to a propensity for hemoptysis in bronchiectatic airways. Small pulmonary arteries eventually display medial hypertrophy, which would be expected in secondary pulmonary hypertension.

The **paranasal sinuses** are uniformly filled with secretions containing inflammatory products, and the epithelial lining displays hyperplastic and hypertrophied secretory elements (see Chapter 429). Polypoid lesions within the sinuses and erosion of bone have been reported. The nasal mucosa may form large or multiple **polyps**, usually from a base surrounding the ostia of the maxillary and ethmoidal sinuses.

The **pancreas** is usually small, occasionally cystic, and often difficult to find at postmortem examination. The extent of involvement varies at birth. In infants, the acini and ducts are often distended and filled with eosinophilic material. In 85–90% of patients, the lesion progresses to complete or almost complete disruption of acini and replacement with fibrous tissue and fat. Infrequently, foci of calcification may be seen on radiographs of the abdomen. The islets of Langerhans contain normal-appearing β cells, although they may begin to show architectural disruption by fibrous tissue in the second decade of life.

The **intestinal tract** shows only minimal changes. Esophageal and duodenal glands are often distended with mucous secretions. Concretions may form in the appendiceal lumen or cecum. Crypts of the appendix and rectum may be dilated and filled with secretions.

Focal biliary cirrhosis secondary to blockage of intrahepatic bile ducts is uncommon in early life, although it is responsible for occasional cases of prolonged neonatal jaundice. This lesion becomes much more prevalent and extensive with age and is found in 70% of patients at postmortem examination. This process can proceed to symptomatic multilobular biliary cirrhosis that has a distinctive pattern of large, irregular parenchymal nodules and interspersed bands of fibrous tissue. Approximately 30–70% of patients have fatty infiltration of the liver, in some cases despite adequate nutrition. At autopsy, hepatic congestion secondary to cor pulmonale can be observed. The gallbladder may be hypoplastic and filled with mucoid material and often contains stones. The epithelial lining often displays extensive mucous metaplasia. Atresia of the cystic duct and stenosis of the distal common bile duct have been observed.

Glands of the uterine cervix are distended with mucus, copious amounts of which collect in the cervical canal. In >95% of males, the body and tail of the epididymis, the vas deferens, and the seminal vesicles are obliterated or atretic, resulting in male infertility.

CLINICAL MANIFESTATIONS

Since the universal adoption of CF NBS, along with the evolution of aggressive and proactive treatment approaches, the clinical face of CF is quite different from what it was in earlier decades. Diagnosis is typically accomplished before 1 month of age, before any obvious clinical symptoms or signs, and treatment is targeted at immediately correcting nutritional deficiencies and delaying the respiratory complications of the disease. The interaction of pathogenic variant heterogeneity and environmental factors leads to highly variable involvement of the lungs, pancreas, and other organs. A summary of the time course of potential development of clinical manifestations is shown in Figure 454.5.

Respiratory Tract

Infants diagnosed by CF NBS are generally asymptomatic from a respiratory standpoint. Nonetheless, the majority are infected with *S. aureus*, *Haemophilus influenza*, or even *P. aeruginosa* within the first month of life, and chest CT scans show characteristic heterogeneous air trapping in ~65% of infants by their first birthday, and bronchiectasis is found in more than

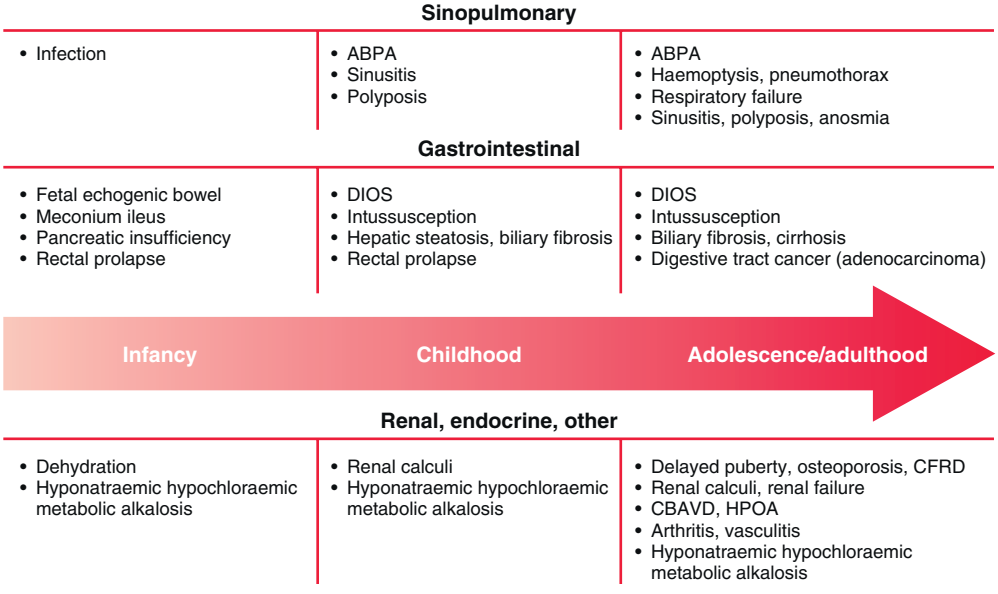

Fig. 454.5 Approximate age of onset of clinical manifestations of cystic fibrosis. ABPA, Allergic bronchopulmonary aspergillosis; CBAVD, congenital bilateral absence of the vas deferens; *CFRD,* cystic fibrosis–related diabetes mellitus; DIOS, distal intestinal obstruction syndrome; HPOA, hypertrophic pulmonary osteoarthritis. *(From O'Sullivan BP, Freedman SD. Cystic fibrosis. Lancet. 2009;373:1891–1902.)*

10% of 1-year-olds and ~60% of 5-year-olds. The earliest symptom is usually a cough that may begin with a viral respiratory tract infection but then persists unless treated with antibiotics. With treatment, the generally realized goal is for patients to remain asymptomatic throughout childhood, except for the periodic development of cough, chest congestion, sputum production, and/or wheezing that define a *pulmonary exacerbation*.

The rate of progression of lung disease is the chief determinant of morbidity and mortality. As lung disease slowly progresses, chronic cough, sputum production, exercise intolerance, shortness of breath, and inability to maintain weight are noted. Common pulmonary complications include atelectasis, hemoptysis, and pneumothorax; these usually appear in late adolescence or beyond. Cor pulmonale, respiratory failure, and death eventually supervene unless lung transplantation is accomplished; this has become increasingly uncommon in childhood. Infection with certain strains of *B. cepacia* and other multidrug-resistant organisms such as non-tuberculous mycobacteria may be associated with particularly rapid pulmonary deterioration.

Children with CF are unlikely to exhibit any abnormal findings on physical exam except during pulmonary exacerbations. Eventual physical findings include increased anteroposterior diameter of the chest, generalized hyperresonance, scattered or localized coarse crackles, and digital clubbing. Expiratory wheezes may be heard, a manifestation of airway inflammation and edema that may or may not be associated with bronchodilator responsiveness. Cyanosis is a late sign. Even though the paranasal sinuses are virtually always opacified radiographically, acute sinusitis is infrequent. Nasal obstruction, rhinorrhea, and anosmia are common, caused by inflamed, swollen mucous membranes or, in some cases, nasal polyposis. Nasal polyps are most troublesome between 5 and 20 years of age and often require repeated surgeries to control.

Intestinal Tract

In 15–20% of newborn infants with CF, the ileum is completely obstructed by meconium **(meconium ileus)**. The frequency is greater among siblings born subsequent to a child with meconium ileus, and concordance is particularly striking in monozygotic twins, reflecting a genetic contribution from one or more unknown modifying genes. Abdominal distention, emesis, and failure to pass meconium appear in the first 24-48 hours of life (see Chapter 135) and often require surgical intervention. Abdominal radiographs (Fig. 454.6) show dilated loops of bowel with air-fluid levels and, frequently, a collection of granular, "ground-glass" material in the lower central abdomen. Rarely, **meconium peritonitis** results from intrauterine rupture of the bowel wall and can be detected radiographically as the presence of peritoneal or scrotal calcifications. These infants may need bowel resection, leading to significant nutritional challenges caused by short bowel syndrome superimposed upon pancreatic insufficiency.

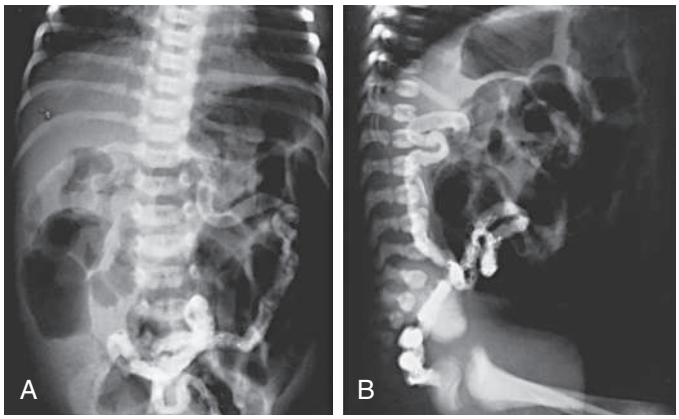

Fig. 454.6 A and B, Contrast enema study in a newborn infant with abdominal distention and failure to pass meconium. Notice the small diameter of the sigmoid and ascending colon and dilated, air-filled loops of small intestine. Several air-fluid levels in the small bowel are visible on the upright lateral view.

Constipation and ileal obstruction with fecal material **(distal intestinal obstruction syndrome [DIOS])** occur in older children, causing cramping abdominal pain, abdominal distention, and obstruction that can be treated with medical approaches to bowel evacuation—typically oral hyperosmotic polyethylene glycol preparations, and occasionally, in more severe cases, hyperosmotic contrast enemas.

More than 85% of children with CF have *exocrine* pancreatic insufficiency, causing protein and fat malabsorption. Symptoms, if untreated, include frequent, bulky, greasy stools and failure to gain weight even when food intake appears to be large. Weight gain can be challenging, but attainment of normal growth and development is an expectation of treatment. A protuberant abdomen, decreased muscle mass, poor growth, and delayed maturation are classic and rarely seen physical signs. Excessive flatus may be a problem even in well-nourished children. Supplementation with fat-soluble vitamin preparations has made deficiencies of vitamins A, E, and K unusual, but vitamin D deficiency continues to be prevalent, and although rickets is rare, osteoporosis is common, especially in older patients and those with more severe lung disease. Class IV-VI pathogenic variants are associated with pancreatic *sufficiency,* but patients with these pathogenic variants are prone to recurrent pancreatitis when they reach adolescence.

Historically a relatively common event, **rectal prolapse** occurs much less frequently as the result of earlier diagnosis and initiation of pancreatic enzyme replacement therapy.

Biliary Tract

Infants may occasionally present with **neonatal jaundice** suggestive of biliary obstruction. Evidence of later liver dysfunction is most often detected in the first 15 years of life and can be found in up to 30% of individuals. **Biliary cirrhosis** develops in about 5–7% of patients. Manifestations can include icterus, ascites, hematemesis from esophageal varices, and evidence of hypersplenism. Biliary colic secondary to cholelithiasis may occur in the second decade or later. Liver disease occurs independent of genotype but is associated with meconium ileus and pancreatic insufficiency.

Cystic Fibrosis–Related Diabetes and Pancreatitis

Endocrine pancreatic insufficiency tends to develop in the second decade and beyond and is more common in patients with a family history of type 2 diabetes mellitus. It most commonly begins with postprandial hyperglycemia and may or may not be accompanied by weight loss or flattening weight gain. Fasting hyperglycemia and elevated hemoglobin A_{1c} are later manifestations. Ketoacidosis usually does not occur because insulin deficiency is relative and not absolute, but eye, kidney, and other vascular complications have been noted in patients living ≥10 years after the onset of hyperglycemia. Recurrent acute pancreatitis occurs occasionally in adolescents and adults who have residual function CFTR pathogenic variants with exocrine pancreatic sufficiency.

Genitourinary Tract

Virtually all males are **azoospermic** because of failure of development of wolffian duct structures, but sexual function is generally unimpaired. The female fertility rate is diminished, especially in women who have poor nutrition or advanced lung disease. Pregnancy is generally tolerated well by women with good pulmonary function but may accelerate pulmonary progression in those with advanced lung disease and may lead to glucose intolerance that persists after the pregnancy is over. Urinary incontinence associated with cough occurs in 18–47% of female children and adolescents.

Sweat Glands

Excessive loss of salt in the sweat predisposes young children to salt depletion episodes, especially during episodes of gastroenteritis and during warm weather. These children may present with **hypochloremic alkalosis**. Hyponatremia is a risk particularly in warm climates. Frequently, parents notice salt *frosting* of the skin or a salty taste when they kiss the child. A few genotypes are associated with relatively normal sweat chloride values.

DIAGNOSIS AND ASSESSMENT

CF is diagnosed when an individual has both a clinical presentation of the disease (such as elevated immunoreactive trypsinogen in the newborn period or signs and symptoms discussed earlier in older patients) and evidence of CFTR dysfunction (physiologic assays and/or the presence of disease-causing CFTR genetic variants) (Table 454.2). This simple formulation is complicated by the existence of CFTR genetic variants that are associated with little or no compromise of CFTR function and are therefore of no or varying clinical consequence, leading to a number of patients who fall into "gray" areas.

DIAGNOSIS OF CF VIA NEWBORN SCREENING

All CF NBS algorithms begin in the first days of life with the measurement of serum immunoreactive trypsinogen (IRT), a pancreatic proenzyme that is elevated in almost all infants with CF. Because IRT levels can fluctuate day by day and season by season, most states set a cutoff level based on an average of IRT levels (e.g., ≥95% percentile). Depending on the state, three different CF NBS algorithms are used:

1. IRT/DNA: This is the most commonly used algorithm. A CFTR gene pathogenic variant screening panel (whose composition varies by state) is applied to the original blood spot. Because not all pathogenic variants are included in the screening panel, the finding of just one CFTR pathogenic variant represents a positive screen. Some states (California, New York) perform gene sequencing from the dried blood spot in response to finding one CFTR gene pathogenic variant.
2. IRT/IRT: The IRT is repeated 2-4 weeks later. In infants without CF, the second IRT is usually normal, whereas in infants with CF, it is persistently elevated, representing a positive screen. This approach has been shown to have lower sensitivity than IRT/DNA.
3. IRT/IRT/DNA: Lower cutoffs are used for IRT than in the states with IRT/IRT algorithms, and in infants with persistently elevated IRT, pathogenic variant screening is performed, and the finding of at least one pathogenic variant represents a positive screen.

A positive CF NBS test only identifies infants with a high likelihood of having CF, but it is not diagnostic for CF. Any infant with a positive CF NBS test should have a sweat chloride test (SCT) performed to confirm the diagnosis of CF. In states using the IRT-IRT algorithm, about 20% of those who have a positive CF NBS are subsequently diagnosed with CF by SCT. In states using the IRT-DNA algorithm, only about 10% of infants who are found to have just one CF-causing pathogenic variant from the screening panel are found to have CF (depending on the pathogenic variant screening panel and ethnic background of the child). Even in cases where two CF-causing pathogenic variants have been identified, sweat testing is indicated to rule out laboratory error or misidentification of newborn blood spots.

Table 454.2 Diagnostic Criteria for Cystic Fibrosis (CF)

Presence of typical clinical features (respiratory, gastrointestinal, or genitourinary)
or
A history of CF in a sibling
or
A positive newborn screening test
plus
Laboratory evidence for CFTR (CF transmembrane regulator) dysfunction:
Two elevated sweat chloride concentrations obtained on separate days
or
Identification of two CF pathogenic variants
or
An abnormal nasal potential difference measurement

DIAGNOSIS OF CYSTIC FIBROSIS OUTSIDE OF NEWBORN SCREENING

Although most cases of CF are diagnosed through NBS, there is still a need to consider the diagnosis in the occasional older patient. This is because NBS is not performed everywhere, and even for individuals who were screened, there is the possibility of a false negative. Most older patients whose diagnosis was missed early in life will have unusual class IV, V, or VI pathogenic variants and therefore *normal* pancreatic function. A CF diagnosis in individuals outside of NBS relies on (1) clinical evidence, such as a chronic productive cough resulting from either bronchitis or chronic sinusitis, nasal polyps, allergic bronchopulmonary aspergillosis or unexplained bronchiectasis, congenital bilateral absence of the vas deferens (CBAVD) (in males) or recurrent pancreatitis, and (2) evidence of CFTR dysfunction (such as CFTR molecular genetic analysis, SCT, or other CFTR physiologic tests).

Sweat Testing

The sweat test, which involves using pilocarpine iontophoresis to collect sweat and performing chemical analysis of its chloride content, is the standard approach to the diagnosis of CF. The procedure requires meticulous attention to detail, and its accuracy can only be assumed when performed at CF Foundation–accredited care centers. An electric current is used to carry pilocarpine into the skin of the forearm and locally stimulate the sweat glands because the measurement is validated under conditions of maximal sweat production. Sweat testing is accurate at any postnatal age, but adequate sweat rates are harder to attain in infants less than 36 weeks gestational age and/or less than 2 kg in weight. Positive results should be confirmed; for a negative result, the test should be repeated if suspicion of the diagnosis remains.

More than 60 mmol/L of chloride in sweat is diagnostic of CF when one or more criteria are present. In individuals with a positive NBS, a sweat chloride level less than 30 mmol/L indicates that CF is unlikely. Borderline (or intermediate) values of 30-59 mmol/L have been reported in patients of all ages who have CF with atypical involvement and require further testing. Table 454.3 lists the conditions associated with false-negative and false-positive sweat test results.

Table 454.3 Conditions Associated with False-Positive and False-Negative Sweat Test Results

WITH FALSE-POSITIVE RESULTS
Eczema (atopic dermatitis)
Ectodermal dysplasia
Malnutrition/failure to thrive/deprivation
Anorexia nervosa
Congenital adrenal hyperplasia
Adrenal insufficiency
Glucose-6-phosphatase deficiency
Mauriac syndrome
Fucosidosis
Familial hypoparathyroidism
Hypothyroidism
Nephrogenic diabetes insipidus
Pseudohypoaldosteronism
Klinefelter syndrome
Familial cholestasis syndrome
Autonomic dysfunction
Prostaglandin E infusions
Munchausen syndrome by proxy
WITH FALSE-NEGATIVE RESULTS
Dilution
Malnutrition
Edema
Insufficient sweat quantity
Hyponatremia
Cystic fibrosis transmembrane conductance regulator pathogenic variants with preserved sweat duct function

DNA Testing

Several commercial laboratories provide screening panels that test for the most common CFTR pathogenic variants. The American College of Medical Genetics recommends at least 23; other panels screen for >100 pathogenic variants. The sensitivity of these panels depends on the race/ethnicity of the population tested, but is always well under 100%, so it is important to view them as screening, but not definitive, diagnostic tests. Whole CFTR gene sequencing with additional attention to deletions and duplications is available but is expensive and only helpful in very select situations.

Other Physiologic Measures of CFTR Function

The finding of increased potential differences across nasal epithelium **(nasal potential difference)**, that is the increased voltage response to topical amiloride application, followed by the absence of a voltage response to a β-adrenergic agonist, has been used to confirm the diagnosis of CF in patients with equivocal or frankly normal sweat chloride values. Intestinal current measurements may also provide additional helpful information, particularly in children who are unable to cooperate with nasal potential difference testing. These procedures are primarily used in research applications and have never undergone extensive validation as a clinical tool.

OTHER LABORATORY TESTING OF IMPORTANCE IN DIAGNOSIS AND MANAGEMENT

Pancreatic Function

The diagnosis of pancreatic insufficiency can be made by the quantification of *elastase-1 activity* in a fresh stool sample by an enzyme-linked immunosorbent assay specific for human elastase. The quantification of fat malabsorption with a 72-hour stool collection is rarely performed in the clinical setting. CF-related diabetes affects approximately 20% of adolescents and 40–50% of adults, and clinical guidelines recommend yearly oral glucose tolerance testing (OGTT) after age 10. OGTT may sometimes be clinically indicated at an earlier age. Spot testing of blood and urine glucose levels and glycosylated hemoglobin levels are not sufficiently sensitive.

Radiology

Hyperinflation of lungs occurs early and is often accompanied by nonspecific peribronchial thickening (Fig. 454.7). Bronchial thickening and plugging and ring shadows suggesting bronchiectasis usually appear first in the upper lobes. Nodular densities, patchy atelectasis, and confluent infiltrate follow. Hilar lymph nodes may be prominent. With advanced disease, impressive hyperinflation with markedly depressed diaphragms, anterior bowing of the sternum, and a narrow cardiac shadow are noted.

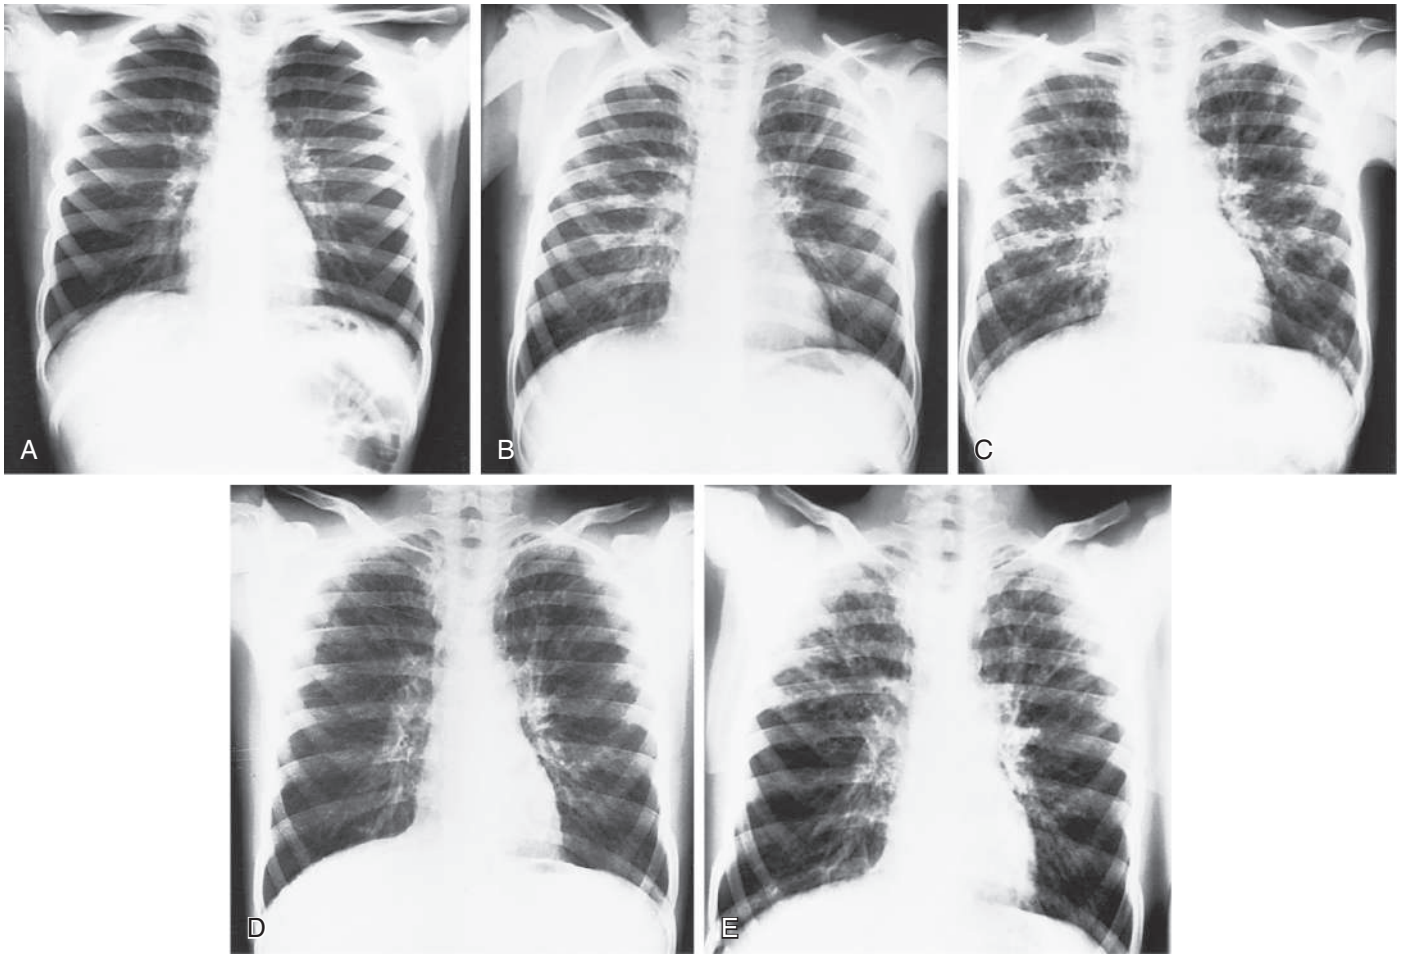

Fig. 454.7 Serial radiographs in a child show the changing appearance of cystic fibrosis over 6 yr. **A,** At 9 yr, frontal radiograph shows minimal peribronchial thickening and hyperaerated lungs indistinguishable from asthma. **B,** Nineteen mo later, the radiographic picture has worsened considerably. Extensive peribronchial thickening is now noted. Mucoid impaction of the bronchus is seen in the left upper lobe, and hilar shadows have become abnormally prominent. **C,** Ten mo later, further deterioration is obvious. Widespread typical changes of cystic fibrosis (CF) are noted throughout both lungs. **D,** Follow-up studies show considerable improvement, which suggested that some of the changes evident on (C) were from superimposed infection. **E,** One yr later, note the progressive changes of CF—most severe in the upper lobes bilaterally. *(From Long FR, Druhan SM, Kuhn JP. Diseases of the bronchi and pulmonary aeration. In Slovis T, ed. Caffey's Pediatric Diagnostic Imaging, 11th ed. Philadelphia: Mosby; 2008: Fig. 73-54.)*

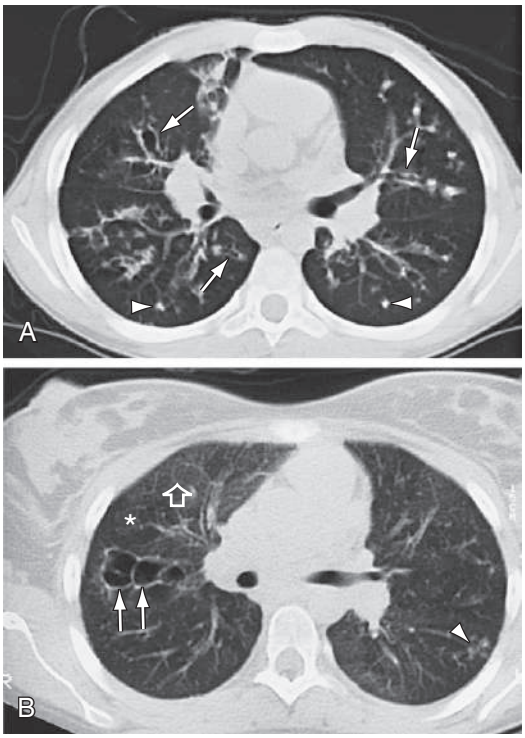

Fig. 454.8 CT scans of the chest in cystic fibrosis. **A,** A 12-yr-old male with moderate lung disease. Airway and parenchymal changes are present throughout both lungs. Multiple areas of bronchiectasis *(arrows)* and mucous plugging *(arrowheads)* can be seen. **B,** A 19-yr-old female has mostly normal lung with one area of saccular bronchiectasis in the right upper lobe *(arrows)* and a focal area of peripheral mucous plugging in the left lower lobe *(arrowhead).* Lung density is heterogeneous with areas of normal lung *(open arrow)* and areas of low attenuation reflecting segmental and subsegmental air trapping *(asterisk).*

Cyst formation, extensive bronchiectasis, dilated pulmonary artery segments, and segmental or lobar atelectasis is often apparent with advanced disease. Most CF centers obtain chest radiographs (posteroanterior [PA] and lateral) at least annually. CT of the chest can detect heterogeneous hyperinflation and localized thickening of bronchial airway walls, mucous plugging, focal hyperinflation, and bronchiectasis (Fig. 454.8). CT abnormalities are commonly seen as early as the first year of life and even in asymptomatic children with normal lung function.

Radiographs of paranasal sinuses reveal panopacification and, often, failure of frontal sinus development. CT provides better resolution of sinus changes if this information is required clinically.

Fetal ultrasonography may show pancreatic changes indicative of CF and suggest ileal obstruction with meconium early in the second trimester, but this finding is not predictive of meconium ileus at birth.

Pulmonary Function

Infant pulmonary function testing is done routinely for clinical evaluation at a few CF centers, but given its complexity and the need for sedation, for the most part it is reserved for research protocols. Lung clearance index (LCI), measured by multiple breath washout, can be done in infants and young children and is a sensitive measure of ventilation inhomogeneity caused by small airways disease. Currently it is primarily used for research, but given its ease and applicability, it may be adopted as a standard monitoring tool in the future as CF care centers become more accustomed to its use.

Standard pulmonary function studies are usually obtained starting at about 4 years of age and are routinely done by age 6. **Forced expiratory volume in 1 second** (FEV_1) is the measurement that has been shown to correlate most closely with mortality and shows a gradual decline averaging 2–3% per year throughout childhood. Although a small number of children may already show evidence of airway obstruction

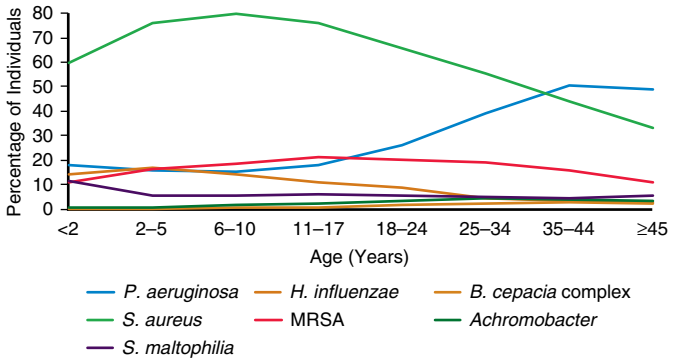

Fig. 454.9 Prevalence of respiratory microorganisms by age cohort, 2021. *(From the Cystic Fibrosis Patient Registry 2021. Annual Data Report. p. 30. © 2022 Cystic Fibrosis Foundation. Bethesda, Maryland. https://www.cff.org/sites/default/files/2021-11/Patient-Registry-Annual-Data-Report.pdf)*

by age 6, trends over the past several decades, as reported by the CFF patient registry, show a steady improvement in average FEV_1 of the CF population. The proportion of people with CF age 18 years who are in the normal/mild lung disease category (FEV_1 ≥70% predicted) has increased from 33.8% in 1989 to 78.3% in 2019. The proportion in the severe lung disease category (FEV_1 <40% predicted) has decreased from 24.0% in 1988 to 2.6% in 2019. Residual volume and functional residual capacity are increased early in the course of lung disease and are the cause of decreasing forced vital capacity (FVC) measurement. Restrictive changes, characterized by declining total lung capacity and vital capacity, correlate with extensive lung injury and fibrosis and are a late finding. Testing at each clinic visit is recommended to evaluate the course of the pulmonary involvement and allow for early intervention when clinically significant decrements are documented—an acute drop in FEV_1 is probably the most sensitive indicator of a pulmonary exacerbation that should be treated with systemic antibiotics.

Microbiologic Studies

H. influenza and *S. aureus* are the most common organisms recovered in young children (Fig. 454.9). *Pseudomonas* may be acquired early and is an organism of key significance. *P. aeruginosa* appears to have a special propensity for the CF airway and over time characteristically develops a biofilm associated with a mucoid appearance in the microbiology lab and which correlates with more rapid progression of lung disease. Once *P. aeruginosa* develops a mucoid phenotype, it is extremely difficult to eradicate from the airway. A wide range of other organisms are frequently recovered, particularly in advanced lung disease; they include a variety of gram-negative rods, including the *B. cepacia* complex, which may be associated with a fulminant downhill course **(cepacia syndrome)**; *Stenotrophomonas maltophilia* and *Achromobacter xylosoxidans;* assorted fungi, especially *Aspergillus fumigatus,* which is most important because of the relatively common development of **allergic bronchopulmonary aspergillosis**; and nontuberculous mycobacterial species, especially *Mycobacterium avium* complex and *Mycobacterium abscessus*. Airway cultures are obtained regularly, most typically using oropharyngeal swabs in young children, and then sputum (which may be induced) in older children capable of expectoration. Oropharyngeal swabs typically give a good indication of the lower airway flora, but fiberoptic bronchoscopy may be used to gather lower respiratory tract secretions of infants and young children who do not expectorate if there is a concern for false-negative cultures, especially regarding the presence of *P. aeruginosa*.

The CF airway microbiome consists of a large number of additional organisms, especially anaerobes that are identified through antigen detection but not culture methods. The significance of this finding and its therapeutic implications remain somewhat unclear, but it has long been appreciated that response to antibiotic treatment of pulmonary exacerbations is not always predictable based on culture and sensitivity of airway cultures.

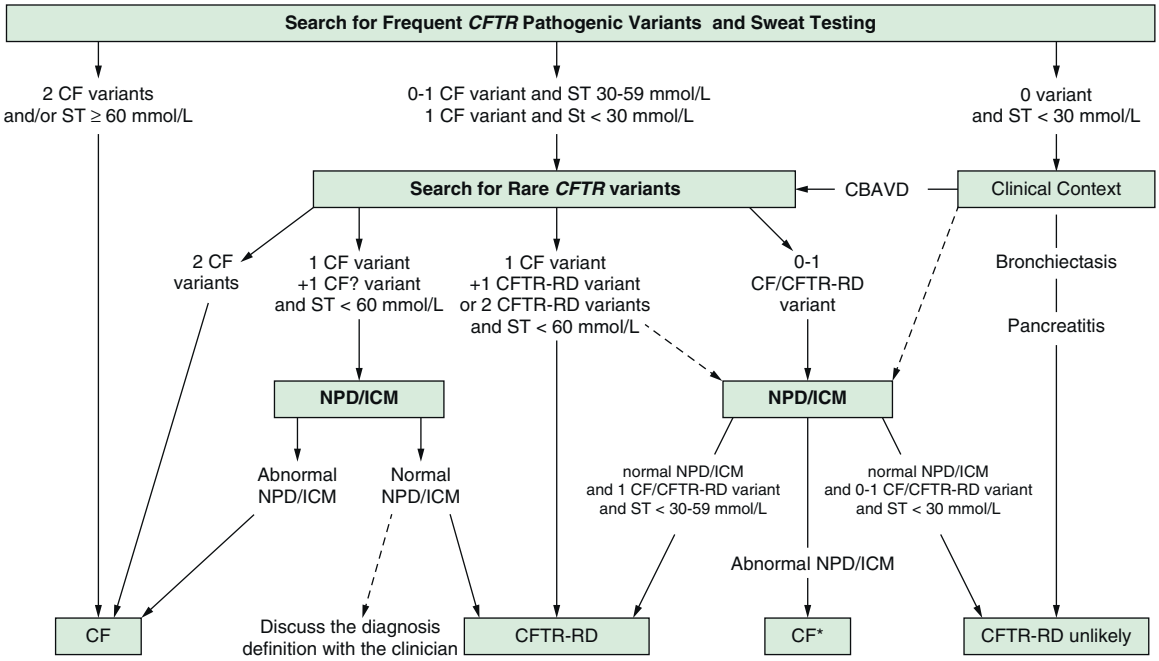

Fig. 454.10 2015 European Cystic Fibrosis Society recommended algorithm for diagnosis of CFTR-RD. Global diagnostic algorithm for CF and CFTR-RD. A global flowchart of genetic and functional diagnostic testing in CF and CFTR-RD is presented. CBAVD, Congenital bilateral absence of the vas deferens; CF, cystic fibrosis; CF? pathogenic variant, pathogenic variant of unproven or uncertain clinical significance; CF*, diagnosis of CF or consider this diagnosis; CFTR, cystic fibrosis transmembrane conductance regulator; CFTR-RD, CFTR-related disorders; ICM, intestinal current measurement; NPD, nasal potential difference; ST, sweat test (repeated; false positive should be excluded/sought in a specialized center). *(From Bombieri C, Claustres M, De Boeck K, et al. Recommendations for the classification of diseases as CFTR-related disorders. J Cyst Fibros. 2011;10[Suppl 2]:S86–102, Fig 1.)*

MANIFESTATIONS OF REDUCED CFTR FUNCTION THAT DO NOT MEET CRITERIA FOR CF

CFTR-Related Metabolic Syndrome

There is a subset of infants with a positive newborn screen for CF who have inconclusive diagnostic testing. The term for this condition, used in the United States, is *CFTR-related metabolic syndrome* (CRMS); in Europe, the analogous term is *CF screen positive, inconclusive diagnosis* (CFSPID). Data from the CF Foundation National Patient Registry show that approximately one infant is diagnosed with CRMS for every five cases of CF. An infant is determined to have CRMS if they are asymptomatic with a positive CF NBS test and either (1) sweat test <30 mmol/L and two *CFTR* pathogenic variants, at least one of which has unclear phenotypic consequences, or (2) sweat test 30-59 mmol/L and zero or one CF-causing CFTR pathogenic variant.

CRMS should be *distinguished* from CFTR-related disorder (CFTR-RD), described later, in that CRMS is a diagnosis that arises only from CF NBS in otherwise asymptomatic individuals.

Data on long-term outcomes of infants with CRMS are limited because universal CF NBS is relatively new and CRMS has only recently been recognized. The majority of CRMS infants appear to have normal growth and do not develop any pulmonary manifestations of CF, although it is not unusual for them to grow *P. aeruginosa* from their airways in the absence of any other clinical manifestations. However, a small percentage (~5–10%) will develop signs and symptoms of CF, including measures of CFTR dysfunction such as a clinically elevated sweat chloride or abnormalities in other CFTR functional assays. This is a diagnosis that it is important for the general pediatrician to be aware of, because these children are often lost to follow-up by CF care centers.

CFTR-Related Disorder

The diagnosis of CFTR-RD has been defined as a monosymptomatic clinical entity associated with CFTR dysfunction that does not fulfill the diagnostic criteria for CF. Common manifestations include CBAVD, recurrent pancreatitis, chronic sinusitis, nasal polyposis, or bronchiectasis. This is more typically diagnosed in adults but sometimes might appear in late adolescence. An approach to the evaluation of patients with CFTR-RD is seen in Figure 454.10.

TREATMENT

General Approach to Care

Initial efforts after diagnosis should be intensive and should include baseline assessment, initiation of treatment to prevent pulmonary involvement in young infants or reverse it in those diagnosed later, nutritional maintenance or remediation, and education of the patient and parents. Follow-up evaluations are scheduled every 1-3 months, depending on the age at diagnosis, because many aspects of the condition require careful monitoring. An interval history and physical examination should be obtained at each visit. A sputum sample or, if that is not available, a lower pharyngeal swab taken during or after a forced cough is obtained for culture and antibiotic susceptibility studies. Because irreversible loss of pulmonary function from low-grade infection can occur gradually and without acute symptoms, emphasis is placed on a thorough pulmonary history and physical exam and routine pulmonary function testing. Table 454.4 lists symptoms and signs that suggest the need for more intensive antibiotic and physical therapy (PT). Protection against exposure to MRSA, *P. aeruginosa, B. cepacian,* and other resistant gram-negative organisms is essential, including contact isolation procedures and careful attention to cleaning of inhalation therapy equipment. A nurse, physical therapist, respiratory therapist, social worker, and dietitian, as members of the multidisciplinary care team, should evaluate children regularly and contribute to the development of a comprehensive daily care plan. Considerable education and programs to empower families and older children to take responsibility for care are likely to result in the best adherence to daily care programs. Screening patients and caregivers for anxiety and depression annually is expected to identify issues that can interfere with adherence to daily care. Standardization of practice, on the part of both caregivers and families, as well as close monitoring and early intervention for new or increasing symptoms, appears to result in the best long-term outcomes.

Because secretions of CF patients are not adequately hydrated, attention in early childhood to oral hydration, especially during warm weather or with acute gastroenteritis, may minimize complications associated with impaired mucous clearance. Intravenous therapy for dehydration should be initiated early.

Table 454.4 Symptoms and Signs Associated with Exacerbation of Pulmonary Infection in Patients with Cystic Fibrosis

SYMPTOMS
Increased frequency and duration of cough
Increased sputum production
Change in appearance of sputum
Increased shortness of breath
Decreased exercise tolerance
Decreased appetite
Feeling of increased congestion in the chest
SIGNS
Increased respiratory rate
Use of accessory muscles for breathing
Intercostal retractions
Change in results of auscultatory examination of chest
Decline in measures of pulmonary function consistent with the presence of obstructive airway disease
Fever and leukocytosis
Weight loss
New infiltrate on chest radiograph

From Ramsey B. Management of pulmonary disease in patients with cystic fibrosis. *N Engl J Med.* 1996;335:179.

The goal of therapy is to maintain a stable condition for prolonged periods. This can be accomplished for most patients by interval evaluation and adjustments of the home treatment program. Some children have episodic acute or low-grade chronic lung infection that progresses. For these patients, intensive inhalation and airway clearance and intravenous antibiotics are indicated. Improvement is most reliably accomplished in a hospital setting; selected patients have demonstrated successful outcomes while completing these treatments at home. Intravenous antibiotics may be required infrequently or as often as every 2-3 months. The goal of treatment is to return patients to their previous pulmonary and functional status.

The basic daily care program varies according to the age of the child, the degree of pulmonary involvement, other system involvement, and the time available for therapy. The major components of this care are pulmonary and nutritional therapies. Because therapy is medication intensive, iatrogenic problems frequently arise. Monitoring for complications is also an important part of management.

Cystic Fibrosis Transmembrane Conductance Regulator Modulator Therapies

CFTR modulator therapies are small molecules taken orally that correct the processing and function of the variant CFTR protein in multiple organs and reduce or correct manifestations of disease. They have been developed to target specific classes of pathogenic variants (see Fig. 454.2). Ivacaftor is a small-molecule potentiator of the CFTR pathogenic variant G551D (present in ~5% of patients). Ivacaftor activates the CFTR-G551D variant protein, a class III CFTR pathogenic variant that results in protein localized to the plasma membrane but loss of chloride channel function (Table 454.5; Fig. 454.11). Ivacaftor therapy results in improvement in FEV_1 by an average of 10.6%, decreases the frequency of pulmonary exacerbations by

Table 454.5 Cystic Fibrosis Transmembrane Regulator Modulators for Cystic Fibrosis

DRUG	FDA-APPROVED INDICATION	FORMULATIONS	USUAL DOSAGE
Ivacaftor	4 mo with a responsive pathogenic variant*	25, 50, 75 mg granule packets† 150 mg tablets	<6 yr: weight-based dosing‡; ≥6 yr: 150 mg q12h

Modified from The Medical Letter on Drugs and Therapeutics: Tezacaftor/Ivacaftor (Symdeko) for cystic fibrosis. *Med Lett.* 2018;60(1558):174–176, Table 3.

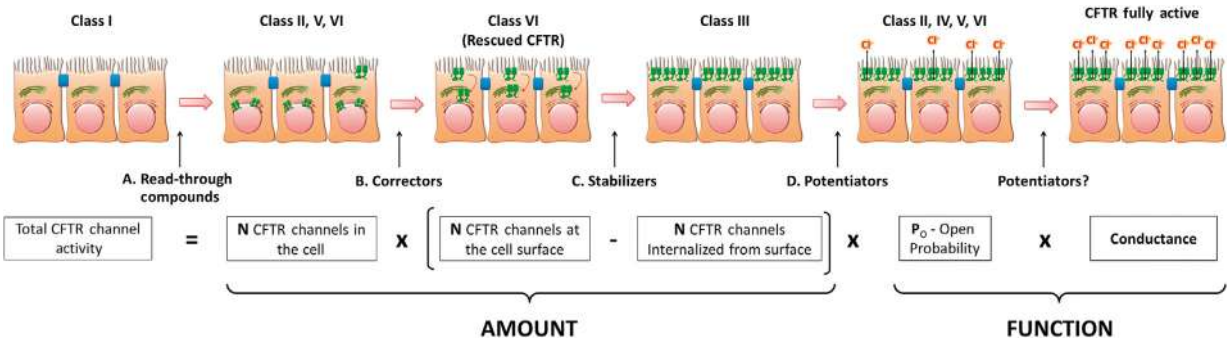

Fig. 454.11 Cystic fibrosis transmembrane conductance regulator *(CFTR)* pharmacologic modulators have different modes of action. **A,** Read-through compounds, which include aminoglycoside antibiotics (e.g., gentamicin, tobramycin), act by suppressing premature termination codons (PTCs), thus permitting translation to continue to the normal termination of the transcript and thus increasing the total amount of complete CFTR being produced in the cell. **B,** Correctors (e.g., VX-809, also known as lumacaftor; VX-661) potentially promote folding of variant CFTR protein, allowing it to escape ER degradation and reach the cell surface, thus increasing the number of channels present at the plasma membrane. **C,** Stabilizers include compounds (e.g., hepatocyte growth factor) that enhance CFTR retention/anchoring at the cell surface, thus also contributing to increase the number of channels present at the cell surface. **D,** Potentiators (e.g., VX-770, also known as ivacaftor) activate CFTR, that is, increase the open probability *(P_o)* of the channel by regulating its gating and possibly also the conductance. *(From Bell SC, De Boeck K, Amaral MD. New pharmacological approaches for cystic fibrosis: promises, progress, pitfalls. Pharmacol Therapeu. 2015;145:19–34, Fig. 4.)*

55%, decreases sweat chloride by an average of 48 mEq/L, and increases weight gain by an average of 2.7 kg. Ivacaftor is approved for patients older than 2 years of age with class III and class IV pathogenic variants.

The combination of ivacaftor with lumacaftor, a corrector that stabilizes misfolded F508del and enables trafficking of the variant molecule to the apical cell membrane where it is potentiated by ivacaftor, is available for patients older than 6 years of age who are homozygous for the F508del pathogenic variant (see Fig. 454.11). This medication is associated with smaller increments in pulmonary and nutritional outcomes but is an important proof-of-concept treatment.

Tezacaftor and ivacaftor is another combination indicated for patients ≥6 years with one or two Phe508del alleles. This combination improves predicted FEV_1 and overall well-being (see Table 454.5). VX-445 combined with tezacaftor-ivacaftor adds another CFTR correction agent; the triple combination improves predicted FEV_1 and reduces sweat chloride levels.

Elexacaftor/tezacaftor/ivacaftor, a triple combination therapy for patients ≥6 years with at least one copy of Phe508del alleles was approved in 2019 (see Table 454.5). This therapy is a highly effective modulator, and 90% of patients with CF are eligible to use this treatment. In a phase 3 randomized, double-blind trial for patients homozygous for Phe508del comparing elexacaftor/tezacaftor/ivacaftor to tezacaftor/ivacaftor alone, patients on triple therapy had a significant increase in FEV_1 percent predicted of 10% and a dramatic decrease in sweat chloride levels by 45 mM compared with double therapy at 4 weeks. In a phase 3 randomized, double-blind, placebo-controlled clinical trial for patients with one copy of Phe508del, triple therapy was associated with a decrease in sweat chloride by 41.8 mmol/L and a marked increase in FEV_1 percent predicted of 14% at 24 weeks. The success of these highly effective CFTR modulator therapies, ivacaftor for class III pathogenic variants and elexacaftor/tezacaftor/ivacaftor for Phe508del, has been life-changing. Ivacaftor and the triple combination therapy are being evaluated for therapeutic efficacy in younger children and infants with CF.

However, at least 10% of patients with CF have pathogenic variants that are not responsive to these highly effective modulator therapies. Patients with class I pathogenic variants caused by premature termination codons and failure to translate CFTR protein will require new approaches to therapy to acquire normal CFTR protein and function. Gene therapy, gene editing, and antisense oligonucleotide therapeutic approaches are currently being developed.

Pulmonary Therapy

The object of pulmonary therapy is to clear secretions from airways and to control infection. When a child is not doing well, every potentially useful aspect of therapy should be reconsidered.

Inhalation Therapy

Human recombinant Dnase (2.5 mg) enzymatically dissolves extracellular DNA released by neutrophils, a major contributor to the characteristically sticky and viscous CF airway secretions. Recombinant human Dnase is usually given as a single daily aerosol dose; it improves pulmonary function, decreases the number of pulmonary exacerbations, and promotes a sense of well-being. Benefit for those with mild, moderate, and severe lung disease has been documented. Improvement is sustained for 12 months or longer with continuous therapy.

Nebulized hypertonic saline, acting as a hyperosmolar agent, is believed to draw water into the airway and rehydrate mucus and the periciliary fluid layer, resulting in improved mucociliary clearance. Seven percent hypertonic saline nebulized 2-4 times daily increases mucous clearance and reduces pulmonary exacerbation, with only a slight short-term improvement in pulmonary function.

Airway Clearance Therapy

Airway clearance treatment begins in infancy with chest percussion (with or without postural drainage) and derives its rationale from the idea that cough clears mucus from large airways, but chest vibrations are required to shear secretions from the airway wall and move secretions from small airways, where expiratory flow rates are low. **Chest PT** can be particularly useful for patients with CF because they accumulate secretions in small airways first, even before the onset of symptoms. Cessation of chest PT in children with mild to moderate airflow limitation results in deterioration of lung function within 3 weeks, and prompt improvement of function occurs when therapy is resumed, but it is less clear which available modality is best. Airway clearance therapy is recommended 2-4 times a day, depending on the severity of lung dysfunction, and usually increased during acute exacerbations. Cough, huffing, or forced expirations are encouraged intermittently throughout the session. Vest-type mechanical percussors *(high-frequency chest wall oscillation)* are commonly used past infancy because of their convenience, as are a variety of oscillatory positive expiratory pressure devices (such as Acapella and Aerobika) and other controlled breathing techniques (e.g., *autogenic drainage*). Routine aerobic exercise appears to slow the rate of decline of pulmonary function, and benefit has also been documented with weight training. No one airway clearance technique can be shown to be superior to any other, so all modes should be considered in the development of an airway clearance prescription. Adherence to daily therapy is important but rarely achieved; therefore airway clearance technique plans are individualized for each patient.

Antibiotic Therapy

Antibiotics are the mainstay of therapy designed to control progression of lung infection. The goal is to reduce the intensity of endobronchial infection and to delay progressive lung damage. The usual guidelines

Table 454.6 Antimicrobial Agents for Cystic Fibrosis Lung Infection

ROUTE	ORGANISMS	AGENTS	DOSAGE (mg/kg/24 hr)	NO. DOSES/24 hr

for acute chest infections, such as fever, tachypnea, or chest pain, are often absent. Consequently, all aspects of the patient's history and examination, including anorexia, weight loss, and diminished activity, must be used to guide the frequency and duration of therapy. Antibiotic treatment varies from intermittent short courses of one antibiotic to nearly continuous treatment with one or more antibiotics. Dosages for some antibiotics are often 2-3 times the amount recommended for minor infections because patients with CF have proportionately more lean body mass and higher clearance rates for many antibiotics than other individuals. In addition, it is difficult to achieve effective drug levels of many antimicrobials in respiratory tract secretions.

Oral Antibiotic Therapy

Indications for oral antibiotic therapy in a patient with CF include the presence of respiratory tract symptoms, physical signs, or changes in pulmonary function testing or chest x-ray. Treatment is guided by identification of pathogenic organisms in respiratory tract cultures and in vitro sensitivity testing. Common organisms, including *S. aureus (MRSA or methicillin-susceptible S. aureus [MSSA]),* nontypeable *H. influenzae, P. aeruginosa, B. cepacian,* and other gram-negative rods, are encountered with increasing frequency. The usual course of therapy is 2 weeks, and maximal doses are recommended. Table 454.6 lists useful oral antibiotics. The quinolones are the only broadly effective oral antibiotics for *Pseudomonas* infection, but resistance against these agents may emerge. Macrolides may reduce the virulence properties of *P. aeruginosa,* such as biofilm production, and contribute antiinflammatory effects. Long-term therapy with azithromycin 3 times a week improves lung function in patients with chronic *P. aeruginosa* infection.

Aerosolized Antibiotic Therapy

Aerosolized antibiotics are often used as part of daily therapy when the airways are infected with *P. aeruginosa*. Aerosolized tobramycin inhalation solution or powder, or aztreonam inhalation solution used as a suppressive therapy (on 1 month, off 1 month), may reduce symptoms, improve pulmonary function, and decrease the occurrence of pulmonary exacerbations. Although these therapies are sometimes used in acute pulmonary exacerbations, the evidence to support this application is limited.

Another important indication for aerosolized antibiotic therapy is to eradicate *P. aeruginosa* in the airways after initial detection. Early infection may be cleared for months to several years in this way, although eventual reinfection is common. Other antibiotics have been used via

inhalation, including liposomal amikacin and levofloxacin for *P. aeruginosa,* and there was no inferiority of efficacy compared with inhaled tobramycin.

Intravenous Antibiotic Therapy

For the patient who has not responded to oral antibiotics and intensive home measures with return of signs, symptoms, and FEV_1 to baseline, intravenous antibiotic therapy is indicated. This therapy is usually initiated in the hospital but is sometimes completed on an ambulatory basis if the likelihood of complete adherence to the therapeutic regimen is good. The ideal duration of treatment is unknown; although many patients show improvement within 7 days, many CF physicians believe that it is usually advisable to extend the period of treatment to at least 14 days. Permanent intravenous access can be provided for long-term or frequent courses of therapy in the hospital or at home. Thrombophilia screening should be considered before the use of totally implantable intravenous devices or for recurring problems with venous catheters.

Table 454.6 lists commonly used intravenous antibiotics. In general, treatment of *Pseudomonas* infection is thought to require two-drug therapy. A third agent may be given for optimal coverage of *S. aureus* or other organisms. Aminoglycosides are usually effective when given every 24 hours to minimize toxicity and optimize convenience. Some CF physicians use peak and trough levels to guide dosing, but most clinical pharmacists recommend measuring levels at other times, commonly 2 and 12 hours, to use pharmacokinetic calculations to guide dosing. Changes in therapy should be guided by lack of improvement more than by culture results; sensitivities do not always predict response to therapy, and this may be because of the presence of other organisms that are not detected by culture methods. If patients do not show improvement, complications such as right heart failure; asthma; or infection with viruses, *A. fumigatus* (especially allergic bronchopulmonary aspergillosis, ABPA) (see Chapter 283), nontuberculous mycobacteria (see Chapter 263), or other unusual organisms should be considered. *B. cepacia* complex and *Acinetobacter* are gram-negative rods that may be particularly refractory to antimicrobial therapy. Infection control in both the outpatient and inpatient medical setting is critically important to prevent nosocomial spread of resistant bacterial organisms between patients.

Bronchodilator Therapy

Reversible airway obstruction occurs in many children with CF, sometimes in conjunction with frank asthma or allergic bronchopulmonary aspergillosis. Reversible obstruction is conventionally defined as improvement of ≥12% in FEV_1 or FVC after inhalation of a bronchodilator. In many patients with CF, these may improve by only 5–10% (physiologic response), but subjects may report subjective benefit.

Antiinflammatory Agents

Corticosteroids are useful for the treatment of allergic bronchopulmonary aspergillosis and severe asthma occasionally encountered in children with CF. Prolonged systemic corticosteroid treatment of CF lung disease reduces the decline in lung function modestly but causes predictably prohibitive side effects. Inhaled corticosteroids have theoretical appeal, but there are contradictory and weak data regarding efficacy unless the patient has clinically diagnosable asthma. Ibuprofen, given chronically in high doses adjusted to achieve a peak serum concentration of 50-100 μg/mL, is associated with a slowing of disease progression, particularly in younger patients with mild lung disease. However, there are concerns regarding side effects of nonsteroidal antiinflammatory drugs, so this therapy has not gained broad acceptance. Macrolide antibiotics have an antiinflammatory effect, and 3 days/week of azithromycin has been shown to reduce the likelihood of the development of pulmonary exacerbations, especially in patients with chronic *Pseudomonas* airway infection, so this is a commonly used therapy.

Other Therapies

Attempts to clear recalcitrant atelectasis and airway plugging with bronchopulmonary lavage and direct instillation of various medications are sometimes used in exceptional cases; there is no evidence for sustained benefit from repeated procedures. Expectorants such as iodides and guaifenesin do not effectively assist with the removal of secretions from the respiratory tract. Inspiratory muscle training can enhance maximum oxygen consumption during exercise along with FEV_1.

TREATMENT OF PULMONARY COMPLICATIONS

Atelectasis

Lobar atelectasis occurs relatively infrequently; it may be asymptomatic and noted only at the time of a routine chest radiograph. Aggressive intravenous therapy with antibiotics and increased chest PT directed at the affected lobe may be effective. If there is no improvement in 5-7 days, bronchoscopic examination of the airways may be indicated. If the atelectasis does not resolve, continued intensive home therapy is indicated because atelectasis may resolve during a period of weeks or months.

Hemoptysis

Endobronchial bleeding usually reflects airway wall erosion into hypertrophied bronchial vessels secondary to infection. Although more common in patients with advanced disease, it is sometimes seen in adolescents with relatively mild lung disease. Blood streaking of sputum is particularly common. Small-volume hemoptysis (<20 mL) is usually viewed as a need for intensified antimicrobial therapy and chest PT. **Massive hemoptysis**, defined as total blood loss of ≥250 mL in a 24-hr period, is rare in the first decade and occurs in <1% of adolescents, but it requires close monitoring and the capability to replace blood losses rapidly. Bronchoscopy rarely reveals the site of bleeding. Bronchial artery embolization can be useful to control persistent, significant hemoptysis.

Pneumothorax

Pneumothorax (see Chapter 461) is encountered uncommonly in children and teenagers with CF, although it may lead to significant compromise in lung function and occasionally may be life-threatening. The episode may be asymptomatic but is often attended by chest and shoulder pain, shortness of breath, or hemoptysis. A small air collection that does not grow can be observed closely. Chest tube placement with or without pleurodesis is often the initial therapy. Intravenous antibiotics are also begun on admission. Video-assisted thoracoscopic surgery (VATS) with plication of blebs, apical pleural stripping, and basal pleural abrasion should be considered if the air leak persists. Surgical intervention is usually well tolerated even in cases of advanced lung disease. The thoracotomy tube is removed as soon as possible. Previous pneumothorax with or without pleurodesis is not a contraindication to subsequent lung transplantation.

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis occurs in 5–10% of patients with CF and may manifest as wheezing, increased cough, shortness of breath, and marked hyperinflation or, most commonly, a decrease in FEV_1 that does not respond to antibiotic therapy (see Chapter 283). In some patients, a chest radiograph shows new focal infiltrates. A highly elevated total serum immunoglobulin E (IgE) level (>1,000) is usually the initial indication of the diagnosis. The presence of rust-colored sputum, the recovery of *Aspergillus* organisms from the sputum, a positive skin test for *A. fumigatus,* the demonstration of specific IgE and IgG antibodies against *A. fumigatus,* or the presence of eosinophils in a fresh sputum sample supports the diagnosis. Treatment is directed at controlling the inflammatory reaction with oral corticosteroids. Oral antifungals are usually reserved for patients who relapse after initial steroid treatment. For refractory cases, omalizumab, humanized monoclonal anti-IgE, has been effective.

Nontuberculous Mycobacteria Infection

See Chapter 263.

Injured airways with poor clearance may be colonized by *M. avium*-complex but also *M. abscessus, Mycobacterium chelonae,* and *Mycobacterium kansasii.* Distinguishing endobronchial colonization (frequent) from invasive infection (infrequent) is challenging. Persistent fevers and new infiltrates or cystic lesions coupled with the finding of acid-fast organisms on sputum smear suggest infection. Infection with these organisms, or at least its recognition, has become increasingly

common. Treatment is prolonged and requires multiple antimicrobial agents. Symptoms may improve, but the nontuberculous mycobacteria are not usually cleared from the lungs.

Sleep-Disordered Breathing

Particularly with advanced pulmonary disease and during chest exacerbations, individuals with CF may experience more sleep arousals, less time in rapid eye movement sleep, nocturnal hypoxemia, hypercapnia, and associated neurobehavioral impairment. Nocturnal hypoxemia may hasten the onset of pulmonary hypertension and right-sided heart failure. Efficacy of specific interventions for this complication of CF has not been systematically assessed. Prompt treatment of airway symptoms and nocturnal oxygen supplementation or bilevel positive airway pressure support should be considered in selected cases, especially in patients with advanced lung disease.

Acute Respiratory Failure

Acute respiratory failure (see Chapter 86) rarely occurs in patients with mild to moderate lung disease and is usually the result of a severe viral or other infectious illness. Because patients with this complication can regain their previous status, intensive therapy is indicated. In addition to aerosol, postural drainage, and intravenous antibiotic treatment, oxygen is required to raise the arterial Pa_{O_2}. An increasing P_{CO_2} may require ventilatory assistance. Endotracheal or bronchoscopic suction may be necessary to clear airway inspissated secretions and can be repeated daily. Right-sided heart failure should be treated vigorously. High-dose steroids have been anecdotally reported to be of benefit in this setting. Recovery is often slow. Intensive intravenous antibiotic therapy and postural drainage should be continued for 1-2 weeks after the patient has regained baseline status.

Chronic Respiratory Failure

Patients with CF acquire chronic respiratory failure after prolonged deterioration of lung function. Although this complication can occur at any age, it is seen most frequently in adult patients. Because a long-standing Pa_{O_2} <50 mm Hg promotes the development of right-sided heart failure, patients usually benefit from low-flow oxygen to raise arterial P_{O_2} to ≥55 mm Hg. Increasing hypercapnia may prevent the use of optimal fraction of inspired oxygen. Most patients improve somewhat with intensive antibiotic and pulmonary therapy measures and can be discharged from the hospital. Low-flow oxygen therapy is needed at home, especially with sleep. Noninvasive ventilatory support can improve gas exchange and has been documented to enhance quality of life. Ventilatory support may be particularly useful for patients awaiting lung transplantation. These patients usually display pulmonary hypertension and cor pulmonale, and this complication should be treated. Caution should be exercised to avoid ventilation-suppressing metabolic alkalosis that results from CF-related chloride depletion and, in many cases, from diuretic-induced bicarbonate retention. Chronic pain (headache, chest pain, abdominal pain, and limb pain) is frequent at the end of life and responds to judicious use of analgesics, including opioids. Dyspnea has been ameliorated with nebulized fentanyl.

Pulmonary Hypertension and Cor Pulmonale

Individuals with long-standing, advanced pulmonary disease, especially those with severe hypoxemia (Pa_{O_2} <50 mm Hg), often acquire pulmonary hypertension and chronic right-sided heart failure. Evidence for concomitant left ventricular dysfunction is often found. The arterial P_{O_2} should be maintained at >50 mm Hg, if possible, and hypercarbia corrected with noninvasive ventilation or intubation if necessary. Intensive pulmonary therapy, including intravenous antibiotics, is most important. Adjunctive therapy with salt restriction, diuretics, and pulmonary vasodilators may be indicated. The prognosis for heart failure is poor, but a number of patients survive for ≥5 years after the appearance of heart failure. Heart-lung transplantation may be an option.

Lung Transplantation

Lung transplantation is an option for end-stage lung disease (see Chapter 492). Criteria for referral continue to be a subject of investigation and ideally include estimates of longevity with and without transplant based on lung function and exercise tolerance data. Survival and quality of life after lung transplantation are better in patients with CF than other chronic lung diseases, probably because of the relatively younger age of recipients with CF, but the current estimated 5-year survival is about 50%, somewhat reduced compared with that of other solid organ transplants. Because of bronchiolitis obliterans (see Chapter 443.1) and other transplant-related complications, transplanted lungs cannot be expected to function for the lifetime of a recipient, and repeat transplantation is increasingly common. The demand for donor lungs exceeds the supply, and waiting lists and duration of waits continue to be a problem. Importantly, since the initiation of treatment with elexacaftor/tezacaftor/ivacaftor, some patients with chronic lung disease have significantly improved so that they no longer require listing for lung transplantation.

Nutritional Therapy

Up to 90% of patients with CF have loss of exocrine pancreatic function leading to inadequate digestion and absorption of fats and proteins. They require dietary adjustment and augmentation, pancreatic enzyme replacement, and supplementary vitamins. In general, children with CF need to exceed the usual required daily caloric intake to grow. Daily supplements of the fat-soluble vitamins are required.

Diet

Historically, at the time of diagnosis, many infants presented with nutritional deficits; this situation has changed because of newborn screening, but even at 2-4 weeks, it is not uncommon to see that weight gain has begun to fall off the standard curve.

Most children with CF have a higher-than-normal caloric need because of malabsorption despite the use of pancreatic enzyme supplementation. Encouragement to eat high-calorie foods is important and often begins with more concentrated, high-calorie formulas in the first year. Even so, most mothers can breastfeed successfully. It is vitally important to promote adequate weight gain in the early years, both because of a clear relationship to later lung function and because early deficiencies make later catch-up growth more difficult. Not infrequently, feeding problems can negatively affect parent–child interactions at meal time, and behavioral interventions can improve caloric intake. The liberal use of appetite stimulants, especially cyproheptadine, in early childhood makes the struggle a bit easier. Poorly controlled lung disease increases metabolism and decreases appetite and needs to be considered when efforts to improve weight gain are unsuccessful.

Maintenance of good weight gain and body mass index in the first year of life leads to better long-term preservation of lung function, but there is a strong correlation between body mass index and FEV_1 that persists through all ages in people with CF. Better nutrition also leads to improved quality of life and psychologic well-being and provides better reserves when weight loss occurs in association with intermittent acute pulmonary exacerbations.

Malabsorption is an important contributor to nutritional deficiencies, and it is important to ensure that pancreatic enzyme dosing is adequate and consistently being taken correctly with all meals and feedings. Appetite stimulants when cyproheptadine is not successful may include megestrol, oxandrolone, dronabinol, antidepressants such as mirtazapine, and even growth hormone. CF-related diabetes needs to be ruled out.

When all these therapies fail, weight stabilization or gain can be achieved with nocturnal feeding via nasogastric tube or gastrostomy tube. These are most commonly resorted to in infants and adolescents, the two age-groups that have the most difficulty with weight gain because of high-normal demands.

Pancreatic Enzyme Replacement

Pancreatic exocrine replacement therapy given with ingested food reduces, but does not fully correct, stool fat and nitrogen losses. Current products are enteric-coated, pH-sensitive enzyme microspheres that come in capsules and are given to children before they can swallow by opening the capsule and mixing the beads in small amounts of acidic foods such as applesauce. Strengths ranging from 3 to 40,000 IU of lipase/capsule are available. Administration of excessive doses has been linked to fibrosing colonopathy and **colonic strictures**, so

recommendations are for enzyme dosing to stay below 2,500 lipase units/kg/meal in most circumstances. Snacks should also be covered. Some enzyme replacement therapies provide bicarbonate in addition to the enzymes, which may be helpful for a subset of patients to correct acid pH in the duodenum, which is caused by a lack of exocrine pancreatic secretions; neutralization of duodenal pH permits optimal activation of enteric-coated pancreatic exocrine replacement therapy granules. Some individuals prefer proton pump inhibitor therapy to achieve the same effect.

Vitamin and Mineral Supplements

Because pancreatic insufficiency results in malabsorption of fat-soluble vitamins (A, D, E, K), vitamin supplementation is recommended. Several vitamin preparations containing all four vitamins for patients with CF are available. They should be taken daily. Despite this supplementation, vitamin D deficiency is common and should be treated with doses of cholecalciferol (vitamin D3) rather than ergocalciferol (vitamin D2). The CF Foundation recommends that all individuals with CF, from birth to 12 months of age, be treated with an initial dose of 400-500 IU vitamin D3 per day, from 12 months to 10 years of age, an initial dose of 800 to 1000 IU of vitamin D3 per day, and from 10 years of age and older, an initial dose of 800 to 2000 IU of vitamin D3 per day. Higher doses are recommended for those who are vitamin D deficient. Salt supplementation is also needed during infancy and is started at the time of diagnosis. There may be additional vitamin and micronutrient needs if a child with CF required an intestinal resection as a newborn as a result of meconium ileus.

TREATMENT OF INTESTINAL COMPLICATIONS

Meconium Ileus

When meconium ileus (see Chapter 135) is suspected, contrast enemas with reflux of contrast material into the ileum not only confirm the diagnosis but may also result in the passage of meconium and clearing of the obstruction. Children in whom this procedure fails require operative intervention. Children who have had meconium ileus are at greater risk for nutritional deficiency and are more likely to develop problems with DIOS when older. Infants with meconium ileus should be assumed to have CF unless proven otherwise.

Distal Intestinal Obstruction Syndrome and Other Causes of Abdominal Symptoms

Despite appropriate pancreatic enzyme replacement, a number of patients accumulate fecal material in the terminal portion of the ileum and in the cecum, which may result in partial or complete obstruction. For intermittent symptoms, pancreatic enzyme replacement should be continued or even increased, and stool hydrators such as polyethylene glycol should be given. If this fails or symptoms are more severe, large-volume bowel lavage with a balanced salt solution containing polyethylene glycol may be taken by mouth or by nasogastric tube. When there is complete obstruction, a contrast enema, accompanied by large amounts of intravenous fluids, can be therapeutic.

Rectal Prolapse

See Chapter 392.5.

Although uncommon, rectal prolapse occurs most often in infants with CF and less frequently in older children with the disease. It was much more frequently seen in the past among undiagnosed young children with steatorrhea, malnutrition, and repetitive cough. The prolapsed rectum can usually be replaced manually by continuous gentle pressure with the patient in the knee-chest position. To prevent an immediate recurrence, the buttocks can be temporally taped closed. Adequate pancreatic enzymes, stool softener, and control of pulmonary infection result in improvement. On very rare occasions, a patient may continue to have rectal prolapse and may require referral to a pediatric surgeon.

Hepatobiliary Disease

A wide range of hepatobiliary complications are observed in CF, including asymptomatic elevations in liver function tests, biliary cirrhosis, and portal hypertension. Often liver function abnormalities (elevations in aspartate aminotransferase [AST], alanine aminotransferase [ALT], gamma-glutamyl transferase [GGT]) associated with biliary cirrhosis are treated with ursodeoxycholic acid, leading to a reduction in these values. However, the evidence to support ursodeoxycholic acid's effectiveness in preventing the progression of CF-related liver disease has not been clearly documented. Portal hypertension with esophageal varices, hypersplenism, or ascites occurs in ≤8% of children with CF (see Chapter 415).

Obstructive jaundice in newborns with CF needs no specific therapy once the etiology has been established. End-stage liver disease is an indication for liver transplantation in children with CF (see Chapter 416).

Pancreatitis

Recurrent pancreatitis is seen primarily in patients with pancreatic sufficiency, and it can lead to the development of pancreatic insufficiency. Patients can be treated with pancreatic enzyme therapy and a low-fat diet (in well-nourished patients) to rest the pancreas. Further treatment of this disorder is discussed in Chapter 399.

Cystic Fibrosis–Related Hyperglycemia and Diabetes

Onset of hyperglycemia occurs most frequently *after* the first decade. Approximately 20% of young adults are treated for hyperglycemia, although the incidence of CF-related diabetes may be up to 50% in adults with CF. Ketoacidosis is rarely encountered. The pathogenesis includes both impaired insulin secretion and insulin resistance. Routine screening consisting of an annual 2-hour OGTT is recommended in children older than 10 years of age, although some cases may begin earlier. Although glucose intolerance with blood sugars that remain less than 200 are not treated unless nutrition is compromised or lung function seems affected, recent data suggest the prediabetic state is associated with clinical decline, so close monitoring is warranted. The development of significant hyperglycemia favors acquisition of *P. aeruginosa* and *B. cepacia* in the airways and may adversely affect pulmonary function. Thus careful control of blood glucose level is an important goal. When treatment is indicated, insulin should be instituted, as it is the only therapy shown to improve the nutritional and metabolic outcomes in CFRD. In addition to insulin therapy, patients are often encouraged to exercise, which has been shown to reduce postprandial glycemic excursions. Medical nutritional therapy for CFRD differs from that recommended in type 1 diabetes and type 2 diabetes, as patients are encouraged to continue the nutritional therapy needed to manage CF, that is a higher-caloric diet that is high in fat and salt and not carbohydrate restricted. Strict carbohydrate counting with adjustments in insulin dosing is essential for good glycemic control. Patients with CFRD are at risk for microvascular complications, including retinopathy, nephropathy, and neuropathy, providing an additional rationale for good control of blood glucose levels. These long-term vascular complications of diabetes are more commonly observed in adults with CFRD, as they occur more commonly after a decade of the disease.

Bone and Joint Complications

Hypertrophic osteoarthropathy causes elevation of the periosteum over the distal portions of long bones and bone pain, overlying edema, and joint effusions. Acetaminophen or ibuprofen may provide relief. Control of lung infection usually reduces symptoms. Intermittent arthropathy unrelated to other rheumatologic disorders occurs occasionally, has no recognized pathogenesis, and usually responds to nonsteroidal antiinflammatory agents. Back pain or rib fractures from vigorous coughing may require pain management to permit adequate airway clearance. These and other fractures may stem from diminished bone mineralization, the result of reduced vitamin D absorption, corticosteroid therapy, diminished weight-bearing exercises, and perhaps other factors. There may be a bone phenotype in CF that is unrelated to therapies or nutritional status and may be related to CFTR dysfunction.

OTHER COMPLICATIONS

Nasal Polyps

Nasal polyps (see Chapter 427) occur in 15–20% of patients with CF and are most prevalent in the second decade of life. Local corticosteroids and nasal decongestants occasionally provide some relief. When the polyps completely obstruct the nasal airway, rhinorrhea becomes constant, or widening of the nasal bridge is noticed, surgical removal of the polyps is

indicated; polyps may recur promptly or after a symptom-free interval of months to years. Polyps inexplicably stop developing in many adults.

Rhinosinusitis

Opacification of paranasal sinuses is universal in CF and is not an indication for intervention. Acute or chronic sinus-related symptoms are treated initially with antimicrobials, with or without maxillary sinus aspiration for culture. Functional endoscopic sinus surgery has anecdotally provided benefit.

Salt Depletion

Salt losses from sweat in patients with CF can be high, especially in warm arid climates. Children should have free access to salt, especially when thirsty in hot weather. Salt supplements are often prescribed to newborns and to children who live in hot weather climates. Hypochloremic alkalosis should be suspected in any patient who feels unwell in hot weather or who has had symptoms of gastroenteritis, and prompt fluid and electrolyte therapy should be instituted as needed.

Anxiety and Depression

The stress and emotional impact of caring for CF is significant. Studies have found high rates of depression and anxiety in both patients and their parent caregivers, 2-3 times that of the general population. Positive screening for depression in particular is associated with decreased lung function, lower body mass index, worse adherence, worse health-related quality of life, more frequent hospitalizations, and increased mortality. Annual screening for anxiety and depression, with psychologic and/or pharmacologic interventions and follow-up, is therefore indicated.

Surgery

Patients with good or excellent pulmonary status can tolerate general anesthesia without any intensive pulmonary measures before the procedure but should be adherent to their usual prescribed airway clearance therapy. Those with moderate or severe pulmonary infection usually do better with a 1- to 2-week course of intensive antibiotic treatment and increased airway clearance before surgery. If this approach is impossible, prompt intravenous antibiotic therapy is indicated once it is recognized that major surgery is required. General anesthesia may provide an opportunity to perform bronchoscopy to evaluate the airway and obtain good cultures, and this should be considered in any child with CF who will undergo surgery for any indication.

After major surgery, cough should be encouraged, and airway clearance treatments should be reinstituted as soon as possible, usually within 24 hours.

PROGNOSIS

CF remains a life-limiting disorder, although survival has dramatically improved (Figs. 454.12 and 454.13). With exceptions, most children remain relatively healthy into adolescence or adulthood. The slow progression of lung disease eventually does reach disabling proportions. Life table data indicate a median cumulative survival of more than 40 years, and the expectation is younger children with the disease have a life expectancy far in excess of this estimate. Outcomes are variable and related to CFTR pathogenic variant class, modifier genes, biologic and chemical exposures, disease management, and socioeconomic status. With the advent of highly effective CFTR modulator therapies, the landscape is expected to change even more dramatically. Not only will quality of life and longevity further improve, but investigations have begun into how the burden of care may be lessened by a decrease in the current dependence on onerous daily airway clearance therapies and the need for recurrent hospitalizations for pulmonary exacerbations.

Children with CF should not be restricted in their activities. A high percentage eventually attend and graduate from college. Most adults with CF find satisfactory employment, and an increasing number marry. Transitioning care from pediatric to adult care centers by 21 years of age is an important objective and requires a thoughtful, supportive approach involving both the pediatric and internal medicine specialists.

With increasing life span for patients with CF, a new set of psychosocial considerations has emerged, including the impact of anxiety and depression, dependence-independence issues, self-care, peer relationships, sexuality, reproduction, substance abuse, educational and vocational planning, medical care costs and other financial burdens, and anxiety concerning health and prognosis. Many of these issues are best addressed in an anticipatory fashion, before the onset of psychosocial dysfunction. With appropriate medical and psychosocial support, children and adolescents with CF generally cope well. Achievement of an independent and productive adulthood is a realistic goal for many.

Chapter 455

Primary Ciliary Dyskinesia (Immotile Cilia Syndrome, Kartagener Syndrome)

Thomas W. Ferkol Jr.

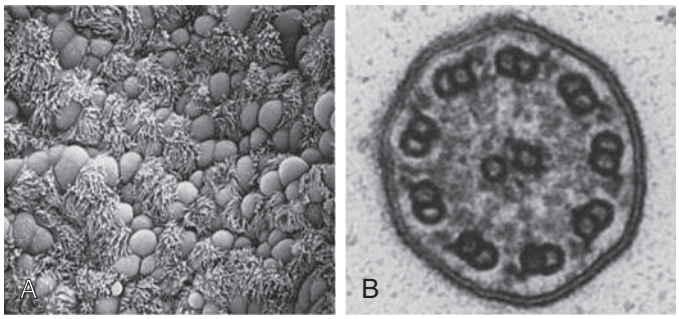

Fig. 455.1 Electron photomicrographs showing an airway epithelium grown in primary culture showing ciliated and nonciliated cells (**A**) and a normal motor cilium (**B**).

See also Chapter 101.3.

Primary ciliary dyskinesia (PCD) is an inherited disorder characterized by ciliary dysfunction leading to chronic sinopulmonary disease, persistent middle ear effusions, laterality defects, and infertility. The reported prevalence in the general population varies, ranging between 1 in 2,200 and 40,000 live births, but in children with repeated respiratory infections, it has been estimated to be as high as 5%.

NORMAL CILIARY ULTRASTRUCTURE AND FUNCTION

Three types of cilia exist in humans: motile cilia, primary (sensory) cilia, and nodal cilia. The respiratory epithelium in the nasopharynx, middle ear, paranasal sinuses, and larger airways are lined by a ciliated, pseudostratified columnar epithelium that is essential for mucociliary clearance. A mature ciliated epithelial cell has approximately 200 uniform **motile cilia**, hairlike organelles that move fluids, mucus, and inhaled particulates vectorially from conducting airways (Fig. 455.1). Motile cilia are anatomically and functionally oriented in the same direction, moving with intracellular and intercellular synchrony. Anchored by a basal body to the apical cytoplasm and extending from the apical cell surface into the airway lumen, each cilium is a complex, specialized structure, composed of hundreds of proteins. A cilium contains a central fibrillar structure, or axoneme, that consists of helical protofilaments made of alpha- and beta-tubulin monomers. A circular array of peripheral microtubular doublets are arranged around a central pair, leading to the characteristic "9+2" arrangement seen on cross-sectional views on transmission electron microscopy (see Fig. 455.1). Distinct inner and outer dynein arms are attached to the A microtubule. Each dynein arm is a multimer, containing multiple adenosine triphosphatases, called *dyneins,* that serve as motors of the cilium and promote microtubule sliding, which is converted into bending. The inner dynein arm influences the bend shape of the cilium, whereas the outer dynein arm controls beat force and frequency. The inner dynein arm and radial spokes are also parts of the dynein regulatory complex, a key regulator of motor activity. Nexin links connecting adjacent outer microtubular doublets limit the degree of sliding between microtubules. All these structures lead to synchronized ciliary beating, resulting in a ciliary stroke and coordinated beating at a frequency constant throughout the airway, ranging between 8 and 14 hertz, but this can be negatively affected by several factors, such as anesthetics and dehydration. Alternatively, beat frequency may be accelerated by exposure to irritants or bioactive molecules, including β-adrenergic agents, acetylcholine, and serotonin. Cilia beat frequency can be increased through the activity of nitric oxide synthases that are localized in the apical cytoplasm. The coordinated wavelike pattern of ciliary motion has

important functions in fluid and cell movement, and any disturbance in the precise, orchestrated movement of the cilia can lead to disease.

Primary (sensory) cilia are solitary, immotile organelles present during interphase on most cell types. These cilia lack a central microtubule doublet and dynein arms, thus creating a "9+0" arrangement (Fig. 455.2). Once considered nonfunctional vestigial remnants, primary cilia are important signaling organelles that sense the extracellular environment. They are mechanoreceptors, chemosensors, and osmosensors and, in specialized cases, detect changes in light, temperature, and gravity. Primary cilia defects (ciliopathies) are linked to wide-ranging pediatric conditions, such as various polycystic kidney diseases, nephronophthisis, Bardet-Biedl syndrome, Meckel-Gruber syndrome, Joubert syndrome, Alström syndrome, Ellis-van Creveld syndrome, and Jeune thoracic dystrophy (see Chapter 101.3).

The third type of cilia exists only during a brief period of embryonic development. **Nodal cilia** have a "9+0" microtubule arrangement similar to that of primary cilia, but they exhibit a whirling, rotational movement (see Fig. 455.2), resulting in leftward flow of extracellular fluid that establishes body sidedness. Nodal cilia defects result in body orientation abnormalities, such as **situs inversus totalis**, **situs ambiguus**, and **heterotaxy** associated with congenital heart disease, asplenia, and polysplenia (see Chapter 480.11).

GENETICS OF PRIMARY CILIARY DYSKINESIA

PCD is a genetically heterogeneous disorder, usually inherited by an autosomal recessive pattern, but autosomal dominant and X-linked inheritance are known. Pathogenic variants in any of the hundreds of proteins that are involved in ciliary assembly, structure, or function could theoretically cause disease. Indeed, 50 different genes have been linked to PCD (Fig. 455.3), including those that encode proteins integral to the outer dynein arm, dynein regulatory complex, radial spoke, and central apparatus proteins. Pathogenic variants in genes coding several cytoplasmic proteins not part of the cilia axoneme have also been identified, leading to defective protein transport and cilia assembly. Over 70% of all people with PCD tested have pathogenic variants in one of these genes. In addition, motile ciliopathies *distinct* from classical PCD have been described. Children with biallelic variants in *CCNO* and *MCIDAS,* two proteins required for centriole production, have oligocilia and clinical features similar to PCD.

Insights into the genetic bases of motile ciliopathies have also yielded greater understanding of genotype-phenotype relationships in PCD. For instance, cross-sectional and longitudinal studies showed that children with the inner dynein arm–microtubular disorganization defect, primarily the result of biallelic pathogenic variants in *CCDC39* or *CCDC40,* had more severe lung disease. In contrast, people with pathogenic variants in *RSPH1* appear to have milder respiratory phenotypes.

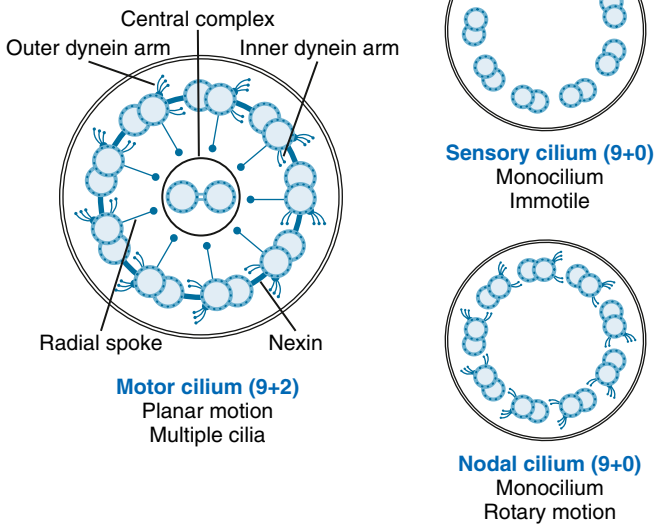

Fig. 455.2 Schemata showing the three general classes of normal cilia: motile cilia (motile "9+2"), nodal cilia (motile "9+0"), and primary cilia (nonmotile "9+0"), which demonstrate the complex structure and arrangement of the ciliary axoneme.

CLINICAL MANIFESTATIONS OF PRIMARY CILIARY DYSKINESIA

PCD has several characteristic clinical features (Table 455.1). **Neonatal respiratory distress** (NRD) is a common feature, and most affected term newborns develop increased work of breathing, tachypnea, and upper and middle lobe atelectasis on chest radiographs. The association of respiratory distress in *term neonates* with PCD has been underappreciated. Often diagnosed with transient tachypnea of the newborn or pneumonia, PCD infants frequently require supplemental oxygen flow for days to weeks.

Chronic, year-round productive (wet) cough that begins before 6 months of age is another characteristic feature of PCD. Bacterial cultures of sputum or lavage fluid frequently yield nontypeable *Haemophilus influenzae* (see Chapter 240), *Staphylococcus aureus* (see Chapter 227.1), *Streptococcus pneumoniae* (see Chapter 228), and *Pseudomonas aeruginosa* (see Chapter 251.1). Persistent airway infection and inflammation lead to **bronchiectasis**, even in preschool children (see Chapter 452). Children with PCD also have a higher prevalence of pectus excavatum and scoliosis.

Roughly 80% of patients with PCD have **chronic rhinosinusitis**, manifested by daily nasal congestion and copious, watery nasal

Table 455.2 Consensus-Based Primary Ciliary Dyskinesia (PCD) Diagnostic Criteria by Age

NEWBORNS (0-1 MO OF AGE)
Situs inversus totalis and unexplained neonatal respiratory distress (NRD) at term birth, plus at least one of the following: • Diagnostic ciliary ultrastructure on electron micrographs • Two pathogenic variants in PCD-associated gene
CHILDREN (1 MO TO 5 YR)
Two or more major PCD clinical criteria (NRD,* daily wet cough, persistent nasal congestion, laterality defect), plus at least one of the following (nasal nitric oxide not included in this age-group because it is not yet sufficiently tested): • Diagnostic ciliary ultrastructure on electron micrographs • Two pathogenic variants in one PCD-associated gene • Persistent and diagnostic ciliary waveform abnormalities on high-speed videomicroscopy on multiple occasions
CHILDREN (5-18 YR OF AGE) AND ADULTS
Two or more PCD clinical criteria (NRD,* daily productive cough or bronchiectasis, persistent nasal congestion, laterality defect), plus at least one of the following: • Nasal nitric oxide during plateau <77 nL/min on two occasions, >2 mo apart (with CF excluded) • Diagnostic ciliary ultrastructure on electron micrographs • Two pathogenic variants in one PCD-associated gene • Persistent and diagnostic ciliary waveform abnormalities on high-speed videomicroscopy on multiple occasions

*In term neonates.

discharge that begins early in infancy and persists into childhood. Inadequate innate mucous clearance leads to chronic sinusitis (see Chapter 429) and nasal polyposis. Middle ear disease occurs in many children with PCD, with varying degrees of **chronic otitis media with effusion**. Both conductive and sensorineural hearing loss occur at increased frequency in people with PCD, though the former is more common. Middle ear findings may be most helpful in distinguishing PCD from cystic fibrosis (CF) (see Chapter 454) or other causes of chronic lung disease.

Left-right laterality defects (e.g., *situs inversus totalis*) are found in ~50% of all children with PCD. Without functional nodal cilia in the embryonic period, thoracoabdominal orientation is random. Approximately 25% of children who have situs inversus totalis have PCD. Thus situs inversus totalis alone does not establish the diagnosis. Other laterality defects, such as **heterotaxy**, are also associated with PCD and may coexist with congenital cardiac defects, asplenia, or polysplenia. PCD should be strongly considered in term infants who have unexplained NRD and situs anomalies.

Most males with PCD have dysmotile spermatozoa because flagellar and ciliary ultrastructure is similar. Male infertility or subfertility is typical but not always found in this disease. Subfertility has also been reported in affected women, possibly related to ciliary dysfunction in the fallopian tubes.

A few case reports have associated neonatal hydrocephalus with PCD. The ependyma of the brain ventricles are lined by ciliated epithelium and are important for cerebrospinal fluid flow through the ventricles and aqueduct of Sylvius. The finding of enlarged brain ventricles on sonograms, when linked with situs inversus totalis, has been proposed as a prenatal diagnostic marker for PCD.

Several conditions have overlapping features of motile and primary ciliopathies. X-linked retinitis pigmentosa has been associated with recurrent respiratory infections in families with *RPGR* gene pathogenic variants. Intraflagellar transport proteins are essential for photoreceptor assembly and, when mutated, lead to apoptosis of the retinal pigment epithelium (see Chapter 670).

DIAGNOSIS OF PRIMARY CILIARY DYSKINESIA

The diagnosis of PCD has been challenging. A high index of suspicion is necessary, but pediatricians should only perform testing in children who have clinical manifestations consistent with the disease. PCD has four criteria-defined features that should be used to screen at-risk children: unexplained NRD in full-term infants, left-right laterality defects, persistent rhinitis that begins before 6 months of age, and daily wet or productive cough that also starts before 6 months of age (Table 455.2). Even though chronic otitis media is common in PCD, many unaffected infants and toddlers also have chronic middle ear involvement, which makes this feature less useful in distinguishing children with PCD from others.

Imaging studies show extensive involvement of the paranasal sinuses. Chest radiographs frequently demonstrate bilateral lung overinflation, peribronchial infiltrates, and lobar atelectasis. Computed x-ray tomography of the chest often reveals bronchiectasis, often involving the anatomic right middle lobe or lingula, even in young children. Situs inversus totalis in a child who has chronic respiratory tract symptoms is highly suggestive of PCD, but this configuration occurs in only 50% of people with the condition. Pulmonary function tests may be normal early but demonstrate obstructive airway disease as the disease progresses. Typical findings include decreased forced expiratory volume in 1 second (FEV_1), reduced expiratory flow rates, and increased residual volume. Bronchodilator responsiveness is variable. Longitudinal analyses of children with PCD show wide variation in intrathoracic airway obstruction.

No single test will diagnose every person with PCD. Historically, transmission electron microscopy has been the gold standard to assess structural defects within the cilium. These ultrastructural defects are found in cilia throughout the upper and lower airways and oviduct and in sperm flagella. Curettage from the nasal epithelium or endobronchial brushing can provide an adequate specimen for review. Identification of a specific, previously established defect in the ciliary structure with concurrent phenotypic features is sufficient to make the diagnosis. There are several characteristic ciliary abnormalities: outer dynein arm defects, combined inner and outer dynein arm defects, and inner

dynein arm defects with microtubular disorganization (see Fig. 455.3). Inner dynein arm defects alone are largely artifactual. It is important to note that ultrastructural examination of cilia as a diagnostic test for PCD has limitations. First, the absence of axonemal defects does not exclude PCD; nearly 30% of affected individuals have normal ciliary ultrastructure. Other children with symptoms consistent with PCD have been found to have ciliary aplasia or few motile cilia on the epithelial surface (see Fig. 455.3)

Careful interpretation of the ultrastructural findings is necessary because ciliary defects can be acquired. Nonspecific changes (e.g., compound cilia or blebs) may be seen in relation to exposure to environmental pollutants or infection. Frequently, the diagnosis of PCD can be delayed or missed because of inadequate tissue collection or sample processing or misinterpretation of ciliary defects. Some investigators have advocated culturing of airway epithelial cells and allowing the secondary changes to resolve. Alternatively, immunofluorescent staining for axonemal protein markers may overcome some limitations of transmission electron microscopy.

Another useful approach has exploited the observation that nasal nitric oxide concentrations are reduced in subjects with PCD. Because nasal nitric oxide measurements are relatively easy to perform and noninvasive, this method is a valuable screen for PCD. When compared to other diagnostic tools, nasal nitric oxide can be sensitive and specific for PCD in cooperative older children and adults. Unfortunately, few studies in children under 5 years have been reported, and the accuracy of nasal nitric oxide measurements in infants has not been established. It is important to note that children who have pathogenic variants in some PCD-associated genes can have nondiagnostic nasal nitric oxide concentrations. Conversely, people with CF (see Chapter 454) or primary immunodeficiencies (see Chapter 165), conditions that have clinical features that overlap with PCD, can have reduced nasal nitric oxide levels. Thus reduced nasal nitric oxide concentrations alone are never sufficient to make the diagnosis of PCD.

Qualitative tests to assess ciliary function have been used to screen for PCD. Ciliary beat frequency measurements using standard light microscopy have been used as a screen, but this approach can be misleading and should never be used as a diagnostic tool. High-resolution, high-speed digital imaging of ciliary motion in multiple planes permits comprehensive analysis of cilia beating, which has shown that certain beat patterns are associated with specific ultrastructural defects. This technique is available only at specialized centers, primarily in Europe, and requires sophisticated software and expertise.

PCD is highly heterogenic owing to the large number of proteins involved in cilia assembly, structure, and function. Advances in gene sequencing techniques have led to the identification of a growing number of disease-associated genes. Genetic testing has become increasingly available and is considered a first-line test for PCD, incorporated into published diagnostic algorithms. Nevertheless, current, commercially available testing for pathogenic variants in at least 30 genes will only identify approximately 70% of affected children (see Fig. 455.3).

TREATMENT

No therapies have been shown to correct ciliary dysfunction in PCD. Many of the treatments applied to children with the condition are similar to those used in other chronic suppurative lung diseases characterized by impaired airway clearance and bronchiectasis, such as CF (see Chapter 454), but few have been adequately studied to demonstrate efficacy in PCD.

Strategies to enhance mucociliary clearance are central to PCD therapy, and routine airway clearance techniques using postural drainage, percussion vests, positive expiratory pressure devices, or other techniques should be instituted daily. Because ciliary function is impaired, cough becomes a critical mechanism for mucous clearance and should not be suppressed. Exercise can enhance airway clearance in people with PCD and should be encouraged. Inhaled hypertonic saline and mucolytic agents are often used in CF care, but only small case series or single-site clinical trials showed any improvement in people with PCD after treatment. Thrice-weekly azithromycin as an antiinflammatory agent is reported to reduce the frequency of pulmonary exacerbations but has no effect on lung function or quality-of-life measures.

When children with PCD develop increasing respiratory symptoms consistent with infection, antimicrobial therapy should be instituted based on respiratory culture results and bacterial sensitivities. Maintenance therapy with inhaled or oral antibiotics can be used cautiously in patients with PCD who have bronchiectasis or frequent respiratory exacerbations. Immunizations against pertussis, influenza, and pneumococci are cornerstones of care. Additional preventive measures include avoidance of cigarette or marijuana smoke, electronic cigarette aerosols, and other airway irritants.

Rarely, surgical resection of bronchiectatic lung has been performed on people with PCD, typically in cases of localized disease with severe hemoptysis or intractable infections. It is unclear whether surgical interventions provide reduction in symptoms or survival benefit.

Progression to end-stage lung disease and respiratory failure has been reported in people with PCD. Adults have undergone successful heart-lung, double-lung, or living-donor lobar lung transplantation. Situs inversus totalis complicates the procedure because of anatomic considerations. Otherwise, survival is similar to that for other transplant recipients.

Treatment of chronic otitis media and middle ear effusions in people with PCD is controversial. Myringotomy tubes are frequently placed in affected children, and some studies reported enhanced hearing in children with chronic conductive hearing loss after the procedure. However, others did not find improvement in hearing acuity. Intractable mucoid otorrhea, tympanosclerosis, and permanent membrane perforation are known complications of myringotomy tubes in people with PCD, leading some to recommend against surgical management. Although hearing tends to improve with time, children and adolescents with PCD should be routinely screened and hearing aids used when necessary.

Chronic rhinitis and sinusitis are frequent clinical manifestations of PCD. No treatments have been shown to be effective, although patients are often treated with nasal washes, paranasal sinus lavage, and systemic antibiotics when they are symptomatic. As with any overuse of antimicrobial agents, the development of resistant organisms is a concern. When nasal symptoms are severe or refractory to medical management, endoscopic sinus surgery can be used to promote drainage or local delivery of medications, but the benefit may be short lived.

PROGNOSIS

Although signs and symptoms related to upper respiratory involvement predominate early in PCD, clinical manifestations of lower respiratory tract disease tend to increase with age and become the leading cause of morbidity and mortality in patients with PCD. It is believed that progression and extent of lung disease can be slowed with early diagnosis and therapy. Routine surveillance studies recommended the following for the care of children with PCD: (1) regular spirometry to monitor pulmonary function, (2) chest imaging, and (3) sputum or oropharyngeal cultures to assess respiratory flora.

Children with PCD usually have a slower decline in pulmonary function than those with CF, and its prognosis and long-term survival are better. Many can have a normal or near-normal life span, whereas others experience progressive bronchiectasis and respiratory deterioration at a younger age.

Chapter 456

Diffuse Lung Diseases in Childhood

See also Chapter 448.

456.1 Inherited Disorders of Surfactant Metabolism

Jennifer A. Wambach, Lawrence M. Nogee, Aaron Hamvas, and F. Sessions Cole III

Pulmonary surfactant is a mixture of phospholipids and proteins synthesized, packaged, and secreted by alveolar type II pneumocytes (AEC2s) that line the distal air spaces. This mixture forms a monolayer at the air-liquid interface that lowers surface tension at end expiration of the respiratory cycle, preventing atelectasis and ventilation-perfusion mismatch. Four surfactant-associated proteins have been characterized: surfactant proteins A and D (SP-A, SP-D) participate in host defense in the lung, whereas surfactant proteins B and C (SP-B, SP-C) contribute to the surface tension–lowering activity of pulmonary surfactant. The adenosine triphosphate–binding cassette protein member A3, ABCA3, is a transporter located on the limiting membrane of lamellar bodies, the intracellular storage organelle for surfactant within AEC2s, and has an essential role in surfactant phospholipid metabolism. The proper expression of the surfactant proteins and ABCA3 is dependent on a number of transcription factors, particularly thyroid transcription factor 1 (TTF-1). Two genes for SP-A *(SFTPA1, SFTPA2)* and one gene for SP-D *(SFTPD)* are located on human chromosome 10, whereas single genes encode SP-B *(SFTPB)*, SP-C *(SFTPC)*, TTF-1 *(NKX2-1)*, and ABCA3 *(ABCA3)*, which are located on human chromosomes 2, 8, 14, and 16, respectively. Inherited disorders of SP-B, SP-C, ABCA3, and TTF-1 have been recognized in humans and are collectively termed **surfactant dysfunction disorders** (Table 456.1). Variants in *SFTPD* have not been associated with disease, and pathogenic variants in the genes encoding SP-A have only been found in adults with idiopathic pulmonary fibrosis or lung cancer.

PATHOLOGY

These disorders share a unique constellation of features, including AEC2 hyperplasia, alveolar macrophage accumulation, interstitial thickening and inflammation, and alveolar proteinosis. A number of different descriptive terms have historically been applied to these disorders, including ones borrowed from adult forms of interstitial lung disease (**desquamative interstitial pneumonia**, nonspecific interstitial pneumonia) and a disorder unique to infancy **(chronic pneumonitis of infancy)**. These diagnoses in infants and children are strongly indicative of surfactant dysfunction disorders but do not distinguish which gene is responsible. Because the prognosis and inheritance patterns differ depending on the gene involved, genetic testing should be offered when one of these conditions is reported in the lung biopsy or autopsy of an infant or child. Other disorders, including genetic causes of **pulmonary alveolar proteinosis** (see Chapter 456.2), and disorders of immune dysregulation can be associated with similar pathologies.

DEFICIENCY OF SURFACTANT PROTEIN B (SURFACTANT METABOLISM DYSFUNCTION, PULMONARY, 1; SMDP1; OMIM #265120)

Clinical Manifestations

Infants with an inherited deficiency of SP-B present in the *immediate* neonatal period with respiratory failure. This autosomal recessive disorder is clinically and radiographically similar to the respiratory distress syndrome (RDS) of premature infants (see Chapter 126) but typically affects full-term infants. The initial degree of respiratory distress is variable, but the disease is progressive and is refractory to

Table 456.1 Comparison of Surfactant Dysfunction Disorders

	SP-B DEFICIENCY	SP-C DISEASE	ABCA3 DEFICIENCY	TTF-1 DISORDERS
Gene name	*SFTPB*	*SFTPC*	*ABCA3*	*NKX2-1*
Age of onset	Birth	Birth to adulthood	Birth to childhood; rarely adult	Birth to childhood
Inheritance	Recessive	Dominant/sporadic	Recessive	Sporadic/dominant
Mechanism	Loss of function	Gain in toxic function or dominant negative	Loss of function	Loss of function Gain in function
Natural history	Lethal	Variable	Generally lethal, may be chronic	Variable
DIAGNOSIS				
Biochemical (tracheal aspirate)	Absence of SP-B and presence of incompletely processed proSP-C	None	None	None
Genetic (DNA)	Sequence *SFTPB*	Sequence *SFTPC*	Sequence *ABCA3*; copy number variant detection	Sequence *NKX2-1*; copy number variant detection
Ultrastructural (lung biopsy–electron microscopy)	Disorganized lamellar bodies	Not specific; may have dense aggregates	Small dense lamellar bodies with eccentrically placed dense cores	Variable
Treatment	Lung transplantation or compassionate care	Supportive care, lung transplantation if progressing	Lung transplantation or compassionate care for infants with biallelic null variants; lung transplantation for other variants if progressing	Supportive care; treat coexisting conditions (hypothyroidism)

SP, Surfactant protein.

mechanical ventilation, surfactant replacement therapy, and glucocorticoid administration. Almost all affected infants have died without lung transplantation, but prolonged survival is possible in cases of partial deficiency of SP-B. Humans heterozygous for loss-of-function variants in *SFTPB* are clinically healthy as adults but may be at increased risk for obstructive lung disease if they also have a history of smoking.

Genetics

Multiple loss-of-function variants in *SFTPB* have been identified. The most common is a net two base-pair insertion in codon 133 (originally termed *121ins2,* currently termed *c.397delCinsGAA, p.Pro133Glufs*95*) that results in a frameshift, an unstable SP-B messenger RNA (mRNA) transcript, and absence of SP-B protein production. This pathogenic variant has accounted for 60–70% of the alleles found to date in infants identified with SP-B deficiency and is present in approximately 0.07% of European-descent individuals in large-scale sequencing projects. Most other pathogenic variants have been family-specific. A large deletion encompassing two exons of *SFTPB* has also been reported.

Diagnosis

A rapid, definitive diagnosis can be established with sequence analysis of *SFTPB,* which is available through clinical laboratories (Genetic Testing Registry, https://www.ncbi.nlm.nih.gov/gtr). Sequencing of *SFTPB* is usually performed as part of a multigene panel using next-generation sequencing (NGS) methods that includes genes for other surfactant dysfunction disorders and can be designed to detect deletions or duplications of one or more exons (copy number variants). For families in which *SFTPB* variants were previously identified, antenatal diagnosis can be established by preimplantation genetic diagnosis (PGD) or molecular assays of DNA from chorionic villous biopsy or amniocytes, which permit advanced planning of a therapeutic regimen. Other laboratory tests remain investigational, including analysis of tracheal aspirate (effluent) for the presence or absence of SP-B protein and for incompletely processed precursor proSP-C peptides that have been identified in SP-B–deficient human infants. Immunostaining of lung biopsy tissue for the surfactant proteins can also support the diagnosis, although immunohistochemical assays for SP-B and SP-C are also generally available only on a research basis. Staining for SP-B is usually absent, but robust extracellular staining for proSP-C because of incompletely processed proSP-C peptides is observed and is diagnostic for SP-B deficiency. Such studies require a lung biopsy in a critically ill infant but may be performed on lung blocks acquired at the time of autopsy, allowing for retrospective diagnosis. With electron microscopy, a lack of tubular myelin, disorganized lamellar bodies, and an accumulation of abnormal-appearing multivesicular bodies suggest abnormal lipid packaging and secretion.

SURFACTANT PROTEIN C–ASSOCIATED INTERSTITIAL LUNG DISEASE (SURFACTANT METABOLISM DYSFUNCTION, PULMONARY, 2; SMDP2; OMIM #610913)

SP-C is a very low molecular weight, extremely hydrophobic protein that, along with SP-B, enhances the surface tension–lowering properties of surfactant phospholipids. The mature SP-C protein (35 amino acids) is derived from proteolytic processing of a larger precursor protein (proSP-C).

Clinical Manifestations

The clinical presentation of patients with *SFTPC* pathogenic variants is quite variable. Some patients present at birth with symptoms, signs, and radiographic findings typical of RDS. Others present later in life, *ranging from early infancy until well into adulthood,* with gradual onset of respiratory insufficiency, hypoxemia, failure to thrive, and chest radiograph findings of **interstitial lung disease**, or as **pulmonary fibrosis** in the fifth or sixth decade of life. The age and severity of disease vary even within families with the same *SFTPC* variant. The natural history is also quite variable, with some patients improving either spontaneously or as the result of therapy or prolonged mechanical ventilation, some with persistent respiratory insufficiency, and some progressing to the point of requiring lung transplantation. This variability in presentation, severity, and course of the disease does not appear to correlate with the specific *SFTPC* variant and also hinders accurate assessment of prognosis.

Genetics

Multiple pathogenic variants in *SFTPC* have been identified in association with acute and chronic lung disease in patients ranging in age from newborn to adult. A pathogenic variant on only *one SFTPC* allele is sufficient to cause disease. Approximately half of these variants arise spontaneously, resulting in sporadic disease, but the remainder are inherited as a *dominant trait*. *SFTPC* pathogenic variants have been identified in diverse racial and ethnic groups. A threonine substitution for isoleucine in codon 73 (termed *p.I73T* or *p.Ile73Thr*) has accounted for 25–35% of the cases identified to date but is rare (not identified in gnomAD in ~140,000 individuals). Pathogenic variants in *SFTPC* are thought to cause disease because of a toxic gain in function resulting from the production of misfolded or abnormal proSP-C that accumulates within the AEC2 and causes cellular injury or alters the normal intracellular routing of proSP-C. Lung tissue from individuals with pathogenic variants in *SFTPC* demonstrates accumulation of pro-SPC. Many pathogenic *SFTPC* variants are located in the carboxy-terminal domain of pro-SP-C, which has a similar homology to other members of the *BRICHOS* family of membrane proteins, the abnormal aggregation of which have been implicated in the pathophysiology of familial dementia and some cancers. Pathogenic variants within the BRICHOS domain (amino acid residues 90-197) of *SFTPC* result in aggregation of misfolded protein in the endoplasmic reticulum, activation of the unfolded protein response, inflammation, and subsequent fibrosis. Non-BRICHOS domain pathogenic variants result in mistrafficking of pro-SPC to the plasma membrane and endosomes rather than the lamellar bodies, a late block in macroautophagy, inflammation, and subsequent fibrosis. The different underlying pathogenic mechanisms of *SFTPC* variants do not appear to correlate with the clinical presentation and may necessitate different therapeutic approaches.

Diagnosis

Sequencing of *SFTPC,* the only definitive diagnostic test, is available usually as part of an NGS multiple-gene panel in clinical laboratories. Because most *SFTPC* pathogenic variants are missense variants, distinguishing true disease-causing variants from rare yet benign sequence variants may be difficult. Immunostaining of lung tissue may demonstrate proSP-C aggregates but is available only on a research basis.

DISEASE CAUSED BY PATHOGENIC VARIANTS IN *ABCA3* (SURFACTANT METABOLISM DYSFUNCTION, PULMONARY, 3; SMDP3; OMIM #610921)

Clinical Manifestations

Lung disease caused by pathogenic variants in *ABCA3* generally presents as either a severe, lethal form that manifests in the *immediate newborn period,* clinically similar to SP-B deficiency, or a chronic form that appears most typically in the first year of life with **interstitial lung disease** similar to SP-C–associated interstitial lung disease. Infants who are homozygous or compound heterozygous for null variants, that is, the variant is predicted to result in the absence of protein expression (i.e., nonsense or frameshift variants), typically present with lethal neonatal respiratory failure, whereas infants with missense, in-frame insertion/deletions or splicing variants have more variable age of onset and outcomes. Heterozygosity for an *ABCA3* variant may contribute to the risk for RDS in late preterm and term infants, who, in contrast to ABCA3-deficient infants with variants on both alleles, may eventually completely recover from their initial lung disease.

Genetics

Recessive variants in *ABCA3* were first described among infants who presented with lethal RDS in the newborn period, but now have been identified in older infants and children with **interstitial lung disease**. There is considerable allelic heterogeneity: more than 400 variants

scattered throughout the gene have been identified, most of which are family-specific. The presence of null variants on both alleles that are predicted to preclude any ABCA3 production has been associated with early-onset disease and a uniformly fatal prognosis without lung transplant. A missense variant that results in a valine substitution for glutamine in codon 292 (p.Glu292Val or p.E292V) in association with a second *ABCA3* variant has been found in children with severe neonatal respiratory failure and in older children with interstitial lung disease and is present in approximately 0.7% of European-descent individuals. *ABCA3* variants have been identified in diverse racial and ethnic groups. The precise frequency of disease is unknown; large-scale sequencing projects indicate that the overall carrier rate for *ABCA3* variants may be as high as 1 in 50 to 1 in 70 individuals. However, many *ABCA3* variants are private, have not been previously identified in affected individuals, and functional data are only available for a limited number of disease-associated variants, thereby limiting these estimates. Two mechanistic classes of *ABCA3* variants have been identified: those that disrupt intracellular trafficking of ABCA3 to the lamellar bodies with retention of the variant protein in the endoplasmic reticulum and those that traffic normally but impair adenosine triphosphate (ATP)–mediated phospholipid transport into the lamellar bodies. ABCA3 deficiency may contribute to a substantial proportion of *unexplained fatal lung disease* in term infants and of *interstitial lung disease* in older children.

Diagnosis

Sequence analysis of *ABCA3* is available in clinical laboratories, usually as part of an NGS multiple-gene panel, and is the most definitive approach for diagnosis. Considerable variation in *ABCA3* necessitates careful interpretation regarding the functionality of an individual variant and its contribution to the clinical presentation. Additionally, *sequence analysis is not 100% sensitive,* as functionally significant variants may exist in untranslated regions that are not generally analyzed. As large deletions spanning one or more exons have been identified, it is important that the gene panel be able to detect such variants. In situations when the sequence analysis results are inconclusive, lung biopsy with electron microscopy to examine lamellar body morphology may be a useful adjunct to the diagnostic approach. Small lamellar bodies that contain electron-dense inclusions may be observed in association with *ABCA3* pathogenic variants. These findings support the hypothesis that ABCA3 function is necessary for lamellar body biogenesis. There are no biochemical markers to establish the diagnosis.

DISEASE CAUSED BY PATHOGENIC VARIANTS IN *NKX2-1* (THYROID TRANSCRIPTION FACTOR 1, CHOREOATHETOSIS, HYPOTHYROIDISM, AND NEONATAL RESPIRATORY DISTRESS, OMIM #600635)

Clinical Manifestations

A large deletion of the region of chromosome 14 (14q13.3) encompassing the *NKX2-1* locus was first recognized in an infant with *hypothyroidism* and *neonatal RDS*. Multiple large deletions involving the *NKX2-1* locus and contiguous genes as well as missense, frameshift, nonsense, and small insertion or deletion variants scattered throughout the gene have been reported in individuals with hypothyroidism, lung disease, and neurologic symptoms, including benign familial chorea. Manifestation of dysfunction in all three organ systems has been referred to as **brain-thyroid-lung syndrome**, but disease may manifest in only one or two organ systems. The lung disease can range from severe and eventually *lethal neonatal respiratory distress* to *chronic lung disease in childhood and adulthood*. Recurrent pulmonary infections have been reported, likely caused by reduced expression of the pulmonary collectins, SP-A and SP-D, but could also result from decreased expression of other *NKX2-1* transcriptionally regulated proteins. No clear genotype-phenotype correlations have emerged, but children harboring complete gene deletions have generally had more severe and earlier-onset disease. This observation could also be related to the deletion of other adjacent genes. Although limited data are available, the pulmonary phenotype may depend on the expression of which *NKX2-1* target genes are most affected. Children with decreased SP-B or ABCA3 expression may present with acute neonatal respiratory failure, whereas those with decreased SP-C or pulmonary collectin expression are more likely to have chronic lung disease.

Genetics

The *NKX2-1* gene is small, spanning less than 3,000 bases, with only three exons. TTF-1 is expressed not only in the lung but also in the thyroid gland and in the central nervous system. In the lung it is important for the expression of a wide variety of proteins, including the surfactant proteins, ABCA3, club cell secretory protein, and many others. Two transcripts that differ depending on whether the transcriptional start site is in the first or second exon have been recognized, although the shorter transcript is the predominant transcript in the lung. Most *NKX2-1* pathogenic variants are thought to result in a loss of function, with the mechanism of disease thus being haploinsufficiency, but discordant effects on different target genes have been reported. Loss-of-function variants in *NKX2-1* are rare in large sequencing projects, but the prevalence of disease is unknown. Pathogenic variants in diverse ethnic groups have been recognized. Most reported variants and deletions have occurred de novo, resulting in sporadic disease, but familial disease transmitted in a dominant manner has been recognized.

Diagnosis

Sequence analysis of the *NKX2-1* gene is available through clinical laboratories, usually as part of an NGS multiple-gene panel, and is the preferred method for diagnosis. Because large deletions comprise a significant fraction of reported variant alleles, specific methods to assess for deletions should also be performed, such as a chromosomal microarray or gene-targeted deletion/duplication analysis. A pathogenic variant on one allele is sufficient to cause disease. Although isolated pulmonary disease has been recognized, the majority of reported affected individuals have manifestations in two or more other organ systems. Thus the presence of **hypothyroidism** or neurologic abnormality in a proband or a family history of chorea should prompt consideration of the diagnosis. The most specific neurologic finding is **chorea**, but hypotonia, developmental delay, ataxia, and dysarthria have been reported. In very young, nonambulatory infants the neurologic symptoms may not be evident, or muscle weakness or hypotonia may be attributed to the severity of lung disease or a result of the hypothyroidism. Affected individuals may not be overtly hypothyroid but have compensated hypothyroidism with borderline low thyroxine (T_4) and high thyroid-stimulating hormone levels. The lung pathology associated with *NKX2-1* pathogenic variants may be typical of that of other surfactant dysfunction disorders, but because *NKX2-1* is important for lung development, growth abnormalities and arrested pulmonary development also may be seen. Immunostaining studies of surfactant protein expression have yielded variable results, with decreased expression of one or more surfactant-related proteins observed in some patients. No characteristic electron microscopy findings have been identified.

TREATMENT OF SURFACTANT DYSFUNCTION DISORDERS

Virtually all patients with SP-B deficiency die within the first year of life. Conventional neonatal intensive care interventions can maintain extrapulmonary organ function for a limited time (weeks to several months). Replacement therapy with commercially available surfactants is ineffective. Lung transplantation has been successful, but the pretransplantation, transplantation, and posttransplantation medical and surgical care is highly specialized and available only at pediatric pulmonary transplantation centers. Prompt recognition is critical if patients are to be considered for lung transplantation. Palliative care consultation is helpful.

No specific treatment is available for patients with lung disease caused by pathogenic variants in *SFTPC* or *ABCA3*. Therapeutic approaches used for interstitial lung diseases, such as the use of corticosteroids, quinolones, and macrolide antibiotics, have been reported but not systematically evaluated (Fig. 456.1). Infants with severe and progressive respiratory failure attributable to ABCA3 deficiency may be candidates

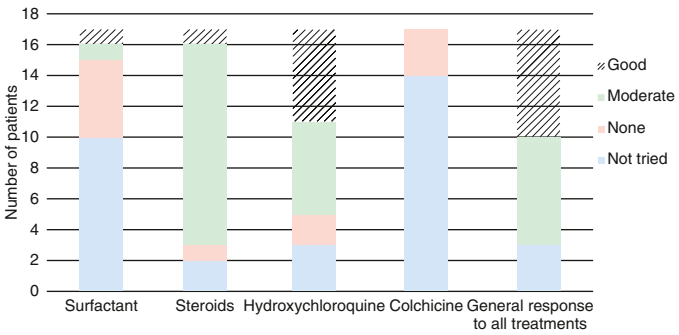

Fig. 456.1 Response to therapies for 17 patients with *SFTPC* variants. *(Data from Kröner C, Reu S, Teusch V, et al. Genotype alone does not predict the clinical course of SFTPC deficiency in paediatric patients. Eur Respir J. 2015;46:197–206.)*

for lung transplantation. The variable natural history of patients with *SFTPC* variants and older children with ABCA3 deficiency makes predictions of prognosis difficult. Lung transplantation is reserved for patients with progressive and refractory respiratory failure who would otherwise qualify for transplantation irrespective of their diagnosis.

Treatment for patients with *NKX2-1* variants is largely supportive. Hypothyroidism, if present, should be treated with thyroid hormone replacement. Corticosteroids and other agents used for other types of surfactant dysfunction have not been formally evaluated. Some individuals have progressive lung disease and have undergone lung transplantation. The variable progression of disease and presence of extrapulmonary disease may make evaluation and selection of subjects for transplantation particularly difficult.

Parents of children with surfactant dysfunction disorders should be offered genetic counseling to inform recurrence risk for future pregnancies, to present antenatal diagnostic options and offer delivery at a center with neonatal intensive care, and to facilitate discussions regarding whether testing should be offered to other family members who may not be symptomatic.

456.2 Pulmonary Alveolar Proteinosis

Jennifer A. Wambach, Lawrence M. Nogee, F. Sessions Cole III, and Aaron Hamvas

Pulmonary alveolar proteinosis (PAP) is a rare syndrome characterized by the intraalveolar and terminal airway accumulation of surfactant leading to progressive hypoxemic respiratory failure. PAP can result from abnormalities in surfactant production or surfactant clearance. Histopathologic examination shows distal air spaces are filled with a granular, eosinophilic material that stains positively with periodic acid–Schiff reagent and is diastase resistant. This material contains large amounts of surfactant proteins and lipids, and the primary mechanism for its accumulation is impaired catabolism by alveolar macrophages. PAP is classified as either *primary* due to disruption of granulocyte-macrophage colony-stimulating factor (GM-CSF) signaling or *secondary* due to several different diseases that reduce alveolar macrophage number or function (Table 456.2). A fulminant, usually lethal, form of PAP manifesting shortly after birth has been termed **congenital alveolar proteinosis**, but because this condition is caused by disrupted surfactant metabolism or surfactant dysfunction within alveolar type II cells, the disease is included under inherited disorders of surfactant metabolism (see Chapter 456.1).

ETIOLOGY AND PATHOPHYSIOLOGY

Primary Alveolar Proteinosis

Disordered signaling of GM-CSF leading to impaired alveolar macrophage maturation is the major underlying cause of primary PAP in children and adults. Most cases of primary PAP in older children and adults are mediated by *neutralizing autoantibodies* directed against GM-CSF, which can be detected in serum and bronchoalveolar lavage (BAL) fluid. These autoantibodies block binding of GM-CSF to its receptor, thereby inhibiting alveolar macrophage maturation and function and surfactant clearance. Variants in the genes encoding both the α and β subunits of the GM-CSF receptor *(CSF2RA, CSFR2B)* in children with PAP account for a genetic basis for some cases of primary PAP in childhood.

Secondary Alveolar Proteinosis

Alveolar proteinosis has also been reported in children, including young infants, with **lysinuric protein intolerance**, a rare autosomal recessive disorder caused by pathogenic variants in the cationic amino acid transporter SLC7A7 (see Chapter 105.14). These children generally present with vomiting, hyperammonemia, and failure to thrive, although their pulmonary disease may prove fatal. A case of *recurrence* of the disease after lung transplantation supports a primary role for alveolar macrophage dysfunction in the pathogenesis of PAP associated with lysinuric protein intolerance. PAP is also a prominent feature in patients with biallelic variants in the gene encoding methionyl tRNA synthetase *(MARS)*, who have a multiorgan phenotype that also includes liver disease as a prominent feature and is prevalent among individuals on Reunion Island. The mechanism for PAP in patients with *MARS* variants is unknown. Heterozygous variants in the gene encoding the transcription factor GATA2 have also been associated with a phenotype that includes PAP, as well as immune deficiencies, myelodysplasia, and lymphatic abnormalities. The mechanism for PAP in patients with such variants likely is related to the role of GATA2 in alveolar macrophage development. Heterozygous gain-in-function variants in the *OAS1* gene have been identified in infants and children with a phenotype that includes PAP, hypogammaglobulinemia, and immune dysfunction. *OASl* gene products are important in the innate immune response to viral infection, and gene activation leads to inhibition of protein synthesis and apoptosis, with apoptosis of alveolar macrophages likely resulting in PAP. PAP may also be associated with some subtypes of Niemann-Pick disease (see Chapter 106.4).

Secondary alveolar proteinosis also may occur in association with *infection,* particularly in immunocompromised individuals. However, because the same pathologic process occurs in severely immunodeficient mice raised in a pathogen-free environment, it is not clear whether this phenotype results from a secondary infection or the underlying immunodeficiency. Environmental exposures to dust, silica, and chemicals and chemotherapeutic agents; hematologic disorders (myelodysplastic syndrome); and nonhematologic malignancies have also been associated with the development of secondary alveolar proteinosis.

CLINICAL MANIFESTATIONS

Infants and children with PAP present with dyspnea, fatigue, cough, weight loss, chest pain, or hemoptysis. In the later stages, cyanosis and digital clubbing may be seen. Pulmonary function changes include decreased diffusing capacity of carbon monoxide, lung volumes with a restrictive abnormality, and arterial blood gas values indicating marked hypoxemia and/or chronic respiratory acidosis. Alveolar proteinosis in infants and children is rare, and males are affected three times as often as females.

DIAGNOSIS

Histopathologic examination of lung biopsy specimens currently remains the gold standard for diagnosis of PAP in children, although this is likely to change as molecular tests become available. Immunohistochemical staining reveals abundant quantities of alveolar and intracellular surfactant proteins A, B, and D. Latex agglutination tests for the presence of anti–GM-CSF antibodies in BAL fluid or blood are highly sensitive and specific for the autoimmune forms of alveolar proteinosis. Elevations of GM-CSF in peripheral blood suggest a GM-CSF receptor defect, and molecular analysis of these genes should be pursued. The examination of sputum or BAL fluid for surfactant components has been used for diagnosis in adults, but these methods have not been validated in children. Examination of peripheral blood and/or bone marrow for clonogenic stimulation of monocyte-macrophage

precursors, GM-CSF receptor and ligand expression, and GM-CSF binding and signaling studies are available through research protocols.

TREATMENT

The natural history of primary PAP is highly variable, making prognostic and therapeutic decisions difficult. Total lung lavage has been associated with prolonged remission of PAP in adults and remains a therapeutic option for patients with childhood PAP (Fig. 456.2). Younger infants with PAP may be more likely to have genetic mechanisms underlying their disease, and the role of repeated BAL in children has not been well studied, nor is it likely to be effective. It may provide a temporizing measure in some circumstances and may benefit patients with autoimmune or secondary PAP. Subcutaneous or inhaled administration of recombinant GM-CSF may improve pulmonary function in some adults with later-onset PAP. The role of exogenous GM-CSF treatment in children has not been well studied, although successful treatment with inhaled recombinant GM-CSF (molgramostim) has been reported in adults with autoimmune-mediated PAP. Because children with GM-CSF receptor defects generally have high serum levels of GM-CSF, exogenous GM-CSF seems unlikely to be effective in most such cases. Depending on the nature of the variant(s) responsible for the deficiency, some responsiveness of the receptor may be retained such that a response to exogenous GM-CSF is possible. Because the primary defect for PAP resides in the alveolar macrophage, which is a bone marrow–derived cell, lung transplantation would not be expected to correct primary PAP.

Chapter 457

Pulmonary Hemosiderosis

Mary A. Nevin

Pulmonary hemorrhage may be characterized as focal or diffuse based on the location(s) of bleeding (see Chapter 458.2). The diagnosis of pulmonary hemosiderosis refers to the subset of patients with **diffuse alveolar hemorrhage (DAH)**. Bleeding in DAH occurs as a result of injury to the microvasculature of the lung and may be slow and insidious because of the low-pressure pulmonary circulation. Pulmonary hemosiderosis has classically been characterized by the triad of iron-deficiency anemia, hemoptysis, and radiographic evidence of alveolar infiltration. However, many of those affected, particularly young patients, are likely to present atypically, and a high index of suspicion for this condition must be maintained. Pulmonary hemosiderosis can exist in isolation, but more commonly occurs in association with an underlying condition. Defining a precise etiology for hemorrhage may be elusive. A diagnosis of **idiopathic pulmonary hemosiderosis (IPH)** is made when DAH occurs in isolation and an exhaustive evaluation for an underlying pathologic etiology is found to be unrevealing or nondiagnostic.

ETIOLOGY

The pathogenesis of pulmonary hemosiderosis is diverse, but DAH may be classified based on histopathologic examination. Three histopathologic patterns have been described: pulmonary capillaritis, bland pulmonary hemorrhage, and diffuse alveolar damage. Of these, pulmonary capillaritis is most frequently encountered and appears to carry a negative prognosis in those affected with DAH.

The histopathologic finding of **pulmonary capillaritis** is characterized by neutrophilic inflammation of the alveolar interstitium, endothelial edema, and fibrinoid necrosis. DAH with pulmonary capillaritis is frequently associated with an underlying systemic vasculitic process or collagen vascular disease.

Disorders associated with pulmonary capillaritis include systemic lupus erythematosus (SLE; see Chapter 199), drug-induced capillaritis, anti–glomerular basement membrane (GBM) antibody syndrome (Goodpasture syndrome), IgA vasculitis (Henoch-Schönlein purpura) (see Chapter 210), and antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis, including granulomatosis with polyangiitis (formerly Wegener granulomatosis), microscopic polyangiitis (MPA; see Chapter 210), and eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome). Additional etiologies of pulmonary capillaritis include primary antiphospholipid antibody syndrome, rheumatoid arthritis, hypocomplementemic urticarial vasculitis, and acute lung transplant rejection. DAH in individuals with ANCA-associated vasculitis (granulomatosis with polyangiitis and microscopic polyangiitis) is frequently associated with pathologic evidence of pulmonary capillaritis. In patients with Goodpasture syndrome, antiphospholipid syndrome, and SLE, DAH has been reported with pathologic evidence of capillaritis, but bland hemorrhage has also been described. Isolated pulmonary capillaritis may also be seen in the absence of ANCA positivity.

Drugs, including propylthiouracil, aspirin, hydralazine, and tumor necrosis factor alpha (TNF-α) antagonists, have been implicated as an etiology for pulmonary capillaritis and DAH. Finally, alveolar hemorrhage with capillaritis has been increasingly described as a complication of hematopoietic cell transplantation

Pulmonary hemosiderosis with the histopathologic finding of **bland hemorrhage** is found when there is an absence of alveolar capillary inflammation or endothelial and cellular disruption. Both anti-GBM disease and SLE may be associated with bland hemorrhage, although the finding of capillaritis is more typical. Other causes of bland hemorrhage include cardiac or cardiopulmonary derangements (pulmonary hypertension, mitral stenosis, mitral regurgitation, arteriovenous malformation), disseminated intravascular coagulation (DIC), coagulopathies, and anticoagulant therapy. Bland hemorrhage is also described in IPH.

Diffuse alveolar damage (DAD) is characterized by diffuse alveolar and interstitial edema with hyaline membrane formation. It is the pathognomonic finding in acute respiratory distress syndrome (ARDS) and is seen with a variety of infections, including opportunistic pathogens in immunocompromised individuals. Drug toxicity (sirolimus, nitrofurantoin, amphetamines, vaping), radiation therapy, and pulmonary embolus and infarction are other described etiologies for DAD with pulmonary hemorrhage. Table 457.1 provides a summary and classification of the diagnoses that may manifest with recurrent or chronic pulmonary hemorrhage.

EPIDEMIOLOGY

Disorders that present as DAH are highly variable in their severity and in their associated symptomatology and identifiable

Table 457.1 Diffuse Alveolar Hemorrhage Syndromes

DISORDERS WITH PULMONARY CAPILLARITIS
Granulomatosis with polyangiitis (Wegener granulomatosis)
Microscopic polyangiitis
Systemic lupus erythematosus (SLE)
Systemic sclerosis
Polymyositis
Anti-GBM antibody syndrome (Goodpasture)
Antiphospholipid antibody syndrome

Cryoglobulinemia
Endocarditis
Drug-induced capillaritis (retinoic acid, propylthiouracil, etanercept, infliximab, hydralazine)
Idiopathic pulmonary-renal syndrome
Acute lung transplant rejection
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)
Hematopoietic cell transplantation
DISORDERS WITH BLAND HEMORRHAGE
Anti-GBM antibody syndrome (Goodpasture)
Systemic lupus erythematosus (SLE)
Idiopathic pulmonary hemosiderosis
Heiner syndrome
Acute idiopathic pulmonary hemorrhage of infancy
Thrombocytopenia syndromes (ITP, TTP)
Hemolytic uremic syndrome
Mitral stenosis
Celiac disease (Lane-Hamilton syndrome)
Nonaccidental trauma
Drugs (anticoagulation, toxins)
DISORDERS WITH DIFFUSE ALVEOLAR DAMAGE
Systemic lupus erythematosus (SLE)
Polymyositis
Immunodeficiency and opportunistic infection
Pulmonary infarction
Radiation therapy
Acute respiratory distress syndrome (ARDS)
Pulmonary hypertension
Pulmonary edema
Drugs (amphetamines, propylthiouracil, penicillamine, vaping)

Modified from Susarla SC, Fan LL. Diffuse alveolar hemorrhage syndromes in children. *Curr Opin Pediatr.* 2007;19:314–320.

abnormalities in laboratory testing; the diagnosis may be significantly delayed, making frequency estimates unreliable. Similarly, the prevalence of IPH is largely unknown. Of children and young adults diagnosed with IPH in the past, it has been postulated that the etiology of the hemorrhage might have been discovered if they had been studied with the newer and more advanced diagnostics available today; specific serologic testing has vastly improved our ability to appreciate immune-mediated disease. Estimates of prevalence obtained from Swedish and Japanese retrospective case analyses vary from 0.24 to 1.23 cases per million. Children and adolescents have traditionally accounted for 30% of cases. The ratio of affected males:females is 1:1 in the childhood diagnosis group, and males are only slightly more affected in the group diagnosed as young adults. In pediatric and adolescents undergoing allogeneic hematopoietic cell transplantation, pulmonary hemorrhage has been described in 2% of the population.

PATHOLOGY

DAH has been associated with diffuse inflammation, cytokine activation, and autoimmune responses. Elevations of both ferritin and interleukin (IL)-6 have been described as key factors in the exaggerated inflammatory response seen in pulmonary hemorrhage. In pulmonary capillaritis, key histologic features include (1) fibrin thrombi, which occlude capillaries, (2) fibrin clots adherent to interalveolar septae, (3) fibrinoid necrosis of capillary walls, and (4) interstitial erythrocytes and hemosiderin. Illustrative but nonspecific pathologic findings, such as vascular smooth muscle hypertrophy (pulmonary hypertension) or thrombosis (vascular thrombosis with infarction), may be found in those disorders that cause DAH without pulmonary capillaritis. The finding of blood in the airways or alveoli is representative of a recent hemorrhage. With repeated episodes of pulmonary hemorrhage, lung tissue appears brown secondary to this presence of hemosiderin. The presence of persistent blood in three bronchoalveolar lavage (BAL) specimens from the same lobe is highly suggestive of the diagnosis. **Hemosiderin-laden macrophages *(HLMs)*** are seen with recovering, recurrent, or chronic pulmonary hemorrhage and are identifiable both in BSL fluid and in pathologic specimens of lung tissue. Approximately 48 hours is necessary for the alveolar macrophages to convert iron from erythrocytes into hemosiderin. In a murine model, HLMs appear 3 days after a single episode of pulmonary hemorrhage and peak at 7-10 days. HLMs may be detectable for weeks to months after a hemorrhagic event. Other nonspecific pathologic findings include thickening of alveolar septa, goblet cell hyperplasia, and hypertrophy of type II pneumocytes. Fibrosis may be seen with chronic disease.

PATHOPHYSIOLOGY

Diffuse Alveolar Hemorrhage Associated with Pulmonary Capillaritis

Granulomatosis with polyangiitis is a recognized etiology for DAH in children (see Chapter 448.3). This disease is classically characterized by necrotizing granuloma formation (with or without cavitation) of the upper and lower respiratory tract and by a necrotizing glomerulonephritis and small vessel vasculitis. In children, presentations attributable to the upper airway, including subglottic stenosis, may suggest the diagnosis. The presence of ANCAs may be helpful in diagnosis and management, but the clinician must be aware that other ANCA-positive vasculitides, such as MPA and **eosinophilic granulomatosis with polyangiitis**, may share this nonspecific laboratory finding. In small vessel vasculitides, ANCAs cause an inflammatory reaction that results in injury to the microvasculature. Antiproteinase-3 antibodies (cANCAs) are classically associated with granulomatosis with polyangiitis, whereas antimyeloperoxidase antibodies (pANCAs) are typically found in patients with MPA.

Patients with **MPA** (previously the microscopic variant of polyarteritis nodosa) demonstrate a systemic necrotizing vasculitis with a predilection for small vessels (venules, arterioles, capillaries) but without necrotizing granuloma formation. This diagnosis is precluded by the finding of immune complex deposition in order to differentiate MPA from other diseases (Henoch-Schönlein purpura, cryoglobulinemic vasculitis) that are associated with immune complex–mediated small vessel vasculitis.

Anti-GBM antibody syndrome (Goodpasture disease) is an immune complex–mediated disease in which anti-GBM antibody binds to the basement membrane of both the alveolus and the glomerulus. GBM antibodies attach to type IV collagen contained in the vascular endothelium. At the alveolar level, immunoglobulin (Ig) G, IgM, and complement are deposited at alveolar septa. Electron microscopy shows disruption of basement membranes and vascular integrity, which allows blood to escape into alveolar spaces.

Although alveolar hemorrhage is a relatively uncommon complication in SLE, its occurrence is often severe and potentially life-threatening; mortality rates exceed 50% in some cohorts, and early recognition is crucial to allow timely implementation of immunomodulatory therapies.

In **IgA vasculitis (Henoch-Schönlein purpura),** pulmonary hemorrhage is a rare but recognized complication. Pathologic findings have included transmural neutrophilic infiltration of small vessels, alveolar septal inflammation, and intraalveolar hemorrhage. Vasculitis is the proposed mechanism for hemorrhage.

Pulmonary renal syndromes are defined as those where pulmonary and renal disease manifestations are predominant. These include the aforementioned granulomatosis with polyangiitis, anti-GBM antibody syndrome, SLE, and MPA. As Henoch-Schönlein purpura may also have renal involvement, it has been suggested for inclusion as a pulmonary renal syndrome.

Pulmonary Hemorrhage in Infancy

An infant's neonatal course may be complicated by pulmonary hemorrhage. The most common diagnoses in infants with DAH are congenital heart disease (including pulmonary hypertension) and prematurity. Additional diagnostic considerations in an infant with pulmonary hemorrhage include congenital or acquired lung disease (congenital diaphragmatic hernia, sepsis), congenital or acquired coagulopathies (extracorporeal membrane oxygenation [ECMO], liver failure), and infection. Pulmonary hemorrhage in infants may be unrecognized if the volume of blood is insufficient to reach the proximal airways. Even with more significant blood loss, the tussive force of an infant may be insufficient to produce hemoptysis. Because the radiographic findings in pulmonary hemorrhage may be appreciated instead as a worsening picture of respiratory distress syndrome, edema, or infection, a high index of suspicion is required.

Acute Idiopathic Pulmonary Hemorrhage of Infancy

In 1994 and 1997, case reports suggested clusters of infantile pulmonary hemorrhage in association with environmental exposure to *Stachybotrys chartarum*. A review by the Centers for Disease Control and Prevention did not support an association between exposure to the mold and infantile pulmonary hemorrhage. Acute idiopathic pulmonary hemorrhage of infancy (AIPHI) has been defined as pulmonary hemorrhage in a previously healthy infant who is less than 1 year of age and born at a gestational age of greater than 32 weeks. Three criteria must simultaneously be met; these include (1) the sudden onset of bleeding or "frank" evidence of blood in the airway; (2) severe presentation leading to respiratory distress or failure and resulting in hospitalization in intensive care with intubation and mechanical ventilation; and (3) diffuse bilateral pulmonary infiltrates found on chest radiographs or computerized tomographic imaging. AIPHI is believed to be a rare diagnosis, and an exhaustive search for an identifiable etiology of pulmonary hemorrhage is advocated.

Pulmonary hemosiderosis in association with non-IgE–mediated cow's milk hypersensitivity is characterized by variable and

reversible (with elimination of cow's milk protein) symptoms of milk intolerance in infants and young children. Symptoms can include grossly bloody or occult heme-positive stools, vomiting, failure to thrive, gastroesophageal reflux, upper airway congestion, and iron-deficiency anemia. Association with pulmonary hemorrhage has remained controversial, but multiple case series have provided support for the anecdotal association.

A number of case reports and case series have suggested an association between **celiac disease** (see Chapter 384) and DAH. In these reports, a resolution of intestinal and pulmonary symptoms along with resolution of radiographic disease has been seen after the adoption of a gluten-free diet. Consideration of testing for celiac disease in those patients with pulmonary hemorrhage and suggestive gastrointestinal symptomatology may be warranted.

DAH has been described in association with numerous other conditions. These are typically noninflammatory in nature and may be diversely attributable to cardiac, vascular, lymphatic, or hematologic etiologies. DAH has also rarely been attributed to nonaccidental trauma.

The diagnosis of IPH is a diagnosis of exclusion and is only made when there is evidence of chronic or recurrent DAH and when exhaustive evaluations for primary or secondary etiologies have negative results. Renal and systemic involvement should be absent, and a biopsy specimen should not reveal any evidence of granulomatous disease, vasculitis, infection, infarction, immune complex deposition, or malignancy. Some patients initially diagnosed with IPH will later be found to have Goodpasture syndrome, SLE, or MPA; therefore some cases of IPH may represent unrecognized immune-mediated disorders.

CLINICAL MANIFESTATIONS

The clinical presentation of pulmonary hemosiderosis is highly variable. In most symptomatic cases, DAH is heralded by symptoms of hemoptysis and dyspnea with associated hypoxemia and the finding of alveolar infiltration on chest radiograph. The diagnosis may be problematic, as young children often lack the ability to effectively expectorate and may not present with hemoptysis. Because the presence of blood in the lung is a trigger for airway irritation and inflammation, the patient may present after an episode of hemorrhage with wheezing, cough, dyspnea, and ventilatory derangements, reflecting bronchospasm, edema, mucus plugging, and inflammation; this presentation may result in an incorrect diagnosis of asthma or bronchiolitis. A lack of pulmonary symptoms does not preclude the diagnosis of DAH, and children may present only with chronic fatigue or pallor. In particular, young infants and children with DAH may come to attention with entirely nonspecific and nonpulmonary symptomatology such as failure to thrive or jaundice.

Primary or reported symptoms may reflect an underlying and associated disease process or comorbid condition. Presentations can vary widely from a relative lack of symptoms to shock or sudden death. Bleeding may occasionally be recognized from the presence of alveolar infiltrates on a chest radiograph alone. It should be noted, however, that the absence of an infiltrate does not rule out an ongoing hemorrhagic process.

On physical examination, the patient may be pale with tachycardia and tachypnea. During an acute exacerbation, children are frequently febrile. Examination of the chest may reveal retractions and differential or decreased aeration, with crackles or wheezes. The patient may present in shock with respiratory failure from massive hemoptysis.

LABORATORY FINDINGS AND DIAGNOSIS

Bronchoscopic evaluation is an important tool in the diagnosis of pulmonary hemosiderosis. The yield is highest if performed within the first 48-72 hours after an acute hemorrhage. Cultures should be sent for bacterial, viral, fungal, and mycobacterial pathogens. In addition, the evaluation of BAL fluid with silver stain for pneumocystis is advocated. When the pulmonologist recovers persistent or worsening blood with repeated BAL of the same lung segment, the diagnosis of DAH is supported. The presence of greater than 20% HLMs in BAL fluid is considered diagnostic. In the absence of bronchoscopy, sputum or pulmonary secretions should be analyzed for significant evidence of blood or HLMs and may provide supportive evidence in a patient who is able to adequately expectorate secretions from the lower airway. Gastric secretions may also reveal HLMs.

Pulmonary hemorrhage is classically associated with a microcytic, hypochromic anemia. Reduced serum iron levels, a decreased or normal total iron-binding capacity, and normal to increased ferritin levels may be found with chronic disease. The reticulocyte count is frequently elevated. Patients with pulmonary capillaritis have lower hematocrits and higher erythrocyte sedimentation rates. The anemia of IPH can mimic a hemolytic anemia. Elevations of plasma bilirubin are caused by absorption and breakdown of hemoglobin in the alveoli. Any or all of these hematologic manifestations may be absent in the presence of recent hemorrhage.

White blood cell count and differential should be evaluated for evidence of infection and eosinophilia. A peripheral smear and direct Coombs test may suggest a vasculitic process. A stool specimen positive for occult blood may suggest associated gastrointestinal disease but can also reflect swallowed blood. Renal and liver functions should be reviewed. A urinalysis should be obtained to assess for evidence of a pulmonary-renal syndrome. A coagulation profile, quantitative immunoglobulins (including IgE), and complement studies are recommended. Testing for von Willebrand disease is also indicated.

Testing for ANCA (cANCA, pANCA), antinuclear antibody, anti–double-stranded DNA, rheumatoid factor, antiphospholipid antibody (APL), myeloperoxidase, lupus anticoagulant, anticardiolipin antibody, and anti-GBM antibody evaluates for a number of immune-mediated and vasculitic processes that may be associated with pulmonary capillaritis.

Chest x-rays may reveal evidence of acute or chronic disease. Hyperaeration is frequently seen, especially during an acute hemorrhage. Infiltrates are typically symmetric and may spare the apices of the lung. Atelectasis may be appreciated. With chronic disease, fibrosis, lymphadenopathy, and nodularity may be seen. High-resolution CT imaging may reveal diffuse ground-glass opacification and alveolar opacification. With large bleeds, a fluid collection may be appreciated.

The presence of a cardiac murmur, cardiomegaly on x-ray, or a clinical suspicion of congenital or acquired heart disease suggests the need for a complete cardiac evaluation, including electrocardiogram and echocardiogram.

Pulmonary function tests generally reveal obstructive lung disease in the acute period. With more chronic disease, fibrosis and restrictive disease tend to predominate. Oxygen saturation levels may be decreased. Lung volumes may reveal air trapping acutely and decreases in total lung capacity chronically. The diffusing capacity of carbon monoxide may be low or normal in the chronic phase but is likely to be elevated in the setting of an acute hemorrhage, because carbon monoxide binds to the hemoglobin in extravasated red blood cells.

Lung biopsy is warranted when DAH occurs without discernible etiology, extrapulmonary disease, serologic evidence of vasculitis, or circulating GBM antibodies. When surgically obtained, pulmonary tissue should be evaluated for evidence of immune complex deposition, inflammatory change in the pulmonary vascular bed, and granulomatous disease. Transbronchial biopsy is not generally recommended, as the lung involvement in DAH is frequently nonhomogeneous and "patchy" in character.

Many have supported a diagnosis of IPH without lung biopsy if the patient has a typical presentation with diffuse infiltration on

radiography, anemia, HLMs in BAL, sputum or gastric aspirate, absence of systemic disease, and negative serology for immune-mediated disease. However, a number of patients meeting these criteria have been proven to have pulmonary capillaritis on review of pathologic lung tissue specimens. Therefore a lung biopsy may be recommended in an effort to guide therapy or determine prognosis in an individual with DAH of unknown etiology.

TREATMENT

Supportive therapy, including volume resuscitation, ventilatory support, supplemental oxygen, and transfusion of blood products, may be warranted in the patient presenting acutely with pulmonary hemorrhage. In the presence of ARDS, high oxygen concentrations and high positive end-expiratory pressure (PEEP) may be required. Surgical or medical therapy should be directed at any treatable underlying condition. High-dose systemic corticosteroids are frequently used as first-line treatment and are expected to be of particular benefit in the setting of immune-mediated disease. Steroids inhibit the acute inflammatory response (neutrophil influx, cytokine storm) associated with hemorrhage and may decrease progression toward fibrotic disease. High-dose steroids may contribute to morbidity and mortality in patients who have an infectious etiology for their hemorrhage and in those who are immunocompromised. A thorough evaluation for immunocompetence and pan-cultures for infectious organisms are therefore strongly advocated.

Medication dosing may vary with regard to primary diagnosis, age, comorbidities, and other factors. Clinical-pharmacologic correlation is advocated. Low- to moderate-dose treatment regimens may be provided in the form of methylprednisolone 2-4 mg/kg/day divided every 6-12 hours or in the form of prednisone 0.5-1 mg/kg daily and decreased to every other day after resolution of acute symptoms. High-dose corticosteroid therapy generally uses 10-30 mg/kg/day of IV methylprednisolone for 3-5 days and is followed by a tapering dose over 4-6 weeks. Successful treatment is also associated with the use of pulse steroid therapy; methylprednisolone may be given at a dose of 10-30 mg/kg (maximum 1 g) infused over 1 hour for 3-5 consecutive days and repeated weekly or monthly. Early treatment with corticosteroids appears to decrease episodes of hemorrhage, but high doses of steroids carry the risk of renal disease, immunosuppression, and potentially fatal infections.

A variety of steroid-sparing and alternative immunosuppressive agents, including cyclophosphamide, Cytoxan, azathioprine, hydroxychloroquine, methotrexate, 6-mercaptopurine, and IVIG, have all been used successfully as adjunctive therapy in patients with severe, chronic, unremitting, or recurrent hemorrhage.

Plasmapheresis is a recognized adjunctive therapy for DAH with pulmonary capillaritis in ANCA-associated vasculitis, SLE, and anti-GBM antibody disease. Pheresis is generally performed daily or every other day for 14 days. In each plasma exchange, the total volume of plasma is replaced with fresh-frozen plasma (FFP) or albumin. In recent analyses, the long-term efficacy of plasmapheresis as compared with corticosteroid therapy has been questioned. At this time, treatment guidelines suggest the use of plasmapheresis in patients with ANCA-associated vasculitis who are critically ill with hypoxemic respiratory failure.

Rituximab has evolved as an additional adjunctive therapeutic option. It is a monoclonal antibody that targets CD-20 and has been found to be an effective option for individuals with connective tissue and autoimmune disorders.

Any coagulopathic disorders should be corrected in an effort to achieve hemostasis. Cryoprecipitates, FFP, and platelets may be transfused depending on the identified deficiency. Vitamin K may also be supplemented.

Prothrombotic factors, including antifibrinolytics such as tranexamic acid (TXA), thrombin, and factor VIIa, have been used in the treatment of DAH. TXA acts by preventing the conversion of plasminogen into plasmin and hinders fibrinolysis. Inhalational TXA has been associated with favorable treatment outcomes in children with DAH. TXA has been described as being less efficacious in those with hematologic malignancies and those individuals with massive or recurrent bleeding. Further study is indicated to define associated risk and populations expected to benefit most consistently from this therapy.

Recombinant factor VIIa (FVIIa) may be used in an effort to achieve hemostasis in those with massive hemorrhage. A therapeutic response to low doses of FVIIa has been reported with direct intrapulmonary instillation, but the use of this agent is still anecdotal outside of hemophilia. Factor VIIa appears to decrease the requirement for transfusions and to be an effective adjunctive therapy for critically ill children with massive hemorrhage. The efficacy of FVIIa in neonates and infants less than 1 year of age is yet to be established.

In the most critically ill children, additional life-sustaining interventions may be required; ECMO combined with immunosuppression was reported to be successful in allowing recovery from a severe hemorrhage with hypoxemic respiratory failure in the setting of pANCA-positive MPA. In neonatal and infantile pulmonary hemorrhage, clinical improvement in blood gas and ventilatory requirements have been described with intrapulmonary administration of exogenous surfactant.

The potential adverse effects of these pharmacologic and therapeutic interventions should be recognized, and treated patients must be closely monitored for drug-related complications. Cushing syndrome, systemic hypertension, diabetes, and immunodeficiency are well-recognized complications of chronic steroid therapy. Thrombocytopenia in association with low-dose cyclophosphamide has also been reported. Chronically immunosuppressed patients are at risk for opportunistic infection; *Legionella* pneumonia infection has been described in a survivor of IPH.

In chronic disease, progression to debilitating pulmonary fibrosis has been described. Lung transplantation has been performed in patients with IPH refractory to immunosuppressive therapy. In one reported case study, IPH recurred in the transplanted lung.

PROGNOSIS

The outcome of patients suffering from DAH is multideterminant; underlying disease process, recurrence patterns, severity of hemorrhage, and delays in presentation are recognized prognostic factors. Some conditions respond well to immunosuppressive therapies, and remissions of disease are well documented. Other syndromes, especially those associated with pulmonary capillaritis, carry a poorer prognosis. In IPH, mortality is generally attributable to massive hemorrhage or, alternatively, to progressive fibrosis, respiratory insufficiency, and right-sided heart failure.

The long-term prognosis in patients with IPH varies among studies. Initial case study reviews suggested an average survival after symptom onset of only 2.5 years. Subsequent reviews have demonstrated vastly improved 5-year (86%) and 8-year (93%) survival in association with the use of immunosuppressive therapies. In IPH, the presence of hypoxia at clinical presentation and a positive antinuclear antibody have been demonstrated to be risk factors for recurrence.

Chapter 458

Pulmonary Embolism, Infarction, and Hemorrhage

458.1 Pulmonary Embolus and Infarction

Mary A. Nevin

Venous thromboembolism (VTE) is a term that describes both deep venous thrombosis (DVT) and pulmonary embolism (PE). PE is defined as obstruction of a pulmonary artery, typically as a result of thrombus formation. Although VTE remains relatively rare in occurrence, these events have become recognized as increasingly prevalent clinical problems and are associated with significant morbidity and mortality in the pediatric population. An increased incidence of VTE has been described in infants, children, and adolescents; this has been attributed to multiple factors, including increased survival from previously fatal critical and chronic illnesses, the increased use of central venous catheters, and improved diagnostic tools. Pulmonary emboli are more likely to be silent or to present atypically in infants and children as compared to adults, and a delay in diagnosis is commonly encountered. A diagnosis of PE may only be discovered on postmortem examination. In a retrospective study of PE found at the time of autopsy, the investigators discovered antemortem consideration of the diagnosis in only 15% of cases. Although children are more likely than their adult counterparts to have one or more predisposing factors favoring VTE (Table 458.1), a PE is often the first presenting symptom, and a high index of suspicion is needed to allow timely and accurate recognition as well as optimal management of PE in children.

ETIOLOGY

In the adult population, PE and VTE may be idiopathic in ~30% of patients. Children with DVT and PE are much more likely to have one or more identifiable conditions or circumstances placing them at risk. At least one identifiable risk factor for PE and VTE has been found in ≥80% of affected children. Most children have multiple and coexisting risk factors. In the pediatric population, the most common risk factors for VTE include the presence of an indwelling central venous catheter, congenital heart disease or vascular anomalies, trauma, immobility, recent surgery, malignancy, congenital and acquired thrombophilia, obesity and pregnancy, or hormonal drug therapies, including oral contraceptives. Individuals with nephrotic syndrome, inflammatory bowel disease, systemic lupus erythematosus, and sickle cell disease are also recognized as being at increased risk for thromboembolic disease. Both SARS-CoV-2/COVID-19 infection and the COVID-19–associated multisystem inflammatory syndrome in children (MIS-C) have been associated with a hypercoagulable state and increased risk for VTE, particularly in children and young adults who are critically ill with respiratory complications.

Although an embolus can also consist of air, septic material, amniotic fluid, or neoplastic tissue, emboli most commonly originate from thrombus formation. The most common risk factor for VTE in children is the presence of a central venous catheter (CVC); these indwelling lines are used for long-term administration of chemotherapy, antibiotics, and parental nutrition. The presence of a catheter in a vessel lumen, as well as instilled medications, can induce endothelial damage and favor thrombus formation. The use of a CVC is associated with ~90% of recognized VTE in neonates and ~30–60% of VTE in children. Septic emboli are rare in children but have been seen in osteomyelitis, endocarditis, Lemierre syndrome, and individuals with cellulitis.

Children with malignancy are recognized as being at high risk for VTE. Thromboembolic disease has been described in 7–16% of those with soft tissue sarcoma and in 5.2% of individuals with acute lymphocytic leukemia (ALL). A child with malignancy may have numerous risk factors that relate to both the primary disease process and therapeutic interventions. Infection related to chronic immunosuppression, indwelling catheters, and the hypercoagulable state of malignancy itself are additional factors that favor VTE. Chemotherapeutic agents such as L-asparaginase have been implicated as conferring risk for VTE. In addition, steroids may contribute to the risk of VTE by increasing factor VIII. In a retrospective cohort of patients with VTE, pediatric malignancy was the chronic medical condition most strongly associated with recurrent VTE.

In the neonatal period, VTE is frequently associated with the presence of an indwelling CVC. Comorbid medical conditions often confer additional risk for thromboembolic disease in the neonate; the most common associated diagnoses are congenital heart disease and sepsis. Another known contributor is the relative immaturity of newborn infant coagulation; plasma concentrations of vitamin K–dependent coagulation factors (II, VII, IX, X); factors XII, XI, and pre-kallikrein and high molecular weight kininogen are physiologically lower in neonates and children (see Chapter 524). Infants with congenitally acquired homozygous deficiencies of antithrombin, protein C, and protein S may also present with thromboembolic disease in the neonatal period. Testing for these acquired thrombophilias is frequently problematic in this age-group, as physiologic levels of protein S and antithrombin are not seen until 6 months of age, and mature levels of protein C may not occur until a child reaches adolescence. Furthermore, coagulant proteins may be artificially low in the setting of acute VTE (see Chapter 527).

Pulmonary air embolism is a defined entity in the newborn or young infant and is attributed to the conventional ventilation of critically ill (and generally premature) infants with severe pulmonary disease. Usually, the pulmonary air embolism is preceded by an air-leak syndrome. Infants may become symptomatic and critically compromised by as little as 0.4 mL/kg of intravascular air; these physiologic derangements are thought to be secondary to the effects of nitrogen.

Thrombophilia may be inherited or acquired and may manifest in neonates and in older infants, children, and adolescents. **Inherited thrombophilias** include deficiencies of antithrombin, protein C, and protein S, as well as pathogenic variants of factor V Leiden (FVL) and prothrombin G20210 pathogenic variant (see Chapter 527). The most frequent inherited thrombophilia is the FVL pathogenic variant. It is more common in people of European descent and relatively uncommon in those of African and Asian heritage. Acquired thrombophilic conditions include the presence of lupus anticoagulant (may be present without the diagnosis of systemic lupus erythematosus), anticardiolipin antibody, and anti–β_2-glycoprotein 1 antibody. Methylenetetrahydrofolate reductase (MTHFR) pathogenic variants associated with high levels of plasma homocysteine have also been hypothesized to be a risk factor for VTE, but the prognostic significance is unclear, and an isolated MTHFR pathogenic variant is not an absolute indication for VTE prophylaxis. Diagnostic testing for thrombophilic disorders is unlikely to be beneficial in the acute management of VTE but may be indicated to determine risk of recurrent VTE in both the index case and their relatives. Avoidance of prothrombotic risk factors such as oral contraceptive agents may also be recommended in those individuals with an inherited thrombophilia.

Sickle cell disease is associated with an increased risk for PE and pulmonary infarction. The primary risk factor for VTE in sickle cell disease is the presence of an indwelling CVC. Other risk factors for thrombosis include infection, splenectomy, and immobility.

The incidence of VTE in female adolescents 12-18 years of age is ~3 per 10,000. In patients with known exposure to estrogen-containing long-acting reversible contraception (LARC), more than 96% also had one or more comorbidities. Over 50% of those with VTE had four or more comorbidities. The most common comorbid conditions were obesity and tobacco use. Although estrogen is a known procoagulant, VTE in female adolescents does not appear attributable *solely* to estrogen-containing LARC, and additional risk factors should be sought in affected individuals.

EPIDEMIOLOGY

A wide range of incidence of PE has been described in both hospitalized (8.6-57 per 100,000) children and in the general population (0.14-0.9 per 100,000). There is a suggestion that the incidence of PE has increased over time. The etiology for these increases in pediatric thromboembolism is

Table 458.1 Risk Factors for Pulmonary Embolism

ENVIRONMENTAL
Long-haul air travel (>4 hr)
Obesity
Cigarette smoking
Hypertension
Immobility
WOMEN'S HEALTH
Oral contraceptives, including progesterone-only and, especially, third-generation pills
Pregnancy or puerperium
Hormone replacement therapy
Septic abortion
MEDICAL ILLNESS
Personal or family history of prior pulmonary embolism or deep venous thrombosis
Cancer
L-Asparaginase therapy
Heart failure
Chronic obstructive pulmonary disease
Diabetes mellitus
Inflammatory bowel disease
Antipsychotic drug use
Long-term indwelling central venous catheter
Permanent pacemaker
Internal cardiac defibrillator
Stroke with limb paresis
Spinal cord injury
Nursing home confinement or current or repeated hospital admission
SURGICAL
Trauma, including fractures
Orthopedic surgery
General surgery
Neurosurgery, especially craniotomy for brain tumor
Vascular anomalies
May-Turner syndrome
THROMBOPHILIA
Factor V Leiden mutation
Prothrombin gene (20210G A) pathogenic variant
Hyperhomocysteinemia (including pathogenic variant in methylenetetrahydrofolate reductase)
Antiphospholipid antibody syndrome
Deficiency of antithrombin III, protein C, or protein S
High concentrations of factor VIII or XI
Increased lipoprotein (a)
Heparin-induced thrombocytopenia
Paroxysmal nocturnal hemoglobinuria
Nephrotic syndrome
NONTHROMBOTIC
Air
Foreign particles (e.g., hair, talc, as a consequence of intravenous drug misuse)
Amniotic fluid
Bone fragments, bone marrow
Fat
Tumors (Wilms tumor)

Modified from Goldhaber SZ. Pulmonary embolism. *Lancet.* 2004;363:1295–1305.

regarded as multifactorial, with increased survival from chronic and critical illnesses, increased frequency of indwelling CVCs, increased clinical suspicion, and more precise imaging and diagnostic techniques being cited as contributing factors. The 2-year mortality rate from PE in two studies was ~8.5%, with the highest mortality rates occurring in infants. In other analyses, inpatient VTE has been estimated to increase the risk of mortality by two to six times. Massive PE has historically been associated with death in up to 30% of cases. Currently, the mortality from PE in children approximates the rates of mortality from VTE. In survivors of VTE, chronic complications, increased healthcare use, and increased healthcare costs are recognized.

The incidence of pediatric VTE is recognized as having a bimodal distribution, with peaks occurring in infants less than 1 year of age and in adolescence. Males are statistically more likely to have VTE, except for the 13- to 18-year-old age-group, where females are affected more frequently.

Pediatric deaths from isolated pulmonary emboli are rare. The source of the emboli may be lower or upper extremity veins as well as the pelvis and right heart. In adults, the most common location for DVT is the lower leg. However, one pediatric VTE/PE registry found ~65% of DVTs occurring in the upper extremity.

PATHOPHYSIOLOGY

Favorable conditions for thrombus formation include injury to the vessel endothelium, hemostasis, and hypercoagulability. In the case of PE, a thrombus is dislodged from a vein, travels through the right atrium, and lodges within the pulmonary arteries. VTE is most common in segmental pulmonary arteries (52%), with central arteries being obstructed less frequently (6%). In children, emboli that obstruct <50% of the pulmonary circulation are generally clinically silent unless there is significant coexistent cardiopulmonary disease. When greater than 50% of the pulmonary circulation is obstructed, right ventricular afterload is increased, with resultant right ventricular dilation and increases in right ventricular and pulmonary arterial pressures. In severe cases, a reduction of cardiac output and hypotension may result from concomitant decreases in left ventricular filling. In rare instances of death from massive pulmonary embolus, marked increases in pulmonary vascular resistance and heart failure are usually present.

Arterial hypoxemia results from unequal ventilation and perfusion; the occlusion of the involved vessel prevents perfusion of distal alveolar units, thereby creating an increase in dead space and hypoxia with an elevated alveolar-arterial oxygen tension difference (see Chapter 421). The vascular supply to lung tissue is abundant, and pulmonary infarction is unusual with PE but may result from distal arterial occlusion and alveolar hemorrhage.

CLINICAL MANIFESTATIONS

The presentation of VTE is highly variable and more likely to present atypically or silently in the pediatric age-group. A high index of suspicion is therefore necessary. The symptoms reported most in association with PE include chest pain, hypoxia (cyanosis), dyspnea, tachycardia, tachypnea, and syncope. A tenderness, swelling, or palpable cord may be palpated at the location of a DVT. Hemoptysis may also be a presenting symptom. Pleuritic chest pain is the most common presenting symptom in adolescents (84%). Massive PE may manifest as cardiopulmonary (hypotension) failure. Confirmatory testing should follow a clinical suspicion for PE.

In older adolescents and adults, clinical prediction rules have been published and are based on risk factors, clinical signs, and symptoms (Table 458.2). The Pulmonary Embolism Rule Out Criteria (PERC) and Wells criteria are clinical prediction rules that are commonly used in adults but lack reliability in the pediatric population. The Wells score has a sensitivity of 72–86% and a specificity of 60% when applied to children. The PERC tool has a higher sensitivity but a specificity of only 24% in children. When the PERC tool is applied in the pediatric setting, a high false-positive rate is seen, with over 75% of patients without PE having a positive PERC result. In a population at high risk from exposure to ionizing radiation, more discerning tools have been sought for this age-group.

In children and adolescents less than 22 years of age, the risk of PE is low (1.3%) in children who were not receiving estrogen therapy or in those who did not present with tachycardia or hypoxia (SpO_2 <95%); the prediction model reported a sensitivity of 89% and a specificity of 56%. Another clinical prediction model for the diagnosis of PE in adolescents and young adults identified five risk factors, including immobilization, hypercoagulability, exposure to estrogen-containing drugs, indwelling CVC, and a prior history of PE and/or DVT; the probability of PE as demonstrated by computed tomography pulmonary angiography (CTPA) with the presence of any three or more risk factors was 89%, and the probability of PE was extremely low (0.5%) when none of these risk factors were identified. These data and prediction tools may allow risk stratification and optimal use of diagnostic testing, including CTPA, but require prospective analysis and clinical validation.

Table 458.2 Scores to Assess the Clinical Probability of Venous Thromboembolism

WELLS SCORE FOR DEEP VEIN THROMBOSIS	POINTS
Active cancer	+1
Paralysis, paresis, or recent plaster cast on lower extremities	+1
Recent immobilization >3 days or major surgery within past 4 wk	+1
Localized tenderness of deep venous system	+1
Swelling of entire leg	+1
Calf swelling >3 cm compared with asymptomatic side	+1
Unilateral pitting edema	+1
Collateral superficial veins	+1
Previously documented deep vein thrombosis	+1
Alternative diagnosis at least as likely as deep vein thrombosis	−2
Clinical pretest probability	
Unlikely	Total score ≤2 (prevalence 4%)
Likely	Total score >2 (prevalence 27%)
WELLS SCORE FOR PULMONARY EMBOLISM	
Original	
Alternative diagnosis less likely than pulmonary embolism	+3
Clinical signs and symptoms of deep vein thrombosis	+3
Heart rate >100 beats per min	+1.5
Previous deep vein thrombosis or pulmonary embolism	+1.5
Immobilization or surgery within the past 4 wk	+1.5
Active cancer	+1
Hemoptysis	+1
Clinical Pretest Probability	
Low	Total score ≤1 (prevalence 4%)
Intermediate	Total score 2-6 (prevalence 21%)
High	Total score >6 (prevalence 67%)
Unlikely	Total score ≤4 (prevalence 8%)
Likely	Total score >4 (prevalence 41%)
Simplified	
Alternative diagnosis less likely than pulmonary embolism	+1
Clinical signs and symptoms of deep vein thrombosis	+1

Likely	Total score >2 (prevalence 42%)
YEARS CRITERIA FOR PULMONARY EMBOLISM	
Clinical signs of deep vein thrombosis	+1
Hemoptysis	+1
Pulmonary embolism is the most likely diagnosis	+1
Clinical Pretest Probability	
Low	Total score 0 (prevalence 3%)
High	Total score ≥1 (prevalence 23%)
PULMONARY EMBOLISM RULE-OUT CRITERIA	
Age <50 yr	—
Heart rate <100 beats per min	—
Pulse oximetry reading on room air >94%	—
No unilateral leg swelling	—
No hemoptysis	—
No recent trauma or surgery	—
No history of venous thromboembolism	—
No oral hormone use	—

Pulmonary embolism can be considered excluded in patients with all Pulmonary Embolism Rule-Out Criteria and a low clinical pretest probability, assessed by gestalt, or in clinical settings with a low (<5%) prevalence of pulmonary embolism. If any criterion applies, pulmonary embolism cannot be ruled out in these patients. Prevalence estimates correspond to emergency department settings. Vital signs should be age adjusted.

Modified from Khan F, Tritschler T, Kahn SR, Rodger MA. Venous thromboembolism. *Lancet*. 2021;398:64–77.

LABORATORY FINDINGS AND DIAGNOSIS

Blood gas analysis is expected to reveal hypoxemia with an abnormal A-a gradient. Lower-than-normal $Paco_2$ levels may also be seen secondary to hyperventilation, a finding that may persist even when oxygenation is optimized. Abnormalities of oxygenation and ventilation are likely to be less significant in the pediatric population, in the setting of less underlying cardiopulmonary disease and greater reserve. The results of an electrocardiogram and chest radiograph are expected to be nonspecific. ECG findings may include ST-T segment changes, tachycardia, right axis deviation, and right bundle branch block. Chest radiographs are frequently abnormal (88%); the most common finding is cardiomegaly (27%) and pleural

effusion (23%). These studies lack sensitivity and specificity in the diagnosis of PE.

A review of results of a complete blood count and coagulation profile is warranted. Prothrombotic diseases should be highly suspected based on medical or family history; additional laboratory evaluations include fibrinogen assays, protein C, protein S, and antithrombin III studies and analysis for FVL pathogenic variant, along with evaluation for lupus anticoagulant and anticardiolipin antibodies.

Echocardiograms may be used to assess ventricular size and function. An echocardiogram is indicated if there is any suspicion of intracardiac thrombi or endocarditis.

Noninvasive venous ultrasound testing with Doppler flow can be used to confirm DVT in the lower extremities; in pediatrics, the utility of ultrasonography is limited, as it may not detect thrombi in the upper extremities or pelvis (Fig. 458.1A).

In children, D-dimer levels demonstrate reasonable sensitivity but poor specificity for venous thrombosis because D-dimer levels are also increased in infectious, inflammatory, and neoplastic disorders, all of which are also risk factors for PE. Other studies have suggested that D-dimer may be a sensitive tool for PE in adolescents when a level of >750 mg/mL is seen; these data have not been found to be applicable to younger children or neonates.

In the evaluation of a suspected PE, a ventilation–perfusion ($\dot{V}$–$\dot{Q}$) radionuclide scan is a safe diagnostic study associated with exposure to low levels of ionizing radiation. With a definitive or high-probability scan, the likelihood of PE is 85%. With low-probability results, there is still a 20% chance of PE. In addition, children may have difficulty cooperating with the ventilation portion of the $\dot{V}$–$\dot{Q}$ scan.

Although conventional pulmonary angiography had been considered the gold standard for detection of PE, the invasive nature of this study, the high exposure to radiation, and the risk of complications have limited its use. *Computed tomography/multidetector CT with pulmonary angiography has become the diagnostic study of choice for PE* (see Fig. 458.1B). The criteria for PE include two or more consecutive images revealing a complete or partial filling defect of a pulmonary artery. CT studies detect emboli in lobar and segmental vessels with acceptable sensitivities. Poorer sensitivities may be encountered in the evaluation of the subsegmental pulmonary vasculature. Dual-energy scanning provides additional functional and anatomic information without additional radiation exposure. In most institutions, dose reduction techniques can be employed to limit a child's radiation exposure.

Magnetic resonance angiography (MRA) is also considered a viable diagnostic option for patients with VTE. High-resolution 3D contrast-enhanced MRA and time-resolved MRA are sensitive and specific for PE. The lack of ionizing radiation is attractive, but longer imaging times and the need for general anesthesia in most children may limit its use.

TREATMENT

In the acute management of VTE, careful monitoring and support of cardiopulmonary stresses are crucial. Once the affected individual has been stabilized, the primary approach to treatment of VTE is with anticoagulation. Appropriate and timely treatment with anticoagulation may prevent thrombus extension and recurrence. It is also indicated to prevent embolization.

Evaluations for prothrombotic disease must precede anticoagulation. Acute-phase anticoagulation therapy may be provided with unfractionated heparin (UFH) or low molecular weight heparin (LMWH). UFH binds reversibly to antithrombin III and potentiates its ability to inhibit thrombin and coagulation factor Xa. LMWH has become the drug of choice for both short-term and longer-term anticoagulation in children; enoxaparin is the LMWH most used in the pediatric population. It acts similarly to inhibit factor Xa but can be administered subcutaneously, and the need for serum monitoring is decreased. The risk of heparin-induced thrombocytopenia is also decreased with LMWH as compared to UFH. UFH may still be chosen in patients who have an elevated risk of bleeding, as UFH has a shorter half-life than LMWH. UFH is also used preferentially in patients with compromised renal function.

In monitoring of drug levels, laboratories must be aware of the drug chosen in order to use the appropriate assay. For UFH, the therapeutic range is 0.3-0.7 anti-Xa activity units/mL. In LMWH, the therapeutic range is 0.50-1.0 units/mL. When the anti-Xa assay is not available, the activated partial thromboplastin time may be used, with a goal of 60-85 seconds, or approximately 1.5-2 times the upper limit of age-appropriate normal values. The recommended duration of heparinization during acute treatment is 5-10 days; this length of therapy has been extrapolated from adult data. Long-term therapy with heparin should be avoided whenever possible. Side effects include heparin-induced thrombocytopenia, bleeding, and osteoporosis.

Pulmonary embolism and deep vein thrombosis. Lancet. 2012;379:1835–1844, Fig. 2, p. 1838.)*

THERAPEUTIC OPTIONS

Extension of anticoagulation therapy occurs in the subacute phase and may use LMWH, LMWH analogues, or warfarin. Warfarin is a vitamin K antagonist that may be used in children and adolescents; use is generally initiated after establishing effective anticoagulation with heparin because severe congenital deficiencies of protein C may be associated with warfarin skin necrosis. When the international normalized ratio (INR) is measured between 1.0 and 1.3, the starting dose for warfarin in children is recommended as 0.2 mg/kg administered orally once daily. Titration of dosing may be needed to achieve a therapeutic INR of 2 to 3. Dosing requirements may vary, and clinical pharmacologic correlation is required. The INR is generally monitored 5 days after initiating therapy or a similar period after dose changes and weekly thereafter until stable. The INR should be obtained with any evidence of abnormal bleeding and should be discontinued at least 5 days before invasive procedures. The use of an anticoagulation team and/or established treatment algorithms is recommended in order to optimize patient safety.

With the first occurrence of VTE, anticoagulation is recommended for 3-6 months in the setting of an identifiable, reversible, and resolved risk factor (e.g., postoperative state). Longer treatment is indicated in patients with idiopathic VTE (6-12 months) and in those with chronic clinical risk factors (12 months to lifelong). In the setting of a congenital thrombophilic condition, the duration of therapy is often indefinite. Inhibitors of factor Xa (e.g., enoxaparin) may become an alternative therapy for both acute PE and long-term treatment (Table 458.3).

In adults with DVT or PE, subsequent therapy with apixaban, dabigatran, edoxaban, or rivaroxaban (direct oral anticoagulants [DOACs]) is recommended over vitamin K antagonists. Some pediatric centers have adapted this therapy, particularly for adolescent patients. The recommended duration of such therapy for uncomplicated patients is 3 months.

Thrombolytic agents such as recombinant tissue plasminogen activator by peripheral vein may be used in combination with anticoagulants in the early stages of treatment; their use is most likely to be considered in children with hemodynamically significant PE (hypotension, echocardiogram evidence of right ventricular dysfunction) or other severe potential clinical sequelae of VTE. Combined therapy may reduce the incidences of progressive thromboembolism, PE, and postthrombotic syndrome. The mortality rate appears to be unaffected by additional therapies; nonetheless, the additional theoretical risk of hemorrhage limits the use of combination therapy in all but the most compromised patients. The use of thrombolytic agents in patients with active bleeding, recent cerebrovascular accidents, or trauma is contraindicated.

Catheter-assisted thrombus removal (thrombectomy) should be limited to those with large emboli that result in persistent hemodynamic compromise refractory to standard therapy. Catheter-assisted thrombus removal (less often, surgical embolectomy) is indicated in patients with hypotension who are a high bleeding risk or have failed systemic thrombolysis or are in life-threatening shock before systemic thrombolysis can be effective (within hours of thrombolysis). Surgical embolectomy is indicated with embolic Wilms tumor.

In adults with acute proximal DVT of the leg, inferior vena cava filters are used *only* if there is a contraindication to anticoagulation therapy.

PROGNOSIS

Mortality in pediatric patients with PE is likely to be attributable to an underlying disease process rather than to the embolus itself. Short-term complications include major hemorrhage (either because of the thrombosis or secondary to anticoagulation). Chronic complications include recurrence and pulmonary hypertension with the risk of cor pulmonale. Conditions associated with a poorer prognosis include malignancy, infection, and cardiac disease. The mortality rate in children from PE is 2.2%. An exhaustive evaluation for underlying pathology is advocated in an effort to prevent recurrence and progressive disease. Postthrombotic syndrome is a recognized complication of pediatric thrombotic disease. Venous valvular damage can be initiated by the presence of DVT and may result in persistent venous hypertension with ambulation and valvular reflux. Symptoms include edema, pain, increases in pigmentation, and ulcerations. Affected pediatric patients may suffer lifelong disability.

Table 458.3 Anticoagulant Therapies for Deep Vein Thrombosis and Pulmonary Embolism

	ROUTE	RENAL CLEARANCE (%)	HALF-LIFE	INITIAL TREATMENT DOSING	MAINTENANCE TREATMENT DOSING	EXTENDED TREATMENT DOSING
Unfractionated heparin (UFH)	Intravenous	~30	~1.5 hr	Maintain aPTT 1.5 times upper limit of normal		
Low molecular weight heparin (LMWH)	Subcutaneous	~80	3-4 hr	Weight-based dosing	Weight-based dosing*	
Fondaparinux	Subcutaneous	100	17-21 hr	Weight-based dosing	Weight-based dosing	
Vitamin K antagonists	Oral	Negligible	Acenocoumarol 8-11 hr; warfarin 36 hr; phenprocoumon 160 hr	Target at INR at 2.0-3.0 and give parallel heparin treatment for at least 5 days	Maintain INR at 2.0-3.0	Maintain INR at 2.0-3.0
Dabigatran	Oral	~80†	14-17 hr	Requires at least 5 days heparin lead-in	150 mg twice a day	150 mg twice a day
Rivaroxaban	Oral	~33‡	7-11 hr	15 mg twice a day for 3 wk	20 mg once a day	20 mg once a day
Apixaban	Oral	~25‡	8-12 hr	10 mg twice a day for 1 wk	5 mg twice a day	2.5 mg twice a day
Edoxaban	Oral	~35‡	6-11 hr	Requires at least 5 days heparin lead-in	60 mg once a day§	60 mg once a day§
Aspirin	Oral	~10	15 min			80-100 mg once a day

*Treatment with low molecular weight heparin is recommended for patients with active cancer and pregnant women.
†Dabigatran is contraindicated in patients with a creatinine clearance below 30 mL/min.
‡Apixaban, edoxaban, and rivaroxaban are contraindicated in patients with a creatinine clearance below 15 mL/min.
§The recommended edoxaban dose is 30 mg once a day for patients with a creatinine clearance of 30-50 mL/min, a body weight less than or equal to 60 kg, or for those on certain strong P-glycoprotein inhibitors.
Medication dosing may vary with regard to primary diagnosis, age, comorbidities, and other factors. Clinical-pharmacologic correlation is advocated.
aPTT, Activated partial thromboplastin time; INR, international normalized ratio.

458.2 Pulmonary Hemorrhage and Hemoptysis

Mary A. Nevin

Hemoptysis may be defined as the expectoration of blood from the lower respiratory tract. Infants and small children lack the tussive force to expectorate blood, and if blood from the lower airway is expectorated, it is frequently swallowed. Pulmonary hemorrhage in children and adolescents is uncommon but represents a serious and potentially fatal occurrence in children.

ETIOLOGY

Table 458.4 and Table 457.1 in Chapter 457 present conditions that can manifest as pulmonary hemorrhage or hemoptysis in children. The most common etiologies for pulmonary hemorrhage in the neonate and infant are congenital heart disease, premature lung disease, and coagulopathy (congenital or acquired with liver failure or anticoagulant medications). Infection and foreign body aspiration are the most common etiologies for hemoptysis in children. The chronic presence of a foreign body can lead to localized airway inflammation and hemorrhage. Secondary infection may also be present if the foreign body has been in the airway for days to weeks. Bleeding is more likely to occur in association with a chronically retained foreign body of vegetable origin.

Hemorrhage may be related to chronic airway inflammation and infection with bronchiectasis in the setting of cystic fibrosis (CF). Non-CF bronchiectasis may also be seen in children with chronic aspiration disorders, immunodeficiency syndromes, primary ciliary dyskinesia with or without Kartagener syndrome, HIV, and other infections. Hemoptysis attributable to inflammation and erosion of bronchial and bronchiolar airways may therefore occur in these clinical settings as well. Pulmonary hemorrhage caused by infection is also seen in patients with cavitary disease in association with tuberculosis. Hemoptysis may also occasionally reflect the intense inflammation of an acute pulmonary infection such as bronchitis or bronchopneumonia.

Bleeding is frequently encountered in patients with tracheostomies and is often attributable to suction trauma or friable granulation tissue. In these situations, bleeding tends to be limited and responsive to modifications of the care regimen. Rarely, bleeding from a tracheostomy may be brisk and bright red. In this case, otolaryngology should evaluate for the presence of a tracheo-innominate artery fistula.

Cardiopulmonary disease is associated with hemoptysis in children and adolescents. Associated conditions include mitral stenosis, pulmonary edema in the setting of congestive heart failure, high-altitude pulmonary edema (HAPE), pulmonary venous obstructive disease, and pulmonary hypertension. Although early corrective surgical intervention has been associated with improved hemodynamics, collateral circulations may contribute to bleeding.

Traumatic injury to the airway and pulmonary contusion may result from motor vehicle crashes or other direct-force injuries. Children who have been victims of nonaccidental trauma or deliberate suffocation can also be found to have blood in the mouth or airway (see Chapter 17). Factitious hemoptysis may rarely be encountered in the setting of self-inflicted trauma to the oral mucosa by biting or in the setting of factitious disorder by proxy (formerly Munchausen by proxy; see Chapter 17.2).

Rare causes for hemoptysis include tumors and vascular anomalies such as arteriovenous malformations (AVMs) (Fig. 458.2). Congenital vascular malformations in the lung may be seen in the setting of **hereditary hemorrhagic telangiectasia (HHT)**. Symptoms and signs of pulmonary AVM include dyspnea, hemoptysis, poor exercise tolerance, digital clubbing, and cyanosis. A high index of suspicion is needed, as more than half of children with pulmonary AVM may be asymptomatic. AVMs in individuals with HHT may be associated with severe complications, including massive hemoptysis, hemothorax, and stroke. In individuals with HHT, pulmonary AVMs are prevalent (60%) and can occur at any age. Any tumors or lesions must be cautiously investigated when encountered with a flexible fiberoptic bronchoscope, as bleeding may be massive and difficult to control.

Bronchial **Dieulafoy disease** has been recognized as a rare etiology for pulmonary hemorrhage. The classic bronchoscopic appearance is a small, submucosal bronchial lesion with a white cap. Massive hemorrhage may ensue. If nonsurgical bronchial artery embolization is not able to achieve hemostasis, surgical resection of the affected lung segment or lobe may be considered.

Table 458.4 Etiology of Pulmonary Hemorrhage (Hemoptysis)

FOCAL HEMORRHAGE
Bronchitis and bronchiectasis (especially cystic fibrosis related)
Infection (acute or chronic), pneumonia, abscess
Tuberculosis
Trauma
Pulmonary arteriovenous malformation (with or without hereditary hemorrhagic telangiectasia)
Foreign body (chronic)
Neoplasm, including hemangioma and metastatic disease
Pulmonary embolus with or without infarction
Bronchogenic cysts
DIFFUSE HEMORRHAGE
Idiopathic of infancy
Congenital heart disease (including pulmonary hypertension, venoocclusive disease, and congestive heart failure)
Prematurity
Cow's milk hyperreactivity (Heiner syndrome)
Goodpasture syndrome
Collagen vascular diseases (systemic lupus erythematosus, rheumatoid arthritis)
IgA vasculitis (Henoch-Schönlein purpura) and other vasculitic disorders
Granulomatous disease (granulomatosis with polyangiitis)
Celiac disease
Coagulopathy (congenital or acquired)
Malignancy
Immunodeficiency
Exogenous toxins, especially inhaled
Hyperammonemia
Pulmonary hypertension
Pulmonary alveolar proteinosis
Idiopathic pulmonary hemosiderosis
Tuberous sclerosis
Lymphangiomyomatosis or lymphangioleiomyomatosis
Physical injury or abuse
Catamenial
Vaping

See also Table 457.1.

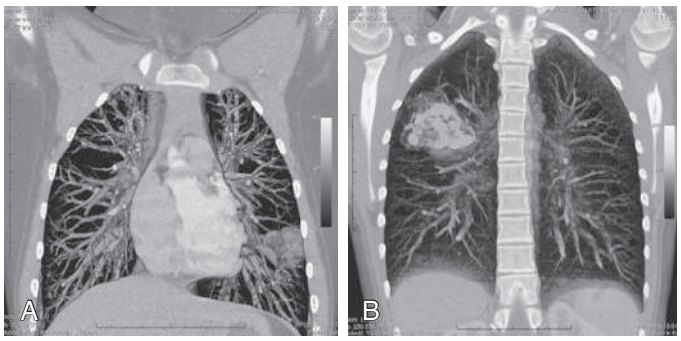

Fig. 458.2 **A**, Volume-rendering reconstruction of the contrast-enhanced spiral CT showing a large arteriovenous fistula in the left upper lobe (lingula). **B**, Volume-rendering reconstruction of the contrast-enhanced spiral CT showing an arteriovenous fistula in the right upper lobe. *(From Grzela K, Krenke K, Kulus M. Pulmonary arteriovenous malformations: clinical and radiological presentation. J Pediatr. 2011;158:856, Figs. 1 and 2.)*

Syndromes associated with vasculitic, autoimmune, and idiopathic disorders may be associated with diffuse alveolar hemorrhage (see Chapter 457).

EPIDEMIOLOGY

The frequency with which pulmonary hemorrhage occurs in the pediatric population is difficult to define. The difficulties in timely diagnosis are primarily related to the variability in disease presentation. As such, the incidence of pulmonary hemorrhage may be significantly underestimated. Chronic bronchiectasis as seen in CF (see Chapter 454) or ciliary dyskinesia (see Chapter 455) can cause hemoptysis, but usually occurs in children older than 10 years of age.

PATHOPHYSIOLOGY

The vascular supply of the lung has two components. The pulmonary artery provides blood to the bronchi to the level of the terminal bronchioles and to the alveolar capillary bed. The pulmonary circulation is characterized by low pressure and high volume. Conversely, the bronchial circulation originates from the aorta or intercostal arteries. The pressure in the bronchial artery circulation is systemic. This circulation provides blood the conducting airways. Hemoptysis may occur from either the pulmonary or bronchial circulation. Bleeding from the pulmonary circulation is expected to be insidious; slow bleeding in the lower airways typically manifests with anemia, fatigue, and dyspnea, and hemoptysis may be absent. Syndromes associated with diffuse alveolar hemorrhage are discussed in Chapter 457. Bleeding from the bronchial circulation may be massive and associated with rapid exsanguination. Blood that comes from the lung is frequently difficult to differentiate from blood that originates at the nasopharynx, mouth, or gastrointestinal (GI) tract. The blood that originates from the airway is classically bright red or rust colored. Alveolar blood may have a frothy appearance. Blood originating from the GI tract is typically brownish in color. The pH of pulmonary blood is alkaline, whereas blood from the GI tract is expected to be acidic.

In patients with CF, chronic endobronchial infection, inflammation, mucus plugging, and thickening of the airway surface layer predispose to growth and dilation of the bronchial arteries. Blood in the airway is highly irritative and initiates an influx of neutrophils and inflammatory mediators that serve to exacerbate the already vibrant inflammatory response. As such, pulmonary hemorrhage may be recurrent in late-stage CF. Massive and life-threatening hemorrhage may occur. With repeated or chronic hemorrhage, pulmonary fibrosis can become a prominent pathologic finding.

CLINICAL MANIFESTATIONS

The presenting symptoms and signs of pulmonary hemorrhage are highly variable in the pediatric population. Older children and young adults experiencing focal hemorrhage may be able to localize the bleeding by a sensation of "warmth" or "bubbling" in the chest. This can occasionally aid the clinician in locating the area involved. Rapid and large-volume blood loss manifests as hypoxemic and hypercarbic respiratory failure and hypovolemic shock. Chronic, insidious blood loss may manifest as anemia, fatigue, dyspnea, or poor exercise tolerance. Severely anemic individuals may present with syncope. Radiographic infiltrates may be seen in a focal or diffuse distribution on chest radiograph. The presence of a cavitary lesion or radiopaque foreign body suggests tubercular or fungal infection and foreign body aspiration, respectively.

LABORATORY FINDINGS AND DIAGNOSIS

A patient with suspected hemorrhage should have a laboratory evaluation with complete blood count and coagulation studies. The complete blood count result may demonstrate a microcytic, hypochromic anemia but may be normal in acute blood loss. The diagnosis of pulmonary hemorrhage is best confirmed by bronchoscopy with direct visualization of bleeding and/or a bronchoalveolar lavage specimen that confirms the presence of **hemosiderin-laden macrophages** on Prussian blue staining. Within 48-72 hours of an episode of bleeding, alveolar macrophages convert the iron from erythrocytes into hemosiderin. It may take weeks to clear these hemosiderin-laden macrophages completely from the alveolar spaces, thereby allowing differentiation between acute and chronic hemorrhage.

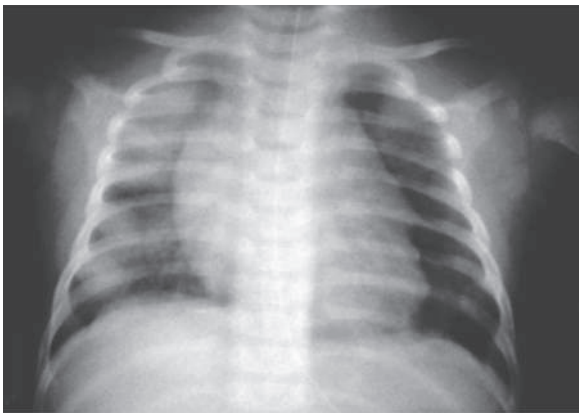

Fig. 458.3 Radiographic appearance of acute idiopathic pulmonary hemorrhage in infancy. *(From Brown CM, Redd SC, Damon SA, Centers for Disease Control and Prevention. Acute idiopathic pulmonary hemorrhage among infants: recommendations from the Working Group for Investigation and Surveillance. MMWR Recomm Rep. 2004;53:1–12.)*

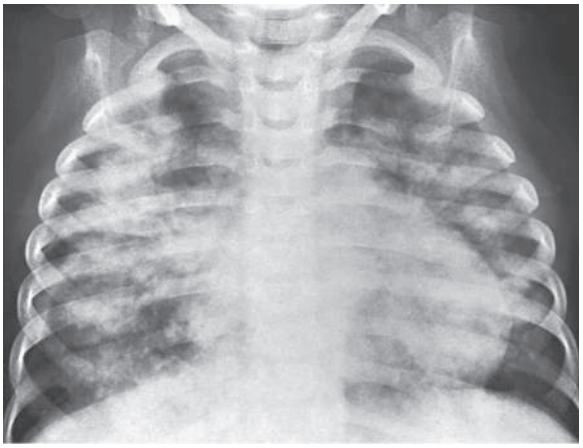

Fig. 458.4 Diffuse pulmonary hemorrhage that was thought to be the result of idiopathic pulmonary hemosiderosis in a 3-yr-old child. Frontal radiograph reveals bilateral air space consolidation that is patchy. Tracheal washing contained large numbers of macrophages filled with hemosiderin. Ten days later, most of the consolidative changes in the lungs had cleared. The patient's anemia was successfully treated with blood transfusion. *(Courtesy Bertram Girdany, MD, Pittsburgh, PA; from Slovis T, ed. Caffey's Pediatric Diagnostic Imaging, 11th ed. Philadelphia: Mosby; 2008.)*

Chest radiographs may demonstrate fluffy bilateral densities, as seen in acute idiopathic pulmonary hemorrhage of infancy (Fig. 458.3) or the patchy consolidation seen in idiopathic pulmonary hemosiderosis (Fig. 458.4). Alveolar infiltrates seen on chest radiograph may be regarded as a representation of recent bleeding, but their absence does not rule out the occurrence of pulmonary hemorrhage. Infiltrates, when present, are often symmetric and diffuse and may be preferentially located in the perihilar regions and lower lobes. The costophrenic angles and lung apices are frequently spared. CT may be indicated to assess for underlying disease processes.

Lung biopsy is rarely necessary unless bleeding is chronic or an etiology cannot be determined with other methods. Pulmonary function testing, including a determination of gas exchange, is important to assess the severity of the ventilatory defect. In older children, spirometry may demonstrate evidence of predominantly obstructive disease in the acute

period. Restrictive disease secondary to fibrosis is typically seen with more chronic disease. Diffusion capacity of carbon monoxide measurements are typically elevated in the setting of pulmonary hemorrhage because of the strong affinity of the intraalveolar hemoglobin for carbon monoxide.

TREATMENT

In mild to moderate hemoptysis (>5 mL blood), potential irritants to the lung (hypertonic saline, DNase, chest physiotherapy, and inhaled antibiotics) are typically held. In patients with CF, vitamin K may be given empirically, given a predilection toward vitamin K deficiency with comorbid pancreatic insufficiency.

In the setting of massive hemorrhage (>240 mL), emergent circulatory and ventilatory support is provided and a requirement for volume resuscitation and transfusion of blood products should be anticipated. If respiratory failure ensues, mechanical ventilatory support with high positive end-expiratory pressure (PEEP) may tamponade a bleeding vessel and improve oxygenation. If bleeding is unilateral, selective ventilation of the unaffected lung may be recommended. Rigid bronchoscopy may be used for localization of bleeding and for removal of debris, but active bleeding may be exacerbated by airway manipulation. In patients with CF who are unstable with massive hemorrhage, proceeding directly to bronchial artery embolization (BAE) has been advocated. Improved outcomes of BAE have been seen when the bleeding vessel is identified by multidetector CT imaging. Cessation of bleeding is achieved in approximately 80% of patients, but bleeding may be recurrent, and more than one BAE may be required. Rare complications include inadvertent embolization of spinal and mesenteric arteries, leading to paralysis and ischemic bowel, respectively. If embolization fails, total or partial lobectomy may be required.

Antifibrinolytic therapy with tranexamic acid (TXA) has been used to control bleeding in patients with hemophilia and in patients with CF, as well as in other conditions (bronchiectasis, tuberculosis, allergic bronchopulmonary aspergillosis). This medication may be administered by inhaled, oral, or parenteral routes. Inhaled TXA may be as effective as intravenous dosing; the inhaled route has fewer systemic effects. The use of this medication is currently off label.

Depending on institutional capabilities, extracorporeal membrane oxygenation (ECMO) and emergent listing for lung transplantation may also be considered for patients with end-stage disease.

Chapter 459

Atelectasis

Ranna A. Rozenfeld

Atelectasis is the incomplete expansion or complete collapse of air-bearing tissue, resulting from obstruction of air intake into the alveolar sacs. Segmental, lobar, or whole lung collapse is associated with the absorption of air contained in the alveoli, which are no longer ventilated.

PATHOPHYSIOLOGY

The causes of atelectasis can be divided into five groups (Table 459.1). Respiratory syncytial virus (see Chapter 307) and other viral infections, including influenza viruses in young children, can cause multiple areas of atelectasis. Mucous plugs are a common predisposing factor to atelectasis. Massive collapse of one or both lungs is most often a postoperative complication but occasionally results from other causes, such as trauma, asthma, pneumonia, tension pneumothorax (see Chapter 461), aspiration of foreign material (see Chapters 435 and 446), paralysis, or after extubation. Massive atelectasis is usually produced by a combination of factors, including immobilization or decreased use of the diaphragm and the respiratory muscles, obstruction of the bronchial tree, and abolition of the cough reflex.

Table 459.1 Anatomic Causes of Atelectasis

CAUSE	CLINICAL EXAMPLES
External compression on the pulmonary parenchyma	Pleural effusion, pneumothorax, intrathoracic tumors, diaphragmatic hernia
Endobronchial obstruction completely obstructing the ingress of air	Enlarged lymph node, tumor, cardiac enlargement, foreign body, mucoid plug, broncholithiasis
Intraluminal obstruction of a bronchus	Foreign body, asthma, granulomatous tissue, tumor, secretions including mucous plugs, bronchiectasis, pulmonary abscess, chronic bronchitis, acute laryngotracheobronchitis, plastic bronchitis
Intrabronchiolar obstruction	Bronchiolitis, interstitial pneumonitis, asthma
Respiratory compromise or paralysis	Neuromuscular abnormalities, osseous deformities, overly restrictive casts and surgical dressings, defective movement of the diaphragm, or restriction of respiratory effort

CLINICAL MANIFESTATIONS

Symptoms vary with the cause and extent of the atelectasis. A small area is likely to be asymptomatic. When a large area of previously normal lung becomes atelectatic, especially when it does so suddenly, dyspnea accompanied by rapid shallow respiration, tachycardia, cough, and often cyanosis occurs. If the obstruction is removed, the symptoms disappear rapidly. Although it was once believed that atelectasis alone can cause fever, studies have shown no association between atelectasis and fever. Physical findings include limitation of chest excursion, decreased breath sound intensity, and coarse crackles. Breath sounds are decreased or absent over extensive atelectatic areas.

Massive atelectasis usually presents with dyspnea, cyanosis, and tachycardia. An affected child is extremely anxious and, if old enough, complains of chest pain. The chest appears flat on the affected side, where decreased respiratory excursion, dullness to percussion, and feeble or absent breath sounds are also noted. Postoperative atelectasis usually manifests within 24 hours of operation but may not occur for several days.

Acute lobar collapse is a frequent occurrence in patients receiving intensive care. If undetected, it can lead to impaired gas exchange, secondary infection, and subsequent pulmonary fibrosis. Initially, hypoxemia may result from ventilation-perfusion mismatch. In contrast to atelectasis in adult patients, in whom the lower lobes and, in particular, the left lower lobe is most often involved, 90% of cases in children involve the upper lobes and 63% involve the right upper lobe. There is also a high incidence of upper lobe atelectasis and, especially, right upper lobe collapse in patients with atelectasis being treated in neonatal intensive care units. This high incidence may be a result of the movement of the endotracheal tube into the right mainstem bronchus, where it obstructs or causes inflammation of the bronchus to the right upper lobe.

DIAGNOSIS

The diagnosis of atelectasis can usually be established by chest radiograph. Typical findings include volume loss and displacement of fissures. Atypical presentations include atelectasis manifesting as a masslike opacity and atelectasis in an unusual location. Lobar atelectasis may be associated with pneumothorax. Several studies have shown

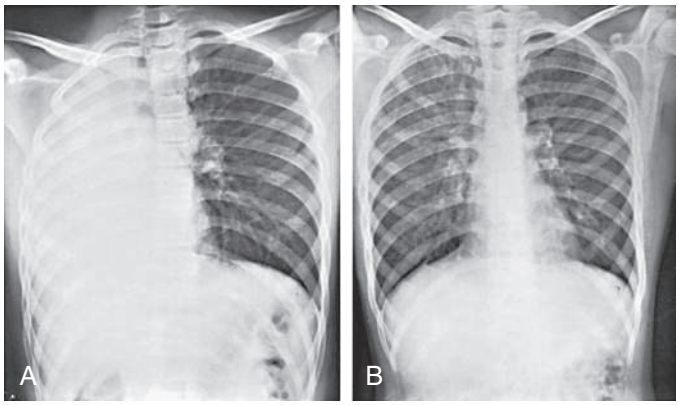

Fig. 459.1 A, Massive atelectasis of the right lung. The patient has asthma. The heart and other mediastinal structures shift to the right during the atelectatic phase. B, Comparison study after reaeration subsequent to bronchoscopic removal of a mucous plug from the right mainstem bronchus.

lung ultrasound to be a viable alternative to chest radiograph when diagnosing atelectasis, especially in patients with neuromuscular disease, to avoid radiation exposure.

In children with asthma, chest radiography demonstrates an abnormality rate of 44%, compared with a thorax high-resolution CT scan abnormality rate of 75%. Children with asthma and atelectasis have an increased incidence of right middle lobe syndrome, acute asthma exacerbations, pneumonia, and upper airway infections.

In foreign-body aspiration, atelectasis is one of the most common radiographic findings. The site of atelectasis usually indicates the site of the foreign body (see Chapter 426.1). Atelectasis is more common when diagnosis of foreign-body aspiration is delayed for greater than 2 weeks. Bronchoscopic examination reveals a collapsed main bronchus when the obstruction is at the tracheobronchial junction and may also disclose the nature of the obstruction.

Massive atelectasis is typically diagnosed on chest radiograph. Typical findings include elevation of the diaphragm, narrowing of the intercostal spaces, and displacement of the mediastinal structures and heart toward the affected side (Fig. 459.1).

TREATMENT

Treatment depends on the cause of the collapse (Table 459.2). If effusion or pneumothorax is responsible, the external compression must first be removed. Often vigorous efforts at cough, deep breathing, and percussion will facilitate expansion. Aspiration with sterile tracheal catheters may facilitate removal of mucous plugs. Continuous positive airway pressure may improve atelectasis.

Bronchoscopic examination is immediately indicated if atelectasis is the result of a foreign body or any other bronchial obstruction that can be relieved. For bilateral atelectasis, bronchoscopic aspiration should also be performed immediately. It is also indicated when an isolated area of atelectasis persists for several weeks. If no anatomic basis for atelectasis is found and no material can be obtained by suctioning, the introduction of a small amount of saline followed by suctioning allows recovery of bronchial secretions for culture and, possibly, for cytologic examination. Frequent changes in the child's position, deep breathing, and chest physiotherapy may be beneficial. Intrapulmonary percussive ventilation is a chest physiotherapy technique that is safe and effective. Oxygen therapy is indicated when there is dyspnea or desaturation. Intermittent positive pressure breathing and incentive spirometry are recommended when atelectasis does not improve after chest physiotherapy.

In some conditions, such as asthma, bronchodilator and corticosteroid treatment may accelerate atelectasis clearance. Recombinant human deoxyribonuclease, which is approved only for the treatment of cystic fibrosis, has been used off-label for patients without cystic fibrosis who have persistent atelectasis. This product reduces the viscosity of purulent bronchial debris. In patients with acute severe asthma, diffuse airway plugging with thick viscous secretions frequently occurs, with the resulting atelectasis often refractory to conventional therapy. Recombinant human deoxyribonuclease is used in the nebulized form for nonintubated patients with acute asthma and intratracheally for atelectasis in intubated asthmatics, with resolution of atelectasis unresponsive to conventional asthma therapies. Recombinant human deoxyribonuclease is also used in ventilated infants and children with atelectasis not caused by asthma.

Table 459.2 Treatment for Atelectasis

CAUSE OF ATELECTASIS	TREATMENT
Pleural effusion or pneumothorax	Relieve compression
Mucous plug	Tracheal or bronchoscopic aspiration Continuous positive airway pressure
Foreign body	Bronchoscopic examination
Asthma	Bronchodilator and corticosteroid treatment Recombinant human deoxyribonuclease (off-label use) Hypertonic saline with or without bronchodilator
Neuromuscular diseases	Intermittent positive pressure breathing Mechanical insufflator-exsufflator Noninvasive bilevel positive pressure ventilation
Cystic fibrosis	Airway clearance therapies Hypertonic saline with or without bronchodilator Recombinant human deoxyribonuclease

Hypertonic saline solution increases mucociliary clearance in patients with asthma, bronchiectasis, and cystic fibrosis and infants with acute bronchiolitis. It is delivered via nebulization either via face mask or endotracheal tube. It can be delivered alone or in combination with a bronchodilator. This therapy is being used in the outpatient and inpatient setting and in both the neonatal intensive care unit and the pediatric intensive care unit to help facilitate airway clearance, though studies of its use in bronchiolitis have had mixed results (see Chapter 439.1). Lobar atelectasis in cystic fibrosis is discussed in Chapter 454.

Atelectasis can occur in patients with neuromuscular diseases. These patients tend to have an ineffective cough and difficulty expelling respiratory tract secretions, which lead to pneumonia and atelectasis. Several devices and treatments are available to assist these patients, including intermittent positive-pressure breathing, a mechanical insufflator-exsufflator, and noninvasive bilevel positive-pressure ventilation via nasal mask or full-face mask. Patients with neuromuscular disease who have undergone surgery are at substantial risk for postoperative atelectasis and subsequent pneumonia. Migrating atelectasis in the newborn infant, a rare and unique presentation, may be secondary to neuromuscular disease.

There is an association between the development of lobar collapse and the requirement for mechanical ventilation. Although lobar collapse is rarely a cause of long-term morbidity, its occurrence may necessitate the prolongation of mechanical ventilation or reintubation. In ventilated patients, positive-end expiratory pressure or continuous positive airway pressure is generally indicated.

Airway clearance therapies used for adults are often recommended and/or used in pediatric populations. However, given the differences in respiratory physiology and anatomy between children and adults, practices applicable to one may or may not apply to the other. Atelectasis caused by cystic fibrosis is the only pediatric entity that clearly benefits from airway clearance therapy, although atelectasis caused by neuromuscular disease, cerebral palsy, or mechanical ventilation probably benefits from such therapy. Thus far, no specific airway clearance therapy has been demonstrated to be superior.

Chapter 460

Pulmonary Tumors

John Palla and Susanna A. McColley

See also Chapter 438.

Primary tumors of the lung are rare in children and adolescents (Table 460.1). An accurate estimate of frequency is currently not possible because the literature is composed of case reports and case series. A high incidence of "inflammatory pseudotumors" further clouds the statistics. Bronchial adenomas (including bronchial carcinoid, adenoid cystic carcinoma, and mucoepidermoid carcinomas) are the most common primary malignant tumors; bronchial carcinoid tumors represent ~80%. Pediatric carcinoid tumors are predominantly low-grade malignancies, but children with these tumors should be evaluated and monitored by a pediatric oncologist. Carcinoid syndrome from a bronchial carcinoid tumor is rare in children. Metastatic lesions are the most common forms of pulmonary malignancy in children; primary processes include Wilms tumor, osteogenic sarcoma, germ cell tumors, and hepatoblastoma (see Part XX, Cancer and Benign Tumors). Adenocarcinoma and undifferentiated histology are the most common pathologic findings in primary lung cancer; pulmonary blastoma is rarer and frequently occurs in the setting of a primary cystic lesion or is associated with a congenital pulmonary airway malformation (see Chapter 444.3). Lymphoma is the most common cause of mediastinal mass in children; other mediastinal tumors include thymoma, thyroid cancer, and teratoma. Neuroblastoma may present as a posterior mediastinal mass.

Table 460.1 Pulmonary Tumors in Children

MALIGNANT
Bronchial adenomas (40–60%)
Carcinoid
Mucoepidermoid carcinoma
Adenoid cystic carcinoma
Pleuropulmonary blastoma (15%)

CLINICAL MANIFESTATIONS AND EVALUATION

There is often a delay in the diagnosis of pediatric pulmonary tumors given their rarity and nonspecific presenting symptoms. Pulmonary tumors may manifest as fever, hemoptysis, wheezing, cough, pleural effusion, chest pain, dyspnea, recurrent or persistent pneumonia, and/or atelectasis. Localized wheezing, and wheezing unresponsive to bronchodilators, can occur with bronchial tumors. Tumors may be suspected from plain chest radiographs; however, CT or MRI imaging of the chest is necessary for precise anatomic definition (Table 460.2; Figs. 460.1 and 460.2). Depending on the

Table 460.2 Imaging Characteristics of Primary Malignant Lung Tumors

NEOPLASM	IMAGING CHARACTERISTICS
Inflammatory myofibroblastic tumor (IMT)	Solitary (95%) or multiple (5%) Usually sharply circumscribed, lobulated mass Typically located in the peripheral portion of the lungs Soft tissue mass with either homogeneous or heterogeneous attenuation may have both solid and cystic and calcific components
Carcinoid or salivary gland tumor	Centrally located lesion: intraluminal soft tissue mass with distal atelectasis or obstructive pneumonitis Peripherally located lesion: oval or lobulated intraluminal or exophytic mass and occasionally calcify
Bronchogenic carcinoma	Central mass lesion with bronchial obstruction or, less commonly, small peripheral lesion
Pleuropulmonary blastoma	Cystic or mixed cystic and solid lesion adjacent to pleura; can be very large, with mediastinal displacement
Epithelioid hemangioendothelioma	Multiple well- or ill-defined nodular opacities up to 3 cm in diameter; very rare in childhood

From Chu WCW, Epelman M, Lee EY. Neoplasia. In Coley BD, ed. *Caffey's Pediatric Diagnostic Imaging*, 13th ed. Philadelphia: Elsevier; 2019: Table 55.3, p. 531.

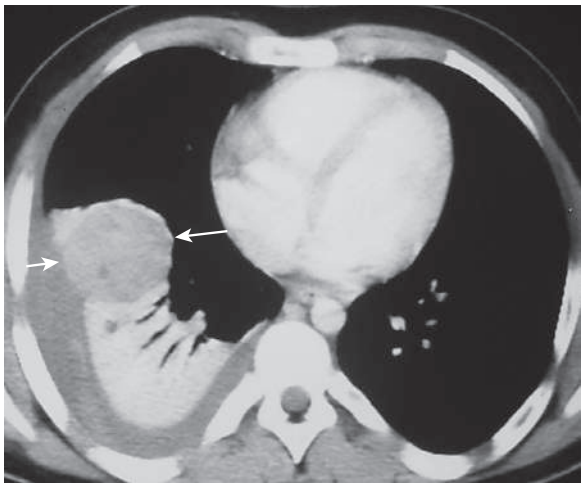

Fig. 460.1 Inflammatory myofibroblastic tumor. An afebrile 13-yr-old male who presented with increasing dyspnea and right-sided pleuritic chest pain. Axial contrast-enhanced CT of the chest shows a rounded heterogeneously enhancing lesion *(arrows)* located adjacent to an area of atelectatic lung. Pleural fluid at the same level demonstrates increased attenuation consistent with a hemothorax. *(Modified from Chu WCW, Epelman M, Lee EY. Neoplasia. In Coley BD, ed. Caffey's Pediatric Diagnostic Imaging, 13th ed. Philadelphia: Elsevier; 2019: Fig. 55.8A, p. 531.)*

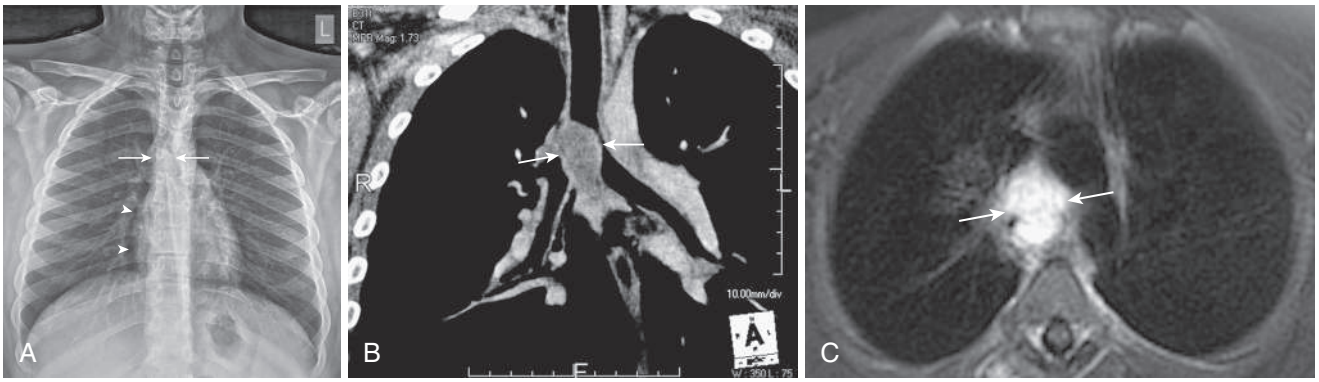

Fig. 460.2 Adenoid cystic carcinoma. A 14-yr-old male with a progressively worsening chronic cough and respiratory difficulty for 1 yr who presented with hoarseness and crepitus over the neck. **A,** Chest radiograph shows pneumomediastinum *(arrowheads)* and an apparent soft tissue density projecting over the carina *(arrows).* **B,** Coronal contrast-enhanced CT image shows a lobulated soft tissue mass *(arrows)* centered near the carina, which results in the narrowing of the adjacent airway. **C,** Axial contrast-enhanced T1-weighted MRI demonstrates avid enhancement of the mass *(arrows). (From Chu WCW, Epelman M, Lee EY. Neoplasia. In Coley BD, ed. Caffey's Pediatric Diagnostic Imaging, 13th ed. Philadelphia: Elsevier; 2019. Fig. 55.11: p. 532.)*

tumor size and location, pulmonary function tests may be normal or may show an obstructive, restrictive, or mixed pattern; there is no responsiveness to bronchodilators. Bronchial tumors are occasionally diagnosed during fiberoptic bronchoscopy performed for persistent or recurrent pulmonary infiltrates or hemoptysis (see Chapter 438).

Patients with symptoms or with radiographic or other laboratory findings suggesting pulmonary malignancy should be evaluated carefully for a tumor at another site before surgical excision is carried out. Isolated primary lesions and isolated metastatic lesions discovered long after the primary tumor has been removed are best treated by excision. The prognosis varies and depends on the type of tumor involved; outcomes for inflammatory pseudotumors and primary pulmonary carcinoid tumors treated with resection are good.

Chapter 461

Pneumothorax

Suraiya K. Haider and Aarthi P. Vemana

Pneumothorax is the accumulation of extrapulmonary air within the chest, most commonly from leakage of air from within the lung. Air leaks can occur spontaneously and be classified as primary or secondary, or occur due to trauma or an iatrogenic cause (Table 461.1). Pneumothorax in the neonatal period is also discussed in Chapter 132.

ETIOLOGY AND EPIDEMIOLOGY

A **primary spontaneous pneumothorax** occurs without trauma or obvious underlying lung disease. Spontaneous pneumothorax with or without exertion occurs occasionally in teenagers and young adults, most frequently in males who are tall and thin and thought to have subpleural blebs. Smoking cigarettes, marijuana, crack cocaine, e-cigarette vaping, and ecstasy/MDMA (methylenedioxymethamphetamine) have been associated with developing a pneumothorax.

A pneumothorax arising as a complication of an underlying lung disorder but without trauma is a **secondary spontaneous pneumothorax.** Familial cases of spontaneous pneumothorax occur and have been associated with pathogenic variants in the folliculin gene *(FCLN).* Over 150 unique *FCLN* variants have been associated with the **Birt-Hogg-Dube syndrome** (skin fibrofolliculomas, multiple basal lung cysts, renal malignancies) or in patients with familial or recurrent spontaneous pneumothoraces. Individuals with other inherited disorders, such as α_1-antitrypsin (see Chapter 442) and homocystinuria, are also predisposed to pneumothorax. Patients with collagen synthesis defects such as vascular Ehlers-Danlos syndrome (see Chapter 700) and Marfan syndrome (see Chapter 743) are at increased risk for the development of pneumothorax.

Pneumothorax can occur in pneumonia, usually with empyema; it can also be secondary to a pulmonary abscess, gangrene, infarct, rupture of a cyst or an emphysematous bleb (in asthma), or foreign bodies in the lung. In infants with staphylococcal pneumonia, the incidence of pneumothorax is relatively high. It can be found in children hospitalized with asthma exacerbations and usually resolves without treatment. Pneumothorax is a serious complication of cystic fibrosis (see Chapter 454). Pneumothorax also occurs in patients with lymphoma or other malignancies and in graft-versus-host disease with bronchiolitis obliterans. Catamenial pneumothorax, an unusual condition that is related to menses, is associated with diaphragmatic defects and pleural blebs.

External chest or abdominal blunt or penetrating trauma can tear a bronchus or abdominal viscus, with leakage of air into the pleural space. Iatrogenic pneumothorax can complicate transthoracic needle aspiration, tracheotomy, subclavian line placement, thoracentesis, or transbronchial biopsy. It may occur during mechanical or noninvasive ventilation, high-flow nasal cannula therapy, acupuncture, and other diagnostic or therapeutic procedures.

Pneumothorax can be associated with a serous effusion (hydropneumothorax), a purulent effusion (pyopneumothorax), or blood (hemopneumothorax). Bilateral pneumothorax is rare after the neonatal period but has been reported after lung transplantation and with *Mycoplasma pneumoniae* infection and tuberculosis.

Table 461.1 Causes of Pneumothorax in Children

SPONTANEOUS

Primary Idiopathic (no underlying lung disease)

Spontaneous rupture of subpleural blebs

Drug use (smoking cigarettes, marijuana, crack cocaine, use of e-cigarettes)

Valsalva maneuver

Secondary (underlying lung disease)

Congenital lung disease
- Congenital pulmonary airway malformation
- Bronchogenic cysts
- Pulmonary hypoplasia
- Birt-Hogg-Dube syndrome

Conditions associated with increased intrathoracic pressure
- Asthma
- Bronchiolitis
- Cystic fibrosis
- Airway foreign body

Infection
- Tuberculosis
- *Pneumocystis jirovecii*
- Echinococcosis
- Pneumatocele
- Lung abscess
- Bronchopleural fistula
- COVID-19 infection

Lung disease
- Langerhans cell histiocytosis
- Tuberous sclerosis
- Marfan syndrome
- Vascular Ehlers-Danlos syndrome
- Pulmonary fibrosis
- Sarcoidosis
- Rheumatoid arthritis, scleroderma, ankylosing spondylitis
- Metastatic neoplasm—usually osteosarcoma (rare)
- Pulmonary blastoma
- Catamenial

TRAUMATIC

Noniatrogenic

Penetrating trauma

Blunt trauma

Iatrogenic

Thoracotomy

Thoracoscopy, thoracentesis

Tracheostomy

Tube or needle puncture

Mechanical ventilation

High-flow therapy (moved from noniatrogenic)

Adapted from Noppen M. Spontaneous pneumothorax: epidemiology, pathophysiology and cause. *Eur Respir Rev.* 2010;19(117):217–219, 2010. Tables 1 & 2, p. 218.

PATHOGENESIS

The tendency of the lung to collapse, or elastic recoil, is balanced in the normal resting state by the inherent tendency of the chest wall to expand outward, creating negative pressure in the intrapleural space. When air enters the pleural space, the lung collapses. Hypoxemia occurs because of alveolar hypoventilation, ventilation-perfusion mismatch, and intrapulmonary shunt. In simple pneumothorax, intrapleural pressure is atmospheric, and the lung collapses up to 30%. In **tension pneumothorax**, a continuing leak causes increasing positive pressure in the pleural space, with further compression of the lung, shift of mediastinal structures toward the contralateral side, and decreases in venous return and cardiac output causing hemodynamic instability.

CLINICAL MANIFESTATIONS

The onset of pneumothorax is usually abrupt, and the severity of symptoms depends on the extent of the lung collapse and the amount of preexisting lung disease. Pneumothorax may cause dyspnea, chest pain, and cyanosis. When it occurs in infancy, symptoms and physical signs may be difficult to recognize. Moderate pneumothorax may cause little displacement of the intrathoracic organs and few or no symptoms. The severity of pain usually does not directly reflect the extent of the collapse.

Usually, there is respiratory distress, with retractions; markedly decreased breath sounds; and a tympanitic percussion note over the involved hemithorax. The larynx, trachea, and heart may be shifted toward the unaffected side. When fluid is present, there is usually a sharply limited area of tympany above a level of flatness to percussion. The presence of bronchial breath sounds or, when fluid is present in the pleural cavity, of gurgling sounds synchronous with respirations suggests an open fistula connecting with air-containing tissues.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of pneumothorax is usually established by radiographic examination (Figs. 461.1-461.6). The amount of air outside the lung varies with time. A radiograph that is taken early shows less lung collapse than one that was taken later if the leak continues. Expiratory views accentuate the contrast between lung markings and the clear area of the pneumothorax (see Fig. 461.1). Variations exist in the measurement techniques defining the size of a pneumothorax. A large pneumothorax is measured by The American College of Chest Physicians as ≥3 cm from the lung apex to the thoracic cupola, and by the British Thoracic Society as ≥2 cm from the lung margin to the chest wall at the level of the hilum (Table 461.2).

It may be difficult to determine whether a pneumothorax is under tension. Tension pneumothorax is present when there is a shift of mediastinal structures away from the side of the air leak. A shift may be absent in situations in which the other hemithorax resists the shift, such as in the case of bilateral pneumothorax. On occasion, the diagnosis of tension pneumothorax is made only based on evidence of circulatory compromise or on hearing a "hiss" of rapid exit of air under tension with the insertion of the thoracostomy tube. When the lungs are both stiff, such as in cystic fibrosis or respiratory distress syndrome, the unaffected lung may not collapse easily, and shift may not occur (see Fig. 461.3).

Pneumothorax must be differentiated from localized or generalized emphysema, an extensive emphysematous bleb, large pulmonary cavities or other cystic formations, diaphragmatic hernia, compensatory overexpansion with contralateral atelectasis, and gaseous distention of the stomach. In most cases, chest radiography or CT differentiates among these possibilities. In addition, CT may identify underlying pathology such as blebs (Fig. 461.7). Further evaluation to determine if a diaphragmatic hernia is present should include a barium swallow with a small amount of barium to demonstrate that it is not free air but is a portion of the gastrointestinal tract that is in the thoracic cavity (see Chapter 131). Ultrasound can also be used to establish the diagnosis.

TREATMENT

Therapy varies with the extent of the collapse and the nature and severity of the underlying disease. A small or even moderate-sized pneumothorax in an otherwise normal child may resolve without specific treatment, usually within 1 week. A small pneumothorax-complicating asthma may also resolve spontaneously. Administering 100% oxygen may hasten resolution, but patients with chronic hypoxemia should be monitored closely during the administration of supplemental oxygen. Pleural pain deserves analgesic treatment.

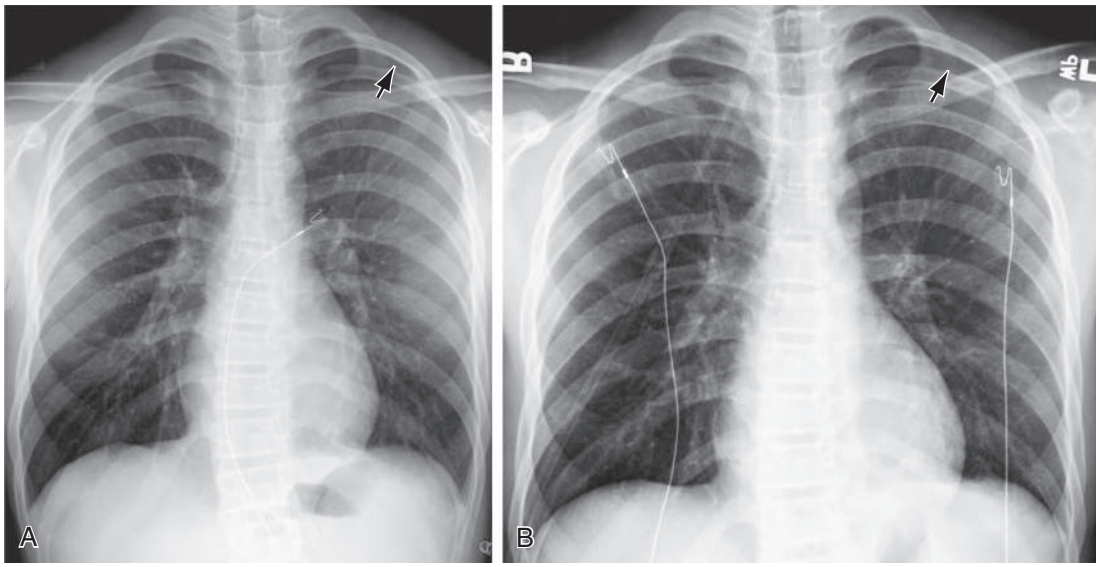

Fig. 461.1 Utility of an expiratory film in detection of a small pneumothorax. **A,** Teenager with stab wound and subtle radiolucency in the left apical region *(arrow)* on inspiratory chest radiograph. The margin of the visceral pleura is very faintly visible. **B,** On an expiratory film, the pneumothorax *(arrow)* is more obvious as the right lung has deflated and become more opaque, providing better contrast with the air in the pleural space.

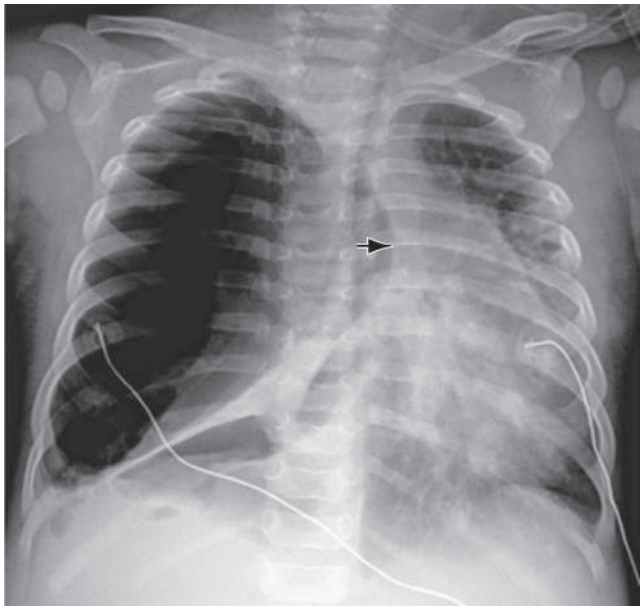

Fig. 461.2 Right pneumothorax, with lung collapse of a compliant lung. Shift of the mediastinum to the left *(arrow)* indicates that this is a tension pneumothorax.

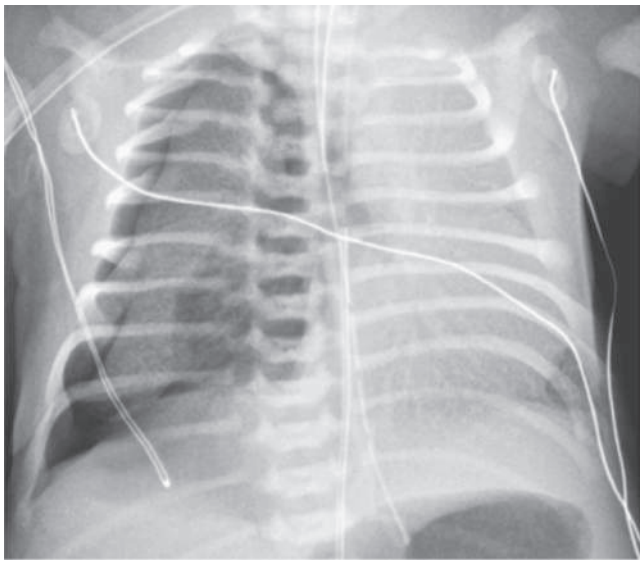

Fig. 461.3 Right pneumothorax, with only limited collapse of a poorly compliant lung.

Needle aspiration into the second intercostal space in the midclavicular line may be required on an emergency basis for tension pneumothorax and is as effective as tube thoracostomy in the emergency room management of primary spontaneous pneumothorax. If the pneumothorax is recurrent, secondary, or under tension, or there is more than a small collapse, catheter drainage or other invasive measures may be necessary. Pneumothorax in patients with cystic fibrosis or Marfan syndrome frequently recurs, and definitive treatment may be justified with the first episode. Similarly, if pneumothorax-complicating malignancy does not improve rapidly with observation, chemical pleurodesis or surgical thoracotomy is often necessary. In cases with severe air leaks or bronchopleural fistula, occlusion with an endobronchial balloon has been successful.

Closed thoracotomy (simple insertion of a chest tube) and drainage of the trapped air through a catheter, the external opening of which is kept in a dependent position under water, is adequate to reexpand the lung in most patients; pigtail catheters are frequently used. Consideration can be given to a sclerosing procedure to induce the formation of

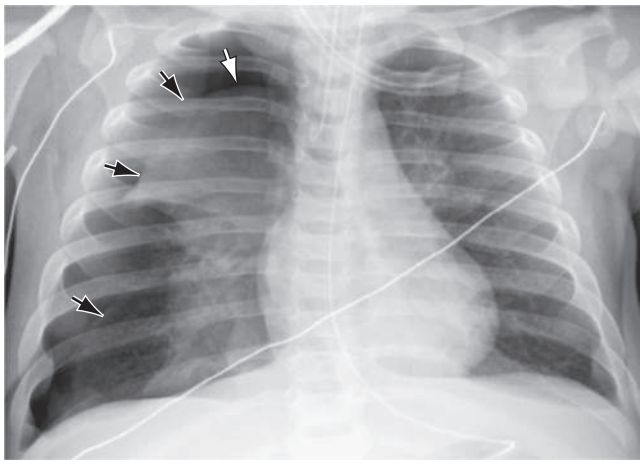

Fig. 461.4 Pneumothorax, with collapse of right lung *(arrows)*, caused by barotrauma in a 7-mo-old child who was intubated for respiratory failure.

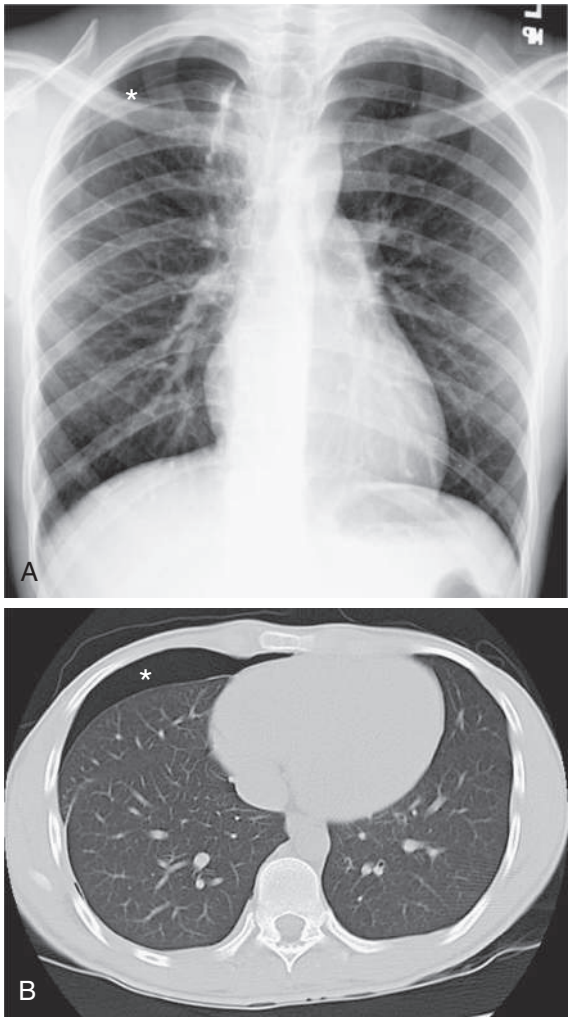

Fig. 461.5 Teenager in whom a spontaneous right pneumothorax developed because of a bleb. Patient had a persistent air leak despite recent surgical resection of the causative apical bleb. Chest radiograph (**A**) and CT scan (**B**) clearly show the persistent pneumothorax *(asterisk)*.

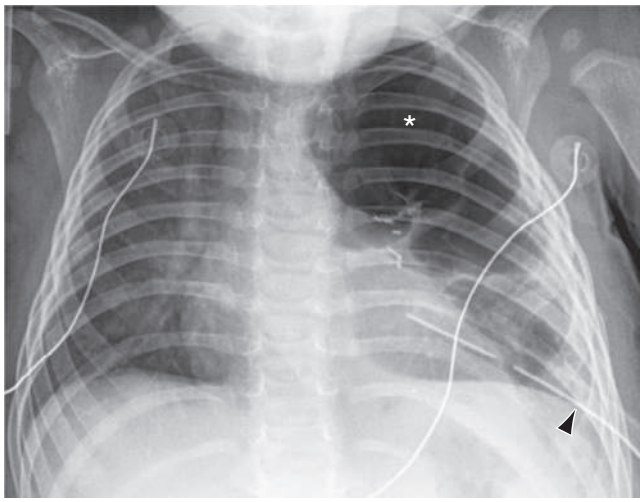

Fig. 461.6 Bronchopleural fistula following surgical resection of the left upper lobe as a result of congenital lobar emphysema. Chest radiograph shows localized pneumothorax *(asterisk)* that persisted despite prior insertion of a large-bore chest tube *(arrowhead)*.

strong adhesions between the lung and chest wall with the introduction of doxycycline or iodopovidone into the pleural space (chemical pleurodesis).

Open thoracotomy through a limited incision, with plication of blebs, closure of the fistula, stripping of the pleura (usually in the apical lung, where the surgeon has direct vision), and basilar pleural abrasion is also an effective treatment for *recurrent* pneumothorax. Stripping and abrading the pleura leaves raw, inflamed surfaces that heal with sealing adhesions. Video-assisted thoracoscopic surgery (VATS) is a preferred therapy for blebectomy, pleural stripping, pleural brushing, and instillation of sclerosing agents, with less morbidity than occurs with traditional open thoracotomy. In cases with a persistent air leak following thoracic surgery, an autologous blood patch pleurodesis may also be considered.

There is a risk of recurrence after surgical treatment in the pediatric population, although this is often not related to surgical failure but rather associated with the formation of new or undetected bullae. Clear benefit for treatment of asymptomatic blebs/bullae in the contralateral lung has not been established in the pediatric population.

Pleural adhesions help prevent recurrent pneumothorax, but they also make subsequent thoracic surgery difficult. When lung transplantation may be a future consideration (e.g., in cystic fibrosis), steps should be taken to avoid, if at all possible, chemical or mechanical pleurodesis. It should also be kept in mind that the longer a chest tube is in place, the greater the chance of pulmonary deterioration, particularly in a patient with cystic fibrosis in whom strong coughing, deep breathing, and postural drainage are important. These are all difficult to accomplish with a chest tube in place.

Chapter 462

Pneumomediastinum

Aarthi P. Vemana and Suraiya K. Haider

Air or gas in the mediastinum is called *pneumomediastinum* and is typically caused by alveolar rupture, which can be due to either a spontaneous or traumatic cause. A spontaneous pneumomediastinum can either be primary without an underlying etiology or can occur secondary to an underlying cause. *Primary* pneumomediastinum can be due to increases in intrathoracic pressure as is seen with a Valsalva maneuver, vomiting, Boerhaave syndrome (esophageal perforation), weightlifting, inhalation of recreational drugs, use of e-cigarettes, recreational use of MDMA, and choking events. Causes of *secondary* pneumomediastinum include lower respiratory tract infections including COVID-19, asthma exacerbations, mechanical ventilation, anorexia nervosa, normal menses, and diabetes mellitus with ketoacidosis. Traumatic causes of pneumomediastinum include both iatrogenic (dental extractions, adenotonsillectomy, high flow nasal cannula therapy, esophageal perforation, inhalation of helium gas, and flexible bronchoscopy) and noniatrogenic (inhaled foreign body and penetrating chest trauma).

PATHOGENESIS

According to the **Macklin effect**, after an intrapulmonary alveolar rupture, air dissects along the pressure gradient through the perivascular sheaths and other soft tissue planes toward the hilum and enters the mediastinum.

CLINICAL MANIFESTATIONS

Dyspnea and transient stabbing chest pain that may radiate to the neck are the principal features of pneumomediastinum. Other symptoms may be present and may include globus pharyngeus, abdominal pain, cough, chest tightness, facial swelling, choking, tachypnea, fever, stridor, and sore throat. Pneumomediastinum is difficult to detect by physical examination alone. Subcutaneous emphysema is present in the majority of patients. When present, **Hamman sign** (a mediastinal "crunch") is nearly pathognomonic for pneumomediastinum. Cardiac dullness to percussion may be decreased, but if the chest is chronically overinflated, it is unlikely that the clinician can be sure of this finding.

LABORATORY FINDINGS

Chest radiography reveals mediastinal air, with a more distinct cardiac border than normal (Figs. 462.1 and 462.2). A "spinnaker sail sign" or "angel wing sign" occurs when air deviates the thymus upward and outward, which is seen more often in pediatric patients. On the lateral projection, the posterior mediastinal structures are clearly defined, there may be a lucent ring ("ring sign") around the right pulmonary artery, and retrosternal air can usually be seen. Vertical streaks of air in the mediastinum and subcutaneous air are often observed (see Fig. 462.1). If a pneumomediastinum is clinically suspected but is not visualized on a chest x-ray, a chest CT can be performed to confirm the diagnosis and identify tracheal injury, if present.

TREATMENT

Treatment is directed primarily at the underlying obstructive pulmonary disease or other precipitating condition. Children who have had pneumomediastinum should be screened for asthma. Analgesics are occasionally needed for chest pain. Children can be observed in the emergency room and discharged if stable. They should be cautioned to avoid heavy lifting and the Valsalva maneuver. Hospital admission with supplemental oxygen administration is more common for patients with secondary pneumomediastinum. In severe cases, consideration should be given to

the use of more invasive interventions, including tracheotomy, surgical repair, and skin incisions over the neck and anterior chest wall. The use of prophylactic antibiotics to prevent deep neck space infections and mediastinitis has not been shown to provide additional benefit.

COMPLICATIONS

Pneumomediastinum is rarely a major problem in older children because the mediastinum can be depressurized by escape of air into the neck or abdomen. In the newborn, however, the rate at which air can leave the mediastinum is limited, and pneumomediastinum can lead to dangerous cardiovascular compromise or pneumothorax (see Chapters 132 and 461).

Chapter 463
Hydrothorax

Aarthi P. Vemana and Suraiya K. Haider

Hydrothorax is a transudative pleural effusion; typically, it is caused by abnormal pressure gradients in the lung. Hydrothorax is most often associated with cardiac, renal, or hepatic disease. It can also be a manifestation of severe nutritional edema and hypoalbuminemia. Rarely, it results from superior vena cava obstruction by neoplasms, enlarged lymph nodes, pulmonary embolism, or adhesions. It may occur from a ventriculoperitoneal (VP) shunt, central venous catheter, peritoneal dialysis, or after corrective spinal fusion for treatment of adolescent idiopathic scoliosis.

CLINICAL MANIFESTATIONS

Hydrothorax is usually bilateral, but in cardiac or hepatic disease it can be limited to the right side or greater on the right than on the left side. The physical signs are the same as those described for serofibrinous pleurisy (see Chapter 451.2), but in hydrothorax there is more rapid shifting of the level of dullness with changes of position. Depending on the etiology, it can be associated with an accumulation of fluid in other parts of the body.

LABORATORY FINDINGS

The fluid is **transudative**, noninflammatory, has few cells, and has a lower specific gravity (<1.015) than that of a serofibrinous exudate (see Chapters 449 and 451). The ratio of pleural fluid to serum total protein is <0.5, the ratio of pleural fluid to serum lactic dehydrogenase is <0.6, and the pleural fluid lactic dehydrogenase value is less than 66% of the upper limit of the normal serum lactic dehydrogenase range. In a patient with a VP shunt, B-transferrin assays and radionuclide tracer shunt series may be helpful for diagnosis. Peritoneal scintigraphy may be considered to evaluate for a peritoneal-pleural leak. In hepatic hydrothorax, the pleural fluid resembles spontaneous bacterial peritonitis, with positive bacterial cultures and polymorphonuclear leukocyte counts >250 cell/mm^3.

TREATMENT

Therapy is directed at the underlying disorder. If a transudative fluid is clinically suspected, aspiration may not be needed unless pressure symptoms are noted or there are atypical symptoms, such as fever, pleuritic pain, or asymmetric effusions. Aspirated fluid may be diagnostic using PCR for bacteria and cytology and flow cytometry for malignancies.

Chapter 464
Hemothorax

Suraiya K. Haider and Aarthi P. Vemana

Hemothorax, an accumulation of blood in the pleural cavity, is rare in children. Bleeding into the chest cavity most commonly occurs after chest trauma, either blunt or penetrating. It can be the result of iatrogenic trauma, including surgical procedures and venous line insertion. Hemothorax can also result from erosion of a blood vessel in association with inflammatory processes, such as tuberculosis

and empyema. It may complicate a variety of congenital anomalies, including sequestration, patent ductus arteriosus, and pulmonary arteriovenous malformation (see Fig. 458.2 in Chapter 458), or occur in association with vascular Ehlers-Danlos syndrome. It is also an occasional manifestation of intrathoracic neoplasms, costal exostoses, blood dyscrasias, bleeding diatheses, thrombolytic therapy, thoracic endometriosis, or rarely COVID-19 infections. Rupture of an aneurysm is unlikely during childhood. Hemothorax may occur spontaneously but is rare in children. A pleural hemorrhage associated with a pneumothorax is a *hemopneumothorax;* it is usually the result of a ruptured bulla with lung volume loss causing a torn pleural adhesion.

CLINICAL MANIFESTATIONS

In addition to the symptoms and signs of pleural effusion (see Chapter 451.2), hemothorax is associated with hemodynamic compromise related to the amount and rapidity of bleeding, with ventilatory collapse. Spontaneous hemothorax presents with sudden onset of chest or back pain or dyspnea and can progress rapidly to hemorrhagic shock.

DIAGNOSIS

The diagnosis of a hemothorax is initially suspected from radiographs, ultrasounds, or CT scans but can be made definitively with thoracentesis (Fig. 464.1). In every case, an effort must be made to determine and treat the cause.

TREATMENT

Therapy includes supplemental oxygen, fluid resuscitation (including possible blood transfusion), and tube thoracostomy. Video-assisted thoracoscopic surgery (VATS) can be considered in most patients with stable vital signs to visualize the source of bleeding, remove blood clots, resect bullae or blebs, and to perform pleurodesis. An open thoracotomy may be indicated if there is uncontrolled bleeding or in a hemodynamically compromised patient. Inadequate removal of blood in extensive hemothorax leading to a retained hemothorax can increase the risk for development of pneumonia, empyema, or substantial restrictive disease secondary to organization of fibrin. Fibrinolytic therapy or a decortication may then be necessary. Embolization is the treatment of choice for an arteriovenous malformation.

Chapter 465
Chylothorax

Suraiya K. Haider and Aarthi P. Vemana

Chylothorax is a pleural collection of fluid formed by the escape of chyle from the thoracic duct or lymphatics into the thoracic cavity. Chylothorax in children occurs most frequently because of thoracic duct injury as a complication of cardiothoracic surgery (post Fontan surgery) (Fig. 465.1). Other cases are associated with chest injury (Fig. 465.2), extracorporeal membrane oxygenation, or primary or metastatic intrathoracic malignancy, particularly lymphoma. In newborns, rapidly increased venous pressure during delivery may lead to thoracic duct rupture. Chylothorax has also been associated with Down syndrome, Noonan syndrome, Turner syndrome, and congenital myotonic dystrophy. Genetic pathogenic variants involving the VEGFC/VEGFR3, PI3K/AKT/mTOR, and RAS/MAPK pathways can impact lymphangiogenesis leading to lymphatic malformations. Refractory chylothorax in the fetus has been associated with a missense variant in integrin $\alpha_9\beta_1$ gene. Persistent or recurrent chylothorax has been described in association with pathogenic variants in the *PIEZO1* gene. Less common causes include lymphangiomatosis (Fig. 465.3), restrictive pulmonary diseases, thrombosis of the duct, superior vena cava, or subclavian vein; tuberculosis or histoplasmosis, Gorham-Stout disease, and congenital anomalies of the lymphatic system (Fig. 465.4). Chylothorax can occur in trauma and child abuse (see Chapter 16). It is important to establish the etiology because treatment varies with the cause. In some patients, no specific cause is identified.

CLINICAL MANIFESTATIONS

The signs and symptoms of chylothorax are the same as those from pleural effusion of similar size, including cough, chest discomfort, and dyspnea. Chyle is not irritating, so pleuritic pain is uncommon. Onset is often gradual. However, after trauma to the thoracic duct, chyle may accumulate in the posterior mediastinum for days and then rupture into the pleural space with sudden onset of dyspnea, hypotension, and hypoxemia. Approximately 50% of newborns with chylothorax present with respiratory distress in the first day of life. Chylothorax is rarely bilateral and usually occurs on the right side.

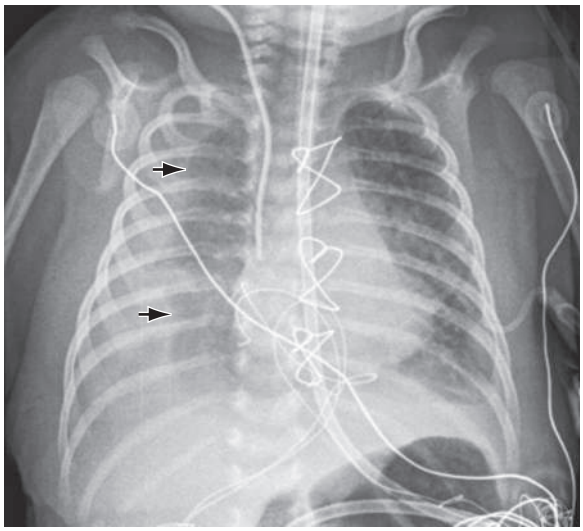

Fig. 465.1 Chylothorax *(arrows)* following cardiac surgery in a 2-wk-old infant.

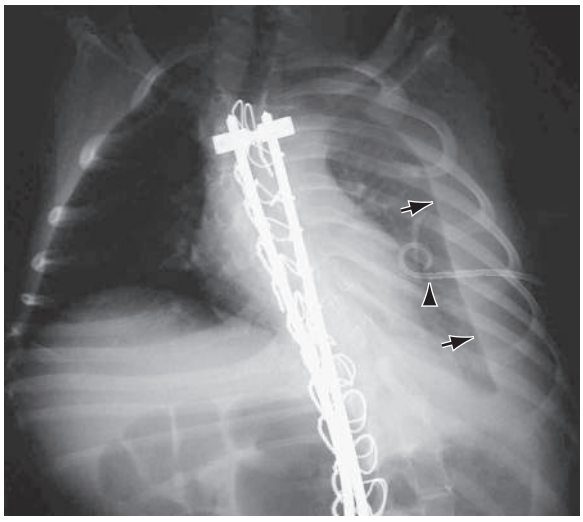

Fig. 465.2 Left chylothorax *(arrows)* following spinal fusion with Harrington rods. It is postulated that the thoracic duct was injured during spine surgery. The pigtail chest tube *(arrowhead)* needed to be retracted to better drain the effusion.

LABORATORY FINDINGS AND IMAGING

Chest radiographs can help to delineate the location of an effusion; CT scans show normal pleural thickness and may demonstrate a mediastinal mass such as a lymphoma, as the etiology of the chylothorax. Thoracentesis demonstrates a chylous effusion, a milky fluid containing triglycerides, protein, lymphocytes, and other constituents of chyle; fluid may be yellow or bloody. In newborn infants or those who are not ingesting food, the fluid may be clear. A pseudochylous milky fluid may be present in chronic serous effusion, in which fatty material arises from degenerative changes in the fluid and not from lymph. In chylothorax, the fluid triglyceride level is >110 mg/dL, the pleural fluid:serum triglyceride ratio is >1.0, and pleural fluid:serum cholesterol ratio is <1.0; lipoprotein analysis reveals chylomicrons. Fluid immunoglobulin levels are elevated. The cells are primarily (>80%) lymphocytes and often exceed 1,000 cells per mm^3. After diagnosing chylothorax, a lymphangiogram can localize the site of the leak, and lymphoscintigraphy may

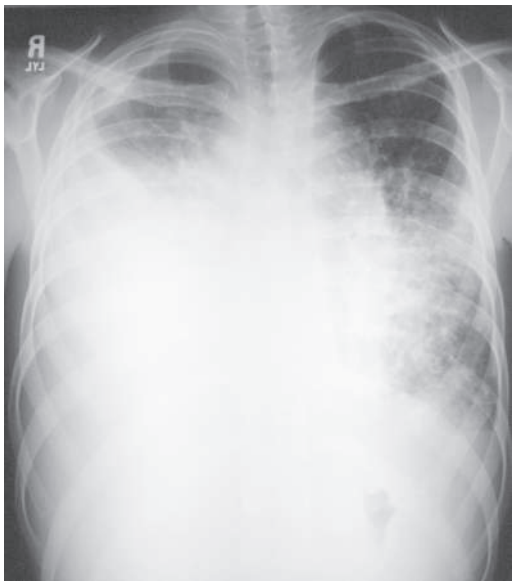

Fig. 465.3 Large right chylous effusion opacifying much of the right thorax in a teenager with pulmonary lymphangiomatosis and hemangiomatosis. Note the associated interstitial lung disease.

demonstrate abnormalities of the lymphatic trunks and peripheral lymphatics. MR lymphangiography also allows for visualization of the peripheral and segments of the central lymphatics. Dynamic contrast-enhanced magnetic resonance lymphangiography can provide real-time evaluation of the central lymphatic flow with good spatial resolution to guide management options.

TREATMENT

Treatment involves symptomatic support and decreasing or stopping chyle accumulation. Management is divided into two categories: nonsurgical and surgical. Nutritional management strategies include a combination of nil-per-os (NPO) and total parenteral nutrition, or enteral feeds using either a low-fat or medium-chain triglyceride diet or defatted human milk (also known as skimmed human milk). Thoracentesis is repeated as needed to relieve pressure symptoms; tube thoracostomy is often performed. Somatostatin and octreotide have been used to manage chylothorax. Various octreotide dosages have been described, including 1–4 μg/kg/hr intravenously and 10 μg/kg/day subcutaneously. Retrospective analyses have shown beneficial effects with the use of steroids, in particular, hydrocortisone, methylprednisolone, and dexamethasone combined with somatostatin or octreotide. Use of propranolol or sirolimus in severe or refractory cases may be effective. Further studies are required to confirm the optimal dosage for steroids, propranolol, and sirolimus. Other therapeutic approaches include pressure control ventilation with positive end-expiratory pressure and inhalation of nitric oxide. If medical management is unsuccessful, surgical options should be considered and can include a pleuroperitoneal shunt, thoracic duct ligation, and pleurodesis with the use of a sclerosing agents such as fibrin glue or povidone-iodine. Treatment is similar for traumatic chylothorax. Chemical pleurodesis or irradiation is used in malignant chylothorax. OK432 (picibanil) has been used to treat fetal and newborn chylothorax. Etilefrine, a sympathomimetic agent with both α- and β-adrenergic activity, has been successfully used in a few patients. Constriction of the thoracic duct by this drug may reduce pleural chyle accumulation. Percutaneous thoracic duct embolization or treatment of other lymphatic vessels is a successful interventional radiology strategy. Surgery should be considered earlier in neonates with massive chylothorax and chyle output of >50 mL/kg/day despite maximum medical therapy for 3 days.

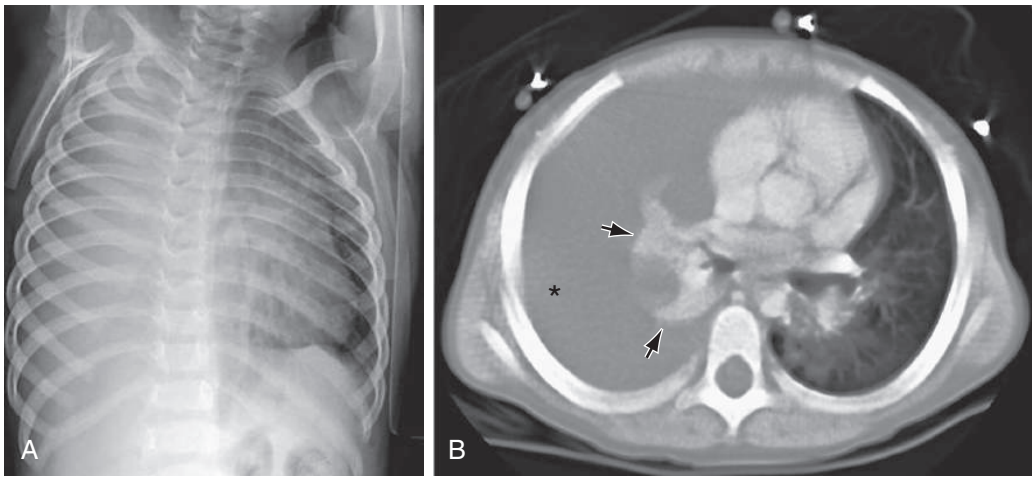

Fig. 465.4 Spontaneous chylothorax in a 4 yr old with a duplication of chromosome 6. **A,** Chest radiograph shows opacification of the right thorax. **B,** CT scan shows the chylous pleural effusion *(asterisk)* compressing the atelectatic right lung *(arrows)*.

COMPLICATIONS

If repeated thoracenteses are required due to the rapid reaccumulation of chyle, malnutrition may occur with significant loss of calories, protein, and electrolytes. Immunodeficiencies, including hypogammaglobulinemia and abnormal cell-mediated immune responses, have been associated with repeated and chronic thoracenteses for chylothorax. The loss of T lymphocytes is associated with increased risk of infection in neonates; otherwise, infection is uncommon, but patients should not receive live virus vaccines. Lack of resolution of chylothorax can lead to malnutrition, infection, and death.

Chapter 466

Bronchopulmonary Dysplasia

Sharon A. McGrath-Morrow and J. Michael Collaco

Bronchopulmonary dysplasia (BPD) is a chronic lung disease of infancy and childhood that occurs primarily in preterm infants born at less than 32 weeks' gestation. BPD is characterized by alveolar hypoplasia, often with concomitant small airway dysfunction and impaired pulmonary vascular growth. Contributing factors to the development of BPD may include early gestational age, low birthweight, lung barotrauma, exposure to hyperoxia, lung inflammation, and pre- and postnatal infections, as well as potential modifier genes and epigenetic factors. The currently accepted definition for diagnosis includes an oxygen requirement for 28 days postnatally, and the disorder is graded as mild, moderate, or severe based on supplemental oxygen and ventilation requirements at specific time points (Table 466.1). For initial inpatient presentation and management, see Chapter 127.

CLINICAL MANIFESTATIONS

Physical findings of the pulmonary exam vary with the severity of the disease and with respiratory illnesses. Although some patients may appear to be comfortably breathing when well, they can experience significant deterioration when ill or with periods of stress due to decreased pulmonary reserve secondary to alveolar hypoplasia and small airway disease. Children with BPD may exhibit tachypnea, head bobbing, and retractions when ill or at baseline depending on the severity of the disease. Although breath sounds may be clear, many patients have baseline wheeze or coarse crackles. A persistent, fixed wheeze or stridor suggests subglottic stenosis (see Chapter 436) or large airway malacia. Fine crackles may be present in patients prone to fluid overload. Chest radiographs may demonstrate air trapping, focal atelectasis, interstitial changes, and/or peribronchial thickening.

The most severely affected patients may require respiratory support to achieve adequate gas exchange. Supplemental oxygen may be required to maintain acceptable oxygen saturations and often is needed to minimize the work of breathing. Chronic respiratory insufficiency may be evidenced as elevation of serum bicarbonate, elevated carbon dioxide on blood gas analysis, hypoxemia, or polycythemia; the most severe cases may require tracheostomy and ventilation to achieve long-term respiratory stability. Patients must be monitored for the development of pulmonary hypertension, especially if they require supplemental oxygen and have chronic respiratory insufficiency.

Aspiration from dysphagia and/or gastroesophageal reflux (GERD) (see Chapter 369) can compromise pulmonary status. The risk of aspiration may increase during periods of illness due to worsening tachypnea and air trapping. Other comorbidities resulting from premature birth that complicate the management of BPD include fixed and functional upper airway obstruction, CNS injuries leading to abnormal control of breathing, abnormal airway tone, increased aspiration risk, gastrointestinal dysmotility, systemic hypertension, and poor growth. Of note, infants with significant lung disease can exhibit growth failure from the elevated energy expenditure essential to maintaining the increased metabolic demands of respiration and/or ongoing hypoxia.

A *pulmonary exacerbation* in a child with BPD is typically triggered during viral respiratory infections. Other frequent risk factors for pulmonary exacerbations may include weather changes, exposure to cigarette smoke, exposure to emissions from vaping devices, attending daycare, and aspiration. During an exacerbation, the infant may exhibit increased work of breathing, crackles, and wheezing, with tachypnea and retractions becoming more prominent. Underlying pulmonary hypertension may worsen with pulmonary exacerbations as well.

Table 466.1 Definition of Bronchopulmonary Dysplasia: Diagnostic Criteria

GESTATIONAL AGE	<32 WEEKS	≥32 WEEKS
Time point of assessment	36 weeks' PMA or discharge to home, whichever comes first	>28 days but <56 days' postnatal age or discharge to home, whichever comes first
TREATMENT WITH >21% OXYGEN FOR AT LEAST 28 DAYS PLUS		
Mild BPD	Breathing room air by 36 weeks' PMA or discharge, whichever comes first	Breathing room air by 56 days' postnatal age or discharge, whichever comes first
Moderate BPD	Need for <30% oxygen at 36 weeks' PMA or discharge, whichever comes first	Need for <30% oxygen at 56 days' postnatal age or discharge, whichever comes first
Severe BPD	Need for ≥30% oxygen and/or positive pressure (PPV or NCPAP) at 36 weeks' PMA or discharge, whichever comes first	Need for ≥30% oxygen and/or positive pressure (PPV or NCPAP) at 56 days' postnatal age or discharge, whichever comes first

BPD, Bronchopulmonary dysplasia; NCPAP, nasal continuous positive airway pressure; PMA, postmenstrual age; PPV, positive pressure ventilation.

TREATMENT

Treatment is directed toward decreasing the work of breathing and normalizing gas exchange to allow for optimal growth and neurodevelopment. After initial hospital discharge, infants and children with BPD are at high risk for rehospitalization. Up to 50% of infants with BPD are readmitted for acute respiratory illnesses within the first 2 years of life. These children also may require multiple daily medications, supplemental oxygen, and/or chronic ventilation.

Adherence to prescribed daily medication regimens may decrease the risk of acute care use and chronic respiratory symptoms; however, there are no standard guidelines for the management of BPD concerning post-NICU care. Although commonly used, there are limited data regarding the efficacy of diuretics in the outpatient setting.

With regard to respiratory support, targeted oxygen saturations should be ≥92% outside of the NICU to ensure adequate growth and neurocognitive development. Pulse-oximetry and polysomnography may be helpful for titration purposes. Before initial hospital discharge, infants and children who require chronic ventilatory support have been shown to benefit from standardized protocols to determine medical readiness, assess familial proficiency in respiratory care, and establish adequate support in an outpatient setting. After discharge, these patients will require close follow-up from pulmonologists and otolaryngologists to manage ventilator titration and weaning and tracheostomy care and decannulation, respectively. As infants and children with tracheostomies are at high risk for adverse events, including death, an awake and alert trained caregiver is recommended at all times.

Pulmonary function testing in children with a history of BPD has consistently demonstrated obstructive small airway disease. Small airway disease in this population may be partially responsive to bronchodilators but may also have a fixed obstructive component. Inhaled corticosteroids and β-agonists may be effective in treating symptoms, such as wheezing or chronic cough.

Adequate caloric intake is important to ensure catch-up lung growth. Some children may require fortified breast milk or formula to achieve adequate growth. Patients at risk for aspiration and those with inadequate oral intake may require tube feeding to meet nutritional goals. Placement of a gastrostomy tube should be considered before discharging home. Aspiration secondary to dysphagia and/or gastroesophageal reflux should be considered in patients with recurrent respiratory symptoms or pneumonia without obvious infectious etiologies. Because of their tenuous respiratory status, some infants and children with BPD may not be able to tolerate even minimal amounts of aspiration from gastroesophageal reflux. There are limited data regarding risks and benefits of antireflux medications in infants with BPD, such as histamine-2 blockers, proton pump inhibitors, and motility agents. Medications that reduce gastric acidity may increase the risk of pneumonia in some children. Consideration for either Nissen fundoplication or gastrojejunostomy tubes may be required in cases of failure of antireflux medical therapy.

Up to 15–25% of infants with severe BPD will be diagnosed with pulmonary hypertension, which may be secondary to decreased pulmonary vascular growth and/or a reactive vascular bed. Other risk factors for developing pulmonary hypertension may include extreme prematurity and decreased intrauterine growth; recurrent aspiration, hypoxia, and hypercarbia may worsen severity. Pulmonary hypertension in infants is associated with increased morbidity and mortality compared to infants without pulmonary hypertension. Although definitive diagnosis of pulmonary hypertension requires cardiac catheterization, in practice transthoracic echocardiography provides a low-risk screening tool. Screening should also attempt to identify potential structural causes of pulmonary hypertension, such as pulmonary vein stenosis. Serum biomarkers, such as brain natriuretic protein, may be useful in tracking response to therapy. Abrupt worsening of pulmonary hypertension *(pulmonary hypertensive crises)* can occur in the context of illnesses and with anesthesia. Crises can occur even in stable children with a history of pulmonary hypertension who become acutely ill. Although pulmonary hypertension that is associated with BPD can improve with adequate lung growth, therapies such as sildenafil and other antipulmonary hypertensive agents have been used in management.

Prevention of respiratory viral illness is vitally important; frequent handwashing by caregivers (especially before they handle the baby) and avoidance of contact with children and adults with current respiratory symptoms are essential. Respiratory syncytial virus (see Chapter 307) immunoprophylaxis should be considered based on the severity of lung disease and the patient's gestational age and current age. Another environmental factor that can worsen respiratory symptoms is exposure to secondhand tobacco smoke (see Chapter 759.1).

PROGNOSIS

The prognosis for infants with BPD is generally good, although the presence of BPD may result in a longer initial hospitalization compared with preterm infants without BPD. Most infants are weaned off of oxygen during the first year of life, and those requiring home mechanical ventilation are often weaned from this support during toddlerhood. Many children exhibit an asthma-like phenotype during early childhood, characterized by episodes of wheezing or coughing triggered by upper respiratory tract infections, exertion, allergens, etc. For some of these children, symptoms improve by school age; others may continue to have asthma-like exacerbations with viral illnesses and exercise throughout childhood that may persist into adulthood. Even asymptomatic patients with a history of BPD can continue to demonstrate small airway flow limitations by spirometry. Lastly, obstructive sleep apnea may also be more common in infants, children, and young adults with a history of BPD.

Chapter 467

Skeletal Diseases Influencing Pulmonary Function

Steven R. Boas and Catherine Kier

Pulmonary function is influenced by the structure of the chest wall (see Chapter 421). Chest wall abnormalities can lead to restrictive or obstructive pulmonary disease, impaired respiratory muscle strength, and decreased ventilatory performance in response to physical stress. The congenital chest wall deformities include *pectus excavatum, pectus carinatum, sternal clefts, Poland syndrome*, and skeletal and *cartilage dysplasias*. Vertebral anomalies such as kyphoscoliosis can alter pulmonary function in children and adolescents.

467.1 Pectus Excavatum (Funnel Chest)

Steven R. Boas and Catherine Kier

ETIOLOGY

Pectus excavatum—midline narrowing of the thoracic cavity—is usually an isolated skeletal abnormality. The cause is unknown. Pectus excavatum can occur in isolation, or it may be associated with a connective tissue disorder—Marfan (see Chapter 743) or Ehlers-Danlos syndrome (see Chapter 700). It may be acquired secondarily to chronic lung disease, neuromuscular disease, or trauma.

EPIDEMIOLOGY

Pectus excavatum occurs in 1 in 400 births with a 9:1 male preponderance and accounts for >90% of congenital chest wall anomalies. There is a positive family history in ~30% of cases.

CLINICAL MANIFESTATIONS

The deformity is present at or shortly after birth in one third of cases but is usually not associated with any symptoms at that time. In time, fatigue, chest pain, palpitations, recurrent respiratory infections, wheezing, stridor, and cough may be present. Decreased exercise tolerance is one of the most common symptoms. Because of the cosmetic nature of this deformity, children may experience significant psychologic stress. Physical examination may reveal sternal depression, protracted shoulders, kyphoscoliosis, dorsal lordosis, inferior rib flares, rib cage rigidity, forward head tilt, scapular winging, and loss of vertebral contours (Fig. 467.1). Patients may exhibit paroxysmal sternal motion and a shift of point of maximal impulse to the left. Innocent systolic murmurs may be heard.

LABORATORY FINDINGS

Lateral chest radiograms demonstrate sternal depression. The Haller index on chest CT (maximal internal transverse diameter of the chest divided by the minimal anteroposterior diameter at the same level) in comparison with age- and gender-appropriate normative values have been used historically to help determine the extent of the anatomic abnormality. However, the correlation of the Haller index with the physiologic compromise or associated systems appears suboptimal. The use of 3D chest optical imaging or "surface scan" is gaining popularity in the evaluation. An electrocardiogram may show a right-axis deviation or Wolff-Parkinson-White syndrome (see Chapter 485); an echocardiogram may demonstrate mitral valve prolapse (see Chapter 477.3) and ventricular compression. Results of static pulmonary function tests may be normal but commonly show an obstructive defect in the lower airways and, less commonly, a restrictive defect as the result of abnormal chest wall mechanics. Exercise testing may demonstrate either normal tolerance or limitations from underlying cardiopulmonary dysfunction that are associated with the severity of the defect. Pulmonary limitations, such as ventilatory limitations and associated flow volume loop abnormalities, are commonly seen in younger children and adolescents, whereas additional cardiac limitations secondary to stroke volume impairments are more commonly seen in older adolescents and young adults.

TREATMENT

Treatment is based on the severity of the deformity and the extent of physiologic compromise as defined by physical examination and physiologic assessment of cardiopulmonary function (lung function and exercise tolerance assessment). Therapeutic options include careful observation, the use of physical therapy to address musculoskeletal compromise, corrective surgery, cosmetic surgery, and noninvasive thoracoscopic techniques. For patients with significant physiologic compromise, surgical correction may improve the cosmetic deformity and may help minimize progression or even improve the cardiopulmonary compromise. The two main surgical interventions are the Ravitch and Nuss procedures. The Nuss procedure is a minimally invasive thoracoscopic repair that has been associated with good cosmetic and functional outcomes.

The extent of the anatomic defect, including the degree of asymmetry, may help determine the appropriate surgical approach. Although surgical repair may result in improved exercise tolerance for some individuals, usually observed at submaximal exercise intensities, many patients do not show improvement in either respiratory or cardiac function. Normalization of lung perfusion scans and maximal voluntary ventilation have also been observed after surgery. Use of a magnetic brace with gradual remodeling (Magnetic Mini Mover procedure) of the pectus deformity is under clinical investigation, with some promising results seen for prepubertal children. Surgically placed silicone implants for cosmetic appearance have also been used with high patient satisfaction. For selected patients, the use of a more noninvasive approach (i.e., cup suction) has been gaining popularity. Regardless of the treatment approach, addressing secondary musculoskeletal findings is commonly employed before and after any intervention.

467.2 Pectus Carinatum and Sternal Clefts

Steven R. Boas and Catherine Kier

PECTUS CARINATUM

Pectus carinatum is a sternal deformity accounting for 5–15% of congenital chest wall anomalies. Anterior displacements of the mid and lower sternum and adjacent costal cartilages are the most common types. They are most commonly associated with protrusion of the upper sternum; depression of the lower sternum occurs in only 15% of patients. Asymmetry of the sternum is common, and localized depression of the lower anterolateral chest is also often observed. Males are affected four times more often than females. There is a high familial occurrence and a common association of mild to moderate scoliosis. Mitral valve disease and coarctation of the aorta are associated with this anomaly. Three types of anatomic deformity occur (upper, lower, and lateral pectus carinatum), with corresponding physiologic changes and treatment algorithms.

CLINICAL MANIFESTATIONS

In early childhood, symptoms appear minimal. School-age children and adolescents commonly complain of dyspnea with mild exertion, decreased endurance with exercise, and exercise-induced wheezing. The incidence of increased respiratory infections and use of asthma

Fig. 467.1 Pectus excavatum in a 15-yr-old male. Note the presence of protracted shoulders, inferior rib flares, and sternal depression.

medication is higher than in nonaffected individuals. On physical examination, a marked increase in the anteroposterior chest diameter is seen, with a resultant reduction in chest excursion and expansion (Fig. 467.2). Spirometry has demonstrated both restrictive and obstructive patterns, although the majority of individuals have normal values. Increases in residual volume are often present and result in tachypnea and diaphragmatic respirations. Exercise testing shows variable results. Chest radiographs show an increased anteroposterior diameter of the chest wall, emphysematous-appearing lungs, and a narrow cardiac shadow. The pectus severity score (width of chest divided by distance between sternum and spine; analogous to the Haller index) is reduced.

TREATMENT

For symptomatic patients with pectus carinatum, minimally invasive surgical correction procedures may result in an improvement of the clinical symptoms. Many surgeons prefer to use **bracing techniques** as a first-line treatment, especially for younger patients. Although surgery is performed for some individuals who are symptomatic, it is often performed for cosmetic and psychologic reasons.

STERNAL CLEFTS

Sternal clefts are rare congenital malformations that result from the failure of the fusion of the sternum during the eighth week of gestation. No familial predisposition has been described. Sternal clefts occur in less than 1% of all chest wall deformities. Sternal clefts are classified as partial or complete. Partial sternal clefts are more common and may involve the superior sternum in association with other lesions, such as vascular dysplasias and supraumbilical raphe, or the inferior sternal clefts, which are often associated with other midline defects (pentalogy of Cantrell). Complete sternal clefts with complete failure of sternal fusion are rare. These disorders may also occur in isolation. The paradoxic movement of thoracic organs with respiration may alter pulmonary mechanics. Rarely, respiratory infections and even significant compromise result. Surgery is required early in life before fixation and immobility occur.

467.3 Asphyxiating Thoracic Dystrophy (Thoracic-Pelvic-Phalangeal Dystrophy)

Steven R. Boas and Catherine Kier

A multisystem autosomal recessive disorder, asphyxiating thoracic dystrophy results in a constricted and narrow rib cage. Also known as *Jeune syndrome*, the disorder is associated with characteristic skeletal abnormalities as well as variable involvement of other systems, including renal, hepatic, neurologic, pancreatic, and retinal abnormalities (see Chapter 741).

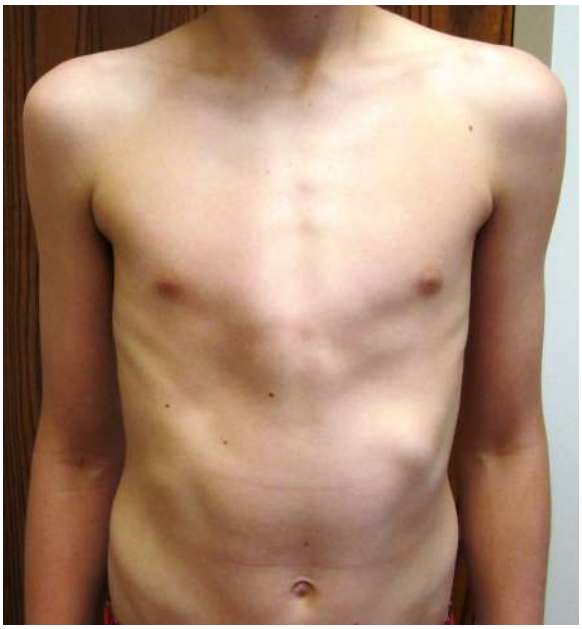

Fig. 467.2 Pectus carinatum in a 13-yr-old male. Note the central sternal prominence.

CLINICAL MANIFESTATIONS

Most patients with this disorder die shortly after birth from respiratory failure, although less-aggressive forms have been reported in older children. For those who survive the neonatal period, progressive respiratory failure often ensues, owing to impaired lung growth, recurrent pneumonia, and atelectasis originating from the rigid chest wall.

DIAGNOSIS

Physical examination reveals a narrowed thorax that, at birth, is much smaller than the head circumference. The ribs are horizontal, and the child has short extremities. Chest radiographs demonstrate a bell-shaped chest cage with short, horizontal, flaring ribs, and high clavicles.

TREATMENT

No specific treatment exists, although thoracoplasty to enlarge the chest wall and long-term mechanical ventilation have been tried. Rib-expanding (vertical expandable prosthetic titanium rib [VEPTR]) procedures have resulted in improved survival (Fig. 467.3).

PROGNOSIS

For some children with asphyxiating thoracic dystrophy, improvement in the bony abnormalities occurs with age. However, children younger than age 1 year often succumb to respiratory infection and failure. Progressive renal disease often occurs in older children. Use of vaccines for influenza and other respiratory pathogens is warranted, as is the aggressive use of antibiotics for respiratory infections.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

467.4 Achondroplasia

Steven R. Boas and Catherine Kier

Achondroplasia is the most common condition characterized by disproportionate short stature (see Chapter 737). This condition is inherited as an autosomal dominant disorder that results in disordered growth. Much has been learned about this disorder, including its genetic origins (95% of cases are caused by pathogenic variants in the gene coding for fibroblast growth factor receptor type 3) and how to minimize its serious complications.

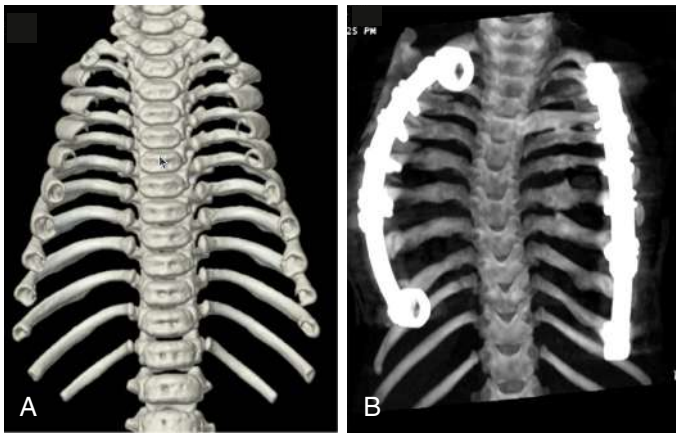

Fig. 467.3 A, Seven-mo-old with Jeune syndrome preoperatively. B, 18 mo after VEPTR insertion. *(From Mayer OH. Chest wall hypoplasia—principles and treatment. Pediatr Respir Rev. 2015;16:30–34, Fig. 3.)*

CLINICAL MANIFESTATIONS

Restrictive pulmonary disease, affecting <5% of children with achondroplasia who are younger than 3 years, is more likely at high elevation. Recurrent infections, cor pulmonale, and dyspnea are commonly associated. There is an increased risk of obstructive sleep apnea or hypopneas. Hypoxemia during sleep is a common feature. Risk of airway malacia is greater than the general population. Onset of restrictive lung disease can begin at a very young age. On examination, the breathing pattern is rapid and shallow, with associated abdominal breathing. The anteroposterior diameter of the thorax is reduced. Special growth curves for chest circumference of patients with achondroplasia from birth to 7 years are available. Three distinct phenotypes exist: phenotypic group 1 patients possess relative adenotonsillar hypertrophy, group 2 patients have muscular upper airway obstruction and progressive hydrocephalus, and group 3 patients have upper airway obstruction without hydrocephalus. Kyphoscoliosis may develop during infancy.

DIAGNOSIS

Pulmonary function tests reveal a reduced vital capacity that is more pronounced in males. The lungs are small but functionally normal. Sleep studies are recommended because of the high prevalence of sleep-disordered breathing. Chest radiographs demonstrate the decreased anteroposterior diameter along with anterior cupping of the ribs. The degree of foramen magnum involvement correlates with the extent of respiratory dysfunction.

TREATMENT

Treatment of sleep apnea, if present, is supportive (see Chapter 31). Physiotherapy and bracing may minimize the complications of both kyphosis and severe lordosis. Aggressive treatment of respiratory infections and scoliosis is warranted.

PROGNOSIS

The life span is normal for most children with this condition, except for the phenotypic groups with hydrocephalus or with severe cervical or lumbar spinal compression.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

467.5 Kyphoscoliosis: Adolescent Idiopathic Scoliosis and Congenital Scoliosis

Steven R. Boas and Catherine Kier

Adolescent idiopathic scoliosis (AIS) is characterized by lateral bending of the spine (see Chapter 720). It commonly affects children during their teen years and during periods of rapid growth. The cause is unknown. Congenital scoliosis is uncommon, affecting females more than males, and is apparent in the first year of life (see Chapter 720.2).

CLINICAL MANIFESTATIONS

The pulmonary manifestations of scoliosis may include chest wall restriction, leading to a reduction in total lung capacity, abnormal gas exchange, airway obstruction, and hypoinflation with associated atelectasis. The angle of scoliosis deformity has been correlated with the degree of lung impairment only for patients with thoracic curves. Vital capacity, forced expiratory volume in 1 sec (FEV_1), work capacity, oxygen consumption, diffusion capacity, chest wall compliance, and partial pressure of arterial oxygen decrease as the severity of thoracic curve increases. These findings can be seen in even mild to moderate AIS (Cobb angle <30 degrees) but generally do not occur in other, nonthoracic curves. Respiratory compromise is often more severe in children younger than 5 years of age with large scoliotic curves. Reduction in peripheral muscle function is associated with AIS through either intrinsic mechanisms or deconditioning. Severe impairment can lead to cor pulmonale or respiratory failure and can occur before 20 years old. Children with severe scoliosis (Cobb's angle >70 degrees), especially males, may have abnormalities of breathing during sleep, and the resultant periods of hypoxemia may contribute to the eventual development of pulmonary hypertension.

DIAGNOSIS

Physical examination and an upright, posteroanterior radiograph with subsequent measurement of the angle of curvature (Cobb technique) remain the gold standard for the assessment of scoliosis. Curves >10 degrees define the presence of scoliosis. Lung volume, respiratory muscle strength, and exercise capacity determination are essential in assessing the degree of respiratory compromise associated with scoliosis.

TREATMENT

Depending on the extent of the curve and the degree of skeletal maturation, treatment options include reassurance, observation, physical therapy, bracing, and surgery (spinal fusion). Influenza vaccine should be administered, given the extent of pulmonary compromise that may coexist. Because vital capacity is a strong predictor for the development of respiratory failure in untreated AIS, surgical goals are to diminish the scoliotic curve, maintain the correction, and prevent deterioration in pulmonary function. Abnormalities of vital capacity and total lung capacity, exercise intolerance, and the rate of change of these variables over time should be taken into consideration for the timing of surgical correction. Preoperative assessment of lung function (i.e., lung volumes, oxygen consumption, muscle strength, ventilation/perfusion) may assist in predicting postsurgical pulmonary difficulties. Many patients undergoing surgical correction may be managed postoperatively without mechanical ventilation. Even patients with mild scoliosis may have pulmonary compromise immediately after spinal fusion, secondary to pain, and a body cast that may restrict breathing and interfere with coughing. Children with a preoperative FEV_1 <40% predicted are at risk for requiring prolonged postoperative mechanical ventilation. Rib-expanding procedures have been successful in severe cases of congenital scoliosis. Choice of surgical approach may also impact lung function postoperatively.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

467.6 Congenital Rib Anomalies

Steven R. Boas and Catherine Kier

Isolated defects of the highest and lowest ribs have minimal clinical pulmonary consequences. Missing midthoracic ribs are associated with the absence of the pectoralis muscle (Poland syndrome), and lung function can become compromised. Associated kyphoscoliosis and hemivertebrae may accompany this defect. If the rib defect is small,

no significant sequelae ensue. When the second to fifth ribs are absent anteriorly, lung herniation and significant abnormal respiration ensue. The lung is soft and nontender and may be easily reducible on examination. Complicating sequelae include severe lung restriction (secondary to scoliosis), cor pulmonale, and congestive heart failure. Symptoms are often minimal but can cause dyspnea. Respiratory distress is rare in infancy.

DIAGNOSIS

Chest radiographs demonstrate the deformation and absence of ribs with secondary scoliosis. Most rib abnormalities are discovered as incidental findings on a chest film.

TREATMENT

If symptoms are severe enough to cause clinical compromise or significant lung herniation, then homologous rib grafting can be performed. Rib-expanding procedures are also of great value. A modified Nuss procedure has been used to correct associated chest wall anomalies with rib abnormalities. Adolescent girls with congenital rib anomalies may require cosmetic breast surgery.

Chapter 468

Chronic Respiratory Insufficiency

468.1 Chronic Respiratory Failure and Long-Term Mechanical Ventilation

Denise M. Goodman and Steven O. Lestrud

Care has improved for the growing population of children with chronic respiratory failure requiring invasive (ventilation through a tracheostomy) and noninvasive (mask ventilation) ventilation, including those with predisposing conditions such as acute respiratory failure, prematurity, and neuromuscular disease. Although it is difficult to determine the prevalence of chronic ventilation, estimates range from approximately 4-6/100,000 children, or 3,000-4,000 children nationally who receive home ventilation. There may be roughly three times more children receiving mask ventilation than invasive mechanical ventilation. The conditions leading to the need for home ventilation are diverse. About 65% of children have a primary neurologic indication, including neuromuscular weakness or abnormal ventilatory control, and ~30% have chronic lung disease (Table 468.1).

Patients with primarily pulmonary indications have a greater likelihood of ultimately being weaned from the need for ventilation than do those with neuromuscular or central nervous system disease. Mortality for patients requiring chronic ventilation is ~12–34%, depending on underlying disease. The lower mortality range is for children with neonatal lung disease, with the higher value for children with complex congenital heart disease. Approximately 12–40% of children are eventually weaned from ventilation and decannulated, reflecting the underlying cause for which ventilation is required. This can usually be accomplished within the first 5 years of life. Nonetheless, the care of these children can be challenging. One study reported that up to 40% of chronically ventilated children are readmitted within the first year of discharge, usually within the first 3 months. Children requiring long-term mechanical ventilation (LMV) benefit from comprehensive care coordination incorporating generalists, specialists, home nursing, therapies, and a durable medical equipment (DME) resource.

Table 468.1 Indications for Long-Term Mechanical Ventilation

PULMONARY/ALVEOLAR
Bronchopulmonary dysplasia (BPD)
Severe acquired lung disease, such as after pediatric acute respiratory distress syndrome (PARDS)
Pulmonary fibrosis syndromes

Rapid-onset obesity with hypothalamic dysregulation, hypoventilation, and autonomic dysfunction (ROHHAD)
Severe ischemic brain injury
Myelomeningocele with Arnold-Chiari type II malformation
Acquired hypoventilation syndromes

MODALITIES FOR RESPIRATORY SUPPORT

The goals of home mechanical ventilation are to maintain adequate oxygenation and ventilation, minimizing metabolic demands of chronic respiratory failure to ensure adequate somatic growth and optimal developmental gains.

Invasive Positive Pressure Ventilation

The term *invasive* designates ventilation through a tracheostomy. Some devices are suitable for both noninvasive positive pressure ventilation (NPPV) and invasive ventilation, whereas other devices are suitable for only one approach. The ideal home ventilator is lightweight, portable, and quiet. All home ventilators differ from hospital-based ventilators in that air movement is affected either by a piston or turbine that is electrically controlled. This contrasts with hospital ventilators, which are often gas-driven. A home ventilator should be able to provide continuous flow and have a wide range of settings (particularly for pressure, volume, pressure support, and rate) that allows ventilatory support from infancy to adulthood. Battery power for the ventilator, both internal and external, should be sufficient to permit unrestricted portability in the home and community. The equipment must also be impervious to electromagnetic interference and must be relatively easy to understand and troubleshoot.

Although families and care teams may at first resist placement, a **tracheostomy** has several advantages. It provides a secure and stable airway, a standardized interface for attaching the ventilator circuit to the patient, and the ability to easily remove airway secretions and deliver inhaled medications. Pediatric tracheostomy tubes typically have a single lumen and may have an inflatable cuff. Tracheostomy tubes with and without cuff inflation should be sized to control the

air leak around the tube and promote adequate gas exchange, yet allow enough space around the tube to facilitate vocalization and prevent tracheal irritation and erosion from the tube. The child's caregivers need to learn stoma care, elective and emergent tracheostomy changes, proper securing of the tube, suctioning of secretions, and recognition of emergencies such as tube obstruction or decannulation.

Optimal Ventilator Support

Factors such as underlying neuromuscular disease; medications such as sedatives, analgesics, steroids, and muscle relaxants; and prolonged immobility, as well as use of mechanical ventilation, may decondition the respiratory muscles and the diaphragm, resulting in muscle weakness. Consequently, it is important to avoid 24 hour a day patient synchrony with ventilation and titrate the amount of ventilator support to prevent fatigue yet facilitate spontaneous breathing. While assessing ventilator needs, frequent evaluation of gas exchange is needed and can usually be done noninvasively. Ventilator settings should be stable for a given period, dictated by the severity of pulmonary disease, before discharge home.

OTHER MANAGEMENT CONSIDERATIONS

Airway Clearance

One of the most important considerations is maintenance of airway patency. Adequate removal of secretions may minimize intercurrent pulmonary infections. In turn, infections may cause a transient increase in secretions, requiring an escalation of clearance strategies. If the child has an adequate cough, then periodic suctioning may be all that is needed. Some children, however, need additional help mobilizing and clearing secretions. This becomes particularly important in children with neuromuscular disease, for whom regularly scheduled clearance therapies are an imperative. **Vest therapy** (high-frequency chest wall oscillation) uses an inflatable vest that encircles the chest. Air inflates and deflates the vest with phasic pulses against the chest wall, loosening secretions. This device still requires a preserved and strong enough cough to expel secretions. The **cough assist** device provides more active airway clearance, delivering a forceful positive pressure adjunct during inspiration and active negative pressure during expiration. Thus the cough is more effective because of the rapid pressure changes. The cough assist can be used with an artificial airway or mask. Controls will set the inspiratory and expiratory pressures and periods.

Inhalation Medications

Clearance of secretions may be promoted with delivery of hypertonic (3% saline) nebulizations. These are often timed to cough-assist sessions to maximize the clearance benefits of both. Children requiring ventilation also commonly need bronchodilators.

Mucolytics and Anticholinergics

Some patients may need additional interventions as a result of excess secretions. Anticholinergic drugs, principally glycopyrrolate, are often effective, but must be dosed carefully to avoid thickening secretions excessively, which can lead to inspissated secretions and life-threatening plugging of the airway. Oral secretions are sometimes amenable to localized injection of botulinum toxin or select surgical ligation of salivary ducts. It is also wise to ensure that the patient is adequately hydrated, as dehydration may produce thick tenacious secretions. At times a mucolytic may be used. Hypertonic saline is the most common mucolytic, but a number of other agents have been tried, such as dornase alfa and *N*-acetylcysteine.

Monitoring

A patient who is ventilated in the home must be electronically and/or physically monitored at all times. Infants and young children, children who are cognitively impaired, and children who are completely tracheostomy dependent for airway patency because of suprastomal obstruction must be under direct observation of the caregivers at all times. Caregivers should also closely monitor children whose pulmonary status is fragile or fluctuant. Continuous monitoring of O_2 saturation and heart rate is recommended during sleep and either continuous or intermittent monitoring during the daytime, depending on patient stability. Patients with congenital central hypoventilation syndrome (CCHS) or pulmonary hypertension are particularly vulnerable to episodes of hypoxemia and/or hypercarbia, and those with pulmonary hypertension are particularly susceptible to rapid drops in O_2 saturation.

Supplemental Oxygen

Supplemental oxygen may be delivered from a tank or concentrator. Whether on room air or oxygen at baseline, even mild intercurrent infections may lead to an increase in oxygen requirement. In these situations, the child should be evaluated in person rather than over the phone to ensure that a more serious illness is not developing.

Physical, Occupational, and Speech Therapy

The technology needed to support physical well-being should not overshadow the inherent needs common to all children—to play, grow, develop, and interact. Ongoing physical therapy, occupational therapy, and speech therapy can help a child reach full potential, and many achieve complete catch-up development. Early intervention programs and access to play groups are important factors to attaining cognitive and social milestones. When typical development is not attainable, therapies can improve mobilization and muscle strength. Core trunk and abdominal strength is particularly important for pulmonary rehabilitation and essential for successful weaning off ventilation. Other important skills include oromotor skills for feeding and communication. Evaluation of swallow is a key component of therapy for children with chronic respiratory failure. Sign language is frequently used for communication because of delayed speech or hearing loss. Audiology specialists should be involved in the assessment of hearing because there is a higher incidence of hearing loss in patients undergoing long-term ventilation.

PREPARING FOR DISCHARGE

A number of threads need to come together for a safe and effective discharge, including medical stability, family education, financial support (insurance or a state waiver program), availability of a DME company, and, when appropriate, home private-duty nursing. A poor outcome may occur with any of the many medical or process factors or family factors, including not only education but also home readiness and psychosocial supports. A standardized discharge process can ensure that all details are addressed, minimizing length of stay and improving safety. An awake and attentive trained caregiver should be in the home of a child with invasive ventilation at all times; this expectation may differ for those receiving NPPV depending on clinical circumstance. For those receiving invasive ventilation, the caregiver may be a nurse, but nursing resources are often scarce, so many programs require two trained family caregivers. The training given to the family includes tracheostomy stoma care, suctioning, equipment expertise, administration of medications, and facility with other devices, such as gastrostomy tubes. In addition, the family is instructed in emergency preparedness, including what to do for acute changes in clinical status, desaturation, or airway obstruction or decannulation. Cardiopulmonary resuscitation training is essential. Parents also need to be able to travel portably with the child and equipment. A standardized emergency bag containing critical tracheostomy and ventilator supplies should accompany the child at all times. Other preparations center around home readiness, including accessibility (number of stairs, if any), members of the household, assuring no smoking in the home, and notification of utility companies such as the electric or heating company to ensure the home is serviced quickly in the event of power interruption. The family must also have a functioning telephone to ensure adequate accessibility and communication between the family and care team. For those going home with invasive mechanical ventilation, both a primary and backup ventilator may be needed, as well as batteries, a self-inflating bag and mask, suctioning equipment, supplemental oxygen, and appropriate monitoring, including a pulse oximeter. The use of high-fidelity

simulation as a means to rehearse skills is increasing. Family training often culminates in an autonomous 24-hour stay *in the hospital* during which time one caregiver must continuously remain awake, and all cares, including ventilator checks, suctioning, tracheostomy tube changes, medications, and the like, are provided by the family.

CARE BY THE GENERAL PEDIATRICIAN

See Chapter 468.4.

Nutrition

Ventilated patients may have nutritional needs that are equal to, greater than, or lesser than those of comparably aged well children. Growth should be tracked at each well child and subspecialty visit. Excessive growth is as harmful as inadequate growth, and excess calories may lead to increased carbon dioxide (CO_2) production. Anthropometry or measured energy expenditure may be needed to assure a more precise prescription of nutritional support. Many children with tracheostomies have oral aversion and/or dyscoordination of swallowing, with resultant risk for aspiration. In these children a gastrostomy tube may ensure adequate nutrition in the interim, while ongoing speech therapy promotes oral feeding.

Infections

Tracheitis (see Chapter 433.2), bronchiolitis (see Chapter 439), and pneumonia (see Chapter 449) are common in patients with chronic respiratory failure. Infections may be caused by community-acquired viruses (adenovirus, influenza, respiratory syncytial virus, parainfluenza, rhinovirus) or community- or hospital-acquired bacteria. Common pathogens are gram-negative, highly antimicrobial-resistant pathogens that may cause further deterioration in pulmonary function. Bacterial infection is most likely in the presence of fever, deteriorating lung function (hypoxia, hypercarbia, tachypnea, and retractions), leukocytosis, and mucopurulent sputum. The presence of leukocytes and organisms on Gram stain of tracheal aspirate, along with the visualization of new infiltrates on radiographs, may be consistent with bacterial infection.

Infection must be distinguished from tracheal *colonization* of bacteria, which is asymptomatic and associated with normal amounts of clear tracheal secretions. Colonization may also be distinguished from infection in that colonization usually has few, if any, white blood cells on Gram stain of tracheal secretions. If infection is suspected, it must be treated with antibiotics, based on the culture and sensitivities of organisms recovered from the tracheal aspirate. At times an inhaled antibiotic such as tobramycin might avert progression of infection. Antibiotics should be used judiciously to prevent further colonization with drug-resistant organisms. However, some patients who have recurrent infections may benefit from prophylaxis with inhaled antibiotics. Clinical decisions will be based on the child's appearance, any increased need for ventilation or supplemental oxygen, and consultation with the subspecialist. A final caveat is that if a respiratory viral panel is desired, this must be obtained from nasal secretions similar to a well child; tracheal aspirate does not provide an appropriate specimen.

CARE BY THE SUBSPECIALTY TEAM

Weaning Off of the Ventilator

Typically, the ventilator settings are reduced, minimizing ventilator parameters to achieve physiologic respiratory rates and 6-8 mL/kg tidal volumes. Subsequent maneuvers will evaluate the patient free breathing, initially with simple observed transition times of 5-10 minutes, extending time off as clinically indicated. This can be done in the outpatient setting during visits with the pulmonologist or other subspecialist responsible for ventilator management. Additional factors that reflect tolerance of increased work of breathing, including weight gain, energy levels, general behavior, and sleep patterns, are also monitored carefully. When the child has completely weaned off ventilator support while awake and is only on the ventilator approximately 6 hours nightly during sleep, a polysomnogram study performed off the ventilator may be considered before complete liberation from the mechanical ventilation device. Successful liberation from mechanical ventilation, if it occurs, often takes place between the ages of 2 and 5 years. One thought is that with ambulation and development of core strength, respiratory reserve improves, facilitating weaning. Even so, residual lung disease is common. Children with a history of bronchopulmonary dysplasia (BPD) and previous ventilator dependence often have significant airway obstruction on pulmonary function testing.

PSYCHOSOCIAL CONSIDERATIONS

Caring for a child on long-term ventilatory support in the home is a complex, physically demanding, emotionally taxing, and expensive process for the family. It changes the family routines, priorities, and overall lifestyle and may adversely affect relationships both within the family and with extended family and friends. Practical considerations include loss of spontaneity in family outings, sleep disturbance, extra expenses, having strangers in the house providing care, and adhering to medical regimens and follow-up visits. Intangible stresses are also prominent, including disruption in the usual parent–child caregiving roles and stresses between parent partners and with other children. The loss of normality, sense of isolation, and concerns regarding what is best for the child are additional sources of distress. All of these stresses are exacerbated by challenges in securing reliable home private-duty nurse resources; this issue may delay hospital discharge and complicate postdischarge care, at times even leading to readmission because of lack of adequate support. For children with a life-limiting condition, there is the additional need to periodically revisit the child's current medical state, sense of well-being, and trajectory of illness, as critical decisions will eventually arise regarding end-of-life care. The general pediatrician can often be a familiar and comfortable safe place to explore these issues, as parents may be conflicted in wanting to be a "good" parent while feeling guilty about their own needs and vulnerabilities. Finally, families may find transportation to frequent outpatient visits difficult; telemedicine may offer an alternative for select situations.

ADULT TRANSITION

There are a growing number of children surviving into adulthood who require chronic ventilation. There are little empiric data regarding this transition, including identifying patients for whom transition is appropriate, implementing a standardized transition process, partnering with adult pulmonologists, or replicating in an adult environment the care coordination provided by the pediatric care team. The pulmonary team ideally initiates ongoing discussions regarding self-care responsibilities and transitioning of medical care to adult providers with the adolescent and his or her parents when the patient reaches the early teens. Discussion about self-care should take into consideration realistic expectations about the adolescent's physical and cognitive capabilities. The actual transition of care occurs for most young adults at age 18-21 years and includes referral to an internist and an adult pulmonologist. Transition of medical care also includes transition from pediatric to adult support services for funding sources and nursing care. Ideally, an outpatient visit that includes current and future adult medical providers together is completed to facilitate communication and formally transition care.

468.2 Congenital Central Hypoventilation Syndrome

Amy Zhou, Susan M. Slattery, Casey M. Rand, and Debra E. Weese-Mayer

CCHS is a clinically complex *neurocristopathy* that includes a variable severity of respiratory and autonomic dysregulation, as well as Hirschsprung disease and neural crest tumors in a subset of patients. In the **classic** CCHS presentation, symptoms of alveolar hypoventilation manifest in the newborn period and during sleep only—with

Table 468.2 Clinical Manifestations of CCHS

ORGAN SYSTEM	CLINICAL MANIFESTATIONS
Ophthalmologic	Decreased/absent pupillary light response Anisocoria Strabismus Lack of convergent gaze Marcus Gunn jaw winking
Respiratory	Alveolar hypoventilation Absent perception of dyspnea
Cardiovascular	Bradycardia Prolonged sinus pauses (>3 seconds) Transient asystole Decreased heart rate variability Low normal daytime blood pressure Orthostatic hypotension Nondipping blood pressure circadian pattern Decreased BP response to exercise Syncope
Gastrointestinal	Hirschsprung disease (20%) Constipation Esophageal dysmotility
Endocrine	Hyperinsulinism Hypoglycemia Hyperglycemia
Neurologic	Decreased anxiety Decreased pain perception Seizures Neurocognitive deficits
Skin	Sporadic profuse sweating
Tumors	Neuroblastoma Ganglioneuroma Ganglioneuroblastoma
Others	Decreased baseline body temperature Poor heat tolerance

CCHS, Congenital central hypoventilation syndrome; BP, blood pressure; GI, gastrointestinal.

From Bishara J, Keens TG, Perez IA. The genetics of congenital central hypoventilation syndrome: clinical implications. *App Clin Genetics*. 2018;11:135–144, Table 1. Originally published by and used with permission from Dove Medical Press Ltd.

diminished tidal volume and a typically monotonous respiratory rate leading to cyanosis and hypercarbia. In more **severe** cases of CCHS, the hypoventilation manifests during wakefulness and sleep. In the **later-onset** cases of CCHS **(LO-CCHS)**, onset of overt symptoms is delayed until 1 month of age or older (often into childhood and adulthood). Hypoventilation is typically during sleep only and usually milder in LO-CCHS. CCHS and LO-CCHS are further characterized by partial to complete failure of peripheral and central chemoreceptors to properly respond to hypercarbia and hypoxemia during wakefulness and sleep, coupled with physiologic and/or anatomic autonomic nervous system (ANS) dysregulation (ANSD). Physiologic dysregulation may include all organ systems affected by the ANS, specifically the respiratory, cardiac, sudomotor, vasomotor, ophthalmologic, neurologic, and enteric systems (Table 468.2). The anatomic or structural ANSD includes Hirschsprung disease and tumors of neural crest origin (neuroblastoma, ganglioneuroma, or ganglioneuroblastoma).

GENETICS

The *PHOX2B* gene is the disease-defining gene for CCHS. *PHOX2B* encodes a highly conserved homeodomain transcription factor, is essential to the embryologic development of the ANS from the neural crest, and is expressed in key regions and systems that explain much of the CCHS phenotype. Individuals with CCHS are *heterozygous* for either a **polyalanine repeat expansion pathogenic variant (PARPV)** in exon 3 of the *PHOX2B* gene (normal number of alanines is 20 with normal genotype 20/20), such that individuals with CCHS have 24-33 alanines on the affected allele (genotype range is 20/24-20/33), or a **nonpolyalanine repeat expansion pathogenic variant (NPARPV)** resulting from a missense, nonsense, frameshift, stop codon, in-frame indels (in-frame insertions, deletions, or duplications), full exon/gene deletions, or splice-site pathologic genetic variant. Approximately 90–92% of cases of CCHS have PARPVs and the remaining 8–10% of cases have NPARPVs (Table 468.3).

Stepwise clinical *PHOX2B* testing for probands with the CCHS phenotype is advised. **Step 1**: *PHOX2B* screening test (fragment analysis), then if negative; **Step 2**: *PHOX2B* sequencing test, then if negative; **Step 3**: *PHOX2B* multiplex ligation-dependent probe amplification (MLPA) test to minimize the risk of false-negative findings, minimize the expense and need for more than one blood sample, and expedite confirmation of the diagnosis.

Genetic counseling is essential for family planning and for delivery room preparation in anticipation of a CCHS birth and ensuring adequate ventilation for the mother during pregnancy. *PHOX2B* testing is also advised for both parents of a child with CCHS to anticipate the risk of recurrence in subsequent pregnancies (if mosaic) and to determine if a parent has yet-undiagnosed LO-CCHS. Fragment analysis *PHOX2B* testing (also known as the *screening test*) will best identify low-level somatic mosaicism. Prenatal testing for a *PHOX2B* variant is clinically available (www.genetests.org) for families with a known *PHOX2B* gene variant.

Ventilator Dependence and Control of Breathing

Patients with CCHS have deficient CO_2 sensitivity during wakefulness *and* sleep such that they do not respond with a normal increase in ventilation in either state, nor do they arouse in response to hypercarbia and/or hypoxemia during sleep. During wakefulness, a subset of patients may respond sufficiently to avoid significant hypercarbia, but most individuals with CCHS have hypoventilation that is severe enough that hypercarbia is apparent in the resting *awake* state. Children with CCHS also have altered sensitivity to hypoxia while awake and asleep. A key feature of CCHS is the *lack* of respiratory distress or sense of asphyxia with physiologic compromise (hypercarbia and/or hypoxemia). This lack of responsiveness to hypercarbia and/or hypoxemia, which can result in respiratory failure, does not consistently improve with advancing age. A subset of older children with CCHS may show an increase in ventilation (specifically an increase in respiratory rate rather than an increase in tidal volume) when they are exercised at various work rates. This response is possibly secondary to neural reflexes from rhythmic limb movements, although an increase in minute ventilation is often insufficient to avoid physiologic compromise.

The greater the number of extra alanines, the more likely the need for continuous ventilatory support, at least among the most common *PHOX2B* PARPV genotypes (20/25, 20/26, 20/27). Although *PHOX2B* genotype seems to anticipate the severity of hypoventilation, it does not correlate with exogenous ventilatory challenge responses. Infants and young children as a group have reasonable ventilatory response slopes while awake, but this advantage seems to vanish by school age.

Hirschsprung Disease (see Chapter 378.4)

Overall, 20% of children with CCHS also have Hirschsprung disease (HSCR), known as *Haddad syndrome,* and any infant or child with CCHS who presents with constipation should undergo rectal biopsy to screen for the absence of ganglion cells. The frequency of Hirschsprung disease seems to increase with the longer polyalanine repeat tracts (genotypes 20/27-20/33) and in those with NPARPVs. Even in cases without frank HSCR disease, individuals with CCHS may display symptoms of gastrointestinal abnormalities such as severe constipation and abnormal esophageal motility, suggesting ganglion cell dysfunction.

Table 468.3 Congenital Central Hypoventilation Syndrome–Related Symptoms by PARPV vs NPARPV and PARPV Genotype

FEATURE		GENOTYPE				
		PARPV GENOTYPE			NPARPVS	
		20/24[1], 20/25	20/26	20/27	NPARPV IN GENERAL	38BP DELETION
Respiratory (hypoventilation)		Asleep only	Awake with exertion and eating and asleep	Awake and asleep	Awake and asleep	Awake and asleep
Cardiac arrhythmia: Abrupt sinus pauses ≥3 seconds warranting cardiac pacemaker		Variable: None with childhood onset; a subset will have prolonged sinus pauses in adulthood	19%	>80%	None with childhood onset to date	
Hirschsprung disease		<0.1%	20–30%	30%	80–90%	95–100% severe long segment disease (i.e., entire colon and some small intestine)
Severe constipation			~50+%	~50+%		
Esophageal dysmotility/dysphagia			First year of life	First year of life		
Neural crest tumors	Neuroblastoma	0%	0%	See footnote 2	50%	
	Ganglioneuroblastoma	0%	0%	0%	<5%	
	Ganglioneuroma	0%	0%	0%	<5%	
ANSD: Pupillary response to light		Normal response	Midsize pupils with attenuated response to light	Small pupils at rest; nearly absent response to light	Large pupils at rest; negligible response to light	

ANSD, Autonomic nervous system dysregulation; NPARPV, nonpolyalanine repeat expansion pathogenic variant (i.e., missense, nonsense, frameshift, stop codon, splice site); PARPV, polyalanine repeat expansion pathogenic variant.

1. Genotype 20/24 would be considered a susceptibility allele (needs another factor to manifest) or a low- or variable-penetrance allele with features that can be triggered by pharmacologic agents (a pharmaco-genetic phenomenon) or a gene × environment interaction (without main effects).

2. Generally 0%; however, an infant with the 20/33 genotype had metastatic neuroblastoma (12).

Seattle (WA): University of Washington, Seattle; 1993-2021. Available from https://www.ncbi.nlm.nih.gov/books/NBK1427/. Table 2, pp. 7–8.

Tumors of Neural Crest Origin (see Chapter 547)

Tumors of neural crest origin are more frequent in patients with NPARPVs (50%) than in those with PARPVs (1%). These extracranial tumors are more often neuroblastomas in individuals with NPARPVs, but ganglioneuromas and ganglioneuroblastomas occur in a small subset of patients.

Cardiac Asystoles

Transient, abrupt, and prolonged sinus pauses have been identified in patients with CCHS, necessitating implantation of cardiac pacemakers when the pauses are ≥3 seconds. Among patients with the most common *PHOX2B* genotypes, 19% of those with the 20/26 genotype and 83% of those with the 20/27 genotype have cardiac pauses of 3 seconds or longer. The risk for sinus pauses among children with NPARPVs is unknown at present.

Heart rate variability is characteristically decreased in CCHS, likely because of reduced cardiac baroreflex sensitivity and blunted sympathetic response. One report demonstrated a genotype-phenotype relationship for heart rate variability during exogenous ventilatory response testing, prompting assessment of risk for sinus pauses. Introduction of 72-hour Holter recordings every 12 months, at a minimum, has allowed for early identification of these abrupt sinus pauses, permitting timely cardiac pacemaker implantation.

Autonomic Nervous System Dysregulation

A higher number of polyalanine repeats on the affected allele among patients with a PARPV is associated with an increased number of physiologic symptoms of ANSD. In addition, there is a spectrum of physiologic ANSD symptoms, including decreased heart rate variability, esophageal/gastric/colonic dysmotility, decreased pupillary response to light, reduced basal body temperature, altered distribution and amount of diaphoresis, altered vasomotor tone, and altered pain and anxiety perception.

Characteristic Facial Morphology

Characteristic facial features have been described for children with CCHS. Using facial photogrammetry, five features were used to correctly predict 86% of CCHS cases and 82% of controls in a matched case control study. A typical CCHS face is characterized by an upper and midface that is short relative to its width, resulting in a characteristic broad, flat, boxlike appearance (Fig. 468.1). The lateral one third of the upper lip vermillion border is overturned so it is flesh-colored instead of pink. Results also suggest that male CCHS patients are more strongly affected than females.

Neuropathology

Brain imaging studies and functional MRI (fMRI) responses have identified structural anomalies in CCHS cases that may contribute to the observed respiratory and autonomic phenotypes. These findings may be primarily the result of *PHOX2B* variant–induced failure of neurogenesis in the human embryo, but a significant contribution from postnatal hypoxic, hypercarbic, or perfusion damage cannot be excluded. The neuroanatomic defects in CCHS are likely the result of focal *PHOX2B* (mis)expression coupled with sequelae of recurrent hypoxemia/hypercarbia in the subset of suboptimally managed patients. The following regions pertinent to respiratory control in the pons and medulla of the brainstem show *PHOX2B* expression: locus coeruleus, dorsal respiratory group, nucleus ambiguus, and parafacial respiratory group, among other areas. Physiologic evidence suggests that the respiratory failure in these children is mostly based on defects in central mechanisms, but peripheral mechanisms (mainly carotid bodies) may also be important.

CLINICAL MANIFESTATIONS

Patients with CCHS usually present with symptoms in the first few hours after birth. Most children are the products of uneventful pregnancies and are term infants with appropriate weight for gestational age. Variable Apgar scores have been reported. The affected infants do not show signs of respiratory distress, but their shallow respirations and respiratory pauses (apnea) usually evolve to respiratory failure with apparent cyanosis in the first days of life. In neonates with CCHS, $Paco_2$ accumulates during sleep to very high levels, sometimes >90 mm Hg, and may decline to normal levels after the infants awaken. This problem becomes most apparent when multiple attempts at extubation fail in an intubated neonate who appears well with ventilatory support but develops respiratory failure without respiratory distress after removal of the support. However, more *severely* affected infants with CCHS hypoventilate awake and asleep; thus the previously described difference in $Paco_2$ between states may not be apparent. Often, the respiratory rate is higher in rapid eye movement (REM) sleep than in non-REM sleep in individuals with CCHS, and in general, respiratory rates are higher in infants and children with CCHS than similarly aged peers with intact control of breathing.

Fig. 468.1 Characteristic CCHS facies. Photographs of representative CCHS. These two children with CCHS both have the representative facies. The female with CCHS (A) has a *PHOX2B* genotype of 20/25, and the male with CCHS (B) has a 20/27 genotype. Note the decreases in sloping of the forehead, upper face height, upper facial inclination, nasolabial angle, upper and lower lip heights, and the inferior inflection of the lateral vermillion border of the upper lip. *(Modified from Todd ES, Weinberg SM, Berry-Kravis EM, et al. Facial phenotype in children and young adults with PHOX2B-determined congenital central hypoventilation syndrome: quantitative pattern of dysmorphology. Pediatr Res. 2006;59:39–45, Fig. 2A and 2C.)*

LO-CCHS should be suspected in infants, children, and adults who have unexplained centrally mediated hypoventilation and/or seizures or cyanosis, especially subsequent to the use of anesthetic agents and/or sedation, acute respiratory illness or recurrent severe respiratory illness with difficulty weaning from ventilator support (and failed extubations), and potentially obstructive sleep apnea (OSA) unresponsive to traditional intervention. These individuals may have other evidence of chronic hypoventilation, including pulmonary hypertension, polycythemia, elevated bicarbonate concentration, difficulty concentrating, and mild unexplained neurocognitive impairment. A heightened level of suspicion has led to increasing numbers of older children and adults diagnosed with LO-CCHS receiving proper treatment. This later presentation reflects the variable penetrance of a subset of *PHOX2B* variants and the potential role of an exogenous cofactor in unmasking the hypoventilation phenotype.

In addition to treatment for the alveolar hypoventilation, children with CCHS require comprehensive physiologic evaluation during sleep and wakefulness, including age-appropriate activities of daily living such as eating, as their hypoxemia and hypercarbia from insufficient artificial ventilation may go unnoticed. It is necessary to provide coordinated care to optimally manage associated multisystem abnormalities such as Hirschsprung disease, tumors of neural crest origin, and symptoms of physiologic ANSD, including cardiac asystole, among other findings (details provided in American Thoracic Society [ATS] 2010 Statement on CCHS) (Table 468.4).

DIFFERENTIAL DIAGNOSIS

Testing should be performed to rule out primary neuromuscular, lung, and cardiac disease as well as an identifiable brainstem lesion that could account for the symptoms characteristic of CCHS (Table 468.5). The availability of clinical *PHOX2B* genetic testing allows for early and definitive diagnosis of CCHS (see Table 468.3). Because individual subfeatures of CCHS mimic many treatable and/or genetic diseases, the following disorders should also be considered: altered airway or intrathoracic anatomy (diagnosis made with bronchoscopy and chest CT), diaphragm dysfunction (diagnosis made with diaphragm fluoroscopy), a structural hindbrain or brainstem abnormality (diagnosis made with MRI of the brain and brainstem), Möbius syndrome (diagnosis made with MRI of the brain and brainstem and neurologic examination), and specific metabolic diseases, such as Leigh syndrome, pyruvate dehydrogenase deficiency, and discrete carnitine deficiency. However, profound hypercarbia without respiratory distress during sleep will quickly lead the clinician to consider the diagnosis of CCHS or LO-CCHS.

MANAGEMENT

Supported Ventilation: Diaphragm Pacing

Depending on the severity of the hypoventilation, the individual with CCHS can have various options for artificial ventilation: positive pressure ventilation (noninvasive via mask or invasive via tracheostomy) or negative pressure ventilation (pneumosuit, chest cuirass, or diaphragm pacing). Chronic mechanical ventilation is addressed in Chapters 468.1 and 468.4. Diaphragm pacing offers another mode of supported ventilation, involving bilateral thoracoscopic implantation of electrodes beneath the phrenic nerves, with connecting wires to subcutaneously implanted receivers. The external transmitter, which is much smaller and lighter in weight than a ventilator, sends a signal to flat, donut-shaped antennae that are placed on the skin over the subcutaneously implanted receivers. A signal travels from the external transmitter to the phrenic nerve to stimulate contraction of the diaphragm. A tracheostomy is typically required, because the pacers induce a negative pressure on inspiration as a result of the contraction of the diaphragm being unopposed by pharyngeal dilatation, resulting

Table 468.4 Recommended Evaluations in Patients with CCHS

	EVALUATION	FREQUENCY	*PHOX2B* GENOTYPE
Pulmonary	Comprehensive physiologic testing during sleep and wakefulness, including continuous pulse oximetry, cardiorespiratory monitoring, capnography, and polysomnography	<3 yr of age: every 6 mo ≥3 yr: annually	All *PHOX2B* PARM and NPARM
Cardiovascular	Ambulatory cardiac monitoring (≥72 hr), blood pressure, and echocardiogram	Annually	All *PHOX2B* PARM and NPARM
Gastrointestinal	Barium enema or anorectal manometry; confirmation by rectal biopsy	At initial diagnosis and subsequently if symptoms appear	20/26-20/33 PARM and NPARM
Neurodevelopmental	Comprehensive neurocognitive tests	<3 yr of age: every 6 mo ≥3 yr: annually	All *PHOX2B* PARM and NPARM
Oncologic	Chest radiograph, abdominal ultrasound, and urine catecholamines (homovanillic acid and vanillylmandelic acid)	0-6 yr of age: every 3 mo 6-10 yr of age: every 6 mo >10 yr of age: per oncologist recommendation	20/28-20/33 PARM and NPARM
Ophthalmologic	Comprehensive ocular testing by an ophthalmologist	Annually	All *PHOX2B* PARM and NPARM

NPARM, Nonpolyalanine repeat expansion mutation; PARM, polyalanine repeat expansion mutation; PHOX2B, paired-like homeobox 2B.

in airway obstruction with paced breaths. Individuals with CCHS who are ventilator-dependent for 24 hours a day are ideal candidates for diaphragm pacing to provide increased ambulatory freedom (without the ventilator tether) while they are awake; however, they still require mechanical ventilator support while they are asleep. This balance between awake pacing and asleep mechanical ventilation allows for a rest from phrenic nerve stimulation at night. In addition, a growing but still limited number of children and adults who require artificial ventilatory support only during sleep are now using diaphragm pacing. This is likely because of the introduction of thoracoscopic diaphragm pacer implantation and shortened postoperative recovery time. However, in the absence of a tracheostomy, diaphragm pacing during sleep may cause airway obstruction at varied levels of the airway, depending on the specific patient. The potential for these obstructions needs to be carefully considered before diaphragm pacer implantation, and certainly before tracheal decannulation.

Monitoring in the Home

Home monitoring for individuals with CCHS and LO-CCHS is *distinctly different* from and more conservative than that for other children requiring long-term ventilation, because CCHS individuals lack innate ventilatory and arousal responses to hypoxemia and hypercarbia. In the event of physiologic compromise, other non-CCHS children will show clinical signs of respiratory distress. By contrast, for children and adults with CCHS and LO-CCHS, the only means of determining adequate ventilation and oxygenation is with objective measures from a pulse oximeter, end-tidal CO_2 monitor, and close supervision of these values by a highly trained registered nurse (RN) in the home and at school. While awake, patients with CCHS themselves are unable to sense or adequately respond to a respiratory challenge that may occur with ensuing respiratory illness, increased exertion, or even the simple activity of eating. At a minimum, it is essential that individuals with CCHS have continuous monitoring with pulse oximetry and end-tidal CO_2 with RN supervision during all sleep time, but ideally 24 hours a day. These recommendations apply to all CCHS and LO-CCHS patients regardless of the nature of their artificial ventilatory support, but especially those with diaphragm pacers, as only the most recent transmitter has mechanical dysfunction alarms intrinsic to the diaphragm pacer device.

Noninvasive Ventilatory Support Equipment

Supplemental oxygen with positive pressure support can be administered by nasal cannula, pillows, nasal mask, or full-face mask via an actual ventilator, but this is suitable only for highly cooperative children with milder hypoventilation during sleep only. Long-term use of mask ventilation in infants and young children may result in

midface dysplasia or pressure wounds. Mask ventilation does not offer the stable airway provided by a tracheostomy with mechanical ventilation, especially in the rapidly developing infant and young child.

Positive Pressure Ventilators

Ideally, a ventilator intended for home use is lightweight and small, quiet so it does not interfere with activities of daily living or sleep, is able to entrain room air, preferably has continuous flow, and has a wide range of settings (particularly for pressure support, pressure, volume, and rate) that allows ventilatory support from infancy to adulthood. Battery power for the ventilator, both internal and external, should be sufficient to permit unrestricted portability in the home and community. The equipment must also be impervious to electromagnetic interference and must be relatively easy to understand and troubleshoot. Children who are chronically ventilated via positive pressure ventilation will require surgical placement of a tracheostomy tube. The tracheostomy tube provides stable access to the airway, a standardized interface for attaching the ventilator circuit to the patient, and the ability to easily remove airway secretions or deliver inhaled medications. Pediatric tracheostomy tubes typically have a single lumen and may have an inflatable tight-to-the-shaft cuff. Tracheostomy tubes with and without cuff inflation should be sized to control the air leak around the tube and promote adequate gas exchange yet allow enough space around the tube to facilitate vocalization and prevent tracheal irritation and erosion from the tube.

Optimizing Neurocognitive Performance

Impaired oxygen delivery to the brain, whether acute or chronic, can have detrimental effects on neurocognitive development. The ATS statement on CCHS recommends positive pressure ventilation via tracheostomy in the first several years of life to ensure optimal oxygenation and ventilation. The method of choice for respiratory support in later years will depend on a variety of factors, including severity of disease, patient age, level of patient and family cooperation, and availability and quality of home healthcare, among other factors. The level of oxygen stability obtained with each modality varies. Thus the method of respiratory assistance, especially in infancy and early childhood, is likely to play a factor in neurocognitive outcome.

Past literature has indicated reduced neurocognitive performance in school-age children with CCHS, with mean full scale intellectual quotient (IQ) values one standard deviation below the normal IQ of 100. Even in preschool years, children with CCHS and the 20/26 and 20/27 *PHOX2B* genotypes demonstrate reduced neurocognitive performance compared to children with the 20/25 genotype. In these cases, *PHOX2B* genotype is clearly associated with both mental and motor outcomes. An association is also found between IQ and CCHS-related features such as severe cyanotic breath holding spells, sinus pauses, seizures, and severity of hypoventilation. One study reported a negative correlation between neurocognitive performance scores and length of polyalanine expansion, suggesting that both the specific gene variant and ventilatory method may influence neurocognitive outcome. Findings from a neurocognition study in preschool-age children suggest the potential for excellent neurocognitive outcome in some patients with CCHS. Neurodevelopmental monitoring would be most beneficial beginning in early infancy and followed closely with advancing age.

Efforts are underway to evaluate and characterize the CCHS phenotype longitudinally through the International CCHS Registry (https://clinicaltrials.gov/show/NCT03088020) (Northwestern University). Delineating markers of disease progression and understanding the clinical manifestations of CCHS with advancing age will provide more accurate guidelines to healthcare providers, allowing physicians, families, and patients to better anticipate healthcare needs of affected individuals and for use as biomarkers for future pharmacologic intervention studies.

468.3 Rapid-Onset Obesity with Hypothalamic Dysfunction, Hypoventilation, and Autonomic Dysregulation

Sarah F. Barclay, Ilya Khaytin, Amy Zhou, Casey M. Rand, and Debra E. Weese-Mayer

Rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation (ROHHAD) is a rare, poorly understood disorder with childhood onset, the first sign of which is sudden, rapid, and extreme weight gain in a previously healthy child. The acronym describes the presenting symptoms and the typical order in which they will manifest or unfold, as the condition evolves over months to years. Despite its rarity, *ROHHAD must be considered whenever rapid-onset obesity is observed in a child, because in the absence of appropriate treatment, a high mortality rate is associated with the severe central hypoventilation that will invariably develop.*

The diagnosis is initially considered after the observation of rapid-onset obesity (15-20 lb gain) after age 1.5 years, accompanied by at least one additional sign of hypothalamic dysfunction (HD). *Central hypoventilation may not be present at the time of rapid weight gain but will develop over time, and artificial ventilatory support will be required at least during sleep, if not 24 hours a day.* Signs of autonomic nervous system dysregulation typically occur after the weight gain, HD, and hypoventilation have been identified. Additionally, approximately 40% of ROHHAD patients will have or develop a tumor of neural crest origin, typically ganglioneuroma or ganglioneuroblastoma (a small number of neuroblastomas have been identified).

ROHHAD is distinct from LO-CCHS (see Chapter 468.2). ROHHAD is primarily distinguished from LO-CCHS by the presence of obesity and other signs of HD and by the absence of a CCHS-related pathogenic *PHOX2B* variant.

CLINICAL MANIFESTATIONS

Children with ROHHAD initially appear healthy, with an unremarkable medical history. The *initial* symptoms present between ages 18 months and 7 years. Typically, the first symptom observed is **rapid-onset obesity**, with weight gain of 15-30 lb in 6-12 months. The growth charts from a representative child followed longitudinally illustrate the characteristic accelerated increase in weight and body mass index (BMI) (Fig. 468.2). This is considered one sign of HD in these patients.

The second common sign of HD, seen in most ROHHAD patients, is **disordered water balance**, including hypernatremia and hyponatremia and both adipsia and polydipsia. **Growth hormone (GH) deficiency** is also observed in most patients. In some, this manifests clinically as slowed growth rate and short stature, whereas in others a failed GH stimulation test is the only manifestation. **Hyperprolactinemia** is observed near universally in patients with ROHHAD. Other symptoms of HD, occurring in >25–50% of ROHHAD patients, include **poor thermoregulation**, **central hypothyroidism**, **central adrenal insufficiency**, and **delayed or precocious puberty**. The number of hypothalamic abnormalities that will be observed and the sequential order in which they will appear are variable, and some symptoms may not manifest for months to 1-2 years after the initial diagnosis. However, all ROHHAD patients will present with at least one of these signs of HD beyond the rapid-onset weight gain.

Sleep-disordered breathing (SDB) is one of the key symptoms of ROHHAD, often manifesting as one of the most severe features of the phenotype, with the greatest potential for severe morbidity and death. More than half of ROHHAD patients have initial **obstructive sleep apnea (OSA)**; although SDB is known to be associated with obesity and OSA is often seen in obese individuals, over time, when the ROHHAD phenotype unfolds, SDB will evolve beyond what could potentially be explained as obesity related. All ROHHAD patients will eventually develop **central alveolar hypoventilation**, requiring artificial ventilation as life support, even when the upper airway obstruction is relieved as an intervention for OSA. About half of ROHHAD patients will require artificial ventilation only during sleep, whereas half will require

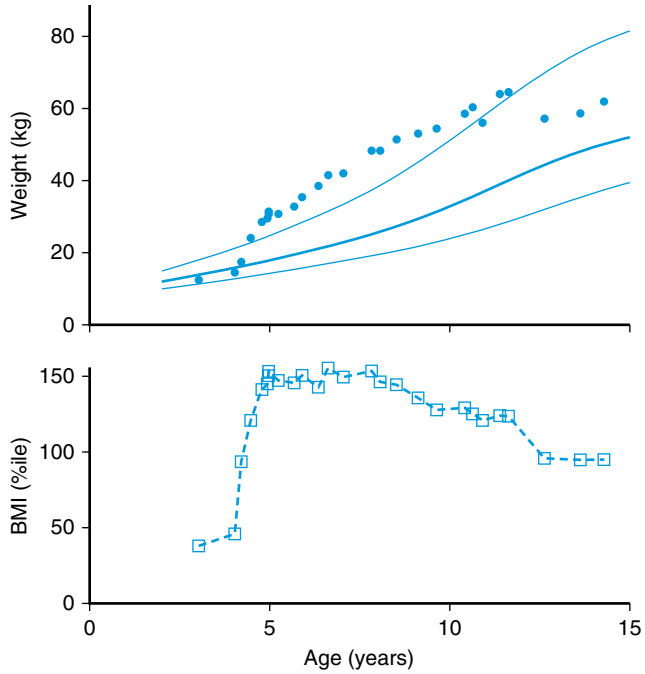

Fig. 468.2 Growth curves of weight and body mass index *(BMI)* from an individual child with ROHHAD. Weight and BMI percentiles for a child with ROHHAD from the time of diagnosis until age 14.3 yr, demonstrating the rapid onset of obesity. Weight and BMI percentiles were calculated using published CDC growth charts and methods. *Solid lines* in weight graph represent 3rd, 50th, and 97th percentiles. *Dots* and *open squares* are individual measurements for the child.

continuous artificial ventilation (during sleep and wakefulness). Up to 50% of children with ROHHAD will have a cardiorespiratory arrest before their hypoventilation is identified and treated. Unfortunately, many ROHHAD patients die from cardiorespiratory arrest because of unrecognized or inadequately managed hypoventilation. Thus if a ROHHAD diagnosis is suspected, it is crucial that a comprehensive respiratory physiology evaluation be performed, including overnight polysomnography and awake physiologic recording in activities of daily living and followed serially long after the hypoventilation is identified and intervention provided.

All ROHHAD patients have symptoms of **autonomic nervous system (ANS) dysregulation (ANSD)**; the specific symptoms and the order and timing of their appearance will vary among patients. The most common manifestations of ANSD in ROHHAD are ophthalmologic, including **pupillary dysfunction**, **strabismus**, and **alacrima**. Many ROHHAD patients will have **gastrointestinal dysmotility**, presenting as either chronic constipation or, less commonly, chronic diarrhea. Other signs of ANSD include **altered sweating**, **decreased body temperature**, **decreased sensitivity to pain**, and **cold hands and feet** indicating altered vasomotor tone. **Bradycardia** is observed in some ROHHAD patients, typically related to **extreme hypothermia**.

Neural crest tumors are observed in ~40% of ROHHAD patients, most frequently ganglioneuromas and ganglioneuroblastomas of the chest or abdomen; rarely a neuroblastoma has been reported. These tumors can occur at any age, so proactive imaging evaluation throughout childhood and adolescence to identify the tumors is essential.

Patients do not always have behavioral or psychologic disorders if artificial ventilation is optimized. For those who do, however, the disorders can be quite severe, including anxiety, depression, rage, lethargy, irritability, aggressiveness, psychosis, and obsessive-compulsive disorder. Developmental disorders described include neurocognitive delay, developmental regression, attention-deficit/hyperactivity disorder, and pervasive developmental disorder. These disorders are most likely accentuated by poorly managed hypoventilation because the majority of ROHHAD patients have no behavioral issues and a normal IQ.

Seizures have been reported in some ROHHAD patients, likely caused by episodes of hypoxemia, when hypoventilation either has not yet been diagnosed or has been inadequately managed.

DIAGNOSIS

The diagnostic criteria for ROHHAD include rapid-onset obesity after 1.5 years of age; central hypoventilation beginning after age 1.5 years; ≥1 of the following signs of HD: disordered water balance, hyperprolactinemia, failed GH stimulation test, central hypothyroidism, corticotropin deficiency, and altered onset of puberty; and features of autonomic dysregulation. Additionally, it must be *confirmed* that no CCHS-related *PHOX2B* pathogenic variant is present to rule out a diagnosis of CCHS or LO-CCHS.

Because no single diagnostic test is currently available for ROHHAD, the diagnosis must be based on observation of the clinical presentation and therefore requires expert consultation in multiple pediatric subspecialties, including respiratory physiology, endocrinology, autonomic medicine, cardiology, oncology, nutrition, critical care, sleep, and psychiatry, with orchestration by the child's pediatrician. When a child with rapid-onset obesity is seen by a general pediatrician or family physician, the steep trajectory of weight gain should signal prompt consideration of a ROHHAD diagnosis, with immediate referral to a center with expertise in this unique constellation of symptoms. Early recognition is critical for a positive outcome in children with ROHHAD. *If alveolar hypoventilation is not identified and aggressively managed, cardiorespiratory arrest can occur and has proved fatal in many cases.*

A **characteristic set of facial features** has been described for CCHS, which, using facial photogrammetry, is able to identify 86% of genetically confirmed CCHS cases (see Chapter 468.2). Although such formal evaluation of ROHHAD facies has not been completed, a preliminary report indicates that ROHHAD patients have similar facial mapping characteristics to CCHS patients, especially the characteristic **"lip trait,"** in which the lateral one third of the upper vermillion border is flesh-colored instead of pink (Fig. 468.3). This is distinct from the general lip changes observed with increasing BMI in a study of adolescent females, which include fuller-looking lips and downturned corners of the mouth.

Initial evaluations should include overnight polysomnography to identify OSA or central hypoventilation, awake comprehensive physiologic recording in age-appropriate activities of daily living, cardiac evaluation to assess for cor pulmonale and rhythm disturbance, endocrine function evaluation, screening for neural crest tumors (chest radiograph, abdominopelvic ultrasound, or meta-iodobenzylguanidine [MIBG] scan), and a behavioral and psychological evaluation, especially if any behavioral, psychologic, or developmental disorders are seen or suspected. Brain imaging should be performed to rule out intracranial lesions that may account for the observed hypothalamic-pituitary abnormalities (using the hypothalamic-pituitary protocol). If the criteria are met and a ROHHAD diagnosis is made, successful management requires ongoing teamwork among the various subspecialists, with a pediatrician team leader to orchestrate all testing, the family, and the child to provide optimized integrated care for the child.

MANAGEMENT

There is currently no cure for ROHHAD. Rather, treatment consists of early identification, meticulous monitoring, and anticipatory along with symptomatic management of the various phenotypic features as they develop ("unfold"). Comprehensive initial evaluations should determine the nature and severity of hypoventilation, HD, and ANSD, and appropriate interventions should be implemented in a time-sensitive manner. Obesity in ROHHAD is very difficult to control, but in consultation with a nutritionist and endocrinologist, the trajectory of advancing weight gain can be diminished with moderate exercise and calorie restriction, leading to improved BMI with advancing age. Specific signs of HD and ANSD should be evaluated by a pediatric endocrinologist and expert in pediatric autonomic medicine, respectively, and treated as necessary longitudinally as the phenotype

Fig. 468.3 Characteristic CCHS "lip trait" shown in a child with ROHHAD. Shown here is the mouth of a child with ROHHAD at age 4 (A) and 11 (B) years. The lateral one third of the upper vermillion border is flesh-colored instead of pink. This is not a characteristic feature of obese faces in general (the upper lip is neural crest in origin).

"unfolds" and "refolds." Such treatments or management strategies may include hormone replacement; regimented fluid intake; ophthalmologic assessment and treatment; longitudinal monitoring of peripheral, core, and ambient temperature; and management of constipation with stool softeners. Disordered water balance to prevent dehydration should be addressed, as well as regulation of heart rate, because bradycardia is seen in some patients (usually with decreased core temperature), though cardiac pacemakers are rarely indicated.

Neural crest tumors should be assessed and resected by a pediatric surgeon together with a pediatric oncologist, because the sheer size of these benign tumors creates serious compromise to surrounding tissues. If no tumor is identified initially, screening should continue every 6 months until adulthood, because a malignant neuroblastoma has been identified in an adolescent ROHHAD patient.

Most critical is the management of hypoventilation. Initial intervention for OSA will likely involve surgical relief of the upper airway obstruction. This will usually unveil central hypoventilation, and initiation of supported ventilation will be required. If no central hypoventilation is identified, the patient should continue to be vigilantly monitored by a respiratory physiologist because all ROHHAD patients will eventually develop central hypoventilation requiring artificial ventilation during sleep at a minimum. Individuals with ROHHAD have attenuated to absent physiologic responsiveness to hypoxemia/hypercarbia, and they lack behavioral awareness of hypoxemia/hypercarbia. Optimal oxygenation and ventilation can then be maintained using a mechanical ventilator with mask initially then, if necessary, by tracheostomy to secure the airway and optimize ventilation. This should be accompanied by highly trained home nursing and continuous monitoring with oximetry and capnography during sleep, with spot checks during wakefulness. The goal should be to maintain hemoglobin saturation values of ≥95% and end-tidal CO_2 values of 35-45 mm Hg, with vigilant evaluation for awake hypoventilation necessitating artificial ventilation up to 24 hours a day as necessary.

Given that the ROHHAD phenotype evolves with advancing age, ongoing care requires regularly scheduled evaluation of all the systems involved to identify and treat further symptoms as they appear. Comprehensive evaluation should ideally occur at a Center of Excellence for ROHHAD and should include respiratory physiology assessment both asleep and awake (in varied levels of age-appropriate exertion, concentrational tasks, quiet play, and eating), screening of chest and abdomen for neural crest tumors in the adrenals or along the sympathetic chain, evaluation of the hypothalamic-pituitary axis with hormonal replacement as necessary, age-appropriate noninvasive evaluation of ANS dysregulation, comprehensive cardiac evaluation for sequelae of recurrent hypoxemia and/or bradycardia, and neurocognitive testing. These evaluations should initially occur at 2- to 3-month intervals, but this schedule may be altered with advancing age, depending on each patient's clinical condition.

With proper and meticulous management, the ROHHAD phenotype has been observed to "refold," with the possibility of achieving weight control, eventually recovering spontaneous awake breathing, and improvement of other autonomic measures. Without proper management, oxygen deprivation can lead to irreversible deterioration in patients. However, with prompt diagnosis and aggressive management, including careful attention to the child's airway, breathing, and circulation, complications can be minimized and the prognosis can be quite favorable, although long-term outcome remains the focus of an international registry (https://clinicaltrials.gov/show/NCT03135730).

Paraneoplastic/Autoimmune Hypothesis

Paraneoplastic syndromes are rare disorders caused by a neoplasm triggering an altered immune response that aberrantly attacks and destroys neurons, leading to the nervous system symptoms. An autoimmune or paraneoplastic basis for ROHHAD has been suggested based on neural crest tumors occurring in 40% of ROHHAD patients and reports of encephalitis seen on autopsy. The evidence so far is conflicting, with some reports supporting the autoimmune hypothesis, whereas others do not. Further, the onset of ROHHAD symptoms often precedes identification of a neural crest tumor in ROHHAD patients, and in many cases, neural crest tumors have not been discovered with MRI or even an autopsy. Of note, with excision of the identified neural crest tumor there has not been consistent "recovery" from ROHHAD. Rather, the ROHHAD phenotype continues to "unfold."

DIFFERENTIAL DIAGNOSIS

Congenital central hypoventilation syndrome is a rare pediatric disorder of the ANS and respiratory control. CCHS is caused by pathogenic variants in the *PHOX2B* gene, which plays an important role in the differentiation and development of the ANS from neural crest progenitor cells (see Chapter 468.2). The hallmark feature of CCHS is life-threatening hypoventilation while sleeping (and, in some cases, also while awake). CCHS patients require artificial ventilatory life support, typically by tracheostomy and mechanical ventilator. Unlike ROHHAD, however, CCHS usually presents in the newborn period, although later-onset CCHS has been diagnosed after 1 month of age, in later childhood, in adolescence, and even in adulthood. CCHS also presents with other symptoms of ANS dysregulation, including altered heart rate regulation, vasomotor tone, and temperature regulation, ophthalmologic manifestations, and reduced gastrointestinal motility. However, CCHS patients *are not* obese and only rarely have isolated measures of HD. When hypoventilation is observed, a simple blood test can confirm a CCHS diagnosis by looking for pathogenic *PHOX2B* variants.

Prader-Willi syndrome (PWS) shares childhood obesity as one of the most prominent features with ROHHAD. PWS is caused by chromosomal abnormalities at chromosome 15q11-q13, specifically by a lack of the paternal contribution at this region (from genomic deletion, uniparental disomy, or imprinting error), whereas methylation differences, loss of heterozygosity, and pathogenic variants in this region

have been ruled out in a ROHHAD cohort. Infants with PWS present with neonatal hypotonia and failure to thrive (malnutrition). Later, children with PWS develop extreme hyperphagia and obesity. Other major symptoms of PWS include intellectual impairment, maladaptive behaviors, short stature caused by GH insufficiency, hypogonadism, and SDB. In addition, many PWS patients show signs of ANS dysregulation, including altered temperature perception and regulation, strabismus, and high pain threshold.

ROHHAD should also be distinguished from other **obesity-related genetic disorders**. Smith-Magenis syndrome, Carpenter syndrome, and 16p11.2 deletion syndrome present with obesity. However, all of them are additionally marked by early developmental delay, unlike ROHHAD, which has normal neurodevelopment in the absence of cardiorespiratory arrest. Therefore testing for genetic causes of obesity should be undertaken in obese children whose phenotype does not appear to match that of ROHHAD.

468.4 Long-Term Ventilation and Technology Support: Indications, Principles, Decision-Making, Pragmatics, and Home Provision

Robert J. Graham

INDICATIONS, GOALS, AND DECISION-MAKING

The decision to implement LMV has many challenges from a diversity of underlying pathophysiology, uncertain disease trajectories, the development of new condition-specific therapies, personal experiences, and values held by providers, patients, parents, and the broader community, variability in resources, and lack of standards. Although optimizing gas exchange (i.e., oxygenation and CO_2 removal), mitigating the impact of intercurrent respiratory infections, and supporting neuromuscular-skeletal limitations, growth, and development remain among the primary objectives, LMV represents a tool for the comprehensive care of children with complex needs.

LMV has a role within the broad spectrum of palliative care. It is used proactively to attenuate cumulative morbidities (respiratory and cardiac) associated with progressive neuromuscular conditions, such as Duchenne muscular dystrophy. LMV is also used reactively when acute illness (e.g., acute respiratory distress syndrome or an acute flaccid myelitis) does not resolve. In infants with premature lung disease or complex airway anomalies, LMV may be implemented as a temporary measure, as these conditions may improve with maturity or surgical interventions. LMV can also represent a bridge to lung transplant for those with intrinsic pulmonary or pulmonary vascular disease. More commonly, LMV has become a destination therapy to optimize symptom management and prolong life in complex conditions. Etiologies of the chronic respiratory failure include but are not limited to congenital anomalies (e.g., complex cardiac conditions, central nervous system disorders, interruptions in aerodigestive morphogenesis, and skeletal dysplasias), acquired central neurologic injuries from perinatal, infectious, traumatic, and hypoxic-ischemic events, metabolic disorders, or progressive neuromuscular conditions. Progress in other areas of medicine, such as gene-targeted therapy in spinal muscular atrophy and myotubular myopathy, may alter the LMV decision-making landscape as families foresee the prospect of improvement.

NONINVASIVE AND TRANSTRACHEAL SUPPORTS

The essential modalities for LMV include negative pressure, noninvasive positive pressure ventilation (NIPPV with either continuous or biphasic support provided through an occlusive mask interface), or transtracheal positive pressure. Considerations for a given child or young adult should include but are not limited to anatomic factors, physiologic goals, long-term care goals, comfort, tolerability/compliance, and safety (mobility/portability, monitoring, device availability and backup, training capacity).

Negative pressure devices, such as the cuirass ventilator, do not require any interface with the face or trachea and are more *natural* from a mechanical perspective. The need for oxygen supplementation is not addressed directly through such a device. *NIPPV* can address dynamic upper airway obstruction and can augment respiratory mechanics and gas exchange. This modality may, however, have limitations if upper airway obstruction is severe or fixed or the need for oxygen supplementation is high. Masks, prongs, and pillows of varying sizes are available for nasal, oral, combination, and full interface, including those for infants. A mouthpiece interface has also been demonstrated to be effective and feasible. The choice of continuous positive airway pressure (CPAP) versus biphasic positive airway pressure (BiPAP) is dependent on the underlying pathophysiology. Conceptually, CPAP can overcome a dynamic upper airway obstruction and allow for spontaneous ventilation, while BiPAP is more versatile in compensating for upper airway obstruction and supporting lung recruitment and gas exchange. CPAP is limited to management of mild OSA. In addition, BiPAP may allow for home escalation for the management of intercurrent illness with oversight of the medical team. Although NIPPV can be maintained 24 hours a day, efficacy of ventilation, difficult airway considerations (i.e., whether the child can anatomically be intubated), developmental needs, implications for midface hypoplasia, and secretion clearance are among factors that affect the decision to pursue tracheostomy placement and invasive LMV.

Transtracheal LMV provides the most secure and effective respiratory support. Fixed and dynamic upper airway obstruction is bypassed with tracheostomy tube placement. Secretions are more readily cleared from the lower airway. Positive pressure and oxygen delivery via a tracheostomy tube more consistently address primary impairments in gas exchange (within limits) as well as mechanical disadvantages from neuromuscular insufficiency and restrictive disease. When possible, placement of a tracheostomy tube in a child should be coordinated at an institution with pediatric expertise, including in long-term tracheostomy care, because the short-term morbidities and, potentially, mortality are not insignificant.

Individuals using NIPPV are at risk for pressure ulcerations on the face and on the scalp. Proper fit of the interface must be assured because a tighter fit is not necessarily commensurate with better support. Alternating masks on a regular basis may alleviate pressure on a given site. Additional nonadhesive dressings can also be used to facilitate the mask seal and minimize skin breakdown. For those with a tracheostomy tube in place, care of tracheostomy ties and regular assessment of the stoma are required. Moisture-wicking dressings can attenuate risk of maceration, but their use should be balanced against the value of exposure to air for drying. Stomal assessment should include evaluation for granulation, fissures, and traction created by additional torque from ventilator tubing, which should be maintained midline and without weight displacement on the tracheostomy tube itself. Any areas of integument interruption are potential niduses for infection and of great concern for immunocompromised hosts.

AUGMENTED SECRETION CLEARANCE

See Chapter 468.1.

AERODIGESTIVE AND COMMUNICATION CONSIDERATIONS

Assessment of swallowing and speaking capacity should be part of an assessment for LMV and may help guide the modality. Implementation of noninvasive or transtracheal supports will not further impair either of these functions. Rather, the underlying condition is the primary determinant. This consideration is most notable in children or young adults with neurologic injury or neuromuscular conditions. Decision-making around placement of a transabdominal gastric or gastrojejunal enteral feeding tube, if not already in place, should coincide with decisions around LMV. Nasogastric tubes, it should be appreciated, may impair the NIPPV mask seal and cause laryngeal irritation in the long term. Antireflux surgery (i.e., fundoplication) should also be discussed

at this time as providers consider ongoing implications of esophageal reflux, aerophagia, and challenges maintaining jejunostomy tubes.

Use of NIPPV must be approached cautiously in those with impaired swallowing, as positive pressure will increase the risk of macroaspiration and microaspiration. Individuals using NIPPV can eat and drink while on support with risk versus benefit determination and assessment of impact on quality of life. Aerophagia on NIPPV is also problematic, regardless of bulbar function and swallowing capacity; abdominal distention is uncomfortable, contributes to satiety and vomiting risk, and further impairs respiratory mechanics with decreased functional residual capacity and increased inspiratory workload. If a gastrostomy is present, active evacuation of swallowed air and use of passive *venting* tubes can be helpful.

Children with swallowing capacity can continue to eat and drink by mouth with a tracheostomy tube in place on LMV. The presence of a cuffed tracheostomy tube does not prevent aspiration if swallowing is impaired. Speaking may be facilitated by LMV, as settings can be increased or a speaking valve used to increased airflow across the vocal cords. Regardless, multidisciplinary care with a speech-language pathologist, feeding specialist, and augmented communication services can be helpful for many children and their families using LMV. Conditioned aversions to oral stimulation can be challenging for infants, but developmental gains should not be impeded by LMV.

GAS EXCHANGE AND VENTILATOR STRATEGIES

Pressure- or volume-regulated modes, spontaneous or controlled settings, and mixed modes are all feasible for NIPPV and transtracheal supports with new devices. The appropriate support should coincide with oxygenation and ventilation goals on a case-by-case basis. Consideration, however, should be given to the site of care and contingencies for presentation to acute cure during intercurrent illness or emergency. Providers should assess limitations in oxygen supplementation outside of the hospital; measured or estimated delivered fractional inspired oxygen (FIO_2) will inform families and providers of capacity when adding oxygen in liters/minute flow to the ventilator circuit; dilution can have a dramatic effect, and achieving FIO_2 >0.60 may be difficult when oxygen is added to a home ventilator circuit. Safety allowances should also account for the duration of portable oxygen provision, which is based upon liter flow and tank/reservoir volume.

Monitoring of CO_2 in the homecare setting is not usual, although portable end-tidal CO_2 devices are available. Conditions such as CCHS warrant vigilance, and parameters for implementation, or titration, of mechanical ventilation should be discussed with families. Recognition that significant and indolent hypercapnia can precede hypoxia is necessary, and long-term effects on cerebral and pulmonary vasculature should be considered. In the absence of direct CO_2 monitoring, periodic measurement of serum bicarbonate may be helpful to assess for renal compensation for altered CO_2 clearance; however, interpretation may be altered in the presence of diuretic therapy, metabolic disease, or ketogenic diets.

CARDIOPULMONARY INTERACTIONS

Closely linked to the gas-exchange goals are considerations for cardiopulmonary interactions. Although there are subtle implications for systemic venous return of any form of positive pressure ventilation, LMV can be used to decrease transmural myocardial load and to optimize right ventricular afterload through lung recruitment and pulmonary vascular reactivity. The prolonged survival of young males with Duchenne muscular dystrophy is in part the result of consistent respiratory support to optimize lung health and to attenuate myocardial dysfunction. Primary or secondary pulmonary hypertension, whether overt or indolent, requires consideration of oxygenation and ventilation goals. Echocardiograms are not required for all children or young adults with LMV, but this modality may be helpful to guide management in cohorts with congenital heart lesions, cardiomyopathies, severe obstructive pulmonary disease, significant central dysregulation, and on a case-by-case basis.

When considering gas-exchange goals and cardiopulmonary interactions, providers must also consider daytime and nocturnal differences. Neuromuscular-derived hypoventilation is more prominent at night, as is upper airway obstructive disease; the latter is more important for those using noninvasive LMV. Daytime support provision must account for increased oxygen consumption and demand based on variable activity and stressors, including environmental temperature. Providers and families must factor in mobility, behavioral tolerance, and quality of life.

CHEST WALL/THORACIC CONFIGURATION

Positive pressure through LMV in early childhood for children with neuromuscular conditions and/or restrictive lung disease is also used to improve thoracic compliance and configuration. Lung inflation can be used to attenuate the impact of thoracic asphyxiation as well as progressive parasol chest deformation in diaphragm-dependent conditions, such spinal muscular atrophy. This use has implications for atelectasis and secretion inspissation, associated pulmonary vasoconstriction, and cumulative restrictive or asymmetric pulmonary mechanics.

NUTRITION AND WEIGHT GAIN

See Chapter 468.1.

DEVELOPMENTAL CONSIDERATIONS

Decisions regarding the LMV modality, noninvasive or transtracheal, requires consideration of development as well. Beyond safety factors, tolerance of interventions, availability of appropriate-sized interfaces, and portability, there remains substantial subjectivity with respect to perspective on the implication for social interactions (i.e., devices covering the face versus a device in the neck). Although there are no published series, long-term or near-continuous NIV also has implications for midface hypoplasia and potentially compounds upper airway obstructive symptoms, as is evident by images of *BiPAP faces*. Swallowing and speech capacity primarily reflect the child's underlying condition and conditioned aversions rather than the LMV itself.

PROJECTED INTERVENTIONS AND NEEDS

The trajectory and management of the underlying disease, as well as symptom management, are the primary drivers in determining the need and duration of LMV. Stakeholders should also consider future interventions, specifically surgical procedures. LMV, noninvasive or transtracheal, can be used to optimize perioperative standing and facilitate recovery and provision of opiate-based analgesia that could alter respiratory drive. The maintenance of a tracheostomy tube in anticipation of sequential surgeries (e.g., spinal instrumentation, craniofacial and airway reconstruction, or serial cardiac interventions) may be required for practical reasons but also minimizes the need for repeated intubation.

PREPARING FOR THE LIVED EXPERIENCE OF LMV AND OTHER TECHNOLOGY SUPPORTS

Emotional challenges are associated with the integration of technology supports into "routine" care and assuming an altered role as a parent and care provider. Addressing practical needs, however, can help attenuate some of the anxiety and allow families to focus on, or revisit, the global goals of care, quality of life, and the role of technology. The family will need to consider each of the following implications.

Financial (e.g., insurance, subsidies, alternative funding, and parental employment): Independent of personal resources, the majority of families with children requiring technology assistance report some degree of financial burden. These costs arise from the direct outlay for equipment and medications, lost work time or need to discontinue/change vocations, home adaptations, and other indirect costs. Accessing a financial counselor or case manager may help identify and navigate through local, state/regional, and government/federal resources. Additional considerations should also be paid to personal trusts, wills, and estate planning, as all of these have implications for long-term benefits and financial supports for the individual with special healthcare needs.

Equipment and supplies: Ideally, the equipment intended for use at home will be tested before discharge to home. Testing ensures proper function and any tolerance. Electrical compatibility with the home

service should be confirmed. Delivery of backup devices (e.g., tracheostomy tubes, including a smaller size for contingency planning; batteries for ventilators; and portable oxygen tanks as a supplement to electric oxygen concentrators) and emergency supplies (e.g., self-inflating respiratory bags, epinephrine for those who have allergy histories, or prophylactic antiepileptic medication for those prone to breakthrough seizures) should be confirmed. Medication supplies and refills should be sufficient to allow for the scheduling of follow-up visits. Providers responsible for recertification or reordering should be identified.

Training: Standards for training and demonstration of competency vary among institutions and across providers. Families and their medical teams should come to an agreement on minimum safety preparation and the number of responsible parties available to assist in the home. Hospital-based training around ventilator use and troubleshooting, central-line care, tracheostomy tube exchanges and suctioning, wound care, and other interventions could include basic life support classes and one-on-one sessions with nurses, respiratory therapists, or other staff, with hands-on or mannequin simulation. Assumption of full care by families while in the hospital can be informative for all stakeholders and reassuring to families; supported replication of the demands of homecare before discharge is ideal.

Augmented staff: Home nursing, hospice, personal care assistants, extended family, and friends represent additional resources for the child and their family. Allowances vary based on the child's age, independence, medical condition, technology dependence, goals of care, and other factors. These individuals may require additional training, but augmenting numbers of proficient homecare providers is crucial for safety and consistency of care. When considering homecare provision, families should consider the type of personnel and how additional supports would allow the child to attend school, the parent to work or maintain the household, continue care when the parent is sick or incapacitated, or assist with other children. The challenges of establishing, training, and maintaining a home staff require time and tolerance, recognizing that the child's safety is the priority.

Monitoring: Conceptually, monitoring is used to detect early physiologic changes, determine adequacy of LMV, and minimize cumulative morbidities or risk of mortality. Continuous direct observation is not practical, or often desirable, in the community setting. Recommendations for monitoring children and young adults on LMV vary based on underlying vulnerability, care setting, activity (e.g., home, long-term care facility, school, or in transport via car), and adjuvant supports (e.g., home nursing or personal care assistant). Pulse oximetry can be used intermittently or on a continuous basis, with oxygen and heart rate parameters determined on a case-by-case basis. Typically, capnography is not available except in cases of central hypoventilation syndromes but can complement oximetry. Internal ventilator alarm settings for both NIPPV and transtracheal ventilators are used to monitor high- and low-pressure parameters and minute ventilation. Stakeholders must acknowledge, however, that internal alarms may be insufficient in the setting of a large mask or peritracheal leak or in the event of a device malfunction.

The child's individual risks and the environmental circumstances drive the balance of extrinsic monitoring (e.g., pulse oximetry and heart rate) and intrinsic device alarms. There are also pragmatic considerations of signal-to-noise when determining monitoring parameters; recurrent false alarms will desensitize providers and may disturb a child's sleep; conversely, wide alarm parameters circumvent early warning systems with significant consequences. Alarm fatigue, as experienced by hospital-based providers, should be discussed, as it can be of great consequence where the resources are not as robust. Simple audio and video monitors (i.e., video cameras) can be used to augment surveillance and may help families in their activities of daily living.

Adaptations to the homecare setting: Modifications to the home may be required to ease care and optimize safety. Ramps for wheelchair access will permit ingress and egress. Lift systems can minimize physical burden and injury risk to providers. Doorways can be expanded to permit access to multiple rooms. Alternative bath and toileting accommodations may be needed. Electrical system upgrades with grounding and increased amperage are often required for equipment demand and safety.

Transportation: Discharge planning for a child or young adult with technology dependence should include transportation to school, community programs, routine family activities, and scheduled or urgent medical services. Proximity (rural or urban), the child's mobility, weather, and the need for monitoring en route are other considerations. Adaptive car seats or car beds can be purchased. Personal vehicles may need expensive modifications, including lifts and power inverters. Allowances may also be required for one person to drive while another (i.e., nurse, parent, or care assistant) tends to the child. If traveling long distances, perhaps on vacation, advanced planning might include identification of hospitals along the route and reciprocal equipment companies to assist with unexpected supply needs.

Air transportation: If a family anticipates travel by plane, contingencies should be made for oxygen support at altitude, recognizing that most commercial airlines pressurize their cabins to the equivalent of 7,000-8,000 feet. Portable oxygen sources may have less liter flow capacity than stationary or home devices; there is also a need to differentiate continuous versus on-demand flow options. Space and limited supplies inflight should be considerations. Power wheelchairs are prone to damage when placed in cargo holds, and ground crews likely require explicit instructions. Providers may need to write letters for airport security and airlines for excess baggage, electronic equipment, medication, and fluid allowance. Families can also consider sending additional supplies to the final destination in advance.

Environmental stressors: Extreme temperatures, heat or cold, variability in humidity, and other environmental variables can greatly affect the well-being of a child with underlying cardiorespiratory insufficiency or other special healthcare needs. Home adaptations to permit climate control for the child's room may be required. Families may consider prewarming, or cooling, vehicles for routine excursions, and limitations on day-to-day activities are warranted at times. Augmented hydration needs should be reviewed with medical providers, along with routine sunscreen and preventive measures.

Preparation for transition to the homecare setting may include a period of quiescence, depending on the circumstances and family preferences. Establishing a period of stability, when there has been no need to alter supports, may minimize unplanned readmissions.

Community Resources

The transition from the acute care or rehabilitation facility to homecare setting is often much anticipated and welcomed. This step can also be frightening and overwhelming, whether it represents the first time home or a return after an acute illness or planned surgery. Hospital-based providers can partner with families to alleviate some anxiety and to avoid potential pitfalls through proactive engagement. Hand-off to outpatient and community stakeholders can include the following:

The community medical practice: Updates on problem lists, projected follow-up, medication and equipment needs, routine health maintenance and preventive measures (e.g., immunizations), special considerations for nutrition, identification of specialty providers and follow-up schedules, and case-specific risks.

First responders: Confirmation that the family has the capacity to call emergency services, outreach to police and ambulance services to outline baseline needs, special condition-specific interventions or precautions, identification of equipment that may need to be taken with the child in the event of an emergency, determination of emergency destination (i.e., local hospital or referral center), and clarification of resuscitation status and life-sustaining therapies.

Therapy programs: Physical, occupational, speech-language/feeding, and other therapists benefit from hospital-based assessments and outlines of expectations, restrictions, and uncertainties.

Educational programs/schools/day habilitation: Integration into community services requires evaluation of developmental needs and potential adaptive settings, equipment, services, staffing, and transportation for all ages.

Power and water: Alerting local housing, social, power, and water authorities to medical necessities can facilitate prioritization of service

restoration during natural disasters or other interruptions and identify programs to defray incurred costs with increased technology-driven electrical usage (e.g., home ventilators, oxygen concentrators, and climate control).

Families may find additional resources through faith-based institutions, nonprofit and advocacy groups (e.g., Kiwanis, Shriners, Boy Scouts), and condition-specific entities, such as the Muscular Dystrophy Association. Outreach to other families with similar circumstances can also be helpful with the caveat that their recommendations reflect their own goals and lived experience with special healthcare needs.

Subacute Care

Local resources for medical services should be identified in advance. This begins with the primary care and first responders but extends to local and regional hospitals. It is important to determine the range of services available and to identify specific providers who would familiarize themselves with a given case. The child with technology dependence will experience intercurrent illnesses or unexpected accidents that require evaluation, but may not always necessitate transport to tertiary care or referral centers. Individual care plans can be developed in conjunction with the family and local providers and may include thresholds for transfer.

Families should also consider bringing home equipment and supplies when presenting to urgent and acute care settings. Devices such as pediatric NIPPV masks and cough-assist machines or compounded medications may not be available at every facility. Short-term evaluations may become protracted, and lack of routine care provision may compound the immediate issues.

Emergency and Acute Care

Providers and families should acknowledge that children with special healthcare needs (CSHCN) and LMV are at risk for repeated hospitalization. Progression of underlying illnesses (e.g., heart failure), planned surgical interventions (e.g., spinal instrumentation, bronchoscopy surveillance, tendon releases), or superimposed acute illnesses (e.g., pneumonia, gastroenteritis, appendicitis, recurrent seizures) may necessitate readmission. Those children who are technology dependent have a higher likelihood of requiring critical care services because of the nature of their needs and their vulnerability. Preventable equipment-related issues may be obviated through the planning described previously. Once hospitalized, CSHCN are at greater risk of medical error and incur more interventions when compared with otherwise healthy children. Parents should be encouraged to develop a medical passport and reference list of providers to facilitate communication and consistency of care. Referencing established care guidelines and, again, developing individualized care plans may be helpful.

Quality of Life

CSHCN of increasing complexity and technology dependence are thriving in the homecare setting as a result of advances in medical care, shared decision-making, community services, and most notably, extensive, vigilant, and proactive care efforts by their families. Adaptations allow for participation in all aspects of family, school, and community activities. Although individual trajectory and subsequent needs may be difficult to predict, all stakeholders should acknowledge the impact of chronic care on the family unit and health-related quality of life. The evolution of a medical home for this cohort of children will require provisions for family mental health, sibling supports, respite, and other measures to optimize outcomes.

TRANSITIONING FROM ACUTE CARE TO REHABILITATION OR COMMUNITY SETTING

Disposition of children and young adults with LMV will vary based on their relative stability, local support services, and goals of care. A proactive, flexible, comprehensive care model is required to assure safe and effective provision. The impacts of care needs on the child and family are inextricably linked.

ROUTINE HEALTH MAINTENANCE

Airway Evaluation

There is no standard for regular airway assessment for children with LMV, specifically those with transtracheal support, but annual evaluation should represent the minimum. Office-based transtracheal tube endoscopy can facilitate assessment of tube upsizing for linear growth, presence of granulation tissue, airway inflammation, and general mucosal integrity. Formal diagnostic laryngoscopy and bronchoscopy under general anesthesia are required to assess for suprastomal and laryngeal-level pathology along with the rare acquired tracheaesophageal fistulae. Independent of routine evaluation, recurrent or unexpected tracheal bleeding may warrant evaluation for a tracheavascular fistula via CT angiogram and bronchoscopy.

Bacterial Colonization

Chronic respiratory failure lends itself to airway bacterial colonization because of alterations in secretion clearance, aerodigestive interactions, the presence of artificial airways with the development of biofilms, and other factors. Hydrophilic and gram-negative bacteria (e.g., *Pseudomonas, Serratia,* and *Stenotrophomonas*) are common. There is no standard of care for determining pathogenicity versus colonization. Use of systemic or inhaled antibacterial agents to decrease colonization load, frequency of tracheostomy tube exchanges to reduce biofilm accumulation, utility of viral screening, and threshold for treatment of an acute lower airway process or tracheitis is provider and case dependent. Providers should appreciate that recurrent empiric antibacterial treatment may select for resistant bacterial strains and has implications for enteric bacterial colonization.

Dental Care

Routine daily and office-based dental care should follow standard recommendations for all children. Extrapolation from the acute care setting and general population would suggest that oropharyngeal care and minimization of bacterial overgrowth would affect the risk of superimposed respiratory illness in LMV and long-term cardiovascular outcomes, respectively. Special consideration with respect to aspiration risk, developmental tolerance, and prophylaxis and procedural sedation for intervention may require engagement of specialty providers.

Immunizations

No immunizations are specifically indicated for individuals receiving LMV. Routine provision is recommended, including seasonal vaccinations for viral pathogens. Expansion of exposure precautions, as experienced during the COVID-19 pandemic, also remain essential.

Radiography, Laboratory, Polysomnography, and Pulmonary Function Testing

There are no recommendations for routine chest radiography, standard or cross-sectional, in the context of LMV. The cumulative radiation exposure would need to be considered. Gas exchange adequacy can often be assessed noninvasively. Venous, capillary, or arterial puncture for determining resting and long-term oxygenation and ventilation status may be of limited utility and validity, as intercurrent illness, technique with tourniquet, and associated agitation will alter results. Condition-specific (e.g., muscular dystrophy) recommendations for polysomnography, spirometry, or pulmonary function testing have been established and may be extrapolated with some validity. Regular assessment may also be helpful when gauging disease trajectory, LMV titration, safety parameters, and weaning potential.

LONG-TERM MECHANICAL VENTILATION WEANING AND TRACHEAL DECANNULATION

Reassessment of the role of LMV should be part of routine and family-centered care. Determination should include but is not limited to the factors described earlier with open discussion of goals of care, developmental appropriateness, physiologic and anatomic consideration, growth implications, new treatments, and contingencies. As there are currently no definitive conditioning regimens or LMV

weaning strategies, providers can determine the value of time off versus decreased level of supports as well as pragmatic considerations for the child and family. Continuity of care, however, holds implicit value. Monitoring provision may need to be increased during weaning.

If tracheal decannulation is required, a formal diagnostic laryngoscopy and bronchoscopy should be considered to rule out granulation (suprastomal and infrastomal) and dynamic airway collapse that may prohibit immediate tracheostomy tube removal. If positive pressure or oxygen supplementation will still be required after decannulation, determination of the child's tolerance of noninvasive ventilation or other interventions (e.g., cough assist) should be determined in advance. Desensitization may be required.

Ultimately, LMV has an increasing role in the support of children and young adults with chronic respiratory failure. Decision-making about any technology supports can be challenging from an emotional, practical, and ethical perspective. As families and other stakeholders explore options, the goal at these consequential junctures should be to align expectations, hopes, and potential lived experiences. Everyone should acknowledge the uncertainties and the potential to withhold, withdraw, and regularly reassess, even in the community setting. As this population of CSHCN and technology dependence ages, transition from pediatric to adult services should also be anticipated.

The Cardiovascular System

PART XVIII

Section 1

Developmental Biology of the Cardiovascular System

Chapter 469

Cardiac Development

Daniel Bernstein and William R. Goodyer

INTRODUCTION

Cardiac defects have traditionally been grouped by common morphologic patterns: for example, **abnormalities of the outflow tracts** (conotruncal lesions such as tetralogy of Fallot and truncus arteriosus) and **abnormalities of atrioventricular septation** (primum atrial septal defect, atrioventricular septal defect). These morphologic categories may be revised or eventually supplanted by new categories as our understanding of the genetic and molecular basis of congenital heart disease progresses.

469.1 Early Cardiac Morphogenesis

Daniel Bernstein and William R. Goodyer

In the early presomite embryo, the first identifiable cardiac progenitor cell clusters migrate from the primitive streak and are arranged in the anterior lateral plate mesoderm on both sides of the embryo's central axis in a horseshoe pattern, also known as the *cardiac crescent*. These cell clusters are marked by their expression of the basic helix-loop-helix (bHLH) transcription factor mesoderm posterior 1 (MESP1) and subsequently form paired cardiac tubes by 18 days of gestation. This *cardiac progenitor zone* is shaped by a balanced gradient of positive and negative signals arising from the tissues surrounding the cardiac mesodermal cells, with signals from the surrounding ventral/lateral tissues promoting cardiogenesis through signaling molecules such as bone morphogenetic protein (BMP), sonic hedgehog (SHH), and fibroblast growth factor 8 (FGF8) and signals from dorsal/medial structures such as members of the canonical Wnt/β-catenin pathway inhibiting cardiogenesis. Cardiogenic signals activate the genetic expression of cardiac-specific transcription factors (e.g., *TBX, GATA, NKX2.5*) to activate developmental cardiac gene expression The paired tubes fuse in the midline on the ventral surface of the embryo to form the primitive *heart tube* by 22 days. This straight heart tube is composed of an outer myocardial layer, an inner endocardium, and a middle layer of extracellular matrix (ECM) known as the *cardiac jelly*. There are two distinct cell lineages: the **first heart field** (regulated mainly by *NKX2.5*) provides precursor cells for the left ventricle and parts of the atria; the **second heart field** (regulated mainly by *ISL1*) provides precursors for the right ventricle, outflow tracts, and caudal aspects of the atria. Premyocardial cells, including epicardial cells and cells derived from the neural crest, continue their migration into the region of the heart tube. Regulation of this early phase of cardiac morphogenesis is controlled in part by the interaction of specific signaling molecules or ligands, usually expressed by one cell type, with specific receptors, usually expressed by another cell type. Positional information is conveyed to the developing cardiac mesoderm by factors such as *retinoids* (isoforms of vitamin A), which bind to specific nuclear receptors and regulate gene transcription. Migration of epithelial cells into the developing heart tube is directed by ECM proteins (e.g., fibronectin) that interact with cell surface receptors (the *integrins*). The clinical importance of these signaling pathways is revealed by the spectrum of **cardiac teratogenic effects** caused by the retinoid-like drug isotretinoin.

As early as 20-22 days, before cardiac looping, the embryonic heart begins to contract and exhibit phases of the cardiac cycle that are surprisingly similar to those in the mature heart. Morphologists initially identified segments of the heart tube that were believed to correspond to structures in the mature heart (Fig. 469.1). The *sinus venosus* (systemic venous system and part of right atrium), *primitive atrium* (right and left atria), *primitive ventricle* (left ventricle), and *bulbus cordis* that can be broken down into three sections (the proximal one third, right ventricle; mid-third, conus cordis to outflow tracts; and distal third, truncus arteriosus to aorta and pulmonary artery). However, this model is oversimplified. Only the **trabecular** (most heavily muscularized) portions of the left ventricular myocardium are present in the early cardiac tube; the cells that will become the inlet portion of the left ventricle migrate into the cardiac tube at a later stage (after looping is initiated). Even later to appear are the primordial cells that give rise to the great arteries (truncus arteriosus), including cells derived from the neural crest, which are not present until after cardiac looping is complete. Chamber-specific transcription factors participate in the differentiation of atria from ventricles and in the right and left ventricles. The bHLH transcription factor gene *(HAND2)* is expressed in the developing right ventricle. Disruption of this gene or of other transcriptional factors such as *MEF2c* in mice leads to hypoplasia of the right ventricle. Other genetic markers of the second heart field (early right ventricle) cells include *IRX4, TBX20, ISL1, TNNT2, MLC2v,* and *TBX1*. The transcription factor *HAND1* is expressed in the developing left ventricle and conotruncus and is also critical to their development. Other genetic markers of the first heart field (early left ventricle) cells include *TBX5, NKX2.5, TNNT2, MLC2v,* and *HCN4*.

One mechanism of how regulation of developmentally coordinated groups of genes is achieved is through the expression of small, noncoding RNAs known as **microRNAs**, each of which regulates the expression of multiple target genes. Another is through modifications in **chromatin**, the DNA scaffolding that acts as a controller of gene expression. Chromatin remodeling mediated by genes or enzymes such as *BRG1, CHD7,* histone demethylases, and methyltransferases is associated with cardiac developmental defects, including septal defects, dilated cardiomyopathy, and double-outlet right ventricle.

469.2 Cardiac Looping

Daniel Bernstein and William R. Goodyer

At approximately 22-24 days, the heart tube begins to bend ventrally and toward the right (see Fig. 469.1). The heart is the first organ to escape from the bilateral symmetry of the early embryo. An asymmetric signaling program that also affects the position of the lungs, liver, spleen, and gastrointestinal tract determines the direction of cardiac looping. During gastrulation, before organ formation begins, asymmetric expression of *SHH* and nodal (a member of the transforming growth factor beta [TGF-β] family) are directed in the lateral

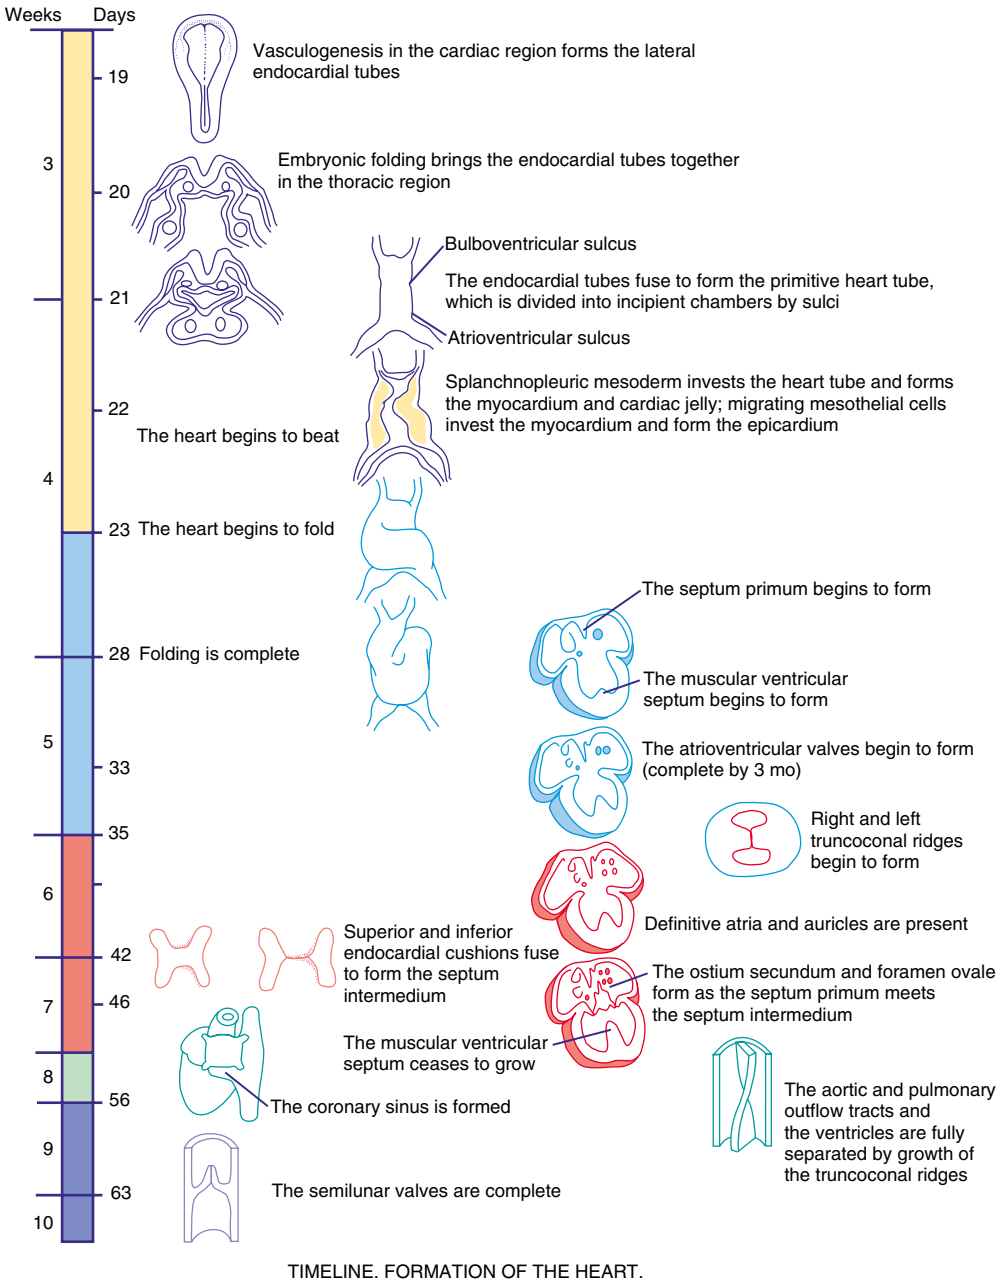

Fig. 469.1 Timeline of cardiac morphogenesis. *(From Larsen WJ. Essentials of Human Embryology. New York: Churchill Livingstone; 1998.)*

mesoderm. These directionality signals set up a concentration gradient between the right and left sides of the embryo in the expression of critical signaling molecules. This asymmetric signaling is then amplified and propagated through the transcription factor gene (*PITX2*), which is expressed on the left side of the early heart tube, *LEFTY1* and *left-right Dynein* (*LRD*). Interestingly, mice in which *LRD* has been inactivated display random left-right (L-R) orientation of the heart and abdominal viscera, with 50% of their hearts looping to the right and 50% looping to the left. Other potential mechanisms of cardiac looping include differential growth rates for myocytes on the convex versus the concave surface of the curve, differential rates of programmed cell death (apoptosis), and mechanical forces generated within myocardial cells at the inner and outer edges of the bending heart tube through their actin cytoskeleton.

Looping brings the future left ventricle leftward and in continuity with the sinus venosus (future left and right atria), whereas the future right ventricle is shifted rightward and in continuity with the truncus arteriosus (future aorta and pulmonary artery). This pattern of development explains the relatively common occurrence of the cardiac anomalies **double-outlet right ventricle** and **double-inlet left ventricle** and the extreme rarity of double-outlet left ventricle and double-inlet right ventricle (see Chapter 479.5). When cardiac looping is abnormal **(situs inversus**, **heterotaxia)**, the incidence of serious cardiac malformations is high, and there are usually associated abnormalities in the L-R patterning of the lungs and abdominal viscera, including absence of the spleen **(asplenia)** or multiple small spleens **(polysplenia)**.

469.3 Cardiac Septation

Daniel Bernstein and William R. Goodyer

When looping is complete, the external appearance of the heart is like that of a mature heart; internally, the structure resembles a single continuous tube, although it now has several bulges resulting in the appearance of primitive chambers. The common atrium (comprising both right and left atria) is connected to the primitive ventricle (future

left ventricle) via the atrioventricular canal. The primitive ventricle is connected to the *bulbus cordis* (future right ventricle) via the *bulboventricular foramen*. The distal portion of the bulbus cordis is connected to the *truncus arteriosus* via an outlet segment (the *conus*).

The heart tube now consists of several layers of myocardium and a single layer of endocardium separated by cardiac jelly (acellular ECM secreted by the myocardium). Septation of the heart begins at approximately day 26 with the ingrowth of large tissue masses, the *endocardial cushions,* at both the atrioventricular and conotruncal junctions (see Fig. 469.1). These cushions consist of protrusions of ECM (cardiac jelly), which, in addition to their role in development, also serve a physiologic function as primitive heart valves. Endocardial cells dedifferentiate and migrate into the cardiac jelly in the region of the endocardial cushions, eventually becoming mesenchymal cells (endothelial-mesenchymal transformation) that will form part of the atrioventricular valves. The endocardium, secondary heart field, and neural crest all contribute to the formation of the valve leaflets. Besides direct contribution to valve tissue, these progenitor cells also interact with each other and with other cells in the heart to orchestrate cardiac valve development.

Complete septation of the atrioventricular canal occurs with fusion of the endocardial cushions. Most of the atrioventricular valve tissue is derived from the ventricular myocardium in a process involving undermining of the ventricular walls. Because this process occurs asymmetrically, the tricuspid valve annulus sits closer to the apex of the heart than the mitral valve annulus. Physical separation of these two valves produces the atrioventricular septum, the absence of which is the primary common defect in patients with **atrioventricular canal defects** (see Chapter 475.5). If the process of undermining is incomplete, the right atrioventricular valve may not separate normally from the ventricular myocardium, a possible cause of **Ebstein anomaly** (see Chapter 479.7).

Septation of the atria begins at around 30 days with growth of the septum primum downward toward the endocardial cushions (see Fig. 469.1). The orifice that remains is the ostium primum. The endocardial cushions then fuse and, together with the completed septum primum, divide the atrioventricular canal into right and left segments. A second opening appears in the posterior portion of the septum primum, the ostium secundum, and it allows a portion of the fetal venous return to the right atrium to pass across to the left atrium. Finally, the septum secundum grows downward, just to the right of the septum primum. Together with a flap of the septum primum, the ridge of the ostium secundum forms the *foramen ovale,* through which fetal blood passes from the inferior vena cava to the left atrium (see Chapter 470).

Septation of the ventricles begins at about embryonic day 25 with protrusions of endocardium in both the inlet (primitive ventricle) and outlet (bulbus cordis) segments of the heart. The inlet protrusions fuse into the bulboventricular septum and extend posteriorly toward the inferior endocardial cushion, where they give rise to the inlet and trabecular portions of the interventricular septum. **Ventricular septal defects** can occur in any portion of the developing interventricular septum (see Chapter 475.6). The outlet or conotruncal septum develops from ridges of cardiac jelly, similar to the atrioventricular cushions. These ridges fuse to form a spiral septum that brings the future pulmonary artery into communication with the anterior and rightward right ventricle and the future aorta into communication with the posterior and leftward left ventricle. Differences in cell growth of the outlet septum lead to lengthening of the segment of smooth muscle beneath the pulmonary valve (conus), a process that separates the tricuspid and pulmonary valves. In contrast, disappearance of the segment beneath the aortic valve leads to fibrous continuity of the mitral and aortic valves. Within the lumen of distal outflow tract, local tissue swellings *(truncal cushions)* arise and are later populated by mesenchymal cells originating from the neural crest, participating in the formation of the semilunar (pulmonary and aortic) valves. Defects in these processes are responsible for **conotruncal** and **aortic arch defects** (truncus arteriosus, tetralogy of Fallot, pulmonary atresia, double-outlet right ventricle, interrupted aortic arch), a group of cardiac anomalies often associated with deletions of the **DiGeorge** critical region of **chromosome 22q11** (see Chapters 472 and 473). The transcription factor gene *(TBX1)* has been implicated as a candidate gene, which may be responsible for DiGeorge syndrome. Several genes have been implicated in valve formation, including *PTPN11,* which encodes the tyrosine phosphatase SHP-2, and when present in a mutated form, is one of the genes responsible for **Noonan syndrome**, associated with pulmonary valve stenosis, and *NOTCH1,* a regulator of cell differentiation associated with aortic valve disease.

469.4 Aortic Arch Development

Daniel Bernstein and William R. Goodyer

The aortic arch, head and neck vessels, proximal pulmonary arteries, and ductus arteriosus develop from the aortic sac, arterial arches, and dorsal aortae. When the straight heart tube develops, the distal outflow portion bifurcates into the right and left first aortic arches, which join the paired dorsal aortae (Fig. 469.2). The dorsal aortae will fuse to form the descending aorta. The proximal aorta from the aortic valve to the left carotid artery arises from the aortic sac. The first and second arches largely regress by about 22 days, with the first aortic arch giving rise to the maxillary artery and the second to the stapedial and hyoid arteries. The third arches participate in the formation of the innominate artery and the common and internal carotid arteries. The right fourth arch gives rise to the innominate and right subclavian arteries, and the left fourth arch participates in formation of the segment of the aortic arch between the left carotid artery and the ductus arteriosus. The fifth arch does not persist as a major structure in the mature circulation. The sixth arches join the more distal pulmonary arteries, with the right sixth arch giving rise to a portion of the proximal right pulmonary artery and the left sixth arch to the proximal left pulmonary artery and to the ductus arteriosus. The aortic arch between the ductus arteriosus and left subclavian artery is derived from the left-sided dorsal aorta, whereas the aortic arch distal to the left subclavian artery is derived from the fused right and left dorsal aortae. Abnormalities in development of the paired aortic arches are responsible for **right aortic arch**, **double aortic arch**, and **vascular rings** (see Chapter 481.1).

469.5 Cardiac Differentiation

Daniel Bernstein and William R. Goodyer

The process by which the totipotential cells of the early embryo become committed to specific cell lineages is termed *differentiation*. Precardiac mesodermal cells differentiate into mature cardiac muscle cells with an appropriate complement of cardiac-specific contractile elements, regulatory proteins, receptors, and ion channels. Expression of the contractile protein myosin occurs at an early stage of cardiac development, even before fusion of the bilateral heart primordia. Differentiation in these early mesodermal cells is regulated by signals from the anterior endoderm, a process known as *induction*. Several putative early signaling molecules include fibroblast growth factor, activin, and insulin. Signaling molecules interact with receptors on the cell surface; these receptors activate second messengers, which in turn activate specific nuclear transcription factor genes (*GATA-4, MEF2, NKX, bHLH,* and retinoic acid receptor family) that induce the expression of specific gene products to regulate cardiac differentiation. Some of the primary disorders of cardiac muscle, the **cardiomyopathies**, may be related to defects in some of these signaling molecules (see Chapter 488).

Developmental processes are chamber specific. Early in development, ventricular myocytes express both ventricular and atrial isoforms of several proteins, such as atrial natriuretic peptide (ANP) and myosin light chain (MLC). Mature ventricular myocytes do not express ANP and express only a ventricular-specific MLC 2v isoform, whereas mature atrial myocytes express ANP and an atrial-specific MLC 2a isoform. Heart failure (see Chapter 491), volume overload (see Chapters 475 and 477), and pressure overload hypertrophy (see Chapter 476)

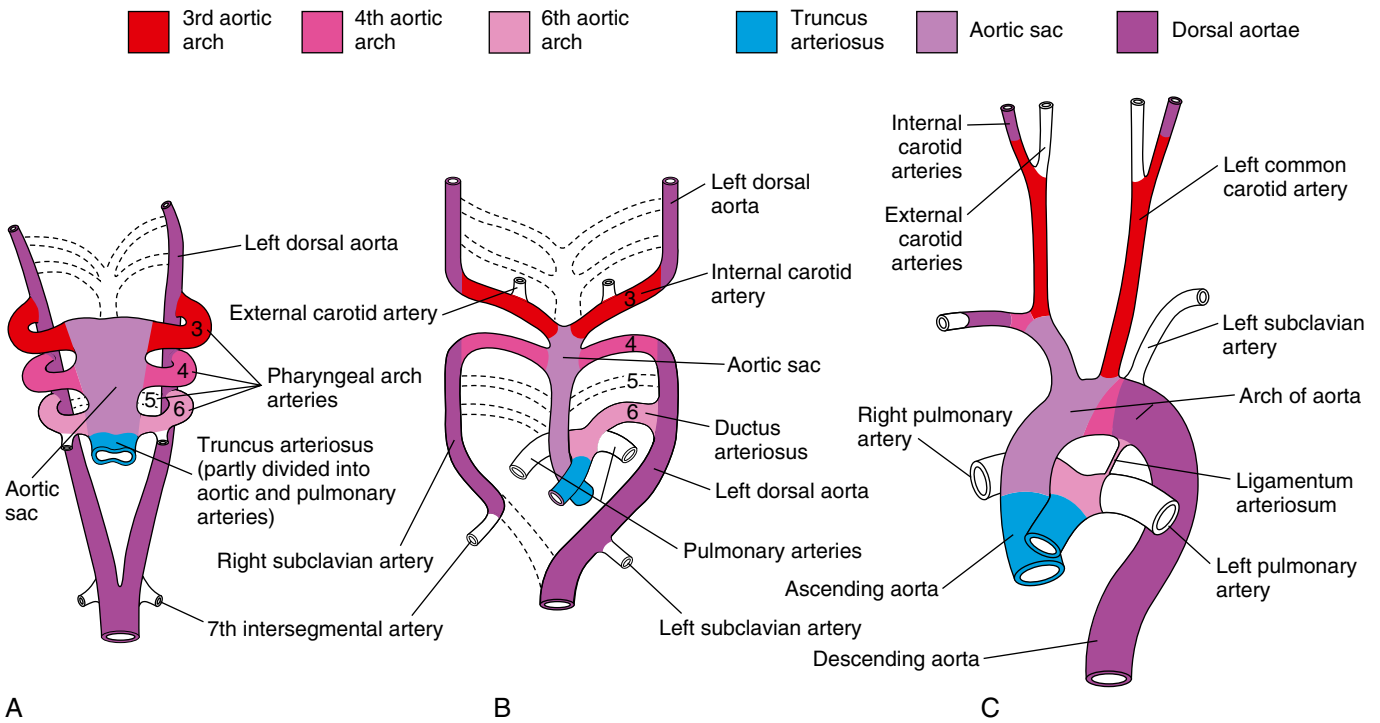

Fig. 469.2 Schematic drawings illustrating the changes that result during transformation of the truncus arteriosus, aortic sac, aortic arches, and dorsal aortae into the adult arterial pattern. The vessels that are *not* shaded or colored are not derived from these structures. **A,** Aortic arches at 6 weeks; by this stage, the first two pairs of aortic arches have largely disappeared. **B,** Aortic arches at 7 weeks; the parts of the dorsal aortae and aortic arches that normally disappear are indicated by *broken lines*. **C,** Arterial vessels of 6-mo-old infant. *(From Moore KL, Persaud TVN, Torchia M. The Developing Human. Philadelphia: Elsevier; 2007.)*

are associated with a recapitulation of fetal cell phenotypes in which mature myocytes re-express fetal proteins. Because different isoforms have different contractile behavior (fast vs slow activation, high vs low adenosine triphosphatase activity), expression of different isoforms may have important functional consequences.

469.6 Developmental Changes in Cardiac Function

Daniel Bernstein and William R. Goodyer

During development, the composition of the myocardium undergoes profound changes that result in an increase in the number and size of myocytes. During prenatal life, this process involves myocyte division **(hyperplasia)**, whereas after the first few postnatal weeks, subsequent cardiac growth occurs mostly by an increase in myocyte size **(hypertrophy)**. The myocytes themselves change shape from round to cylindrical, the proportion of myofibrils (which contain the contractile apparatus) increases, and the myofibrils become more regular in their orientation.

The *plasma membrane* (known as the *sarcolemma* in myocytes) is the location of the ion channels and transmembrane receptors that regulate the exchange of chemical information from the cell surface to the cell interior. Ion fluxes through these channels control the processes of depolarization and repolarization. Developmental changes have been described for the sodium-potassium pump, the sodium-hydrogen exchanger, and voltage-dependent calcium channels. As the myocyte matures, extensions of the sarcolemma develop toward the interior of the cell (the T-tubule system), which dramatically increases its surface area and enhances rapid activation of the myocyte. Regulation of the membrane's α- and β-adrenergic receptors with development enhances the ability of the sympathetic nervous system to control cardiac function as the heart matures.

The *sarcoplasmic reticulum* (SR), a series of tubules surrounding the myofibrils, is the principal mediator of the intracellular calcium concentration. Calcium release to the myofibrils for initiation of contraction is mediated by the ryanodine receptor (RYR), and calcium reuptake for initiation of relaxation is mediated by the sarcoplasmic reticulum calcium ATPase (SERCA). This SR calcium transport system is less well developed in immature hearts, which thus depend more on transport of calcium from outside the cell for contraction. In a mature heart, the majority of the calcium required for contraction comes from within the cardiomyocyte via the SR. This developmental phenomenon may explain the sensitivity of the infant heart to sarcolemmal calcium channel blockers such as verapamil, which can result in a marked depression in contractility (see Chapter 484).

The major contractile proteins (myosin, actin, tropomyosin, and troponin) are organized into the functional unit of cardiac contraction, the *sarcomere*. Each has several isoforms that are expressed differentially by location (atrium vs ventricle) and by developmental stage (embryo, fetus, newborn, adult).

Changes in myocardial structure and myocyte biochemistry result in easily quantifiable differences in cardiac function with development. Fetal cardiac function is less responsive to changes in preload (filling volume). Thus the most effective means of increasing cardiac output in the fetus is through increasing the heart rate. After birth and with further maturation, preload and afterload play an increasing role in regulating cardiac function. The rate of cardiac relaxation is also developmentally regulated. The decreased ability of the immature SR calcium pump (SERCA) to remove calcium from the contractile apparatus is manifested as a decreased ability of the fetal heart to enhance relaxation in response to sympathetic stimulation.

Chapter 470

The Fetal to Neonatal Circulatory Transition

Daniel Bernstein

470.1 The Fetal Circulation

Daniel Bernstein

The transition from the fetal to the postnatal circulation represents one of the most dramatic circulatory adaptations at any time of life. In the fetal circulation, the right and left ventricles exist in a parallel circuit, as opposed to the series circuit of the newborn or adult (Fig. 470.1A). In the fetus, the placenta provides for gas and metabolite exchange. Because the lungs do not provide gas exchange, blood is diverted away from the pulmonary circulation, which is vasoconstricted. Three cardiovascular structures unique to the fetus are important for maintaining this parallel circulation: the *ductus venosus, foramen ovale,* and *ductus arteriosus.*

The placenta is not as efficient an oxygen-exchange organ as the lungs, so that umbilical venous partial pressure of oxygen (Po_2), the highest O_2 level provided to the fetus, is only 30-35 mm Hg. Approximately 50% of the umbilical venous blood enters the hepatic circulation, whereas the rest bypasses the liver and joins the inferior vena cava (IVC) via the ductus venosus, where it partially mixes with poorly oxygenated IVC blood derived from the lower part of the fetal body. This combined lower body plus umbilical venous blood flow (Po_2 of 26-28 mm Hg) enters the right atrium and is preferentially directed by a flap of tissue at the right atrium–IVC junction, the eustachian valve, across the foramen ovale to the left atrium (see Fig. 470.1B). This is the major source of left ventricular (LV) blood flow in the fetus, because pulmonary venous return from the vasoconstricted lungs is minimal. LV blood is then ejected into the ascending aorta, where it supplies predominantly the fetal upper body and brain.

Fetal superior vena cava (SVC) blood, which is considerably less oxygenated (Po_2 of 12-14 mm Hg) than IVC blood, enters the right atrium and preferentially flows across the tricuspid valve, rather than the foramen ovale, into the right ventricle. From the right ventricle, this blood is ejected into the pulmonary artery. Because the pulmonary arterial circulation is vasoconstricted, only approximately 5% of right ventricular (RV) outflow enters the lungs. The major portion of this blood bypasses the lungs and flows right to left through the ductus arteriosus into the descending aorta to perfuse the lower part of the fetal body, including providing flow to the placenta via the two umbilical arteries. Thus the upper part of the fetal body (including the coronary and cerebral arteries and those to the upper extremities) is perfused exclusively from the left ventricle with blood that has a slightly higher Po_2 than the blood perfusing the lower part of the fetal body, which is derived mostly from the right ventricle. Only a small volume of blood from the ascending aorta (10% of fetal cardiac output) flows all the way around the aortic arch (aortic isthmus) to the descending aorta.

The **total fetal cardiac output**—the combined output of both the left and right ventricles—is approximately 450 mL/kg/min. Approximately 65% of descending aortic blood flow returns to the placenta; the remaining 35% perfuses the fetal organs and tissues. In the human fetus, RV output is approximately 1.3 times LV flow. Thus during fetal life the right ventricle is not only pumping against the higher systemic blood pressure but also performing slightly greater volume work than the left ventricle. This results in the RV wall being as thick (hypertrophied) as the LV wall during fetal and immediate neonatal life, explaining the unique features of the neonatal electrocardiogram (showing what would be read as *right ventricular hypertrophy* in an adult).

Blood flow is believed to be an important determinant of growth of fetal cardiac chambers, valves, and blood vessels. Thus in the presence of a narrowing (stenosis) of an upstream structure such as the mitral valve, flow downstream into the left ventricle is limited and LV growth may be compromised, which may be one of the mechanisms of **hypoplastic left heart syndrome** (HLHS; see Chapter 480.10). Similarly, stenosis of a downstream structure such as the aortic valve can also disrupt flow into the LV and contribute to HLHS. Fetal cardiac interventional treatments, currently experimental, are aimed at opening stenotic aortic valves in mid-gestation fetuses and allowing more normal LV growth. However, the outcome of these procedures does not enhance LV growth in all patients, suggesting that in the majority of cases of HLHS there is a different mechanism, suspected to be a defect in the LV cardiomyocytes themselves (i.e., a cell-autonomous defect).

470.2 The Transitional Circulation

Daniel Bernstein

At birth, mechanical expansion of the lungs and an increase in arterial Po_2 result in a rapid decrease in pulmonary vascular resistance (PVR). Concomitantly, removal of the low-resistance placental circulation leads to an increase in systemic vascular resistance (SVR). The output from the right ventricle now flows entirely into the pulmonary circulation, and because PVR becomes lower than SVR, the shunt through the ductus arteriosus reverses and becomes left to right. Over several days the high arterial Po_2 constricts and eventually closes the ductus arteriosus, which eventually becomes the ligamentum arteriosum. The increased volume of pulmonary blood flow returning to the left atrium from the lungs increases left atrial volume and pressure sufficiently to close the flap of the foramen ovale functionally, although the foramen may remain patent on probing with a catheter for several years. A patent foramen ovale can be a source of embolic stroke in later life.

Removal of the placenta from the circulation also results in closure of the ductus venosus. The left ventricle is now coupled to the high-resistance systemic circulation, and its wall thickness and mass begin to increase. In contrast, the right ventricle is now coupled to the low-resistance pulmonary circulation, and its wall thickness and mass decrease. The left ventricle, which in the fetus pumped blood only to the upper part of the body and brain, must now deliver the entire systemic cardiac output (approximately 350 mL/kg/min), an almost 200% increase in output. This marked increase in LV performance is achieved through a combination of hormonal and metabolic signals, including an increase in the level of circulating catecholamines and in the density of myocardial β-adrenergic receptors, through which catecholamines have their effect.

When superimposed on these dramatic physiologic changes, congenital structural cardiac defects often impede this smooth transition and greatly increase the burden on the newborn myocardium. Importantly, because the ductus arteriosus and foramen ovale do not close completely at birth, they can provide a lifesaving pathway for blood to bypass a congenital defect (the patent ductus arteriosus in tetralogy of Fallot, pulmonary atresia, coarctation of aorta or HLHS; the foramen ovale in transposition of the great vessels). Alternatively, persistent fetal pathways can present an additional stress to the circulation (patent ductus arteriosus in the premature infant). Therapeutic agents can be used to either maintain these fetal pathways open (e.g., *prostaglandin E_1*) or hasten their closure (e.g., *indomethacin*). This pharmacology explains why indomethacin and similar drugs are contraindicated or used with extreme caution during the third trimester.

470.3 The Neonatal Circulation

Daniel Bernstein

At birth, the fetal circulation must immediately adapt to extrauterine life as gas exchange is transferred from the placenta to the lungs (see

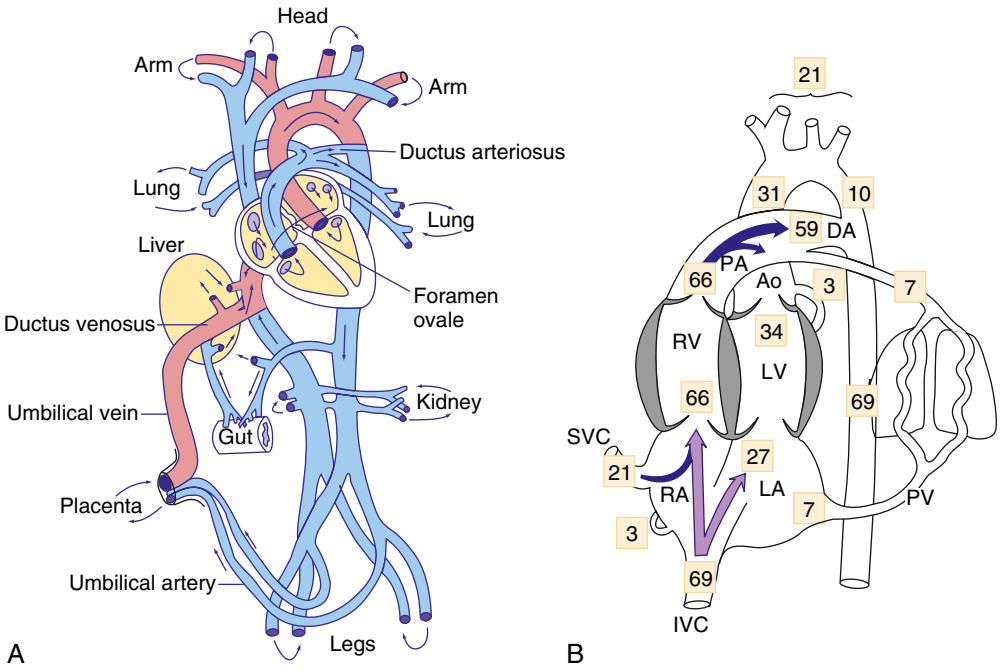

Fig. 470.1 A, The human circulation before birth (partly after Dawes). *Red* indicates more highly oxygenated blood, and *arrows* indicate the direction of flow. More highly oxygenated blood from the placenta passes through the foramen ovale from the right to the left atrium, thus bypassing the lungs. B, Percentages of combined ventricular output that return to the fetal heart, that are ejected by each ventricle, and that flow through the main vascular channels. Figures are those obtained from studies of late-gestation fetal lambs. Ao, Aorta; DA, ductus arteriosus; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary veins; RA, right atrium; RV, right ventricle; SVC, superior vena cava. *(From Rudolph AM. Congenital Diseases of the Heart. Chicago: Year Book; 1974.)*

Chapter 124). Some of these changes are virtually instantaneous with the first breath, whereas others develop over hours or weeks. With the onset of breathing and lung ventilation, pulmonary vascular resistance is greatly decreased because of both active (i.e., Po_2-metabolic-related) and passive (i.e., mechanical stretch-related) pulmonary vasodilation. In a normal neonate, closure of the ductus arteriosus and the fall in PVR decreases pulmonary arterial and RV pressures. The largest decline in PVR from the high fetal levels to the lower "adult" levels in the human infant usually occurs within 2-3 days, but may be prolonged for ≥7 days after birth. However, over the next several weeks of life, PVR continues to decrease further, now secondary to physical remodeling of the pulmonary vasculature, including thinning of vascular smooth muscle and recruitment of new vessels. This decrease in PVR significantly influences the timing of the clinical appearance of many congenital heart lesions dependent on the relative levels of SVR and PVR. For example, the left-to-right shunt through a large ventricular septal defect (VSD) may be minimal in the first week after birth, when PVR is still high. As PVR decreases in the next 1-2 weeks, the volume of the left-to-right shunt through the VSD increases and eventually leads to the signs and symptoms of heart failure.

There are several significant differences between the neonatal circulation and that of older infants: (1) right-to-left or left-to-right shunting may persist across the patent foramen ovale; (2) in the presence of cardiopulmonary disease, continued patency of the ductus arteriosus may allow left-to-right, right-to-left, or bidirectional shunting; (3) the neonatal pulmonary vasculature constricts more vigorously in response to hypoxemia, hypercapnia, and acidosis; (4) the wall thickness and muscle mass of the neonatal left and right ventricles are almost equal; and (5) newborn infants at rest have a relatively high oxygen consumption, associated with a relatively high cardiac output. The newborn cardiac output, indexed to body weight (200 mL/kg/min), falls in the first 2 months of life to approximately 150 mL/kg/min and then more gradually to the normal adult cardiac output of 75 mL/kg/min. Although fetal hemoglobin is beneficial to delivery of oxygen in the low-Po_2 fetal circulation, the high percentage of fetal hemoglobin present in the newborn may actually interfere with delivery of oxygen to tissues in the high-systemic Po_2 neonatal circulation, and therefore adult hemoglobin production begins immediately (see Chapter 124).

The foramen ovale is usually functionally closed by the third month of life, although it is possible to pass a catheter through the overlapping flaps in a large percentage of children and in 15–25% of adults. Functional closure of the ductus arteriosus is usually complete by 10-15 hours of postnatal age in a normal neonate, although the ductus may remain patent much longer in the presence of congenital heart disease, especially when associated with cyanosis. In premature newborn infants, a systolic murmur with late accentuation or a continuous murmur may be audible beneath the left clavicle, and in the context of respiratory distress syndrome, the presence of a patent ductus arteriosus should be suspected (see Chapter 126.1).

The normal ductus arteriosus differs morphologically from the adjoining aorta and pulmonary artery in that the ductus has a significant amount of circularly arranged smooth muscle in its medial layer. During fetal life, patency of the ductus arteriosus appears to be maintained by the combined relaxant effects of low oxygen tension and endogenously produced prostaglandins, specifically prostaglandin E_2. In a full-term neonate, oxygen is the most important factor controlling ductal closure. When the Po_2 of the blood passing through the ductus reaches about 50 mm Hg, the ductal wall begins to constrict. The effects of oxygen on ductal smooth muscle may be direct or mediated by its effects on prostaglandin synthesis. Gestational age also appears to play an important role; the ductus of a premature infant is less responsive to oxygen, even though its musculature is well developed.

470.4 Persistent Pulmonary Hypertension of the Neonate (Persistence of Fetal Circulatory Pathways)

Section 2

Evaluation of the Cardiovascular System and the Child with a Heart Murmur

Chapter 471

History and Physical Examination in Cardiac Evaluation

Daniel Bernstein

One of the most common reasons for cardiac evaluation in young children is the heart murmur; **innocent or functional murmurs (Still murmurs)** may be heard in up to 30% of patients at some time during childhood. Functional murmurs are usually accentuated by fever and first noticed during a visit for an intercurrent illness. Thus the general pediatrician must be able to distinguish those murmurs that are functional from those that are potentially pathologic and refer patients with pathologic-sounding murmurs or murmurs of uncertain nature for evaluation by a pediatric cardiologist.

Patients may require further laboratory evaluation (e.g., electrocardiogram and echocardiogram), or the family may be reassured that no significant problem exists. Although the ready availability of echocardiography may entice the clinician to skip a good history and physical exam, an initial evaluation by a skilled cardiologist is preferred for several reasons: (1) a cardiac examination allows the cardiologist to guide the echocardiographic evaluation toward confirming or eliminating specific diagnoses, thereby increasing its accuracy; (2) because most childhood murmurs are innocent, evaluation by a pediatric cardiologist can eliminate unnecessary and expensive laboratory tests; and (3) the cardiologist's knowledge and experience are important in reassuring the patient's family and preventing unnecessary, and all too common, restrictions on healthy physical activity. An experienced pediatric cardiologist can differentiate an innocent murmur from serious congenital heart disease by history and physical examination alone with high sensitivity and specificity.

HISTORY

The evaluation begins with a comprehensive cardiac history because a diagnosis of a functional murmur can only be made in the absence of any concerning symptoms, signs, or family history. A comprehensive cardiac history starts with details of the perinatal period, including the presence of cyanosis, respiratory distress, or prematurity. **Maternal complications** such as gestational diabetes, teratogenic medications, infections, systemic lupus erythematosus, or substance misuse can be associated with cardiac problems. If cardiac symptoms began during infancy, the timing of the initial symptoms should be noted to provide important clues about the specific cardiac condition.

Many of the symptoms of **heart failure** in infants and children are age specific. In infants, feeding difficulties are common. Inquiry should be made about the frequency of feeding and either the volume of each feeding or the time spent on each breast. An infant with heart failure often takes less volume per feeding and becomes dyspneic or diaphoretic while nursing. After falling asleep exhausted, the baby, inadequately fed, will awaken for the next feeding after a brief time. This cycle continues around the clock and must be carefully differentiated from colic or other feeding disorders. Additional symptoms and signs include those of respiratory distress: rapid breathing, nasal flaring, cyanosis, and chest retractions. In older children, heart failure may be manifested as exercise intolerance, difficulty keeping up with peers during sports or the need for a nap after coming home from school, poor growth, or chronic abdominal complaints. Eliciting a history of fatigue in an older child requires questions about age-specific activities, including stair climbing, walking, bicycle riding, physical education class, and competitive sports; information should be obtained regarding more severe manifestations such as orthopnea and nocturnal dyspnea.

Parents often overlook their baby's **cyanosis** at rest; it may be mistaken for a normal individual variation in color. Cyanosis during crying or exercise, however, is more often noted as abnormal by observant parents. Many infants and toddlers turn "blue around the lips" when crying vigorously or during breath-holding spells; this condition must be carefully differentiated from **cyanotic heart disease** by inquiring about inciting factors, the length of episodes, and whether the tongue and mucous membranes also appear cyanotic. Newborns often have cyanosis of their extremities **(acrocyanosis)** when undressed and cold; this response to cold must be carefully differentiated from true cyanosis, where the mucous membranes are also blue.

Chest pain is an unusual manifestation of cardiac disease in pediatric patients, although it is a frequent cause for referral to a pediatric cardiologist, especially in adolescents. Nonetheless, a careful history, physical examination, and, if indicated, laboratory or imaging tests will assist in identifying the cause of chest pain (Table 471.1). For patients with some forms of repaired congenital heart disease (CHD), for example, those with surgery on the aortic root or those with a history of Kawasaki disease (see Chapter 493.1), chest pain should be evaluated carefully for a coronary etiology.

Cardiac disease may be a manifestation of a known congenital malformation syndrome with typical physical findings (Table 471.2) or a manifestation of a generalized disorder affecting the heart and other organ systems (Table 471.3). **Extracardiac malformations** may be noted in 20–45% of infants with CHD. Between 5% and 10% of patients have a known chromosomal abnormality. Specific gene or whole exome sequencing can enhance the diagnostic approach to CHD (Fig. 471.1).

A careful family history may also reveal early (at age <50 years) coronary artery disease or stroke (suggestive of familial hypercholesterolemia or thrombophilia), sudden death (suggestive of cardiomyopathy or familial arrhythmic disorder), generalized muscle disease (suggestive of one of the muscular dystrophies, dermatomyositis, or familial or metabolic cardiomyopathy), or first-degree relatives with CHD.

GENERAL PHYSICAL EXAMINATION

In the evaluation of a child with a heart murmur, a general physical examination is always performed, with specific attention directed toward the presence of cyanosis, abnormalities in growth, chest wall abnormalities, and any evidence of respiratory distress. Although the murmur may be the most prominent part of the overall examination, any murmur must be placed in context of other physical findings. Associated findings such as quality of the pulses, presence of a ventricular heave or thrill, or splitting of the second heart sound provide important clues to a specific cardiac diagnosis.

Accurate measurement of height and weight and plotting on a standard growth chart are important because both cardiac failure and chronic cyanosis can result in failure to thrive. Growth failure is manifested predominantly by poor weight gain; if length and especially head circumference is also affected, additional congenital malformations or metabolic disorders should be suspected.

Mild cyanosis may be too subtle for early detection, and clubbing of the fingers and toes is not usually manifested until late in the first year of life, even in the presence of severe arterial oxygen desaturation. Cyanosis is best observed over the nail beds, lips, tongue, and mucous membranes. Delayed recognition of cyanosis in infants with darker skin color

Table 471.1 Differential Diagnosis of Chest Pain in Pediatric Patients

MUSCULOSKELETAL (COMMON)
Trauma (accidental, abuse)
Exercise, overuse injury (strain, bursitis)
Costochondritis
Tietze syndrome
Herpes zoster (cutaneous or without rash)
Pleurodynia
Fibrositis
Slipping rib
Rib fracture
Precordial catch
Sickle cell anemia vasoocclusive crisis
Osteomyelitis (rare)
Primary or metastatic tumor (rare)
Fibromyalgia
Nerve entrapment, radiculopathy
PULMONARY (COMMON)
Pneumonia
Pleurisy
Pleurodynia
Asthma
Chronic cough
Pneumothorax
Infarction (sickle cell anemia)
Foreign body
Embolism (rare)
Pulmonary hypertension (rare)
Tumor (rare)
Bronchiectasis
GASTROINTESTINAL (LESS COMMON)
Esophagitis (gastroesophageal reflux, infectious, pill)
Esophageal foreign body
Esophageal spasm
Cholecystitis
Subdiaphragmatic abscess
Perihepatitis (Fitz-Hugh-Curtis syndrome)
Peptic ulcer disease
Pancreatitis
Splenic rupture
CARDIAC (LESS COMMON)
Pericarditis
Postpericardiotomy syndrome
Endocarditis
Myocarditis
Cardiomyopathy
Mitral valve prolapse
Aortic or subaortic stenosis
Arrhythmias (supraventricular, ventricular, tachycardias)
Marfan syndrome (dissecting aortic aneurysm)
Kawasaki disease
Cocaine, sympathomimetic ingestion
Ischemia (familial hypercholesterolemia, anomalous coronary artery, post-repair of congenital heart disease involving reimplantation of the coronary arteries [e.g., d-transposition of the great arteries])
Takotsubo cardiomyopathy (primary or secondary)
IDIOPATHIC (COMMON)
Anxiety, hyperventilation
Panic disorder
OTHER (LESS COMMON)
Spinal cord or nerve root compression
Breast-related pathologic condition (mastalgia)
Castleman disease (lymph node neoplasm)

can lead to delayed treatment and poorer outcomes. Careful observation of the color of the tongue, mucous membranes, and nail beds, where cyanosis is most noticeable, is critical in recognizing cyanosis in these patients. Confirmation with pulse oximetry is easily performed.

Differential cyanosis, manifested as blue lower extremities and pink upper extremities (usually the right arm), is seen with right-to-left shunting across a ductus arteriosus in the presence of coarctation or an interrupted aortic arch. Circumoral cyanosis or blueness around the forehead may be the result of prominent venous plexuses in these areas, rather than decreased arterial oxygen saturation. The extremities of infants often turn blue when the infant is unwrapped and cold (acrocyanosis), and this condition can be distinguished from central cyanosis by examination of the tongue and mucous membranes.

Heart failure in infants and children usually results in some degree of hepatomegaly and occasionally splenomegaly. The sites of **peripheral edema** are age dependent. In infants, edema is usually seen around the eyes and over the flanks, especially on initially waking. Older children and teenagers manifest both periorbital edema and pedal edema. An initial complaint in these older patients may be that their clothes are now too tight.

The **heart rate** of newborn infants is rapid and subject to wide fluctuations (Table 471.4). The average rate ranges from 120 to 140 beats/min and may increase to 170+ beats/min during crying and activity or drop to 70-90 beats/min during sleep. As the child grows older, the average pulse rate decreases and may be as low as 40 beats/min at rest in very athletic adolescents. Persistent **tachycardia** (>200 beats/min in neonates, 150 beats/min in infants, or 120 beats/min in older children), bradycardia, or an irregular heartbeat other than sinus arrhythmia requires investigation to exclude pathologic arrhythmias (see Chapter 484). **Sinus arrhythmia** can usually be distinguished by the rhythmic nature of the heart rate variations, occurring in concert with the respiratory cycle, with a P wave before every QRS complex, and a normal p-wave axis.

Careful evaluation of the character of the **pulses** is an important early step in the physical diagnosis of CHD. A wide pulse pressure with bounding pulses may suggest an aortic runoff lesion such as patent ductus arteriosus (PDA), aortic insufficiency, an arteriovenous communication, or increased cardiac output secondary to anemia, anxiety, or conditions associated with increased catecholamine or thyroid hormone secretion. The presence of diminished pulses in all extremities is associated with pericardial tamponade, left ventricular outflow obstruction, or cardiomyopathy. The radial and femoral pulses should always be palpated simultaneously. Normally, the femoral pulse should be appreciated immediately before the radial pulse. In infants with coarctation of the aorta, the femoral pulses may be decreased. However, in older children with coarctation of the aorta, blood flow to the descending aorta may channel through collateral vessels and results in the femoral pulse being palpable but delayed until after the radial pulse **(radial-femoral delay)**.

Blood pressure (BP) should be measured in either leg and in the right arm to be certain that coarctation of the aorta is not overlooked. Palpation of the femoral or dorsalis pedis pulse, or both, is not reliable alone to exclude coarctation because collaterals may have developed. Most commonly, BP is measured using an automated oscillatory device, but it is often necessary for the physician to manually recheck BP by auscultation. In older children, a cuff that covers approximately two thirds of the upper part of the arm or leg should be used for BP measurement. A cuff that is too small results in falsely high readings, whereas a cuff that is too large records slightly decreased BP. Pediatric clinical facilities should be equipped with 3-, 5-, 7-, 12-, and 18-cm cuffs to accommodate the large spectrum of pediatric patient sizes. When auscultating blood pressure directly, the first Korotkoff sounds indicate systolic pressure. As cuff pressure is slowly decreased, the sounds usually become muffled before they disappear. Diastolic pressure may be recorded when the sounds become muffled (preferred) or when they disappear altogether; the former is usually slightly higher and the latter slightly lower than true diastolic pressure. For lower-extremity BP determination, the stethoscope is placed over the popliteal artery. Typically, the BP recorded in the legs with the cuff technique is approximately 10 mm Hg higher than that in the arms. In infants, BP can be determined by auscultation or palpation.

BP varies with the age of the child and is closely correlated to height and weight. Significant increases occur during adolescence, and many temporary variations take place before the more stable levels of adult life are attained. Exercise, excitement, coughing, crying, and struggling may raise the systolic BP of infants and children as much as 40-50 mm Hg greater than their usual levels. Variability in BP in children of

Table 471.2 Congenital Malformation Syndromes Associated with Congenital Heart Disease

SYNDROME	FEATURES
CHROMOSOMAL DISORDERS	
Trisomy 21 (Down syndrome)	Endocardial cushion defect, VSD, ASD
Trisomy 21p (cat-eye syndrome)	Miscellaneous, total anomalous pulmonary venous return
Trisomy 18	VSD, ASD, PDA, TOF, coarctation of aorta, bicuspid aortic or pulmonary valve
Trisomy 13	VSD, ASD, PDA, coarctation of aorta, bicuspid aortic or pulmonary valve
Trisomy 9	Miscellaneous, VSD
XXXXY	PDA, ASD
Penta X	PDA, VSD
Triploidy	VSD, ASD, PDA
XO (Turner syndrome)	Bicuspid aortic valve, coarctation of aorta
Fragile X	Mitral valve prolapse, aortic root dilatation
Duplication 3q2	Miscellaneous
Deletion 4p	VSD, PDA, aortic stenosis
Deletion 9p	Miscellaneous
Deletion 5p (cri du chat syndrome)	VSD, PDA, ASD, TOF
Deletion 10q	VSD, TOF, conotruncal lesions*
Deletion 13q	VSD
Deletion 18q	VSD
Deletion 1p36	ASD, VSD, PDA, TOF, cardiomyopathy
Deletion/duplication 1q21.1	ASD, VSD, PS
Deletion 17q11 (William syndrome)	Supravalvar AS, branch PS
Deletion 11q 24-25 (Jacobsen syndrome)	VSD, left sided lesions
SYNDROME COMPLEXES	
CHARGE association (*c*oloboma, *h*eart, *a*tresia choanae, *r*etardation, *g*enital, and *e*ar anomalies)	VSD, ASD, PDA, TOF, endocardial cushion defect
DiGeorge sequence, CATCH 22 (*c*ardiac defects, *a*bnormal facies, *t*hymic aplasia, *c*left palate, *h*ypocalcemia, and deletion 22q11)	Aortic arch anomalies, conotruncal anomalies
Alagille syndrome (arteriohepatic dysplasia)	Peripheral pulmonic stenosis, PS, TOF
VATER association (vertebral, *a*nal, *t*racheo*e*sophageal, *r*adial, and *r*enal anomalies)	VSD, TOF, ASD, PDA
FAVS (*f*acio*a*uriculo*v*ertebral *s*pectrum)	TOF, VSD
CHILD (congenital *h*emidysplasia with *i*chthyosiform erythroderma, *l*imb *d*efects)	Miscellaneous
Mulibrey nanism (muscle, liver, brain, eye)	Pericardial thickening, constrictive pericarditis
Asplenia syndrome	Complex cyanotic heart lesions with decreased pulmonary blood flow, transposition of great arteries, anomalous pulmonary venous return, dextrocardia, single ventricle, single atrioventricular valve
Polysplenia syndrome	Acyanotic lesions with increased pulmonary blood flow, azygos continuation of inferior vena cava, partial anomalous pulmonary venous return, dextrocardia, single ventricle, common atrioventricular valve
PHACE syndrome (*p*osterior brain fossa anomalies, facial *h*emangiomas, *a*rterial anomalies, *c*ardiac anomalies and aortic coarctation, *e*ye anomalies)	VSD, PDA, coarctation of aorta, arterial aneurysms
TERATOGENIC AGENTS	
Congenital rubella	PDA, peripheral pulmonic stenosis
Fetal hydantoin syndrome	VSD, ASD, coarctation of aorta, PDA
Fetal alcohol syndrome	ASD, VSD

Table 471.2 Congenital Malformation Syndromes Associated with Congenital Heart Disease—cont'd

SYNDROME	FEATURES
Fetal valproate effects	Coarctation of aorta, hypoplastic left side of heart, aortic stenosis, pulmonary atresia, VSD
Maternal phenylketonuria	VSD, ASD, PDA, coarctation of aorta
Retinoic acid embryopathy	Conotruncal anomalies
OTHERS	
Apert syndrome	VSD
Autosomal dominant polycystic kidney disease	Mitral valve prolapse
Carpenter syndrome	PDA
Conradi syndrome	VSD, PDA
Crouzon disease	PDA, coarctation of aorta
Cutis laxa	Pulmonary hypertension, pulmonic stenosis
De Lange syndrome	VSD
Ellis–van Creveld syndrome	Single atrium, VSD
Holt-Oram syndrome	ASD, VSD, first-degree heart block
Infant of diabetic mother	Hypertrophic cardiomyopathy, VSD, conotruncal anomalies
Kartagener syndrome	Dextrocardia
Meckel-Gruber syndrome	ASD, VSD
Noonan syndrome	Pulmonic stenosis, ASD, cardiomyopathy
Pallister-Hall syndrome	Endocardial cushion defect
Primary ciliary dyskinesia	Heterotaxia disorders
Rubinstein-Taybi syndrome	VSD
Scimitar syndrome	Hypoplasia of right lung, anomalous pulmonary venous return to inferior vena cava
Smith-Lemli-Opitz syndrome	VSD, PDA
TAR syndrome (thrombocytopenia and absent radius)	ASD, TOF
Treacher Collins syndrome	VSD, ASD, PDA

*Conotruncal includes TOF, pulmonary atresia, truncus arteriosus, and transposition of great arteries.
ASD, Atrial septal defect; AV, aortic valve; PDA, patent ductus arteriosus; PS, pulmonary stenosis; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

approximately the same age and body build should be expected, and at least three serial measurements on different dates should be obtained when confirming the diagnosis of hypertension (Figs. 471.2 and 471.3).

Although of little use in infants, in cooperative older children, inspection of the **jugular venous pulse** wave provides information about central venous and right atrial pressure. The neck veins should be inspected with the patient sitting at a 90-degree angle. The external jugular vein should not be visible above the clavicles unless central venous pressure is elevated. Increased venous pressure transmitted to the internal jugular vein may appear as venous pulsations without visible distention; such pulsation is not seen in normal children reclining at an angle of 45 degrees. Because the great veins are in direct communication with the right atrium, changes in pressure and the volume of this chamber are also transmitted to the veins. The one exception occurs in superior vena cava obstruction, in which venous pulsatility is lost.

CARDIAC EXAMINATION

The heart should be examined in a systematic manner, starting with inspection and palpation. Any abnormalities on inspection and/or palpation strongly suggest a pathologic rather than a functional etiology of any heart murmur. A **precordial bulge** to the left of the sternum with or without increased precordial activity suggests cardiac enlargement, especially in younger children where the chest wall is still relatively flexible; such bulges can often best be appreciated by having the child lay supine with the examiner looking up from the child's feet. A **substernal heave** indicates the presence of right ventricular hypertrophy or enlargement, whereas an **apical heave** is noted with left ventricular hypertrophy or enlargement. An overall **hyperdynamic precordium** suggests a volume load such as that found with a large left-to-right shunt, although it may be normal in a thin patient. An overly silent precordium with a barely detectable apical impulse suggests a large pericardial effusion or severe cardiomyopathy but may be normal in an obese patient.

The relationship of the **apical impulse** to the midclavicular line is also helpful in the estimation of cardiac size: the apical impulse shifts laterally and inferiorly with enlargement of the left ventricle. Right-sided apical impulses signify dextrocardia, tension pneumothorax, or left-sided thoracic space-occupying lesions (e.g., diaphragmatic hernia).

Thrills are the palpable equivalent of murmurs and correlate with the area of maximal auscultatory intensity of the murmur. It is important to palpate the suprasternal notch and neck for aortic bruits, which may indicate the presence of aortic stenosis. Right lower sternal border and apical systolic thrills are characteristic of ventricular septal defect (VSD) and mitral insufficiency, respectively. Diastolic thrills are occasionally palpable in the presence of atrioventricular valve stenosis. The timing and localization of thrills should be carefully noted. Although the presence of a thrill is usually linked to a murmur of grade IV or greater, after a patient has had cardiac surgery, the presence of scar within the chest may eliminate the ability to feel a thrill even with a very loud murmur.

Table 471.3 Cardiac Manifestations of Systemic Diseases

SYSTEMIC DISEASE	CARDIAC COMPLICATIONS
INFLAMMATORY DISORDERS	
Sepsis	Hypotension, myocardial dysfunction, pericardial effusion, pulmonary hypertension
COVID-19	Myocarditis, multisystem inflammatory syndrome in children (MIS-C)
Juvenile idiopathic arthritis	Pericarditis, rarely myocarditis
Systemic lupus erythematosus	Pericarditis, Libman-Sacks endocarditis, coronary arteritis, coronary atherosclerosis (with steroids), congenital heart block
Scleroderma	Pulmonary hypertension, myocardial fibrosis, cardiomyopathy
Dermatomyositis	Cardiomyopathy, arrhythmias, heart block
Kawasaki disease	Coronary artery aneurysm and thrombosis, myocardial infarction, myocarditis, valvular insufficiency
Sarcoidosis	Granuloma, fibrosis, amyloidosis, biventricular hypertrophy, arrhythmias
Lyme disease	Arrhythmias, myocarditis
Löffler hypereosinophilic syndrome	Endomyocardial disease
INBORN ERRORS OF METABOLISM	
Refsum disease	Arrhythmia, sudden death
Hunter or Hurler syndrome	Valvular insufficiency, heart failure, hypertension
Fabry disease	Mitral insufficiency, coronary artery disease with myocardial infarction
Glycogen storage disease IIa (Pompe disease)	Short P-R interval, cardiomegaly, heart failure, arrhythmias
Carnitine deficiency	Heart failure, cardiomyopathy
Gaucher disease	Pericarditis
Homocystinuria	Coronary thrombosis
Alkaptonuria	Atherosclerosis, valvular disease
Morquio-Ullrich syndrome	Aortic incompetence
Scheie syndrome	Aortic incompetence
CONNECTIVE TISSUE DISORDERS	
Arterial calcification of infancy	Calcinosis of coronary arteries, aorta, heart failure, hypertension
Marfan syndrome	Aortic and mitral insufficiency, dissecting aortic aneurysm, mitral valve prolapse
Congenital contractural arachnodactyly	Mitral insufficiency or prolapse
Ehlers-Danlos syndrome	Mitral valve prolapse, dilatated aortic root
Osteogenesis imperfecta	Aortic incompetence
Pseudoxanthoma elasticum	Peripheral arterial disease
NEUROMUSCULAR DISORDERS	
Friedreich ataxia	Cardiomyopathy
Duchenne dystrophy	Cardiomyopathy, heart failure
Tuberous sclerosis	Cardiac rhabdomyoma
Familial deafness	Occasionally arrhythmia, sudden death
Neurofibromatosis	Pulmonic stenosis, pheochromocytoma, coarctation of aorta
Riley-Day syndrome	Episodic hypertension, postural hypotension
Von Hippel-Lindau disease	Hemangiomas, pheochromocytomas
ENDOCRINE-METABOLIC DISORDERS	
Graves disease	Tachycardia, arrhythmias, heart failure
Hypothyroidism	Bradycardia, pericardial effusion, cardiomyopathy, low-voltage electrocardiogram
Pheochromocytoma	Hypertension, myocardial ischemia, myocardial fibrosis, cardiomyopathy
Carcinoid	Right-sided endocardial fibrosis

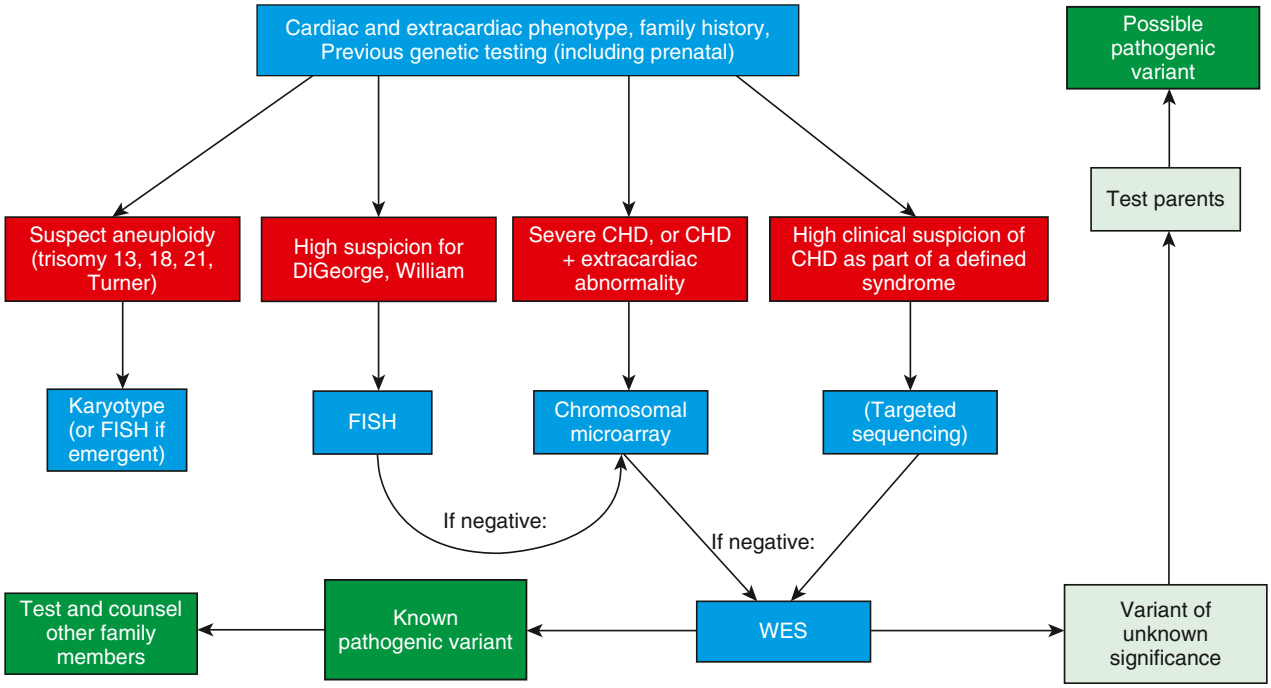

Fig. 471.1 Genetics screening algorithm for congenital heart disease (CHD) patients. FISH, Fluorescence in situ hybridization; WES, whole exome sequencing. *(From Simmons MA, Brueckner M. The genetics of congenital heart disease . . . understanding and improving long-term outcomes in congenital heart disease: a review for the general cardiologist and primary care physician. Curr Opin Pediatr. 2017;29:520–528, Fig 2.)*

Auscultation is an art that improves with practice. The diaphragm of the stethoscope is placed firmly on the chest for high-pitched sounds; a lightly placed bell is optimal for low-pitched sounds. The physician should initially move the stethoscope across the chest, concentrating on the characteristics of the heart sounds; their variation with respiration; and the presence of clicks, rubs, or gallops. Repeat the process, concentrating on murmurs, their maximum location, and their radiation. In some CHDs, such as atrial septal defect (ASD), the murmur is nonspecific and sounds identical to many functional murmurs; it is the abnormality of the second heart sound that points to a pathologic condition. The patient should ideally be supine, lying quietly, and breathing normally. The **first heart sound** (S_1) is best heard at the apex, whereas the **second heart sound** (S_2) should be evaluated at the upper left and right sternal borders. S_1 is caused by closure of the atrioventricular valves (mitral and tricuspid) and can be either single or split. S_2 is caused by closure of the semilunar valves (aortic and pulmonary) (Fig. 471.4). During inspiration, the decrease in intrathoracic pressure results in increased filling of the right side of the heart, which leads to

Table 471.4 Pulse Rates at Rest

AGE	LOWER LIMITS OF NORMAL (beats/min)		AVERAGE (beats/min)		UPPER LIMITS OF NORMAL (beats/min)	
Newborn	70		125		190	
1-11 mo	80		120		160	
2 yr	80		110		130	
4 yr	80		100		120	
6 yr	75		100		115	
8 yr	70		90		110	
10 yr	70		90		110	
	FEMALES	MALES	FEMALES	MALES	FEMALES	MALES
12 yr	70	65	90	85	110	105
14 yr	65	60	85	80	105	100
16 yr	60	55	80	75	100	95
18 yr	55	50	75	70	95	90

an increased right ventricular ejection time and thus delayed closure of the pulmonary valve; inspiration decreases pulmonary venous return, decreasing filling of the left ventricle and moving closure of the aortic valve earlier. Consequently, **splitting of the second heart sound** widens during inspiration and narrows during expiration.

S_2 can appear to be single during expiration, because we can only hear two sounds if they are separated by 20-30 msec. The presence of a normally split S_2 is strong evidence against the diagnosis of ASD, defects associated with pulmonary arterial hypertension, severe pulmonary valve stenosis, aortic and pulmonary atresia, and truncus arteriosus. Wide S_2 splitting is noted in ASD, pulmonary stenosis (where the pulmonary second sound is soft), Ebstein anomaly, total anomalous pulmonary venous return, and right bundle branch block. An accentuated pulmonic component of S_2 with narrow splitting is a sign of pulmonary hypertension. A single S_2 occurs in pulmonary or aortic atresia or severe stenosis, truncus arteriosus, and, often, transposition of the great arteries.

A **third heart sound** (S_3) is best heard with the bell at the apex in mid-diastole, during passive ventricular filling. An S_3 can be pathologic but may be normal in children, often accentuated in patients with fever and tachycardia. A **fourth heart sound** (S_4), occurring in conjunction with atrial systole and the final stages of ventricular filling, may be heard just before the S_1 in late diastole. An S_4 is always pathologic and an indication of decreased ventricular compliance, as occurs in patients with ventricular dysfunction (e.g., in dilated cardiomyopathy). An S_3 may merge with an S_4, a finding known as a **summation gallop**.

Ejection clicks, which are heard in early systole, are usually caused by a mildly to moderately stenotic aortic or pulmonary valve or to a dilated ascending aorta or pulmonary artery. They are heard so close to S_1 that they may be mistaken for a split S_1. However, ejection clicks are heard at the upper left or right sternal borders, whereas a split S_1 is heard at the lower left sternal border or apex. **Aortic** ejection clicks are best heard at the left middle to right upper sternal border and are constant in intensity. They occur in conditions where the aortic valve (mild to moderate aortic stenosis) is stenotic or the aorta is dilated (e.g., tetralogy of Fallot, truncus arteriosus). **Pulmonary** ejection clicks are associated with mild to moderate pulmonary stenosis and are best heard at the left middle to upper sternal border and vary with respiration, often disappearing with inspiration. A good place to hear ejection clicks is right over the sternum, since bone conducts high-frequency sound much better than the muscle of the intercostal spaces. A midsystolic click heard at the apex, often preceding a late systolic murmur, suggests mitral valve prolapse.

Murmurs should be described according to their intensity, pitch, timing (systolic or diastolic), variation in intensity, time to peak intensity, location of maximal intensity, and radiation to other areas. Auscultation for murmurs should be carried out starting at the upper right sternal border then moving slowly across the upper precordium, down the left and right sternal borders, and out to the apex and to the left axilla. Auscultation should also always be performed in the right axilla and over both sides of the back, as many CHD murmurs radiate to these locations. Systolic murmurs are classified as ejection, holosystolic or pansystolic, or late systolic according to the timing of the murmur in relation to S_1 and S_2. The intensity of systolic murmurs is graded from I to VI: **I**, barely audible; **II**, medium intensity; **III**, loud but no thrill; **IV**, loud with a thrill; **V**, very loud but still requiring positioning of the stethoscope at least partly on the chest; and **VI**, so loud that the murmur can be heard with the stethoscope off the chest. In patients who have undergone prior heart surgery, a murmur of grade IV or greater may be heard in the absence of a thrill because of scar tissue, which does not transmit vibrations well, within the chest.

Systolic ejection murmurs start a short time after a well-heard S_1, increase in intensity, peak, and then decrease in intensity; they usually end before S_2. In patients with severe pulmonary stenosis, however, the murmur may extend beyond the first component of S_2, thus obscuring it. **Pansystolic or holosystolic murmurs** begin simultaneously with S_1 and continue throughout systole, on occasion becoming gradually decrescendo. It is important to remember that after closure of the atrioventricular valves (S_1), a brief period occurs during which ventricular pressure increases but the semilunar valves remain closed (isovolumic contraction; see Fig. 471.4). Thus holosystolic murmurs (heard during both isovolumic contraction and the ejection phases of systole) cannot be caused by flow across the semilunar valves because these valves are closed during isovolumic contraction! Holosystolic murmurs must therefore be related to blood exiting the contracting ventricle via either an abnormal opening (VSD) or atrioventricular (mitral or tricuspid) valve insufficiency. Systolic ejection murmurs usually imply increased flow or stenosis across one of the ventricular outflow tracts (aortic or pulmonic). In infants with rapid heart rates, it is often difficult to distinguish between ejection and pansystolic murmurs. If a clear and distinct S_1 can be appreciated, the murmur is most likely ejection in nature.

A **continuous murmur** is a murmur that continues from systole into diastole and indicates continuous flow, such as in the presence of a PDA or other aortopulmonary communication. This murmur should be differentiated from a **to-and-fro murmur**, where the systolic component of the murmur ends at or before S_2 and the diastolic murmur begins after S_2 with semilunar valve closure (aortic stenosis and insufficiency; pulmonary stenosis and insufficiency). A **late systolic murmur** begins well beyond S_1 and continues until the end of systole and is usually heard after a midsystolic click in patients with mitral valve prolapse and insufficiency.

Pediatrics. 1987;79:1–25. Copyright 1987 by the American Academy of Pediatrics.)*

Several types of **diastolic murmurs** (graded I-IV) can be identified. A **decrescendo diastolic murmur** is a blowing murmur usually along the left sternal border that begins with S_2 and diminishes toward mid-diastole. When louder and high-pitched, this murmur is usually associated with aortic valve insufficiency or pulmonary insufficiency related to pulmonary hypertension. When softer and low-pitched, this murmur is usually associated with pulmonary valve insufficiency in the absence of pulmonary hypertension. A to-and-fro murmur is typically noted after surgical repair of the pulmonary outflow tract in patients with tetralogy of Fallot. A **rumbling mid-diastolic murmur** at the left mid and lower sternal border may be caused by increased blood flow across the tricuspid valve, such as occurs with ASD or, much less often, because of actual stenosis of this valve. When this murmur is heard at the apex, it is caused by increased flow across the mitral valve, such as occurs with large left-to-right shunts at the ventricular level (VSDs), at the great vessel level (PDA, aortopulmonary shunts), or with increased flow because of mitral insufficiency. When an apical diastolic rumbling murmur is longer and is accentuated at the end of diastole (presystolic), it usually indicates anatomic mitral valve stenosis.

The absence of a precordial murmur does not rule out significant congenital or acquired heart disease. Congenital heart defects, some of which are ductal dependent, may not demonstrate a murmur if the ductus arteriosus closes. These lesions include pulmonary or tricuspid valve atresia and transposition of the great arteries. Murmurs may seem insignificant in patients with ASDs, anomalous pulmonary venous return, some forms of atrioventricular septal defects, coarctation of the aorta, or anomalous origin of a coronary artery. Careful attention to other components of the physical examination (growth failure, cyanosis, peripheral pulses, precordial impulse, heart sounds) increases the index of suspicion of congenital heart defects in these patients. In contrast, loud murmurs may be present in the absence of structural heart disease, for example, in patients with a large noncardiac arteriovenous malformation, mitral regurgitation caused by left ventricular dilation associated with myocarditis or cardiomyopathy, and severe anemia.

Many murmurs are not associated with significant hemodynamic abnormalities. These murmurs are referred to as *functional, normal, insignificant,* or *innocent*. During routine random auscultation, >30% of children may have an innocent murmur at some time in their lives; this percentage increases when auscultation is done under nonbasal circumstances (high cardiac output because of fever, infection, or anxiety). The most common **innocent murmur** is a medium-loud, medium-pitched, vibratory or "musical," relatively short *systolic ejection murmur,* which is heard best along the left sternal border and has no significant radiation to the apex, base, or back. It is heard most frequently in children between 3 and 7 years of age. The intensity of the murmur often changes with respiration and position and may be attenuated or even disappear in the sitting or prone position. Innocent *pulmonic* murmurs are also common in children and adolescents and originate from normal turbulence during ejection into the pulmonary artery. These are higher pitched, brief, early systolic murmurs of grades I-II in intensity and are best heard in the second left parasternal space with the patient in the supine position. Features suggestive of heart disease include murmurs that are holosystolic, grade III or higher, harsh, located at the left upper sternal border, and associated with an early or midsystolic click or an abnormal S_2.

A **venous hum** is another example of a common innocent murmur heard during childhood. Venous hums are produced by turbulence of blood in the jugular venous system; they have no pathologic significance and may be heard in the neck or anterior portion of the upper part of the chest. Appreciated as a soft humming sound heard in both systole and diastole, it can be exaggerated or made to disappear by

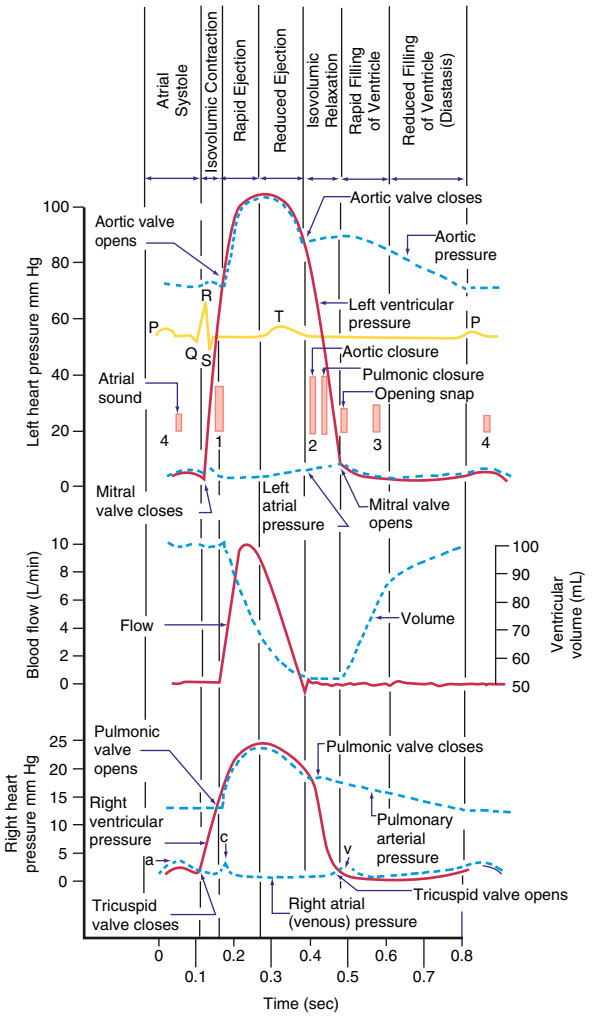

Fig. 471.4 Idealized diagram of the temporal events of a cardiac cycle (the Wiggers diagram).

varying the position of the head, or it can be decreased by lightly compressing the jugular venous system in the neck. These simple maneuvers are sufficient to differentiate a venous hum from the murmurs produced by organic cardiovascular disease, particularly a PDA.

The lack of significance of an innocent murmur should be discussed with the child's parents. It is important to offer complete reassurance because lingering doubts about the importance of a cardiac murmur may have profound effects on child-rearing practices, most often in the form of overprotectiveness. An underlying fear that a cardiac abnormality is present may negatively affect a child's self-image and development. The physician should explain that an innocent murmur is simply a "noise" and does not indicate the presence of a cardiac defect. When asked, "Will it go away?" the best response is to state that because the murmur has no clinical significance, it does not matter whether it "goes away." Parents should be warned that the intensity of the murmur might increase during febrile illnesses, a time when, typically, another physician may examine the child (e.g., in the emergency department). With growth, however, innocent murmurs are less well heard and often disappear completely. If there is a suspicion of structural heart disease, additional studies are indicated to rule out a congenital heart defect. However, "routine" electrocardiographic, chest radiographic, and echocardiographic examinations should be avoided in well children with a clearly innocent murmur.

Chapter 472

Laboratory Cardiac Evaluation

Daniel Bernstein

472.1 Radiologic Cardiac Assessment

Daniel Bernstein

Despite the widespread easy access to advanced imaging techniques, such as echocardiography, computed tomography (CT) scan, and magnetic resonance imaging (MRI), the chest x-ray film remains a highly valuable diagnostic tool and is often the first imaging study performed in a child suspected of having a cardiac defect. It can provide important information about cardiac size and shape, pulmonary blood flow (vascularity), pulmonary edema, and associated lung and thoracic anomalies that may be associated with congenital syndromes (e.g., skeletal dysplasias, extra or deficient number of ribs, abnormal vertebrae, diaphragmatic hernia, previous cardiac surgery). Combined with a careful physical examination, the chest radiograph can help the clinician to establish a diagnosis of congenital heart disease (CHD), as opposed to pulmonary disease, and to narrow the differential diagnosis to specific categories of CHD (e.g., left-to-right shunt lesions vs obstructive lesions).

The most frequently used measurement of cardiac size is the maximal width of the cardiac shadow in a posteroanterior (PA) chest film taken mid-inspiration. A vertical line is drawn down the middle of the sternal shadow, and perpendicular lines are drawn from the sternal line to the extreme right and left borders of the heart; the sum of the lengths of these lines is the **maximal cardiac width**. The **maximal chest width** is obtained by drawing a horizontal line between the right and left inner borders of the rib cage at the level of the top of the right diaphragm. When the maximal cardiac width is more than half the maximal chest width (cardiothoracic ratio >50%), the heart is usually enlarged. Cardiac size should be evaluated only when the film is taken during inspiration with the patient in an upright position, which can be difficult to achieve in younger patients. A diagnosis of "cardiac enlargement" on expiratory or prone films is a common cause of unnecessary referrals and laboratory studies.

The **cardiothoracic ratio** is a less useful index of cardiac enlargement in infants than in older children because the horizontal position of the heart may increase the ratio to about 60% in the absence of true enlargement. Furthermore, the thymus may overlap not only the base of the heart but also virtually the entire mediastinum, thus obscuring the true cardiac silhouette.

A *lateral* chest radiograph may be helpful in infants and in older children with pectus excavatum or other conditions that result in a narrow anteroposterior (AP) chest dimension. The heart may appear small in the lateral view and suggest that the apparent enlargement in the PA projection was caused by either the thymus (anterior mediastinum only) or flattening of the cardiac chambers as a result of a structural chest abnormality.

In the PA view, the left border of the cardiac shadow consists of three convex shadows produced, from above downward, by the aortic knob, the main and left pulmonary arteries, and the left ventricle (Fig. 472.1). In cases of moderate to marked left atrial enlargement, the atrium may be visualized between the pulmonary artery and the left ventricle. The right ventricular outflow tract (RVOT) does not contribute to the shadows formed by the left border of the heart. The aortic knob is not as easily seen in infants and children as in adults. The side of the aortic arch (left or right) can often be inferred as being opposite the side of the midline from which the air-filled trachea is visualized. This observation is important because a right-sided aortic arch is often present in

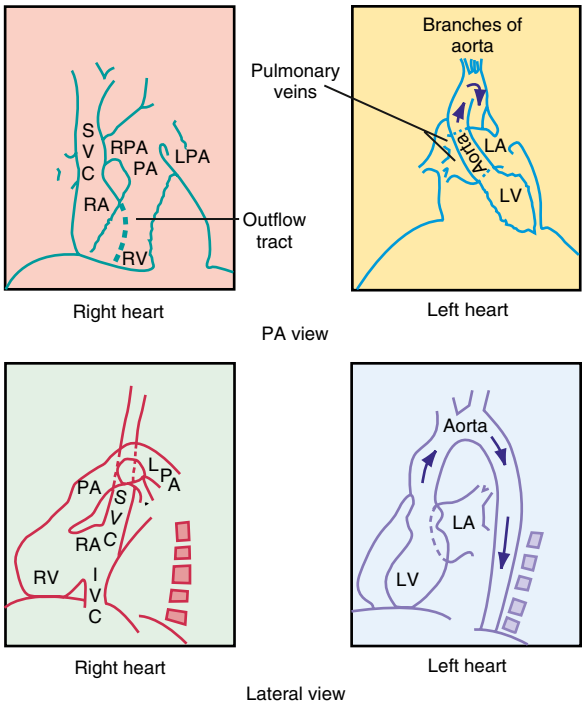

Fig. 472.1 Idealized diagrams showing normal position of the cardiac chambers and great blood vessels. IVC, Inferior vena cava; LA, left atrium; LPA, left pulmonary artery; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava. *(Adapted and redrawn from Dotter CT, Steinberg I. Angiocardiographic interpretation. Radiology. 1949;153:513.)*

cyanotic CHD, particularly in tetralogy of Fallot. Three structures contribute to the right border of the cardiac silhouette. In the view from above, they are the superior vena cava, the ascending aorta, and the right atrium.

Enlargement of cardiac chambers (i.e., increased chamber volume) or major arteries and veins results in prominence of the areas in which these structures are normally outlined on the chest radiograph. In contrast, the electrocardiogram is a more sensitive and accurate index of **ventricular hypertrophy**, which is a thickening of the ventricular wall and may or may not be associated with dilation of the affected cardiac chamber.

The chest radiograph is also an important tool for assessing the degree of pulmonary vascularity. **Pulmonary overcirculation** is usually associated with left-to-right shunt lesions, whereas **pulmonary undercirculation** is associated with obstruction of the RVOT in cyanotic lesions. The esophagus is closely related to the great vessels, and a barium esophagogram can help delineate these structures in the initial evaluation of suspected vascular rings, although this has largely been supplanted by CT.

Echocardiographic examination best defines the morphologic features of intracardiac chambers, cardiac valves, and intracardiac shunts. CT is used as an adjunct to echocardiogram to evaluate extracardiac vascular morphology. MRI is used most often to provide a more quantitative assessment of inflammation as well as ventricular volumes, cardiac function, and shunt and regurgitant fractions than is possible with echocardiogram.

472.2 Electrocardiography

Daniel Bernstein

DEVELOPMENTAL CHANGES

The marked changes that occur in cardiac physiology and chamber dominance during the perinatal transition (see Chapter 470) are reflected in the evolution of the electrocardiogram (ECG) during the neonatal period. Because vascular resistance in the pulmonary and systemic circulations is nearly equal in a term fetus, the intrauterine work of the heart results in an equal mass of both the right and left ventricles. After birth, systemic vascular resistance (SVR) rises when the placental circulation is eliminated, and pulmonary vascular resistance (PVR) falls when the lungs expand. These changes are reflected in the ECG over the first few weeks of life as the right ventricular (RV) wall begins to thin.

The ECG demonstrates these anatomic and hemodynamic features principally by changes in QRS and T-wave morphologic features. Typically, pediatric ECGs include several additional leads rarely used in adults, such as V_3R and V_4R, which are mirror images of leads V_3 and V_4 and are important in the evaluation of **right ventricular hypertrophy** (RVH). On occasion, lead V_1 is inappropriately positioned too far leftward to reflect RV forces accurately. This problem is present particularly in premature infants, in whom the electrocardiographic electrode gel may produce contact among all the precordial leads. An additional lead used in children is V_7, located more laterally than V_6 and useful for assessing left-sided forces.

During the first postnatal days of life, right axis deviation, large R waves, and upright T waves in the right precordial leads (V_3R or V_4R and V_1) are the norm (Fig. 472.2). As PVR decreases in the first few days after birth, the right precordial T waves become negative. In the great majority of cases, this change occurs within the first 48 hours of postnatal life. Upright T waves that persist in leads V_3R, V_4R, or V_1 beyond 1 week of life are an abnormal finding indicating RVH or RV strain, even in the absence of QRS voltage criteria. The T wave in V_1 should never be positive before 6 years of age; however, it may remain negative into adolescence or early adulthood. This finding represents one of the most important yet subtle differences between pediatric and adult ECGs and is a common source of error when adult cardiologists interpret pediatric ECGs.

In a newborn the mean **QRS frontal-plane axis** normally lies in the range of +110 to +180 degrees, reflecting the codominance of the fetal right and left ventricles. The right-sided chest leads reveal a larger positive **(R)** than negative **(S)** wave and may do so for months because the right ventricle remains relatively thick throughout early infancy. Left-sided leads (V_5 and V_6) also reflect right-sided dominance in the early neonatal period, when the R:S ratio in these leads may be <1. A dominant R wave in V_5 and V_6, reflecting left ventricular (LV) forces, quickly becomes evident within the first few days of life (Fig. 472.3). As the child matures, the QRS axis gradually shifts leftward and the RV forces slowly regress. Leads V_1, V_3R, and V_4R display a prominent R wave until 6 months to 8 years of age. Most children have an R:S ratio >1 in lead V_4R until age 4 years. The T waves are inverted in leads V_4R, V_1, V_2, and V_3 during infancy and may remain so into the middle of the second decade of life and beyond. The processes of RV thinning and LV growth are best reflected in the QRS-T pattern over the right precordial leads. The diagnosis of RVH or left ventricular hypertrophy (LVH) in a pediatric patient can be made only with an understanding of the normal developmental physiology of these chambers at various ages until adulthood is reached. As the left ventricle becomes dominant, the ECG evolves to the characteristic pattern of older children (Fig. 472.4) and adults (Fig. 472.5).

Ventricular hypertrophy usually results in increased voltage in the R and S waves in the chest leads. The height of these deflections is governed by the proximity of the specific electrode to the surface of the heart; by the sequence of electrical activation through the ventricles, which can result in variable degrees of cancellation of right vs left forces; and by hypertrophy of the myocardium.

The diagnosis of **pathologic RVH** is difficult in the first week of postnatal life because physiologic RVH is a normal finding. Serial tracings are often necessary to determine whether marked right axis deviation and potentially abnormal right precordial forces or T waves, or both, will persist beyond the neonatal period (Fig. 472.6). In contrast, an adult ECG pattern (see Fig. 472.5) seen in a neonate suggests LVH. The exception is a premature infant, who may display a more "mature" ECG than a full-term infant (Fig. 472.7) as a result of lower PVR secondary

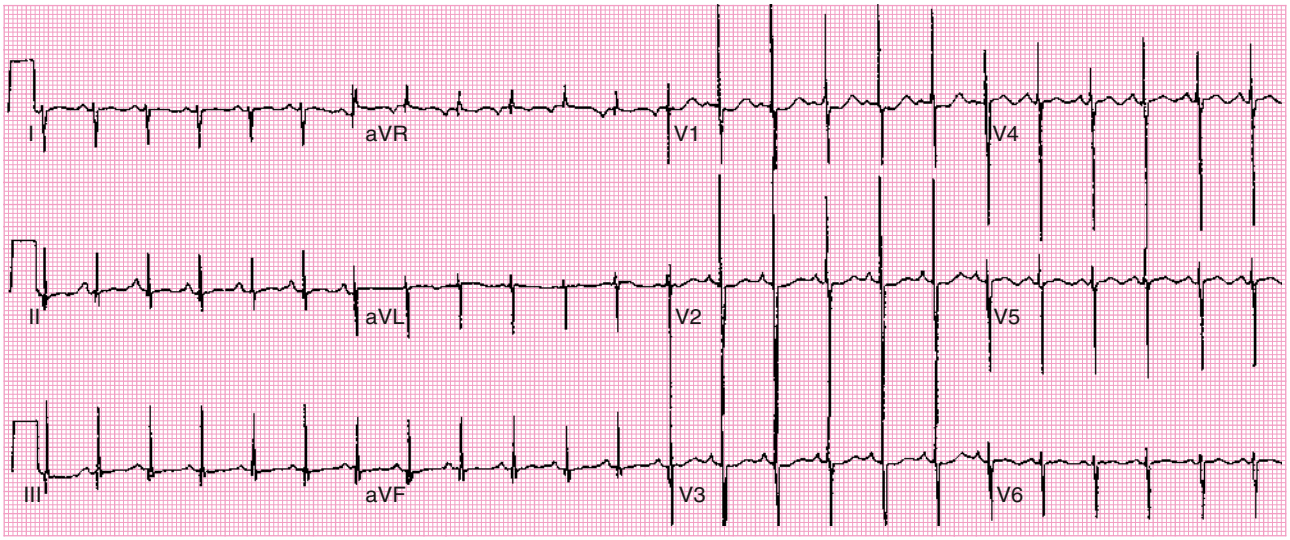

Fig. 472.2 Normal ECG from a 5-day-old, term-gestation infant. The frontal plane QRS axis is 150 degrees. There is prominent voltage in the precordial leads and a suggestion of right ventricular preponderance but not right ventricular hypertrophy. The QRS duration is 60 ms. *(From Gering LE, Knilans TK, Surawicz B, et al. Normal electrocardiograms in the fetus, infants, and children. In: Surawicz B, Knilans TK. Chou's Electrocardiography in Clinical Practice, 6th ed. Philadelphia: Saunders; 2008: Fig. 28.2, p. 651).*

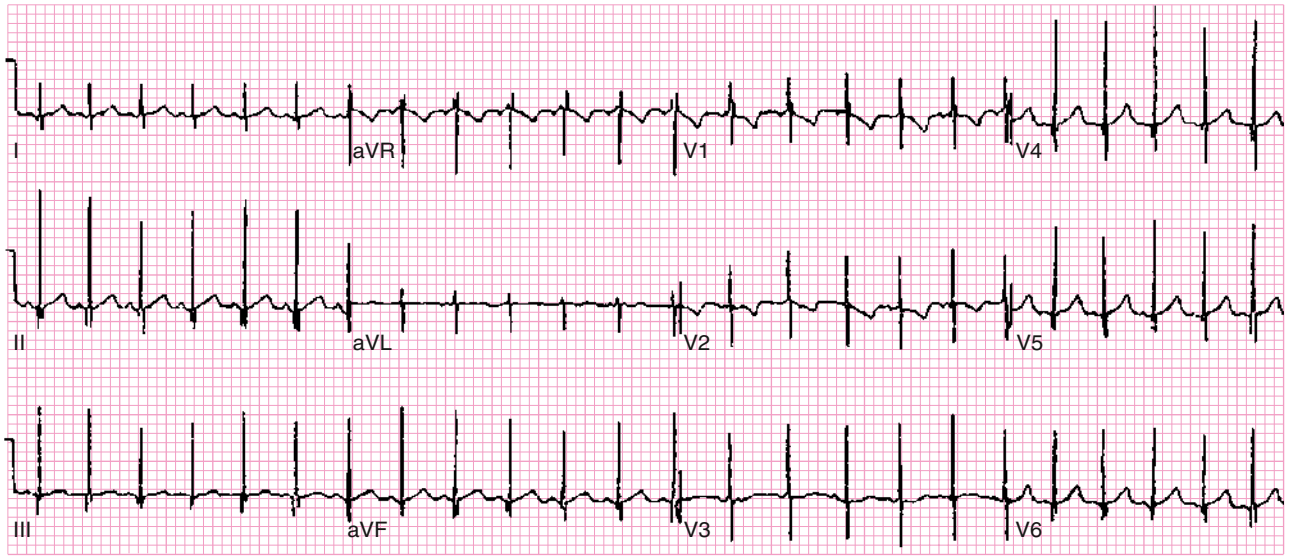

Fig. 472.3 Normal ECG from a healthy 8-mo-old infant. The frontal plane QRS axis is 60 degrees. There is less evidence of right ventricular preponderance than in the newborn tracing, with a smaller R wave in lead V_1 and smaller S wave in lead V_6. *(From Gering LE, Knilans TK, Surawicz B, et al. Normal electrocardiograms in the fetus, infants, and children. In: Surawicz B, Knilans TK. Chou's Electrocardiography in Clinical Practice, 6th ed. Philadelphia: Saunders; 2008: Fig. 28.3, p. 652).*

to underdevelopment of the medial muscular layer of the pulmonary arterioles. Some premature infants display a pattern of generalized low voltage across the precordium.

The ECG should always be evaluated systematically to avoid overlooking a minor but important abnormality. One approach is to begin with an assessment of rate and rhythm, followed by a calculation of the mean frontal-plane QRS axis, measurements of segment intervals, assessment of voltages, and lastly assessment of ST and T-wave abnormalities.

RATE AND RHYTHM

A brief rhythm strip should be examined to assess whether a P wave always precedes each QRS complex. Using the full 12-lead ECG, the P-wave axis should then be estimated as an indication of whether the rhythm is originating from the **sinus node**. If the atria are situated normally in the chest, the P-wave axis should be oriented downward and to the left (i.e., should be upright in leads I and aVF and inverted in lead aVR). With atrial inversion **(situs inversus)**, the P wave may be inverted in lead I. Inverted P waves in leads II and aVF are seen in low atrial, nodal, or junctional rhythms. The absence of P waves indicates a rhythm originating more distally in the conduction system. In this case, the morphologic features of the QRS complexes are important in differentiating a **junctional** (usually a narrow QRS complex) from a **ventricular** (usually a wide QRS complex) rhythm.

P WAVES

Tall (>2.5 mm), narrow, and spiked P waves are indicative of **right atrial enlargement** and are seen in pulmonary stenosis, Ebstein anomaly of the tricuspid valve, tricuspid atresia, and sometimes cor pulmonale. These abnormal waves are most obvious in leads II, V_3R,

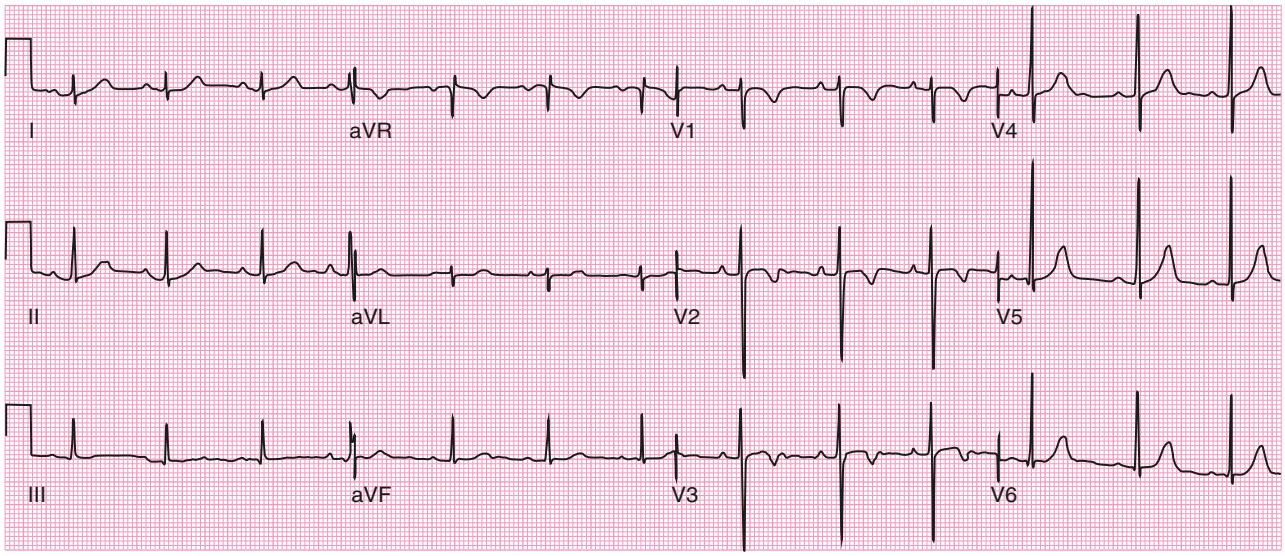

Fig. 472.4 Normal ECG from a healthy 3-yr-old child. The frontal plane QRS axis is 60 degrees. The R/S ratio in lead V_1 is less than 1, and there is no appreciable S wave in lead V_6. The R wave in lead V_6 is more prominent than that of the infant, suggesting more left ventricular preponderance but not left ventricular hypertrophy. *(From Gering LE, Knilans TK, Surawicz B, et al. Normal electrocardiograms in the fetus, infants, and children. In: Surawicz B, Knilans TK. Chou's Electrocardiography in Clinical Practice, 6th ed. Philadelphia: Saunders; 2008: Fig. 28.4, p. 652).*

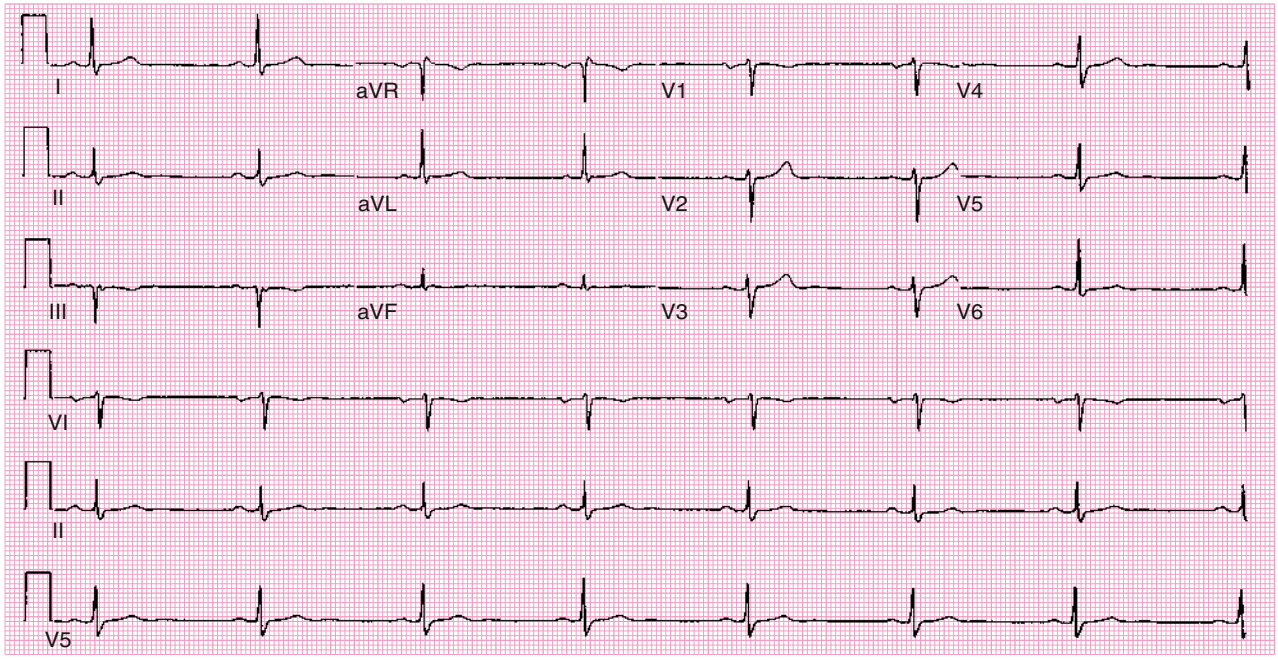

Fig. 472.5 Electrocardiogram of a normal 17-yr-old, a member of the school's track team. At this age the ECG should be similar to that in a normal adult: the dominant wave in V_1 should be the S wave and there is a normal R-wave progression, growing taller across the precordium from right to left. The heart rate is slow at 43 bpm (sinus bradycardia), which can be typical of a performance athlete. Note that all precordial lead T waves are positive, except for V_1. This R-wave progression pattern in a young infant, where there should be right ventricular dominance, would indicate the presence of left ventricular hypertrophy.

and V_1 (Fig. 472.8A). Similar waves are sometimes seen in thyrotoxicosis. **Broad P waves**, commonly **bifid** and sometimes **biphasic**, are indicative of **left atrial enlargement** (Fig. 472.8B). They are seen in some patients with large left-to-right shunts (ventricular septal defect [VSD], patent ductus arteriosus) and with severe mitral stenosis or mitral regurgitation. Left atrial enlargement, however, is one of the most common false-positive readings generated by computerized ECG machines. Flat P waves may be encountered in patients with hyperkalemia.

QRS COMPLEX

Right Ventricular Hypertrophy

For the most accurate assessment of ventricular hypertrophy, pediatric ECGs should include the right precordial leads V_3R and V_4R. The diagnosis of RVH depends on demonstration of the following changes (see Fig. 472.6): (1) a qR pattern in the RV surface leads; (2) a positive T wave in leads V_3R-V_4R and V_1-V_3 between ages 6 days and 6 years; (3) a monophasic R wave in V_3R, V_4R, or V_1; (4) an rsR′ pattern in the right precordial leads with the second R wave

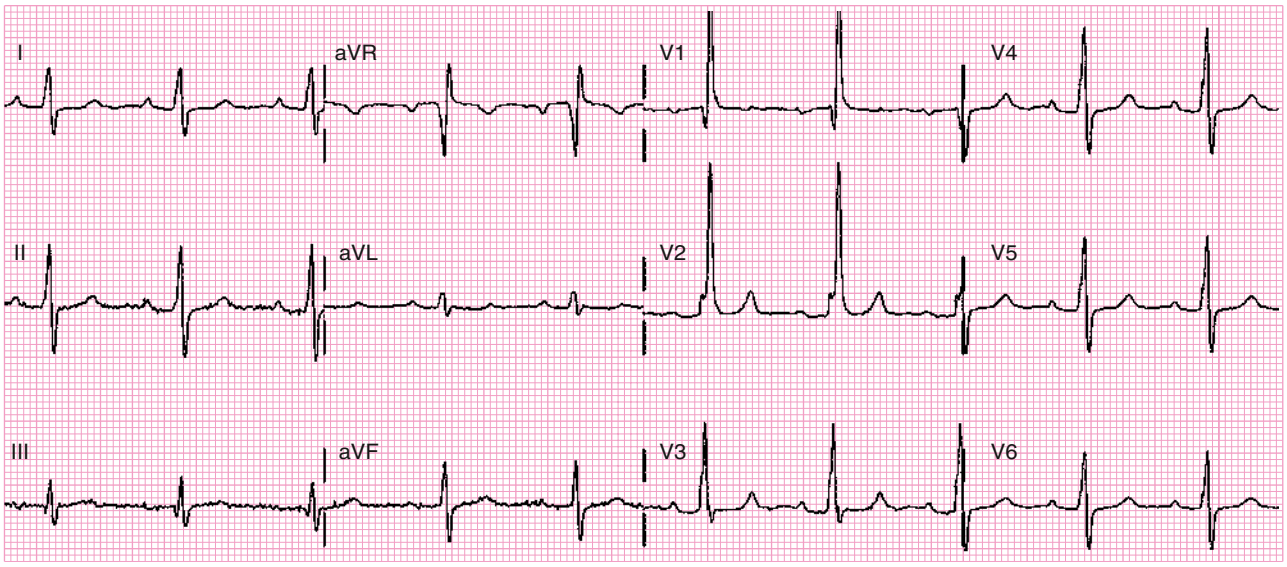

Fig. 472.6 Electrocardiogram of an infant with right ventricular hypertrophy (tetralogy of Fallot). Note the tall R waves in the right precordial leads (V_1-V_2) and deep S waves in V_6. The R-wave progression (taller in the right precordial leads vs the left) is counter to the normal pattern.

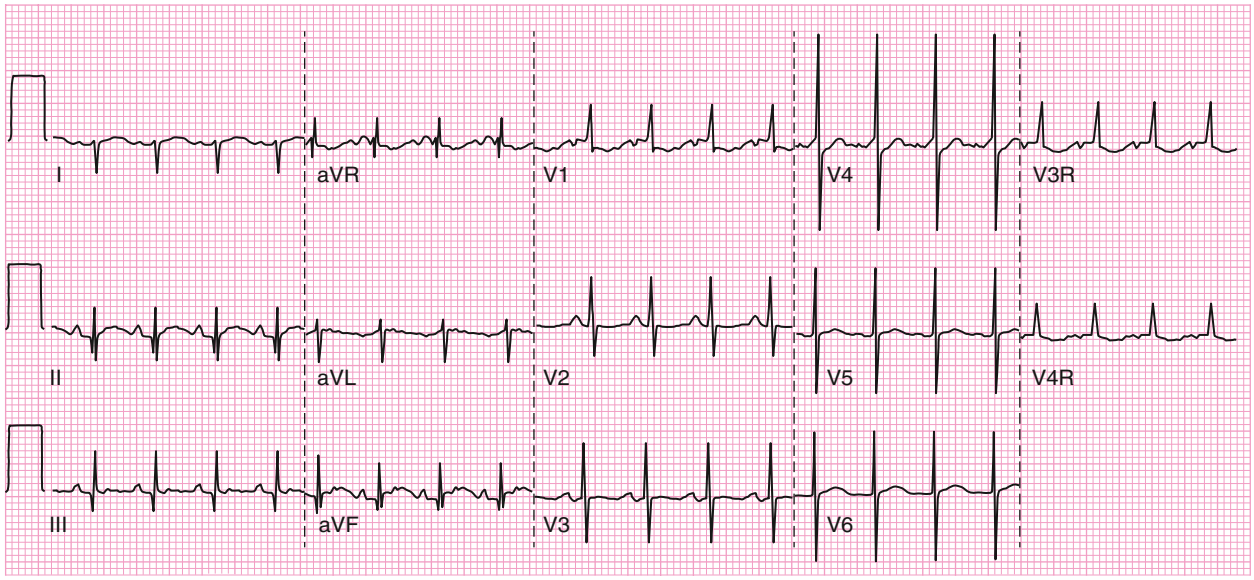

Fig. 472.7 Normal ECG from an 8-day-old, 28-wk-gestation premature infant. The frontal plane QRS axis is 150 degrees, there is a monophasic R wave in lead V_1, and the R/S ratio is less than 1 in lead V_6. This illustrates relative right ventricular preponderance without right ventricular hypertrophy. The QRS duration is less than 40 ms. *(From Gering LE, Knilans TK, Surawicz B, Tavel ME. Normal electrocardiograms in the fetus, infants, and children. In: Surawicz B, Knilans TK. Chou's Electrocardiography in Clinical Practice, 6th ed. Philadelphia: Saunders; 2008: Fig. 28.1, p. 650).*

taller than the first; (5) age-corrected increased voltage of the R wave in leads V_3R-V_4R or the S wave in leads V_6-V_7, or both; (6) marked right axis deviation (>120 degrees in patients beyond the newborn period); and (7) complete reversal of the normal adult precordial RS pattern. At least two of these changes should be present to support a diagnosis of RVH.

Abnormal ventricular loading can be characterized as either pressure overload (as a result of RVOT obstruction, as in pulmonic stenosis) or volume overload (as a result of a left-to-right shunt as in atrial septal defect [ASD], semilunar valve regurgitation, or dilated cardiomyopathy). These two types of abnormal loads result in distinct electrocardiographic patterns. The **pressure overload pattern** is characterized by tall, pure R waves in the right precordial leads. In older children, the T waves in these leads are initially upright and later become inverted. In infants and children <6 years, the T waves in V_3R-V_4R and V_1 are abnormally upright. The **volume overload pattern** (typically seen in patients with ASD) is characterized by an rsR′ pattern (Fig. 472.9) and a slightly increased QRS duration (which is known as a *minor right ventricular conduction delay* rather than a true bundle branch block). Patients with mild to moderate pulmonary stenosis may also exhibit an rsR′ pattern in the right precordial leads.

Left Ventricular Hypertrophy

The following features indicate the presence of LVH (Fig. 472.10): (1) increased voltage (for age) of the S wave in V_3R and V_1 or the R wave in V_6-V_7, or both. In older children and adults, the criteria for LVH **(Sokolow index)** is a combination of S wave in V_1 or V_2 plus R wave in V_5 or V_6 ≥35 mm and (2) a deep Q wave in the left precordial leads. Remember that an infant with an ECG that would be considered "normal" for an older child may in fact have LVH; therefore reference to

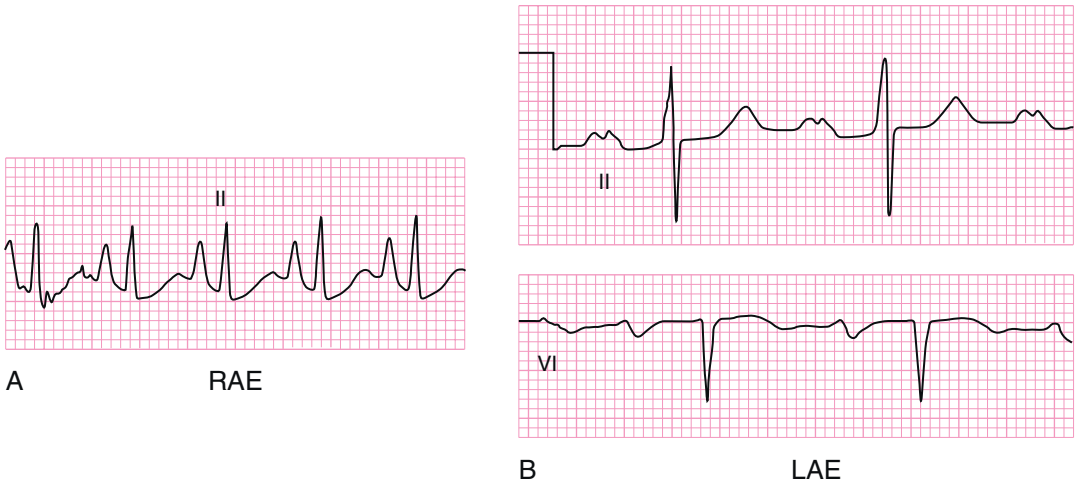

Fig. 472.8 Atrial enlargement. **A,** Peaked narrow P waves in lead II characteristic of right atrial enlargement (RAE). **B,** Wide, bifid, M-shaped P waves in lead II and biphasic p waves in lead V_1 typical of left atrial enlargement (LAE).

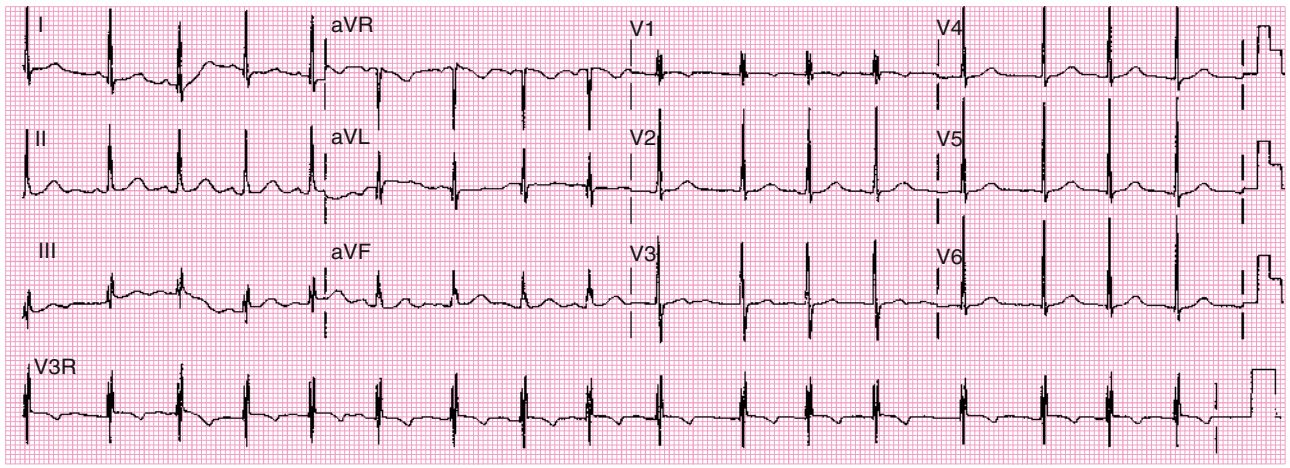

Fig. 472.9 Electrocardiogram showing a minor right ventricular conduction delay characterized by an RsR′ pattern in V_1. Note that the QRS duration is not prolonged (60 msec) as it would be if this were a right bundle branch block (RBBB).

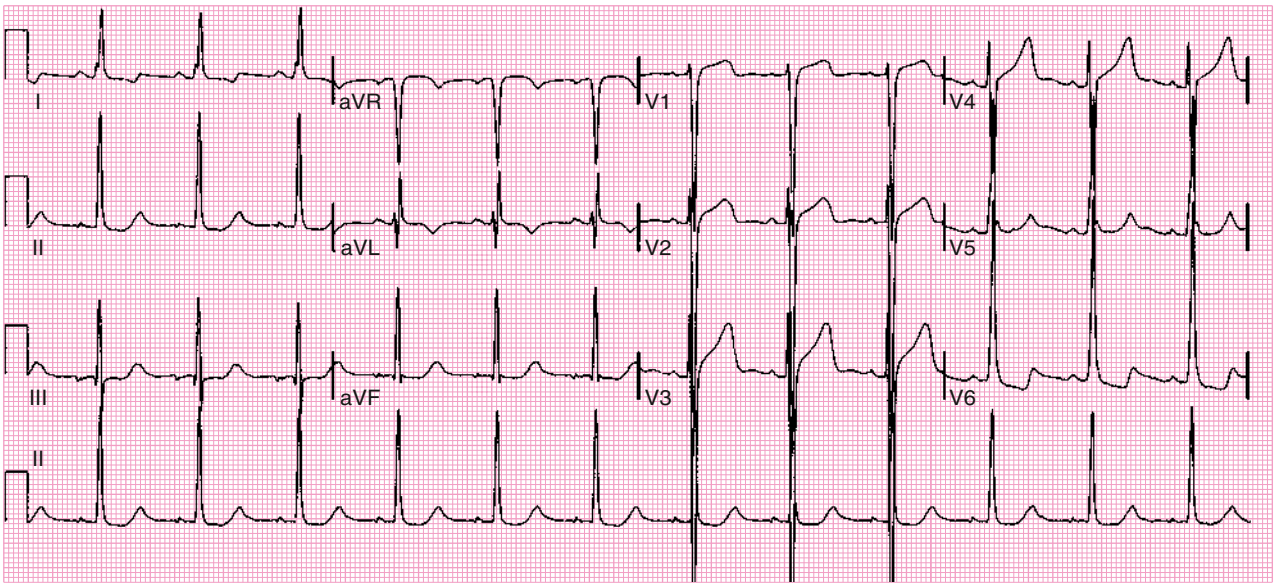

Fig. 472.10 Electrocardiogram showing left ventricular hypertrophy (LVH) in a 12-yr-old child with aortic stenosis. Note the deep S waves in V_1-V_3 and tall R in V_5-V_6. In addition, T-wave inversion is present in lead V_6, a sign of left ventricular strain.

standard voltages for age is always important. Further evidence for LVH includes depression of the ST segments and inversion of the T waves in the left precordial leads (V_5, V_6, and V_7), known as a **left ventricular strain** pattern—these findings suggest the presence of more severe hypertrophy.

Bundle Branch Block

A complete **right bundle branch block** (RBBB; prolonged QRS complex, which is usually upright with an rSR′ in lead V_1; wide S wave in lead V_6) may be congenital or may be acquired after surgery for CHD, especially when a right ventriculotomy has been performed, as in repair of the tetralogy of Fallot. **Left bundle branch block** (LBBB; prolonged QRS complex, which is usually upright with an rSR′ in lead V_6; wide S wave in lead V_1) is less common in children; this pattern is often seen in adults with cardiomyopathy, but much less in children with cardiomyopathy. LBBB may be seen after surgery on the aortic or mitral valve caused by surgical injury to one of the left-sided conduction bundles. Alternatively, a bundle branch block pattern may be indicative of a bypass tract associated with one of the preexcitation syndromes (see Chapter 484).

P-R AND Q-T INTERVALS

The duration of the P-R interval shortens with increasing heart rate; assessment of this interval should be based on age- and rate-corrected nomograms. A long P-R interval is diagnostic of a **first-degree heart block**, the cause of which may be congenital, postoperative (after open heart surgery), inflammatory (myocarditis, pericarditis, Lyme disease, rheumatic fever), or pharmacologic (digitalis, calcium channel blockers).

The duration of the Q-T interval varies with the cardiac rate; a corrected Q-T interval (Q-Tc) can be calculated by dividing the measured Q-T interval by the square root of the preceding R-R interval. A normal Q-Tc should be <0.45. It is often lengthened with hypokalemia and hypocalcemia; in the former, a U wave may be noted at the end of the T wave (Fig. 472.11). A significant number of medications can also lengthen the Q-T interval, so a careful history of medication exposure is important in evaluating a patient with a borderline or long QT interval. A congenitally prolonged Q-T interval may also be seen in children with one of the long QT syndromes (Fig. 472.12). These patients are at high risk for ventricular arrhythmias, including a dangerous form of ventricular tachycardia known as **torsades de pointes**, and sudden death (see Chapter 484.5).

ST SEGMENT AND T-WAVE ABNORMALITIES

Coronary ischemia, leading to typical ST and T-wave abnormalities seen in adults, is rare in children. A slight elevation of the ST segment is often seen in normal teenagers, especially males, and is attributed to **early repolarization** of the heart (Fig. 472.13). It can sometimes be difficult to distinguish between ischemic ST segment changes and benign early repolarization; however, the following characteristics suggest early repolarization: (1) ST elevation limited to the lateral leads (V_5-V_6), (2) a characteristic notch at the J point (junction between the end of the QRS and the beginning of the ST segment), and (3) a concave rather than convex ST segment. Lack of any concerning symptoms is also critical. Early repolarization often resolves with exercise-induced tachycardia. In pericarditis, irritation of the epicardium may cause elevation of the ST segment, followed by abnormal T-wave inversion as healing progresses.

Depression of the ST segment may also occur in coronary ischemia or in any condition that produces myocardial injury, including severe anemia, carbon monoxide poisoning, glycogen storage disease of the heart, myocardial tumors, and mucopolysaccharidoses. An aberrant origin of the left coronary artery from the pulmonary artery may lead to changes indistinguishable from those of acute myocardial infarction in adults. ECG findings of ischemia may be seen in patients with Kawasaki disease who have developed coronary artery aneurysms (see Chapters 208 and 493.1). Similar changes may occur in patients with other rare abnormalities of the coronary arteries and in those with cardiomyopathy, even in the presence of normal coronary arteries. These patterns are often misread in young infants because of the unfamiliarity of pediatricians with this "infarct" pattern, and thus a high index of suspicion must be maintained in infants with dilated cardiomyopathy or with symptoms compatible with coronary ischemia (e.g., inconsolable crying).

Fig. 472.12 Prolonged Q-T interval in a patient with long QT syndrome.

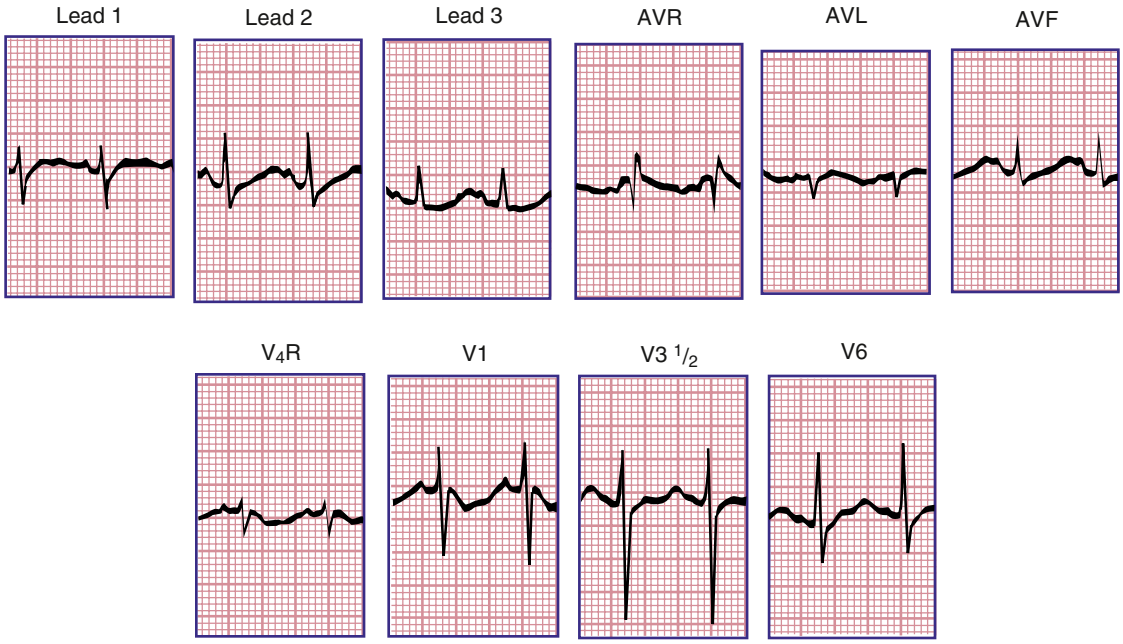

Fig. 472.11 Electrocardiogram in hypokalemia. Serum potassium, 2.7 mEq/L; serum calcium, 4.8 mEq/L at the time of the tracing. Note the widened TU wave and depression of the ST segment in V_4R, V_1, and V_6.

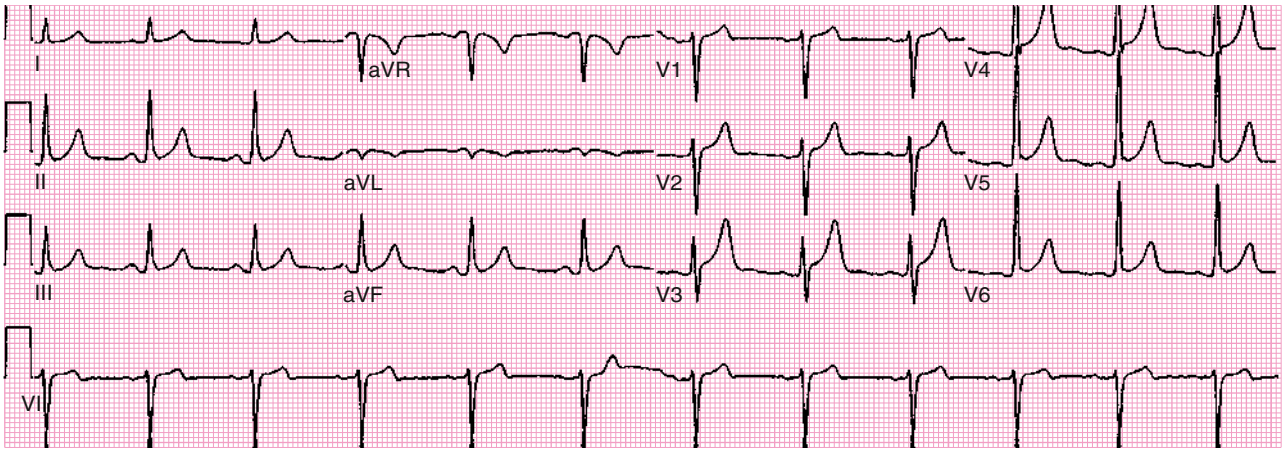

Fig. 472.13 Early repolarization seen in the mid-precordial to lateral leads (V_2-V_5) in a teenage boy. These minor ST segment elevations, with typical concave slope and combined with a high J point, suggest this is a benign variant and not true ischemia.

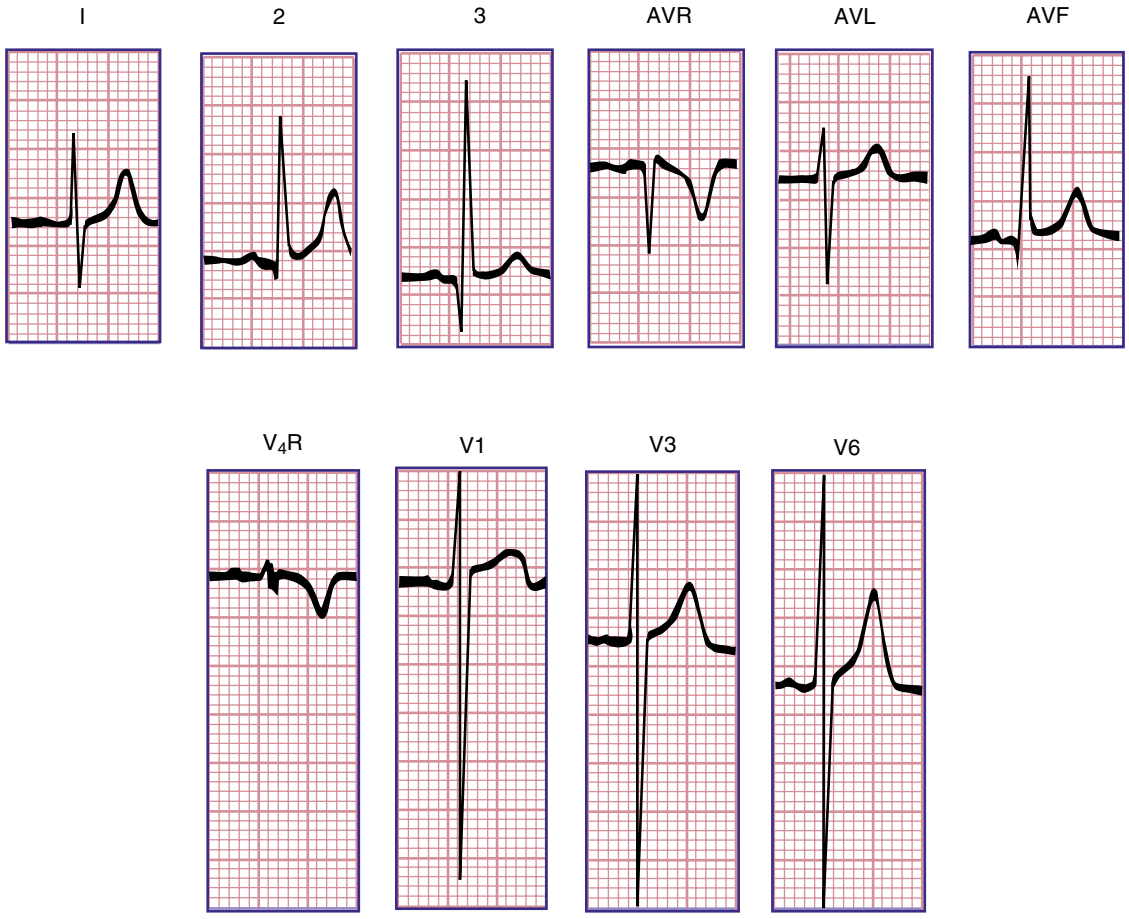

Fig. 472.14 Electrocardiogram in hyperkalemia. Serum potassium, 6.5 mEq/L. Note the tall, tent-shaped T waves, especially in leads 1, 2, and V_6.

T-wave inversion may occur in myocarditis and pericarditis, or it may be a sign of either RVH or LVH and ventricular strain. Hypothyroidism may produce flat or inverted T waves in association with generalized low voltage. In hyperkalemia, the T waves are usually of high voltage and are tent shaped (Fig. 472.14), although tall T waves can be an early sign of myocardial infarction.

472.3 Hematologic Data in Cardiovascular Evaluation

Daniel Bernstein

In acyanotic infants with large left-to-right shunts, the onset of heart failure often coincides with the nadir of the normal physiologic anemia of infancy. Increasing the hematocrit in these patients to >40% may decrease shunt volume and result in an improvement in symptoms; however, this form of treatment is generally reserved for infants who are not otherwise surgical candidates (extremely premature infants or others in whom surgery is delayed for other reasons). In these select infants, regular evaluation of the hematocrit and booster transfusions when appropriate may be helpful in improving growth.

Polycythemia is frequently noted in chronically *cyanotic* patients with right-to-left shunts. Patients with severe polycythemia, rarely seen in this age of early surgical repair, are in a delicate balance between the risks of intravascular thrombosis and a bleeding diathesis. The preparation of cyanotic, polycythemic patients for elective noncardiac surgery, such as dental extraction, includes evaluation and treatment of abnormal coagulation.

Because of the high viscosity of polycythemic blood (hematocrit >65%), patients with unrepaired cyanotic CHD are at risk for the development of **vascular thromboses**, especially of cerebral veins. Dehydration increases the risk of thrombosis, and thus adequate fluid intake must be maintained during hot weather or intercurrent gastrointestinal illnesses. Diuretics should be used with caution in these patients and may need to be decreased if fluid intake is a concern. Polycythemic infants with concomitant **iron deficiency** are at even greater risk for cerebrovascular accidents, thought to be the result of the decreased deformability of microcytic red blood cells. Iron therapy may reduce this risk, but surgical repair of the cardiac anomaly is the best therapy.

Severely cyanotic patients who are inoperable should have periodic determinations of hemoglobin and hematocrit. Increasing polycythemia is often associated with headache, fatigue, dyspnea, or a combination of these conditions. Partial exchange transfusion may be required to treat symptomatic (most often headache or chest pain) individuals whose hematocrit has risen to the 65–70% level. This procedure is not without risk, especially in patients with an extreme elevation in pulmonary vascular resistance. Because these patients do not tolerate wide fluctuations in circulating blood volume, blood should be replaced with fresh-frozen plasma or albumin.

472.4 Echocardiography

Daniel Bernstein

Transthoracic echocardiography (TTE) has replaced cardiac catheterization for the *diagnosis* of most forms of CHD. The echocardiographic examination can be used to evaluate cardiac structures in congenital heart lesions using two-dimensional (2D) and three-dimensional (3D) imaging, estimate intracardiac pressures and gradients across stenotic valves and vessels using **echo-Doppler** and color flow Doppler, quantitate cardiac contractile function (both systolic and diastolic), determine the direction of flow across a defect, examine the integrity of the coronary arteries, and detect the presence of vegetations from endocarditis, pericardial fluid, cardiac tumors, and chamber thrombi.

Echocardiography may also be used to assist in the performance of interventional procedures, including pericardiocentesis, balloon atrial septostomy (see Chapter 480.2), ASD or VSD closure, transcatheter valve implantation, and endocardial biopsy. **Transesophageal echocardiography** (TEE) is used routinely to monitor ventricular function in patients during surgical procedures and can provide an immediate assessment of the results of surgical repair of congenital heart lesions. A complete TTE examination usually entails a combination of M-mode and 2D and 3D imaging, as well as pulsed, continuous, and color Doppler flow studies. Doppler tissue imaging provides a more quantitative assessment of ventricular systolic and diastolic function.

M-MODE ECHOCARDIOGRAPHY

M-mode echocardiography displays a one-dimensional slice of cardiac structure varying over time (Fig. 472.15). It is used mostly for the measurement of cardiac dimensions (wall thickness and chamber size) and cardiac function (fractional shortening, wall thickening). M-mode echocardiography is also useful for assessing the motion of intracardiac structures: the opening and closing of valves and movement of free walls and septa (Fig. 472.16). The most frequently used index of cardiac function in children is **percent fractional shortening** (%FS), which contrasts to adults, where **ejection fraction** is the most common functional measurement. %FS is calculated as (LVED − LVES)/LVED, where LVED is left ventricular dimension at end diastole and LVES is left ventricular dimension at end systole. Normal fractional shortening is approximately 28–42%. Other M-mode indices of cardiac function include the mean velocity of fiber shortening (mean V_{CF}), systolic time intervals (LVPEP = LV preejection period, LVET = LV ejection time), and isovolemic contraction time. M-mode assessments of cardiac function are more susceptible to errors because of differences in wall motion between different segments of the heart (more frequently seen in adults with ischemic heart disease, but which can be seen in

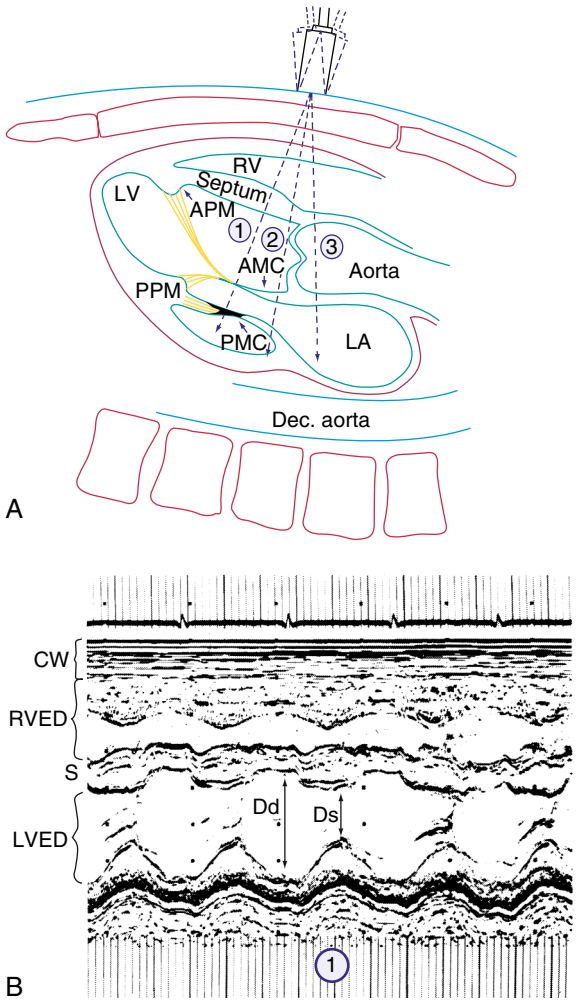

Fig. 472.15 M-mode echocardiogram. A, Diagram of a sagittal section of a heart showing the structures traversed by the echo beam as it is moved superiorly to positions (1), (2), and (3). B, Echocardiogram from transducer position (1); this view is the best one for measuring cardiac dimensions and fractional shortening. Fractional shortening is calculated as (LVED − LVES)/LVED. AMC, Anterior mitral cusp; APM, anterior papillary muscle; Dec. aorta, descending aorta; LA, left atrium; LV, left ventricle; PMC, posterior mitral cusp; PPM, posterior papillary muscle; RV, right ventricle. CW, Chest wall; Ds, LV dimension in systole; LVED, LV dimension at end diastole (Dd); RVED, RV dimension at end diastole.

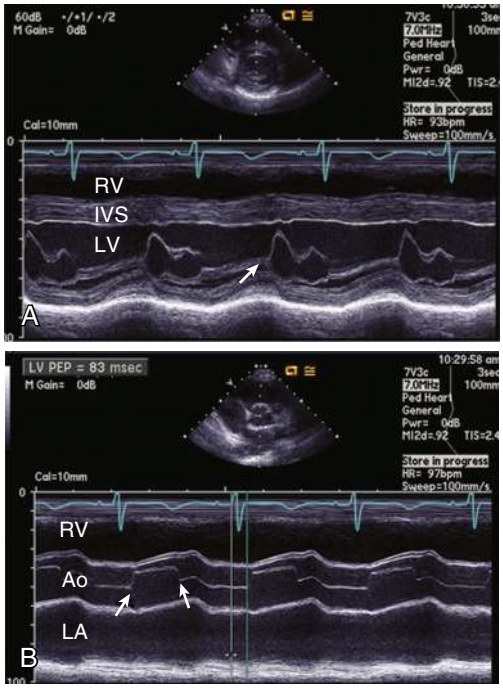

Fig. 472.16 M-mode echocardiograms. The small figure at the top of each panel shows the 2D parasternal short-axis echocardiogram image from which the M-modes are derived. The cursor can be seen midway through the image, indicating the one-dimensional line through which the M-mode is being sampled. **A,** M-mode echocardiogram of a normal mitral valve. *Arrow* shows the opening of the anterior leaflet in early diastole (see ECG tracing earlier for reference). **B,** M-mode echocardiogram of a normal aortic valve. The opening and closing of the aortic leaflets in systole are outlined by the two *arrows*. Ao, Aorta; IVS, interventricular septum; LV, left ventricle; RV, right ventricle.

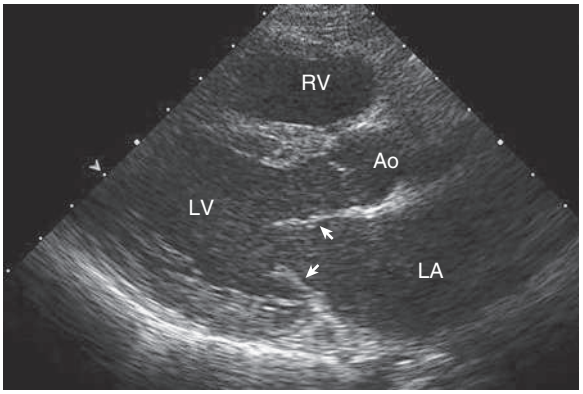

Fig. 472.17 Normal parasternal long-axis echocardiographic window. The transducer is angulated slightly posteriorly, imaging the left-sided cardiac structures. If the transducer were to be angulated more anteriorly, the right ventricular structures would be imaged. The mitral valve leaflets can be seen in the partially open position in early diastole *(arrows)*. The closed aortic valve leaflets can be seen just below the label Ao (aorta). LA, Left atrium; LV, left ventricle; RV, right ventricle.

children with congenital and acquired heart disease, especially after surgical repair).

TWO-DIMENSIONAL ECHOCARDIOGRAPHY

Two-dimensional echocardiography provides a real-time image of cardiac structures. The contracting heart is imaged using several standard views, including parasternal long axis (Fig. 472.17), parasternal short axis (Fig. 472.18), apical four-chamber (Fig. 472.19), subcostal (Fig. 472.20), and suprasternal (Fig. 472.21), each of which emphasizes specific structures. Two-dimensional echocardiography

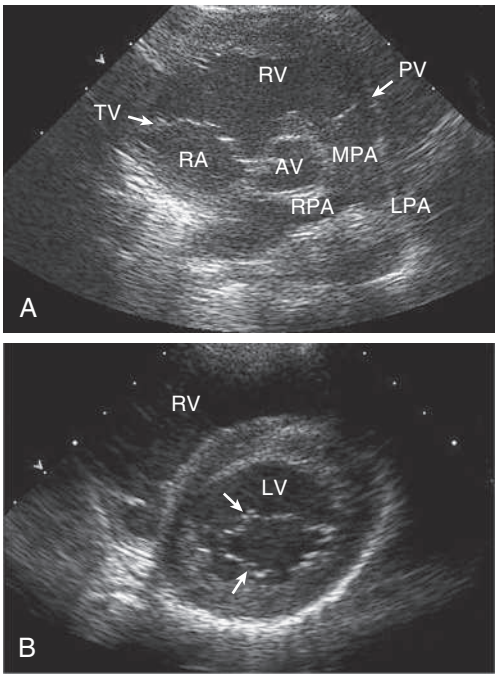

Fig. 472.18 Normal parasternal short-axis echocardiographic windows. **A,** With the transducer angled superiorly and rightward, the aortic valve (AV) is imaged, surrounded by both inflow and outflow portions of the right ventricle (RV). **B,** With the transducer angled inferiorly and leftward, the left ventricular chamber is imaged along with a cross-sectional view of the mitral valve *(arrows)*. LPA, Left pulmonary artery; MPA, main pulmonary artery; PV, pulmonary valve; RA, right atrium; RPA, right pulmonary artery; TV, tricuspid valve. LV, left ventricle; RV, right ventricle.

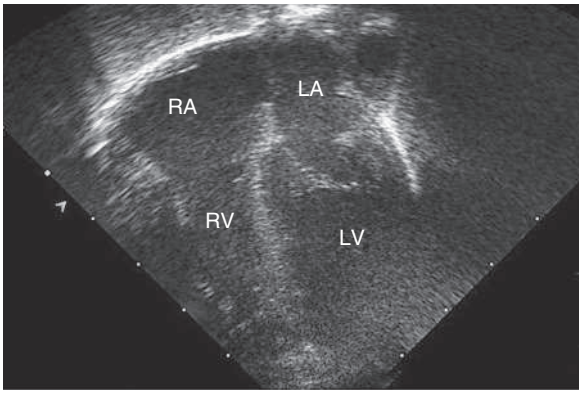

Fig. 472.19 Normal apical four-chamber echocardiographic window showing all four cardiac chambers and both atrioventricular valves opened in diastole. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

has replaced cardiac angiography for the preoperative diagnosis and follow-up of the vast majority of congenital heart lesions. However, when information from the cardiac examination or other studies is not consistent with the echocardiogram, or in very complex defects, cardiac catheterization remains an important tool to confirm the anatomic diagnosis and evaluate the degree of physiologic derangement. MRI is an extremely valuable adjunct to provide a better quantification of ventricular size and function. Cardiac CT is another modality that is valuable to assess cardiac and adjacent vascular structures.

DOPPLER ECHOCARDIOGRAPHY

Doppler echocardiography displays blood flow based on the change in frequency imparted to sound waves by the movement of

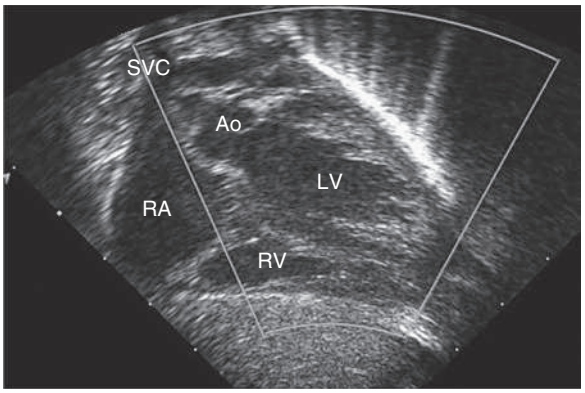

Fig. 472.20 Normal subcostal echocardiographic window showing the left ventricular outflow tract. The right-sided structures are not fully imaged in this view. Ao, Ascending aorta; LV, left ventricle; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

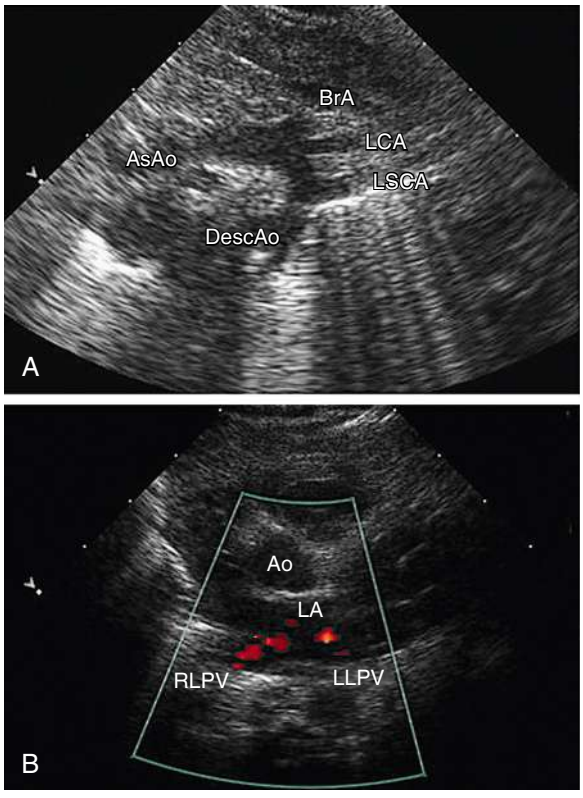

Fig. 472.21 **A,** Normal suprasternal echocardiographic window showing the aortic arch and its major branches. **B,** Normal high parasternal window showing color Doppler imaging of normal pulmonary venous return to the left atrium (LA) of both right (RLPV) and left (LLPV) lower pulmonary veins. AsAo, Ascending aorta; BrA, brachiocephalic artery; DescAo, descending aorta; LCA, left carotid artery; LSCA, left subclavian artery.

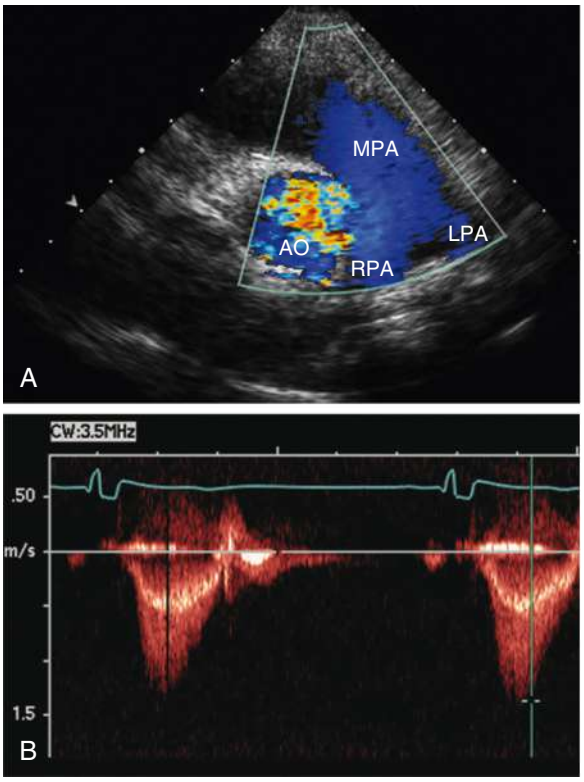

Fig. 472.22 Color and pulsed Doppler evaluation of pulmonary arterial flow. **A,** Color Doppler evaluation of a parasternal short-axis view showing normal flow through the pulmonary valve to the main and branch pulmonary arteries. The color of the Doppler flow is *blue,* indicating that the flow is moving away from the transducer (which is located at the top of the figure, at the apex of the *triangular* ultrasound window). Note that the color assigned to the Doppler signal does not indicate the oxygen saturation of the blood. **B,** Pulsed-wave Doppler flow pattern through the pulmonary valve showing a low velocity of flow (<1.5 m/sec), indicating the absence of a pressure gradient across the valve. The envelope of the flow signal is below the line, indicating that the flow is moving away from the transducer. AO, Aorta; LPA, left pulmonary artery; MPA, main pulmonary artery; RPA, right pulmonary artery.

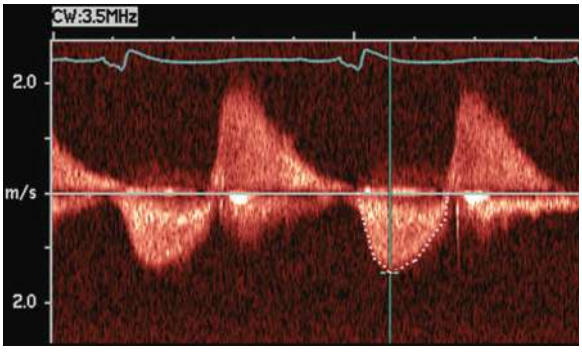

Fig. 472.23 Doppler evaluation of a patient who had previously undergone repair of tetralogy of Fallot and who has mild pulmonary stenosis and moderate pulmonary regurgitation. The tracing shows the to-and-fro flow across the pulmonary valve, with the signal below the line representing forward flow in systole (see ECG tracing for reference) and the signal above the line representing regurgitation during diastole.

erythrocytes. The speed and direction of blood flow in the line of the echo beam change the transducer's reference frequency. This frequency change can be translated into volumetric flow (L/min) data for estimating systemic or pulmonary blood flow and into pressure (mm Hg) data for estimating gradients across valves or across septal defects or vascular communications such as shunts. Color Doppler permits highly accurate assessment of the presence and direction of intracardiac shunts and allows identification of small or multiple left-to-right or right-to-left shunts (Fig. 472.22). The severity of valvular insufficiency can be evaluated qualitatively with both pulsed and color Doppler (Fig. 472.23). Alterations in venous Doppler flow patterns can be used to detect abnormalities of systemic and pulmonary veins, and alterations of atrioventricular valve Doppler flow patterns can be used to assess ventricular

diastolic functional abnormalities, particularly the **E/A ratio**, the ratio of peak velocity flow in diastole (i.e., the ratio of the early diastole E wave to the peak velocity flow in late diastole caused by atrial contraction).

M-mode, 2D, and Doppler echocardiographic methods of assessing LV systolic and diastolic function (e.g., end-systolic wall stress, dobutamine stress echocardiography, Doppler tissue imaging) have proved useful in the serial assessment of patients at risk for the development of both systolic and diastolic ventricular dysfunction and ventricular dyssynchrony (where the coordination of left and right ventricular contraction is abnormal). Such patients include those with cardiomyopathies, those receiving anthracycline drugs for cancer chemotherapy, those at risk for iron overload, and those being monitored for rejection or coronary artery disease after heart transplantation.

THREE-DIMENSIONAL ECHOCARDIOGRAPHY

Real-time 3D echocardiographic reconstruction is most valuable for the detailed assessment of cardiac morphology (Fig. 472.24). Details of valve structure, the size and location of septal defects, abnormalities of the ventricular myocardium, and details of the great vessels, which may not be as readily apparent using 2D imaging, can often be appreciated on 3D echocardiography. Reconstruction of the view that the surgeon will encounter in the operating room makes this technique a valuable adjunct for preoperative imaging.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

TEE is a sensitive imaging technique that produces a clearer view of smaller lesions such as vegetations in endocarditis, especially in larger patients. It is useful in visualizing posteriorly located structures such as the atria, aortic root, and atrioventricular valves. TEE is useful as an intraoperative technique for monitoring cardiac function during both cardiac and noncardiac surgery and for screening for residual cardiac defects after the patient is initially weaned from cardiopulmonary bypass but before being disconnected from the bypass circuit. This technique has been especially helpful in evaluating the degree of residual regurgitation or stenosis after valve repairs and in searching for small muscular VSDs that may have been missed during the closure of larger defects. It is always preferable to make the diagnosis of **excessive valve regurgitation** while the patient is still in the operating room, so that the repair can be revised or the valve replaced, rather than after surgery, when the patient is already in the postoperative care unit. However, hemodynamic measurements made while the chest is open and the patient is still under anesthesia may be different from those made under more normal conditions, as when the patient is ready to be discharged from the hospital.

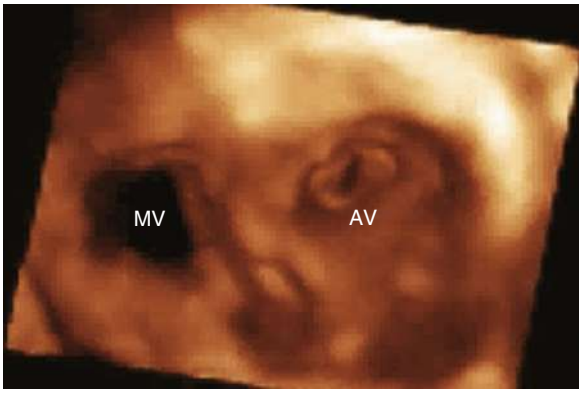

Fig. 472.24 Three-dimensional echocardiogram showing a short-axis view of the left ventricle. AV, Aortic valve; MV, mitral valve. *(Courtesy Dr. Norman Silverman, Stanford University, Stanford, CA.)*

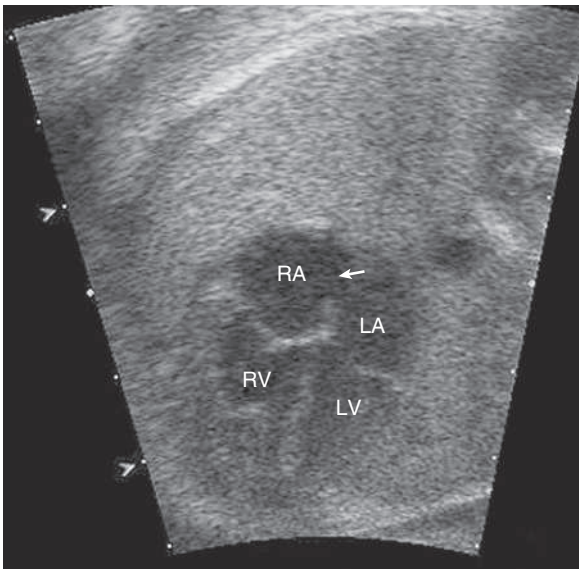

Fig. 472.25 Normal four-chamber view echocardiogram on a fetus at 20 wk of gestation. The foramen ovale *(arrow)* can be seen between the right and left atria. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

FETAL ECHOCARDIOGRAPHY

Fetal echocardiography can be used to evaluate cardiac structures and function or disturbances in cardiac rhythm (Fig. 472.25). Obstetricians may detect a possible heart defect when screening during routine obstetric ultrasonography (e.g., cardiac four-chamber view) or may refer the patient because of unexplained hydrops fetalis, a family history of CHD, or a maternal condition associated with fetal cardiac pathology, such as gestational diabetes, drug use, or infection. Fetal echocardiography can diagnose most significant congenital heart lesions as early as 17-19 weeks of gestation; accuracy at this early stage is limited, however, and families should understand that these studies cannot totally eliminate the possibility of CHD. Serial fetal echocardiograms have also demonstrated the importance of flow disturbance in the pathogenesis of CHD; such studies can show the intrauterine progression of a moderate lesion, such as aortic stenosis, into a more severe lesion, such as **hypoplastic left heart syndrome** (HLHS). M-mode echocardiography can diagnose rhythm disturbances in the fetus and can determine the success of antiarrhythmic therapy administered to the mother. A screening fetal echocardiogram is recommended for women with a previous child or first-degree relative with CHD, for those who are at higher risk of having a child with cardiac disease (e.g., insulin-dependent diabetes, women exposed to teratogenic drugs during early pregnancy), and in any fetus in whom a chromosomal abnormality is suspected or confirmed.

Early detection provides the opportunity to counsel and educate the parents about the severity of the cardiac lesion and potential therapeutic or palliative care options. Referral to a high-risk perinatal service is then performed for further ultrasound screening for associated anomalies of other organs and potential amniocentesis or sequencing of cell-free DNA in maternal blood for karyotyping. For fetuses with ductal dependent lesions, delivery can be planned at a tertiary care center, enhancing safety by avoiding the requirement for postnatal transport of an unstable infant. For fetuses with complex CHD at high risk for complications immediately at birth (e.g., HLHS with intact atrial septum), delivery can be arranged with an operating room and surgeon standing by. In utero treatment of CHD is an experimental procedure, with the most common procedure being aortic balloon valvuloplasty for HLHS.

472.5 Exercise Testing

Daniel Bernstein

The normal cardiorespiratory system adapts to the extensive demands of exercise with a several-fold increase in oxygen consumption and cardiac output. Because of the large reserve capacity for exercise, significant abnormalities in cardiovascular performance may be present without symptoms at rest or during ordinary activities. When patients are evaluated in a resting state, significant abnormalities in cardiac function may not be appreciated, or if detected, their implications for quality of life may not be recognized. Permission for children with cardiovascular disease to participate in various forms of physical activity is frequently based on totally subjective criteria. As the importance of aerobic exercise is increasingly recognized, even for children with complex congenital heart lesions, exercise testing can provide a quantitative evaluation of the child's ability to participate safely in both competitive and noncompetitive sports. Exercise testing can also play an important role in evaluating symptoms and quantitating the severity of cardiac abnormalities. In children with coronary artery abnormalities (e.g., Kawasaki disease or COVID-19 with coronary aneurysms), exercise testing can detect ischemia that might otherwise be overlooked.

In older children, exercise studies are generally performed on a graded treadmill apparatus with timed intervals of increasing grade and speed. In younger children, exercise studies are often performed on a bicycle ergometer. Many laboratories have the capacity to measure both cardiac and pulmonary function noninvasively during exercise. This allows measurement of both resting and maximal oxygen consumption (Vo_{2max}) and the point at which anaerobic threshold is reached, which are important indicators of cardiovascular fitness.

As a child grows, the capacity for muscle work is enhanced with increased body size and skeletal muscle mass. All indices of cardiopulmonary function do not increase in a uniform manner. A major response to exercise is an increase in cardiac output, principally achieved through an increase in heart rate, but stroke volume (SV), systemic venous return, and pulse pressure are also increased. SVR is greatly decreased as the blood vessels in working muscle dilate in response to increasing metabolic demands. As the child becomes older and larger, the response of the heart rate to exercise remains prominent, but cardiac output increases because of growing cardiac volume capacity and thus SV. Responses to dynamic exercise are not dependent solely on age. For any given body surface area, boys have a larger SV than size-matched girls. This increase is also mediated by posture. Augmentation of SV with upright, dynamic exercise is facilitated by the pumping action of working muscles, which overcomes the static effect of gravity and increases systemic venous return.

Dynamic exercise testing defines not only endurance and exercise capacity but also the effect of such exercise on myocardial blood flow and cardiac rhythm. Significant ST segment depression or elevation reflects abnormalities in myocardial perfusion, such as might occur during exercise in children with extremely hypertrophied left ventricles. The **exercise ECG** is considered abnormal if the ST segment depression is >2 mm and extends for at least 0.06 seconds after the J point (onset of the ST segment) in conjunction with a horizontal-, upward-, or downward-sloping ST segment. A decrease in blood pressure before maximal exercise is reached is regarded as a risk indicator in patients with hypertrophic cardiomyopathy. Provocation of rhythm disturbances during an exercise study is an important method of evaluating select patients with known or suspected rhythm disorders. The effect of pharmacologic management can also be tested in this manner.

472.6 Cardiac Imaging Studies

Daniel Bernstein

Magnetic resonance imaging (MRI) and **magnetic resonance angiography (MRA)** are extremely helpful in the diagnosis and management of patients with CHD and inflammatory lesions (Table 472.1). These techniques produce tomographic images of the heart in any projection (Fig. 472.26 and Fig. 472.27), with excellent contrast resolution of fat, myocardium, and lung, as well as moving blood from blood vessel walls. MRI is useful in evaluating areas that are less well visualized by echocardiography, such as distal branch pulmonary artery anatomy and anomalies in systemic and pulmonary venous return.

MRA allows the acquisition of images in several tomographic planes. Within each plane, images are obtained at different phases of the cardiac cycle. Thus when displayed in a dynamic "cine" format, changes in wall thickening, chamber volume, and valve function can be displayed and analyzed. Blood flow velocity and blood flow volume can be calculated. MRA is an excellent technique for following patients serially after repair of complex CHD, such as tetralogy of Fallot. In these patients, MRA can be used to assess RV volume and mass and to quantify the amount of regurgitation through either the pulmonary or tricuspid valve. Other MRI techniques, such as myocardial delayed enhancement and tissue T1 weighting, can be used to quantify areas of myocardial scar in patients with cardiomyopathy or in patients after CHD repair, especially tetralogy of Fallot. **Magnetic resonance spectroscopy**, predominantly a research tool at present, provides a means of demonstrating relative concentrations of high-energy metabolites (adenosine triphosphate, adenosine diphosphate, inorganic phosphate, and phosphocreatine) within regions of the working myocardium.

Computer processing of MRA images allows the noninvasive visualization of the cardiovascular system from inside of the heart or vessels, a technique known as *fly-through imaging.* These images allow the cardiologist to image the interiors of various cardiovascular structures (Fig. 472.28). These techniques are especially helpful in imaging complex peripheral arterial stenoses.

CT scanning can be used to perform rapid, respiration-gated cardiac imaging in children with resolutions down to 0.5 mm. Three-dimensional reconstruction of CT images is especially useful in evaluating branch pulmonary arteries, anomalies in systemic and pulmonary venous return, and great vessel anomalies such as coarctation of the aorta (Fig. 472.29).

Radionuclide angiography may be used to detect and quantify shunts and to analyze the distribution of blood flow to each lung. This technique is particularly useful in quantifying the volume of blood flow distribution between the two lungs in patients with abnormalities of the pulmonary vascular tree or to quantify the success of balloon angioplasty and intravascular stenting procedures. Gated blood pool scanning can be used to calculate hemodynamic measurements, quantify valvular regurgitation, and detect regional wall motion abnormalities. Thallium imaging can be performed to evaluate cardiac muscle perfusion. These methods can be used at the bedside of seriously ill children and can be performed serially, with minimal discomfort and low radiation exposure.

472.7 Diagnostic and Interventional Cardiac Catheterization

Daniel Bernstein

The catheterization laboratory, once the site for initial diagnosis of CHD, has become the center of high-technology interventional procedures, allowing for the nonsurgical repair or palliation of heart defects that once required open heart surgery. Some centers have developed

Table 472.1 Cardiac MRI Assessment of Myocardial Inflammation

CAUSE	SPECIFIC CAUSE OF MECHANISM	KEY MRI FINDING
Infection	Infectious agents can induce cardiac injury by directly infecting cardiomyocytes or through cellular or humoral immune activation Viral: Enteroviruses, coronaviruses, adenoviruses, parvovirus B19, Herpesviridae 6, CMV, EBV, HIV, influenza; SARS-CoV-2 can infect cardiomyocytes by binding to the ACE2 receptor, although immune dysregulation is likely a more prominent mechanism of myocardial injury Bacterial: *Borrelia burgdorferi* (Lyme disease), *Treponema pallidum,* group A streptococcus (likely postinfectious) Protozoal: *Trypanosoma cruzi* (Chagas disease), *Toxoplasma gondii* Parasitic: *Echinococcus granulosus, Trichinella spiralis*	**Viral myocarditis:** Linear subepicardial or midwall LGE, commonly involving the basal inferolateral wall, basal anterior septum, mid-inferolateral wall, and basal to mid-inferior wall, with corresponding T2 hyperintensity or high T2 **Chagas disease:** LGE present in up to 70% of patients, most commonly at the left ventricular apex, apical inferior and lateral wall, and basal to mid-inferolateral wall; LGE is usually midwall or subepicardial and, less commonly, subendocardial or transmural with apical aneurysms **Bacterial and parasitic myocarditis:** Limited data on MRI findings with no specific pattern **COVID-19:** Findings may be similar to non-COVID viral myocarditis, although some studies have indicated a higher prevalence of diffuse myocardial edema, with global elevation of T1 and T2 mapping values
Postvaccination	mRNA COVID-19 vaccines: Proposed mechanisms include immune activation and dysregulation and molecular mimicry between viral spike protein and an unknown cardiac protein	**mRNA COVID-19 vaccination:** There are currently limited MRI data, mostly from case series to date; MRI findings appear to be typical for viral myocarditis, although the severity and extent of MRI abnormalities reported have been relatively mild; axillary lymphadenopathy ipsilateral to the vaccination site may be present and may be a useful clue, particularly if a history of recent vaccine administration is not provided
Systemic disease	Several systemic diseases are associated with myocardial inflammation: Vasculitides: EGPA, Kawasaki disease Connective tissue disorders: Systemic sclerosis, SLE, rheumatoid arthritis, dermatomyositis Granulomatous disease: Sarcoidosis	**EGPA:** MRI findings include patchy midwall and subepicardial LGE with corresponding T2 hyperintensity and subendocardial apical LGE with or without apical thrombus; concomitant pulmonary opacities might be present **SLE:** Patchy or linear midwall and subepicardial LGE in one third of patients; elevated T1 and T2 value decrease after antiinflammatory treatment; higher prevalence of pericardial and pleural effusion and thickening than in other causes of myocarditis **Sarcoidosis**: Patchy and nodular LGE with associated high T2, most common at the basal septum and basal inferolateral segment; associated findings include mediastinal and hilar lymphadenopathy and pulmonary opacities
Drug related	Hypersensitivity reactions: Penicillin, cephalosporins, benzodiazepines, tricyclic antidepressants Toxic reactions: Anthracyclines, amphetamines, cyclophosphamide Immune activation or dysregulation: ICI-related myocarditis	**ICI-related myocarditis**: Diffusely elevated T1 and T2 values in 78% and 43% of patients, respectively; in one study, only 48% of patients met both T1 and T2 modified Lake Louise criteria; LGE present in 48% of patients, most commonly subepicardial or midmyocardial, and predominating in the basal and mid-inferior and inferolateral segments
Other	Hypereosinophilic syndrome, cocaine, postradiation injury, thyrotoxicosis, giant cell myocarditis	**Hypereosinophilic syndrome:** Similar MRI findings to EGPA, with higher prevalence of subendocardial LGE **Giant cell myocarditis:** MRI appearance is similar to cardiac sarcoidosis, although LGE tends to be more extensive and right ventricular involvement more common

ACE2, Angiotensin-converting enzyme 2; CMV, cytomegalovirus; EBV, Epstein-Barr virus; EGPA, eosinophilic granulomatosis with polyangiitis; ICI, immune checkpoint inhibitor; LGE, late gadolinium enhancement; SLE, systemic lupus erythematosus.
From Sanchez Tijmes F, Thavendiranathan P, Udell JA, et al. Cardiac MRI assessment of nonischemic myocardial inflammation: state of the art review and update on myocarditis associated with COVID-19 vaccination. *Radiol Cardiothorac Imaging.* 2021;3(6):e210252, Table 1.

hybrid catheterization laboratories, combining standard fluoroscopic imaging with an operating suite, allowing combined approaches to treat complex congenital heart lesions.

DIAGNOSTIC CARDIAC CATHETERIZATION

Diagnostic catheterization is still performed (1) to assist in the initial diagnosis of some complex congenital heart lesions (e.g., tetralogy of Fallot with pulmonary atresia and major aortopulmonary collateral arteries, pulmonary atresia with intact ventricular septum and coronary sinusoids, HLHS with mitral stenosis); (2) in cases in which other imaging studies are equivocal; (3) in patients for whom hemodynamic assessment is critical (to determine the size of a left-to-right shunt in borderline cases or to determine the presence or absence of pulmonary vascular disease in an older patient with a left-to-right shunt); (4) between stages of repair of complex CHD (e.g., hypoplastic left or right heart syndromes); (5) for long-term surveillance of patients with complex CHD (e.g., after Fontan palliation for single ventricles); (6) for myocardial biopsy in the diagnosis of cardiomyopathy or in screening for cardiac rejection after cardiac transplantation; and (7) for electrophysiologic study in the evaluation of cardiac arrhythmias (see Chapter 484).

Cardiac catheterization should be performed with the patient in as close to a basal state as possible. Conscious sedation or low-level anesthesia is routine. If a deeper level of general anesthesia is required, careful choice of an anesthetic agent is warranted to avoid depression of cardiovascular function and subsequent distortion of the calculations of cardiac output, PVR and SVR, and shunt ratios.

Cardiac catheterization in critically ill infants with CHD should be performed in a center where a pediatric cardiovascular surgical team is available in the event that an operation is required immediately afterward. The complication rate of cardiac catheterization is greatest in critically ill infants; they must be studied in a thermally neutral

environment and monitored closely for hypothermia, hypoglycemia, acidosis, or excessive blood loss.

Catheterization may be limited to the right-sided cardiac structures, the left-sided structures, or both the right and left sides of the heart. The catheter is passed into the heart under fluoroscopic guidance through a percutaneous entry point in a femoral or jugular vein. In infants and in a number of older children, the left side of the heart can be accessed by passing the catheter across a patent foramen ovale to the left atrium and left ventricle. If the foramen is closed, the left side of the heart can be catheterized by passing the catheter retrograde via a percutaneous entry site in the femoral artery or, if necessary, via a transatrial septal puncture. The catheter can also be manipulated through abnormal intracardiac defects (ASD, VSD). Blood samples are obtained for measuring oxygen saturation in each cardiac chamber or blood vessel, allowing the calculation of shunt volumes. Pressures are measured for gradients across septal defects or valves and for calculating valve areas. Radiopaque contrast is injected to delineate cardiac and vascular structures. A catheter with a thermosensor tip (Swan-Ganz catheter) can be used to measure cardiac output by thermodilution. Specialized catheters can be used to measure more sophisticated indices of cardiac function; those with pressure-transducer tips can measure the first derivative of LV pressure (dP/dt). Conductance catheters can be used to generate pressure-volume loops, from which indices of both contractility (end-systolic elastance) and relaxation can be

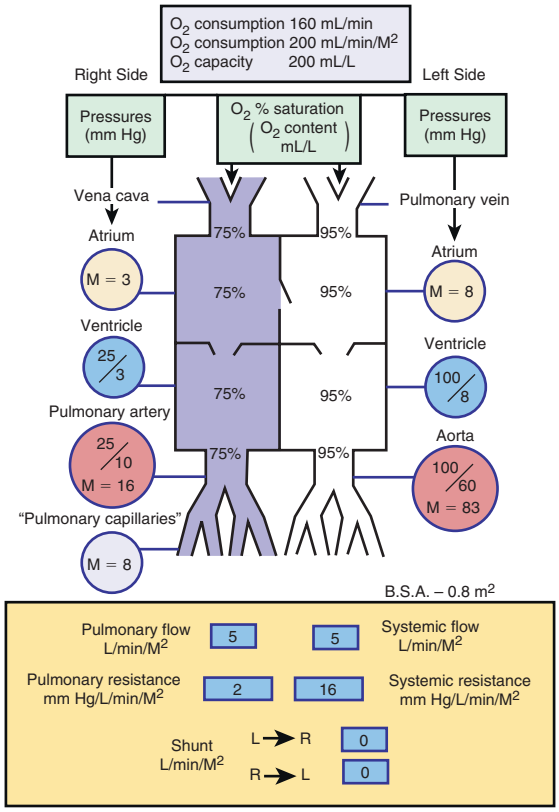

Fig. 472.30 Diagram of normal circulatory dynamics with pressure readings, oxygen content, and percent saturation. B.S.A., body surface area. *(Modified from Nadas AS, Fyler DC. Pediatric Cardiology, 3rd ed. Philadelphia: Saunders; 1972.)*

derived, although these are almost exclusively used in research studies. Complete hemodynamics can be calculated, including cardiac output, intracardiac left-to-right and right-to-left shunts, and SVR and PVR. Figure 472.30 depicts normal circulatory dynamics.

THERMODILUTION MEASUREMENT OF CARDIAC OUTPUT

The thermodilution method for measuring cardiac output is performed with a flow-directed, thermistor-tipped Swan-Ganz catheter. A known change in the heat content of the blood is induced at one point in the circulation (usually the right atrium or inferior vena cava) by injecting room-temperature saline, and the resultant change in temperature is detected at a point downstream (usually the pulmonary artery). This method is used to measure cardiac output in the catheterization laboratory in patients without shunts. Monitoring cardiac output by the thermodilution method can occasionally be useful in managing critically ill infants and children in an intensive care setting after cardiac surgery or in the presence of shock. In this case, a triple-lumen catheter is used for both cardiac output determination and measurement of pulmonary artery and pulmonary capillary wedge pressures.

ANGIOCARDIOGRAPHY

The major blood vessels and individual cardiac chambers may be visualized by selective injection of contrast material into specific chambers or great vessels. **Fluoroscopy** is used to visualize the catheter as it passes through the various heart chambers. After the cardiac catheter is properly placed in the chamber to be studied, contrast medium is injected with a power injector and cineangiograms are exposed. Modern catheterization labs use digital imaging technology, allowing for a significant reduction in radiation exposure. **Biplane cineangiocardiography** allows detailed evaluation of specific cardiac chambers and blood vessels in two planes simultaneously with the injection of a single bolus of contrast material. Various angled views (e.g., left anterior oblique, cranial angulation) are used to display specific anatomic features optimally in individual lesions.

Rapid injection of contrast medium under pressure into the circulation is not without risk, and each injection should be carefully planned. Contrast agents consist of hypertonic solutions, with some containing organic iodides, which can cause complications, including nausea, a generalized burning sensation, central nervous system symptoms, renal insufficiency, and allergic reactions. For patients with known renal insufficiency who require angiography, there are protocols to protect the kidneys involving prehydration and medications. Hypertonicity of the contrast medium may result in transient myocardial depression and a drop in blood pressure, followed soon afterward by tachycardia, an increase in cardiac output, and a shift of interstitial fluid into the circulation. This shift can transiently increase the symptoms of heart failure in critically ill patients.

INTERVENTIONAL CARDIAC CATHETERIZATION

Catheter treatment is the standard of practice for most cases of isolated pulmonary or aortic valve stenosis and for recoarctation of the aorta. A special catheter with a sausage-shaped balloon at the distal end is passed through the obstructed valve. Rapid filling of the balloon with a mixture of contrast material and saline solution results in tearing of the stenotic valve tissue, usually at the site of inappropriately fused raphe. Valvular pulmonary stenosis can be treated successfully by **balloon angioplasty**; in most patients, angioplasty has replaced surgical repair as the initial procedure of choice. The clinical results of this procedure are similar to those obtained by open heart surgery, but without the need for sternotomy or prolonged hospitalization. **Balloon valvuloplasty** for aortic stenosis has also yielded excellent results, although, as with surgery, aortic stenosis often recurs as the child grows, and multiple procedures may thus be required. One complication of both valvuloplasty and surgery is the creation of **valvular insufficiency**. This complication has more serious implications when it occurs on the aortic vs the pulmonary side of the circulation because regurgitation is less well tolerated at systemic arterial pressures.

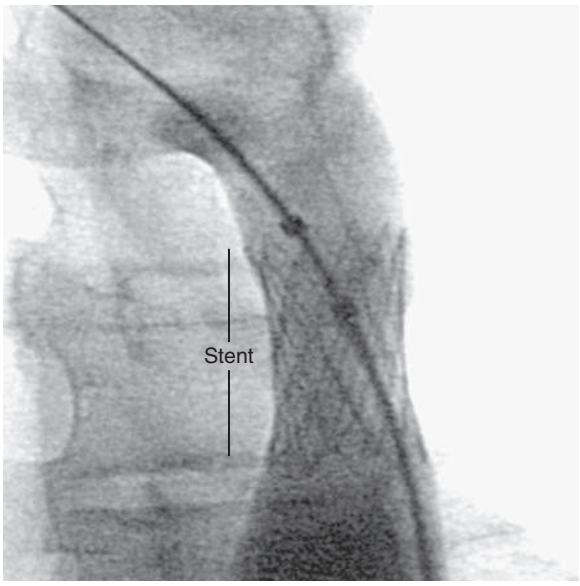

Fig. 472.31 Descending aortic angiogram showing intravascular stent placed in the descending aorta for treatment of recurrent coarctation of the aorta.

Balloon angioplasty is the procedure of choice for patients with restenosis of **coarctation of the aorta** after earlier surgery. It remains controversial whether angioplasty is the best procedure for native (unoperated) coarctation of the aorta in the infant because of greater recurrence risk and reports of late aneurysm formation, and most centers still refer primary coarctation in infants and young children for surgical repair. However, in older patients with previously undiagnosed coarctation, especially those with decreased LV function, primary angioplasty with stent placement may be considered. Other applications of the balloon angioplasty technique include amelioration of mitral stenosis, dilation of surgical conduits (e.g., RV-PA conduits), relief of branch pulmonary artery (PA) narrowing, dilation of systemic or pulmonary venous obstructions, and the pioneering balloon atrial septostomy **(Rashkind procedure)** for transposition of the great arteries (see Chapter 480.2).

Interventional catheterization techniques are being adapted for use in the fetus with lesions such as aortic stenosis to prevent their progression to more complex lesions such as HLHS. In these procedures, after administration of appropriate anesthesia, a needle is passed through the maternal abdominal wall, the uterine wall, and the fetal chest wall and directly into the fetal left ventricle (see Fig. 480.13). A coronary angioplasty balloon catheter is passed through the needle and across the stenotic aortic valve, which is then dilated. With the restoration of normal LV blood flow, it is hoped that normal LV growth potential is restored. Midterm results with this technique in a growing number of patients continue to show mixed results, with good ventricular growth leading to a two-ventricle circulation in approximately 25% of highly preselected patients.

In patients with branch pulmonary artery stenoses, **intravascular stents** are delivered over a balloon catheter and expanded within the vessel lumen (Fig. 472.31). Once placed, the stents can often be dilated to successively greater sizes as the patient grows, although their use in younger infants and children is limited by the extent they can be further expanded.

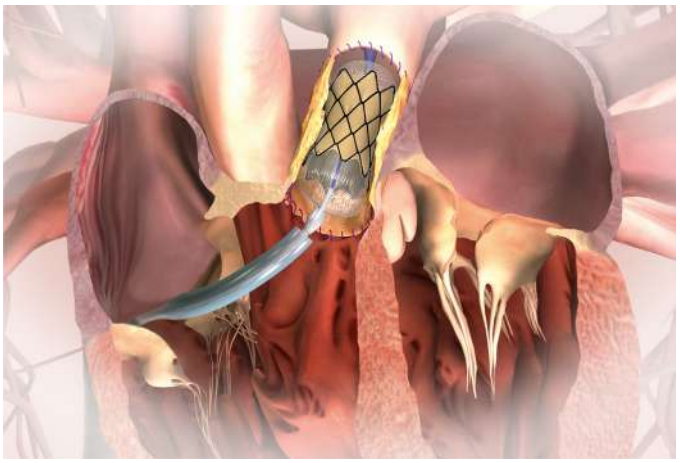

Fig. 472.32 Illustration of implantation of a Melody stent-valve delivered to the pulmonary position by a catheter inserted into the right femoral vein. *(Copyright Medtronic 2017, used with permission.)*

Closure of a small patent ductus arteriosus (PDA) is routinely achieved with catheter-delivered **coils** (see Fig. 475.11), whereas a larger PDA can be closed with a variety of sandwich-type devices. Closure of anomalous vascular connections (coronary fistulas, venovenous collaterals in cyanotic heart lesions) can also be achieved using coils. Secundum ASDs are now routinely closed with a double disk occluder (e.g., **Amplatzer**) device (see Fig. 475.3). Versions of these devices are currently in clinical trials for closure of surgically difficult-to-reach muscular VSDs and for the more common perimembranous VSD. Catheter-delivered devices may also be used as an adjunct to complex surgical repairs (e.g., dilation or stenting of branch pulmonary artery or pulmonary vein stenosis). High-risk patients undergoing the Fontan operation (see Fig. 479.9) often have a small fenestration created between the right and left sides of the circulation to serve as a "pop-off valve" for high right-sided pressure in the early surgical period. Patients with these "fenestrated Fontans" are usually candidates for subsequent closure of the fenestration with a catheter-delivered device.

One of the greatest advances in interventional catheterization over the past decade has been **transcatheter valve implantation**. Typically, a porcine valve is sewn into an expandable stent (commercially available), which is then collapsed around a balloon catheter. The device is positioned across a stenotic or insufficient pulmonary or aortic valve and the balloon inflated, expanding both the stent and the tissue valve. The balloon catheter is then removed, leaving the new valve in place, well anchored by the stent to the walls of the main pulmonary artery or aorta. At this time, the most common application in children is replacement of the **pulmonary valve** (Melody or Harmony Valve) in patients who have had prior surgery for tetralogy of Fallot (usually because of residual pulmonary insufficiency) (Fig. 472.32). In older adults, the most common application is replacement of a stenotic aortic valve (transcatheter aortic valve replacement or TAVR). Stent valves have even been placed in the tricuspid position in children with tricuspid insufficiency. For older patients with mitral and tricuspid valve insufficiency, a clip device (Mitraclip) can be delivered by catheter to create a double-orifice valve, reducing the amount of insufficiency.

Section 3

Congenital Heart Disease

Chapter 473

Epidemiology and Genetic Basis of Congenital Heart Disease

Daniel Bernstein

Congenital heart disease (CHD) occurs in approximately 0.6–1.3% of live births. The incidence is higher in stillborns (3–4%), spontaneous abortuses (10–25%), and premature infants (approximately 2%, excluding patent ductus arteriosus [PDA]). This overall incidence does not include mitral valve prolapse, PDA of preterm infants, and bicuspid aortic valve (present in 1–2% of adults). Congenital cardiac defects have a wide spectrum of severity in infants: approximately 2-3 in 1,000 newborn infants will be symptomatic with heart disease in the first year of life. The diagnosis is established by 1 week of age in 40–50% of patients with CHD and by 1 month of age in 50–60%. Approximately 13% of infants with CHD have associated extracardiac malformations. With advances in both corrective and palliative surgery, 90% of children with CHD survive to adulthood, and in the United States, there are more adults living with CHD than there are children with CHD. Despite these advances, CHD remains the leading cause of death in children with congenital malformations. When patients with repaired or palliated CHD reach older adulthood, the risk of morbidity and mortality begins to increase (see Chapter 483.1). Table 473.1 summarizes the relative frequency of the most common congenital cardiac lesions.

Most congenital defects are well tolerated in the fetus because of the parallel nature of the fetal circulation. Even the most severe cardiac defects, such as **hypoplastic left heart syndrome (HLHS)**, can usually be well compensated for by the fetal circulation. In HLHS the entire fetal cardiac output is ejected by the right ventricle via the ductus arteriosus into both the descending and ascending aortae (the latter filling in a retrograde fashion), so that fetal organ blood flow is minimally perturbed. Because the placenta provides for gas exchange and the normal fetal circulation has mixing between more highly and more poorly oxygenated blood at the foramen ovale and ductus arteriosus, fetal organ oxygen delivery is also not dramatically affected. It is only after birth, when the fetal pathways begin to close and the umbilical cord is cut, that the full hemodynamic impact of an anatomic abnormality becomes apparent. One notable exception is the case of severe regurgitant lesions, most frequently of the tricuspid valve. In these lesions, such as **Ebstein anomaly** of the tricuspid valve or severe right ventricular outflow obstruction (see Chapter 479.7), the parallel fetal circulation cannot compensate for the severe volume or pressure load imposed on the right side of the heart. In utero heart failure, often with fetal pleural and pericardial effusions, and generalized ascites **(nonimmune hydrops fetalis)** may occur.

Although the most significant transitions in the circulation occur in the immediate perinatal period, the circulation continues to undergo changes after birth, and these later changes may also have a hemodynamic impact on cardiac lesions and their apparent incidence. When pulmonary vascular resistance (PVR) falls in the first several weeks of life, left-to-right shunting through intracardiac defects increases and symptoms and signs become more apparent. Thus in patients with a **ventricular septal defect (VSD)**, heart failure is often first noticed between 1 and 3 months of age (see Chapter 475.6) and not in the immediate newborn period. The severity of various defects can also change dramatically with growth; some VSDs may become smaller and even close as the child ages. Alternatively, stenosis of the aortic or pulmonary valve, which may be only moderate in the newborn period, may become worse if valve orifice growth does not keep pace with patient growth (see Chapter 476.5). The physician should always be alert for associated noncardiac congenital malformations, which can adversely affect the patient's prognosis (Tables 473.2 and 473.3). Developmental delay of various degrees is also a concern in many patients with CHD and may have its origins in alterations in fetal blood flow patterns caused by the heart defect, postnatal hypoxemia, and the effects of cardiopulmonary bypass during open heart surgery.

ETIOLOGY

The cause of most congenital heart defects is still unknown. Many cases of CHD are multifactorial and may result from a combination of **genetic** predisposition and an as-yet-to-be-determined **environmental** stimulus. Overall, variants in approximately 400 genes have been identified as potentially causative of CHD. Despite these advances, half of cases still lack a known genetic cause. A small percentage of congenital heart lesions are related to known chromosomal abnormalities, in particular, trisomies 21, 13, and 18 and Turner syndrome; heart disease is found in >90% of patients with trisomy 18, 50% of patients with trisomy 21, and 40% of those with Turner syndrome (see Table 473.3). Ethnic factors may have a role in CHD; certain types of VSDs (supracristal) are more common in Asian children. There are also male:female differences for many common forms of CHD. The risk of CHD increases if a first-degree relative (parent or sibling) is affected, again emphasizing the role of genetics, even if the individual genes have not yet been identified.

A growing list of congenital heart lesions has been associated with specific chromosomal abnormalities, and several have even been linked to specific gene defects (see Table 473.3 and Table 473.4). **Fluorescence**

Table 473.1 Relative Frequency of Major Congenital Heart Lesions*

LESION	% OF ALL LESIONS
Ventricular septal defect	35–30
Atrial septal defect (secundum)	6–8
Patent ductus arteriosus	6–8
Coarctation of aorta	5–7
Tetralogy of Fallot	5–7
Pulmonary valve stenosis	5–7
Aortic valve stenosis	4–7
D-Transposition of great arteries	3–5
Hypoplastic left ventricle	1–3
Hypoplastic right ventricle	1–3
Truncus arteriosus	1–2
Total anomalous pulmonary venous return	1–2
Tricuspid atresia	1–2
Single ventricle	1–2
Double-outlet right ventricle	1–2
Others	5–10

*Excluding patent ductus arteriosus in preterm neonates, bicuspid aortic valve, physiologic peripheral pulmonic stenosis, and mitral valve prolapse.

in situ hybridization (FISH) analysis allows rapid screening of suspected cases if a specific chromosomal abnormality is suspected. Chromosome microarray tools, including **array comparative genome hybridization** and **single nucleotide polymorphism (SNP) arrays**, have identified copy number variations (microdeletions or microduplications) or SNPs in many patients with CHD and suspicion of a congenital anomaly syndrome. These variants are submicroscopic and thus not visible on routine chromosome analysis. Comparative genome hybridization has in many cases replaced routine karyotyping in the clinical workup of newborns with CHD. Overall, 25% of cases of CHD can be associated with a gene alteration using these methodologies. Whole exome and whole genome sequencing are available for clinical genetic evaluations. The advantage of whole genome sequencing is that it allows the assessment of noncoding DNA sequences, which could participate in the regulation of gene expression of cardiac developmental gene pathways (Table 473.5).

A well-characterized genetic cause of CHD is the deletion of a large region (1.5-3 Mb) of chromosome 22q11.2, known as the **DiGeorge**

Table 473.3 Chromosomal Aneuploidies and Copy Number Variants Associated with Congenital Heart Disease

CHROMOSOME CHANGE	MAIN FEATURES	PERCENT WITH CONGENITAL HD	HEART ANOMALY
I. ANEUPLOIDES (IDENTIFIABLE BY ROUTINE KARYOTYPE)			
Trisomy 8 mosaicism	Widely spaced eyes, broad nasal bridge, small jaw, high arched palate, cryptorchidism, renal anomalies, skeletal/vertebral anomalies	25	VSD, PDA, CoA, PVS, TAPVR, TrA
Trisomy 9/mosaicism	Prenatal and postnatal growth restriction, microcephaly, deep-set eyes, low-set ears, severe intellectual disability	65	PDA, LSVC, VSD, TOF/PA, DORV
Trisomy 13 (Patau syndrome)	Cleft lip and palate, scalp defects, hypotelorism, microphthalmia or anophthalmia, colobomata of irides, holoprosencephaly, microcephaly, deafness, severe intellectual disability, rib abnormalities, polydactyly, omphalocele, renal abnormalities, hypospadias, cryptorchidism, uterine abnormalities	57–80	ASD, VSD, PDA, HLHS, laterality defects, atrial isomerism
Trisomy 18 (Edwards syndrome)	IUGR, polyhydramnios, micrognathia, short sternum, hypertonia, rocker-bottom feet, overlapping fingers and toes, TEF, CDH, omphalocele, renal anomalies, biliary atresia, severe intellectual disability	80–90	ASD, VSD, PDA, TOF, DORV, TGA, CoA, BAV, BPV, polyvalvular nodular dysplasia
Trisomy 21 (Down syndrome)	Hypotonia, hyperextensibility, epicanthal folds, up-slanting palpebral fissures, single palmar transverse crease, clinodactyly of fifth finger, brachydactyly, variable intellectual disability, premature aging	40–50	AVSD, VSD, ASD, (TOF, TGA less common)
Monosomy X (Turner syndrome, 45,X)	Lymphedema of hands and feet, widely spaced hypoplastic nipples, webbed neck, primary amenorrhea, short stature, normal intelligence, or mild learning disability	23–35	CoA, BAV, AS, HLHS, aortic dissection
II. CHROMOSOME ABNORMALITIES (IDENTIFIABLE ON KARYOTYPE AND CHROMOSOMAL MICROARRAY)			
3p25 deletion	Prenatal and postnatal growth deficiency, polydactyly, microcephaly, intellectual disability, renal anomalies	33	VSD, AVSD, tricuspid atresia
Deletion 4p16.3 (Wolf-Hirschhorn syndrome)	Microcephaly, widely spaced eyes, broad nasal bridge (Greek helmet appearance), downturned mouth, micrognathia, preauricular skin tags, severe intellectual disability, seizures, poor growth	50–65	ASD, VSD, PDA, LSVC, aortic atresia, dextrocardia, TOF, tricuspid atresia
Deletion 4q	Growth restriction, intellectual disability, cleft palate, broad nasal bridge, micrognathia, abnormal ears, genitourinary defects	50	VSD, PDA, AS, ASD, TOF, CoA
Deletion 5p (cri-du-chat)	Catlike cry, prenatal and postnatal growth restriction, round face, widely spaced eyes, epicanthal folds, single palmar transverse crease, severe intellectual disability	30–60	VSD, ASD, PDA
Deletion 9p syndrome	Craniosynostosis, trigonocephaly, up-slanting palpebral fissures, abnormal ear pinnae, scoliosis, micropenis, cryptorchidism, intellectual disability	35–50	VSD, PDA, PVS
Deletion 10p	Frontal bossing, short down-slanting palpebral fissures, small low-set ears, micrognathia, cleft palate, short neck, urinary/genital and upper-limb anomalies	42	BAV, ASD, VSD, PDA, PVS, CoA
Duplication 10q24-qter	Prenatal growth restriction, intellectual disability, camptodactyly, renal anomalies, cryptorchidism	50	AVSD, VSD
III. COPY NUMBER VARIANTS (IDENTIFIABLE BY CHROMOSOMAL MICROARRY)			
1p36 deletion	Growth deficiency, intellectual disability, microcephaly, deep-set eyes, low-set ears, hearing loss, hypotonia, seizures, CNS defects, genital anomalies	70	PDA, VSD, ASD, BAV, Ebstein anomaly, noncompaction cardiomyopathy

Table 473.3 Chromosomal Aneuploidies and Copy Number Variants Associated with Congenital Heart Disease—cont'd

CHROMOSOME CHANGE	MAIN FEATURES	PERCENT WITH CONGENITAL HD	HEART ANOMALY
1q21.1 deletion	Short stature, microcephaly, colobomas, microphthalmia, hearing loss, seizures, mild intellectual disability, autism spectrum disorder, skeletal malformations	N/A	PDA, VSD, ASD, TrA, TOF
1q21.1 duplication	Large head size, hemivertebrae, variable intellectual disability, variable autistic features, hypospadias, clubfoot	N/A	TOF, TGA, PVS
1q41q42 microdeletion	Growth restriction, intellectual disability, microcephaly, diaphragmatic hernia, seizures, short limbs	40	BAV, ASD, VSD, TGA
1q43q44 microdeletion	Prenatal and postnatal poor growth, intellectual disability, limited speech, microcephaly, deep-set eyes, microcephaly, large low-set ears, cleft palate, agenesis of corpus callosum	N/A	VSD, CoA, HLHS
2q31.1 microdeletion	Prenatal and postnatal poor growth, large ventricles, microcephaly, narrow forehead, down-slanting palpebral fissures, cleft palate/cleft lip, limb defects, hypoplastic genitalia	25	VSD, ASD, PDA
2q37 microdeletion	Short stature, obesity, intellectual disability, sparse hair, arched eyebrows, epicanthal folds, thin upper lip, small hands and feet, clinodactyly	30	VSD, ASD, CoA, hypoplastic aortic arch
Deletion 7q11.23 (Williams-Beuren syndrome)	Infantile hypercalcemia, skeletal and renal anomalies, cognitive deficits, "social" personality, elfin facies	53–85	Supravalvar AS and PS, PPS
8p23.1 deletion	Microcephaly, poor growth, deep-set eyes, malformed ears, small chin, genital anomalies in males, intellectual disability	50–75	AVSD, PVS, VSD, TOF
9q34.3 Subtelomeric deletion (Kleefstra syndrome)	Short stature, obesity, intellectual disability, microcephaly, behavior abnormalities, brain anomalies, hypertelorism, arched eyebrows, midface hypoplasia	31–44	ASD, VSD, TOF, pulmonary arterial stenosis
Deletion 11q (Jacobsen syndrome)	Growth restriction, developmental delay, thrombocytopenia, platelet dysfunction, widely spaced eyes, strabismus, broad nasal bridge, thin upper lip, prominent forehead, intellectual disability	56	HLHS, AS, VSD, CoA, Shone complex
15q24 microdeletion	Prenatal and postnatal growth restriction, intellectual disability, abnormal corpus callosum, microcephaly, high forehead, down-slanting palpebral fissures, tapered eyebrows, abnormal ear pinnae, hearing loss, hypospadias, scoliosis, coloboma, strabismus	40	PDA, pulmonary arterial stenosis, PVS
16p11.2p12.2 microdeletion	Hypotonia, intellectual disability, long narrow face, deep-set eyes, low-set malformed ears	33	TOF, BAV, pulmonary atresia
17q21 microdeletion	Abnormal hair pigmentation, up-slanting palpebral fissures, epicanthal folds, bulbous nasal tip, strabismus, ptosis, long slender fingers, hip dislocation, renal anomalies, spine deformities, cryptorchidism, global developmental delay	27	PVS, ASD, VSD, BAV
Deletion 20p12 (Alagille syndrome)	Bile duct paucity, cholestasis, skeletal or ocular anomalies, broad forehead, widely spaced eyes, underdeveloped mandible	85–94	Peripheral PA hypoplasia, TOF, PVS (left-sided heart lesions and septal defects less common)
22q11.2DS (DiGeorge, velocardiofacial, and conotruncal anomaly face syndrome)	Hypertelorism, micrognathia, low-set posteriorly rotated ears, thymic and parathyroid hypoplasia, hypocalcemia, feeding/speech/learning/behavioral disorders, immunodeficiency, palate/skeletal/renal anomalies, learning disability	75	IAA-B, TrA, isolated aortic arch anomalies, TOF, conoventricular VSD

Table 473.3 Chromosomal Aneuploidies and Copy Number Variants Associated with Congenital Heart Disease—cont'd

CHROMOSOME CHANGE	MAIN FEATURES	PERCENT WITH CONGENITAL HD	HEART ANOMALY
22q11.2 duplication	Very variable phenotype, some with velopharyngeal insufficiency, cleft palate, hearing loss, minor facial anomalies, mild learning disability to normal learning ability, hypotonia, scoliosis, frequent infections	15	TOF, HLHS, VSD, PVS, TrA
22q13 microdeletion (Phelan-McDermid syndrome)	Normal growth, intellectual disability, dolichocephaly, dysplastic ears, pointed chin, large fleshy hands, hypotonia	>25	PDA, VSD, ASD, TAPVR

22q11.2DS, 22q11.2 deletion syndrome; AS, aortic stenosis; ASD, atrial septal defect; AVSD, atrioventricular septal defect; BAV, bicuspid aortic valve; BPV, bicuspid pulmonary valve; CDH, congenital diaphragmatic hernia; CoA, coarctation of the aorta; DORV, double-outlet right ventricle; HD, heart disease; HLHS, hypoplastic left heart syndrome; IAA-B, interrupted aortic arch type B; IUGR, intrauterine growth retardation; LSVC, persistent left superior vena cava; N/A, not available; PA, pulmonary artery; PDA, patent ductus arteriosus; PPS, peripheral pulmonary stenosis; PS, pulmonary stenosis; PVS, pulmonic valve stenosis; TAPVR, total anomalous pulmonary venous return; TEF, tracheoesophageal fistula; TGA, D-transposition of the great arteries; TOF, tetralogy of Fallot; TOF/PA, tetralogy of Fallot with pulmonary atresia; TrA, truncus arteriosus; VSD, ventricular septal defect.

Table 473.4 Disease Genes for Nonsyndromic Congenital Cardiovascular Disease

GENE	CARDIOVASCULAR MALFORMATION	NONSYNDROMIC (NS) OR SYNDROMIC (S)
TRANSCRIPTION FACTORS		
CITED2	ASD, VSD	NS
GATA4	ASD, VSD, AVSD, PVS, TOF	NS
GATA6	PTA, TOF	NS
MED13L	TGA	NS
NR2F2	AVSD, AS, CoA, VSD, HLHS, TOF	NS
NKX2-5	ASD, atrioventricular conduction delay, TOF, HLHS	NS
NKX2.6	PTA	NS
TBX20	ASD, VSD, MS, DCM	NS
ZFPM2/FOG2	TOF, DORV	NS
CELL SIGNALING AND ADHESION PROTEINS		
ACVR1/ALK2	AVSD	NS
CRELD1	ASD, AVSD	NS
GJA1	HLHS, VSD, PA	S (oculodentodigital dysplasia) and NS
JAG1	TOF, PVS, PAS	S (Alagille syndrome) and NS
NOTCH1	BAV, AS, HLHS, TOF, PVS	S (Adams-Oliver syndrome) and NS
PDGFRA	TAPVR	NS
SMAD6	BAV, CoA, AS	NS
TAB2	BAV, AS, TOF	NS
STRUCTURAL PROTEINS		
ACTC1	ASD, HCM, DCM, LVNC	NS
DCHS1	MVP	NS
ELN	SVAS	S (Williams-Beuren syndrome) and NS
MYH6	ASD, HCM, DCM	NS
MYH7	Ebstein anomaly, LVNC, HCM, DCM	NS
MYH11	PDA, TAA	NS

AS, Aortic valve stenosis; ASD, atrial septal defect; AVSD, atrioventricular septal defect; BAV, bicuspid aortic valve; CoA, coarctation of aorta; DCM, dilated cardiomyopathy; DORV, double-outlet right ventricle; HCM, hypertrophic cardiomyopathy; HLHS, hypoplastic left heart syndrome; LVNC, left ventricular noncompaction cardiomyopathy; MS, mitral valve stenosis; MVP, mitral valve prolapse; NS, nonsyndromic; PA, pulmonary atresia; PAS, pulmonary artery stenosis; PDA, patent ductus arteriosus; PTA, persistent truncus arteriosus; PVS, pulmonary vein stenosis; S, syndromic; SVAS, supravalvar aortic stenosis; TAA, thoracic aortic aneurysm; TAPVR, total anomalous pulmonary venous return; TGA, transposition of great arteries; TOF, tetralogy of Fallot; and VSD, ventricular septal defect.
From Pierpont ME, Brueckner M, Chung WK, et al. Genetic basis for congenital heart disease: revisited: a scientific statement from the American Heart Association. *Circulation.* 2018;138(21):e653–e711, Table 8.

Table 473.5 Clinical Genetic Tests

	GENOMIC VS TARGETED	ANEUPLOIDIES AND CHROMOSOMAL REARRANGEMENTS	COPY NUMBER VARIATION	SNPs AND INDELs	EXAMPLE OF CLINICAL USE
Karyotype	Genomic	+++	+	–	Confirmation of trisomy 21
Array CGH	Genomic	++	+++	–	Multiple congenital anomalies without obvious syndromic association
FISH	Targeted	+	+	–	Suspected 22q11.2 deletion syndrome
Gene panel testing	Targeted	–	+	+++	Suspected monogenic disease with a small differential diagnosis
Exome sequencing	Genomic	–	–	+++	Broad genetic differential diagnosis without obvious syndromic association, or previous negative panel testing
Genome sequencing	Genomic	+	+	+++	Broad genetic differential diagnosis without obvious syndromic association, or previous negative panel testing and need for rapid turnaround time

Sensitivity of tests for the types of genetic variation are indicated as not detected (–), low (+), medium (++), or high (+++). Array CGH indicates comparative genomic hybridization using arrays; FISH, fluorescence in situ hybridization; INDEL, insertion or deletion; and SNP, single nucleotide polymorphism.
From Pierpont ME, Brueckner M, Chung WK, et al. Genetic basis for congenital heart disease: revisited: a scientific statement from the American Heart Association. *Circulation.* 2018;138(21):e653–e711, Table 1.

critical region. At least 30 genes have been mapped to the deleted region; *Tbx1,* a transcription factor involved in early outflow tract development, is one gene that has been implicated as a possible cause of DiGeorge syndrome. The estimated prevalence of 22q11.2 deletions is 1 in 4,000 live births; these occur in 2% of all patients with CHD. Cardiac lesions associated with 22q11.2 deletions are most often seen in association with either DiGeorge syndrome or **Shprintzen (velocardiofacial) syndrome**. The acronym **CATCH 22** has been used to summarize the major components of these syndromes: **C**ardiac defects, **A**bnormal facies, **T**hymic aplasia, **C**left palate, and **H**ypocalcemia. The specific cardiac anomalies are **conotruncal** defects (tetralogy of Fallot, truncus arteriosus, double-outlet right ventricle, subarterial VSD) and **branchial arch** defects (coarctation of the aorta, interrupted aortic arch, right aortic arch). Congenital airway anomalies such as tracheomalacia and bronchomalacia are sometimes present. In addition to extracardiac defects, studies in adults with repaired tetralogy of Fallot have linked the presence of a 22q11.2 microdeletion to increased all-cause mortality. Although the risk of recurrence is extremely low in the absence of a parental 22q11.2 deletion, the risk rises to 50% if one parent carries the deletion. More than 90% of patients with the clinical features of DiGeorge syndrome have a deletion at 22q11.2. A second genetic locus on the short arm of chromosome 10 (10p13p14) has also been identified, the deletion of which shares some, but not all, phenotypic characteristics with the 22q11.2 deletion; patients with del(10p) have an increased incidence of sensorineural hearing loss.

Other structural heart lesions associated with specific chromosomal abnormalities include **familial secundum atrial septal defect** (ASD) associated with **heart block** (the transcription factor Nkx2.5 on chromosome 5q35), familial ASD without heart block (the transcription factor GATA4), **Alagille syndrome** (Jagged1 on chromosome 20p12), and **Williams syndrome** (elastin on chromosome 7q11). Of interest, patients with VSDs and atrioventricular septal defects have been found to have multiple Nkx2.5 pathogenic variants in cells isolated from diseased heart tissues, but not from normal heart tissues or from circulating lymphocytes, indicating a potential role for *somatic* rather than germline changes leading to mosaicism in the pathogenesis of congenital heart defects. Tables 473.2 to 473.4 are a compilation of known genetic causes of CHD.

The most progress in identifying the genetic origin of cardiovascular disease has been made in the genetic **cardiomyopathies**, and in particular, **hypertrophic cardiomyopathy** (HCM). Over 1,000 different pathogenic variants in over a dozen genes have been implicated, most of which encode proteins of the cardiac sarcomere, either the contractile thick filament (myosin) or associated regulatory subunits (e.g., troponin or myosin binding protein C), although variants in metabolic/mitochondrial genes are also common in those presenting with HCM in infancy and early childhood. Variants of the cardiac β-**myosin heavy-chain gene *MYH7*** and the **myosin-binding protein C** gene are the most common (Table 473.6), with additional common variants including cardiac troponin T and I, α-tropomyosin, regulatory and essential myosin light chains, titin, and α-myosin heavy chain. Some patients (~15%) may carry variants in more than one sarcomeric gene. Routine clinical laboratory tests are available for most of these genes, so that patients with clinical findings of HCM or children of parents who have been diagnosed with HCM should be tested. However, not all genes causing HCM have been identified, so a negative test does not eliminate a genetic cause.

Progress has also been made in identifying the genetic basis of **dilated cardiomyopathy**, which is familial in 20–30% of cases. Autosomal dominant inheritance is most often encountered, and similar to HCM, multiple genes have been identified (see Table 473.3). X-linked inheritance accounts for 5–10% of cases of familial dilated cardiomyopathy. Pathogenic variants in the dystrophin gene are the most common in this group, causing **Duchenne or Becker muscular dystrophy**. Variants in the gene encoding tafazzin are associated with **Barth syndrome** and for some cases of isolated noncompaction of the left ventricle (LVNC). Autosomal recessive inheritance is associated with a variant in cardiac troponin I. Mitochondrial myopathies may be caused by alterations of enzymes of the electron transport chain encoded by nuclear DNA or enzymes of fatty acid oxidation encoded by mitochondrial DNA. Table 473.6 is a compilation of the most common genetic causes of cardiomyopathy.

The genetic basis of **heritable arrhythmias**, most notably the **long QT syndromes**, has been linked to pathogenic variants of genes coding for subunits of cardiac potassium and sodium channels (Table 473.7). Other heritable arrhythmias include **arrhythmogenic right ventricular dysplasia**, familial atrial fibrillation, familial complete heart block, and **Brugada syndrome**. Table 473.7 is a compilation of the most common genetic causes of arrhythmias.

Of all cases of CHD, 2–4% are associated with known environmental or adverse maternal conditions and teratogenic influences, including

Table 473.6 Genetics of Hypertrophic Cardiomyopathies

CARDIOMYOPATHY	CHROMOSOMAL LOCATION	GENE
Hypertrophic cardiomyopathy	14q1	β-Myosin heavy chain
	15q2	α-Tropomyosin
	1q31	Troponin T
	19p13.2-19q13.2	Troponin I
	11p13-q13	Myosin-binding protein C
	12q23	Cardiac slow myosin regulatory light chain
	13p21	Ventricular slow myosin essential light chain
	2q31	Titin
	3p25	Caveolin-3
	Mitochondrial DNA	tRNA-glycine
	Mitochondrial DNA	tRNA-isoleucine
Hypertrophic cardiomyopathy with Wolff-Parkinson-White syndrome	7q36.1	AMP-activated protein kinase
OTHER GENETIC DISEASES CAUSING CARDIAC HYPERTROPHY		
Familial amyloid disease	18q12.1	Transthyretin (TTR)
Noonan syndrome	12q24.1, 2p22.1, 3p25, 12p12.1	Protein tyrosine phosphatase 11 (PTPN11), son of sevenless homolog 1 (SOS1), RAF1 protooncogene, GTPase KRAS
Fabry disease	Xq22	α-Galactoside A (GLA)
Danon disease	Xq24	Lysosomal-associated membrane protein 2 (LAMP2)
Hereditary hemochromatosis	6p21.3	Hereditary hemochromatosis protein (HFE)
Pompe disease	17q25	Acid α-glucosidase (GAA)
Dilated cardiomyopathy		
X-linked	Xp21	Dystrophin
	Xp28	Tafazzin
Autosomal recessive	19p13.2-19q13.2	Troponin I

Autosomal dominant: Genes encoding multiple proteins have been identified, including cardiac actin; desmin; δ-sarcoglycan; β-myosin heavy chain; cardiac troponin C and T; α-tropomyosin; titin; metavinculin; myosin-binding protein C; muscle LIM protein; α-actinin-2; phospholamban; Cypher/LIM binding domain 3; α-myosin heavy chain; SUR2A (regulatory subunit of K_{ATP} channel); and lamin A/C.

Isolated noncompaction of the left ventricle: Autosomal dominant, autosomal recessive, X-linked, and mitochondrial inheritance patterns have been reported. Genes that have been implicated include those for α-dystrobrevin, Cypher/ZASP, lamin A/C, tafazzin, MIB1, and LIM domain-binding protein 3 (LDB3).

Partially adapted from Dunn KE, Caleshu C, Cirino AL, et al. A clinical approach to inherited hypertrophy: the use of family history in diagnosis, risk assessment, and management. *Circ Cardiovasc Genet.* 2013;6:118–131.

maternal diabetes mellitus, maternal phenylketonuria, or systemic lupus erythematosus; congenital rubella syndrome; and maternal ingestion of drugs (lithium, ethanol, warfarin, thalidomide, antimetabolites, vitamin A derivatives, anticonvulsant agents). Associated noncardiac malformations noted in identifiable syndromes may be seen in as many as 25% of patients with CHD.

Gender differences in the occurrence of specific cardiac lesions have been identified. Transposition of the great arteries and left-sided obstructive lesions are slightly more common in males (65%), whereas ASD, VSD, PDA, and pulmonic stenosis are more common in females. No ethnic differences in the occurrence of congenital heart lesions as a whole have been noted, although there are some exceptions: supracristal VSD in children of Asian background and transposition of the great arteries, which has a higher occurrence in White infants.

GENETIC COUNSELING

Parents who have a child with CHD require counseling regarding the probability of a cardiac malformation occurring in subsequent children (Table 473.8 and see Chapter 98.1). Except for syndromes caused by a pathogenic variant of a single gene, many forms of CHD, but not all, are still relegated to a multifactorial inheritance pattern, which should result in a low risk of recurrence. When more genetic etiologies are identified, these risks are constantly updated; therefore consultation with a cardiac geneticist or genetic counselor is important.

The degree of severity may vary, as may the presence of associated defects. Careful echocardiographic screening of first-degree relatives will often uncover mild forms of CHD that were clinically silent. For example, the incidence of bicuspid aortic valve is more than double (5% vs 2% in the general population) in the relatives of children with left ventricular outflow obstruction (aortic stenosis, coarctation of the aorta, HLHS). Consultation with a knowledgeable genetic counselor is the most reliable way of providing the family with up-to-date information regarding the risk of recurrence.

Fetal echocardiography improves the rate of detection of congenital heart lesions in at-risk patients (see Chapter 472.4). This type of ultrasound is much more comprehensive than the screening ultrasound performed by an obstetrician and is usually performed and interpreted by a pediatric cardiologist specializing in fetal echocardiography. The resolution and accuracy of fetal echocardiography are excellent but are not perfect; families should be counseled that a normal fetal echocardiogram does not guarantee the absence of CHD. Congenital heart lesions may evolve in the course of the pregnancy; moderate aortic

Table 473.7 Genetics of Arrhythmias

ARRHYTHMIA	CHROMOSOMAL LOCATION	GENE(S) IMPLICATED
Complete heart block	19q13	Not known
Long QT syndrome		
LQT1 (autosomal dominant)	11p15.5	*KVLQT1* (K^+ channel)
LQT2 (autosomal dominant)	7q35	*HERG* (K^+ channel)
LQT3 (autosomal dominant)	3p21	*SCN5A* (Na^+ channel)
LQT4 (autosomal dominant)	4q25-27	Not known
LQT5 (autosomal dominant)	21q22-q22	*KCNE1* (K^+ channel)
LQT6	21q22.1	*KCNE2* (K^+ channel)
LQT7	17q23	KCNJ2 (K^+ channel)
LQT8	12p13.3	CACNAIC (L type Ca^{2+} channel)
LQT9	3p25	CAV-3 (caveolin-3, Na^+ current)
LQT10	11q23	SCN4B (Na^+ channel)
LQT11	7q21	AKAP9 (A-kinase anchoring protein)
LQT12	20q11.21	SNTA1 (A1-synthrophin)
LQT13	11q24.3	KCNJ5 (K^+ channel)
Jervell and Lange-Nielsen syndrome (autosomal recessive, congenital deafness)	11p15.5 21q22.1	*KVLQT1* (K^+ channel), KCNE1 (K^+ channel)
Arrhythmogenic right ventricular dysplasia (ARVD): 11 genes are now associated with ARVD (*ARVD1* through *ARVD11*) usually with autosomal dominant inheritance, but with variable penetrance. These genes include *TGFβ_3* (transforming growth factor β), *RYR2* (ryanodine receptor), *LAMR1* (laminin receptor-1), *PTPLA* (protein tyrosine phosphatase), *DSP* (desmoplakin), *PKP2* (plakophilin-2), *DSG2* (desmoglein), and *DSC2* (desmocollin).		
Familial atrial fibrillation (autosomal dominant)	10q22-q24, 6q14-16	Not known
	11p15.5	*KVLQT1* (K^+ channel)
	11p15.5	*KCNQ1* (K^+ channel)
	21q22	*KCNE2* (K^+ channel)
	17q23.1-q24.2	*KCNJ2* (K^+ channel)
	7q35-q36	*KCNH2* (K^+ channel)
Brugada syndrome (right bundle branch block, ST segment elevation, unexpected sudden death)	3p21-p24	*SCN5A* (Na^+ channel), rarely CACNA1C, HCN4, TRPM4
	3p22-p24	*GPD1L* (glycerol-3-phosphate dehydrogenase)
Catecholaminergic polymorphic ventricular tachycardia	1q43	*RYR2* (autosomal dominant)
	1p13.1	*CASQ2* (autosomal recessive)

stenosis with a normal-sized left ventricle at 18 weeks of gestation may progress to aortic atresia with a hypoplastic left ventricle by 34 weeks because of decreased flow through the atria, ventricle, and aorta in the latter half of gestation. This progression has prompted initial clinical trials of interventional treatment, such as fetal aortic balloon valvuloplasty, for the prevention of HLHS (see Chapter 472.7). In addition to diagnosing CHD in utero and subsequent parental counseling, the benefit of fetal ultrasound is that it allows for careful planning of perinatal care, especially in cases where immediate intervention in the neonatal period is warranted.

Chapter 474

Evaluation and Screening of the Infant or Child with Congenital Heart Disease

Daniel Bernstein

The initial evaluation for suspected congenital heart disease (CHD) involves a systematic approach with two major components (Fig. 474.1). First, congenital cardiac defects can be divided into two major groups based on the presence or absence of **cyanosis**, which can be determined by physical examination aided by pulse oximetry. Second, these groups can usually be further subdivided based on whether the chest radiograph shows evidence of increased, normal, or decreased pulmonary vascular markings. Next, the electrocardiogram (ECG) can be used to determine whether right, left, or biventricular **hypertrophy** exists. The character of the heart sounds and the presence and character of any murmurs further narrow the differential diagnosis. The final diagnosis is then confirmed by echocardiography, cardiac computed tomography (CT) or magnetic resonance imaging (MRI), and/or cardiac catheterization. In a cyanotic or otherwise sick newborn, echocardiographic exam, if available, should not be delayed while awaiting these other modalities.

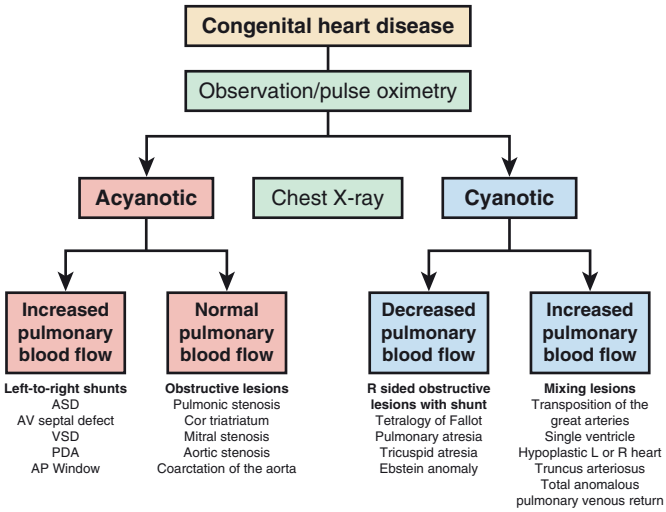

Fig. 474.1 A general algorithmic approach to the initial diagnosis of congenital heart disease, based on observation/pulse oximetry and chest x-ray, to separate patients into four major physiologic subgroups of congenital heart disease. This schematic is a broad, but useful, diagnostic overview; only the most common forms of congenital heart disease are included. A patient's initial presentation may sometimes straddle two of these physiologic groups and can evolve between them over the first week or two of life. For example, in a patient with a VSD, the pulmonary blood flow will be relatively normal in the newborn period and only increase as the pulmonary vascular resistance begins to drop. Similarly, a patient with a mixing lesion may not show pulmonary overcirculation at birth. ASD, Atrial septal defect; AV, atrioventricular; VSD, ventricular septal defect; PDA, patent ductus arteriosus, AP, aortopulmonary; L, left; R, right

Routine **pulse oximetry screening** is recommended for all newborns to detect unsuspected critical cyanotic CHD; lesions include hypoplastic left heart syndrome, pulmonary atresia, tetralogy of Fallot, total anomalous pulmonary venous return, transposition of the great arteries, tricuspid atresia, truncus arteriosus, neonatal coarctation of the aorta, and aortic arch hypoplasia/atresia. Many of these lesions are ductal dependent, and if the ductus arteriosus closes, severe cardiac decompensation will ensue. In addition, pulse oximetry may detect respiratory disorders and primary pulmonary hypertension. Screening is performed between 24 and 48 hours of life and before discharge in asymptomatic newborns. The neonate passes if the oxygen saturation is 95% or greater in the right hand or either foot AND the difference is 3% or less between the right hand and foot. The screen is failed if the saturation is less than 90% in either the right hand or foot. If it is between 90% and 94% OR there is more than a 3% difference between the right arm and foot, the screen should be repeated once in 1 hour. If the saturation is 90–94% OR there is a 3% difference after the third screen, urgent **echocardiography** is indicated. In addition, a careful reexamination of the pulses and blood pressure in the upper and lower extremity and cardiac auscultation are indicated in children with an initial positive screen.

ACYANOTIC CONGENITAL HEART LESIONS

Acyanotic congenital heart lesions can be classified according to the predominant physiologic load that they place on the heart. Although many congenital heart lesions induce more than one physiologic disturbance, it is helpful to focus on the primary load abnormality for purposes of classification. The most common lesions are those that produce a **volume load**, and the most common of these are the left-to-right shunt lesions. Atrioventricular (AV) valve regurgitation and dilated cardiomyopathies are other causes of increased volume load. The second major class of lesions causes an increase in **pressure load**, most often secondary to ventricular outflow obstruction (pulmonic or aortic valve stenosis) or narrowing of a great vessel (branch pulmonary artery stenosis or coarctation of the aorta). The chest radiograph and ECG are useful tools for differentiating between these major classes of volume- and pressure-overload lesions while awaiting confirmation with echocardiography.

Lesions Resulting in Increased Volume Load

The most common lesions resulting in increased volume load are those that cause **left-to-right shunting** (see Chapter 475): atrial septal defect (ASD), ventricular septal defect (VSD), atrioventricular septal defects (previously known as *AV canal* or *endocardial cushion defects*), and patent ductus arteriosus. The pathophysiologic common denominator in this group is the presence of a **communication** between the systemic and pulmonary sides of the circulation, which results in **shunting** of fully oxygenated blood back into the lungs for a second passage. This shunt can be quantitated by calculating the ratio of pulmonary-to-systemic blood flow (Qp:Qs). Thus a 3:1 shunt implies three times the normal pulmonary blood flow, which is a moderately large shunt likely to cause symptoms of heart failure.

The direction and magnitude of the shunt across such a communication depend on the size of the defect, the relative pulmonary and systemic pressures and vascular resistances, and the compliances of the two chambers connected by the defect. These factors are dynamic and may change dramatically with age; intracardiac defects may grow smaller with time; pulmonary vascular resistance (PVR), which is high in the immediate newborn period, decreases to normal adult levels by several weeks of life; and chronic exposure of the pulmonary circulation to high pressure and blood flow results in a gradual increase in PVR (**Eisenmenger physiology**; see Chapter 482.2). Thus a lesion such as a large VSD may be associated with little shunting and few symptoms during the initial first 2 weeks of life. When PVR declines over the next 2-4 weeks, the volume of the left-to-right shunt increases, and symptoms begin to appear.

The increased volume of blood in the lungs decreases pulmonary compliance and increases the work of breathing. Fluid leaks into the interstitial space and alveoli and causes pulmonary edema. The infant develops the symptoms we refer to as **heart failure**, such as tachypnea, tachycardia, sweating, chest retractions, nasal flaring, and wheezing. For children with large left-to-right shunts, however, the term *heart failure* is a misnomer; total left ventricular output is not decreased but is several times greater than normal, although much of this output is ineffective because it returns through the defect back to the lungs. To maintain this high level of left ventricular output, heart rate and stroke volume are increased, in part mediated by the Frank-Starling relation as the increased ventricular volume stretches the cardiac sarcomeres and in part mediated by an increase in sympathetic nervous system activity. The increase in catecholamine release, combined with the increased work of breathing, results in an elevation in total body oxygen consumption (caused by increased β-receptor stimulation), often beyond the oxygen transport ability of the circulation. Sympathetic activation leads to peripheral vasoconstriction (caused by increased α-receptor stimulation) and to the additional symptoms of sweating and irritability, and the imbalance between oxygen supply and demand leads to failure to thrive. Remodeling of the heart occurs, with predominantly chamber dilation caused by the increased volume load and a lesser degree of hypertrophy. If left untreated, the PVR eventually begins to rise, and by several years of age, the shunt volume will decrease and symptoms will appear to improve. If still uncorrected, the shunt will eventually reverse to right-to-left as the PVR rises (see Chapter 482.2). At this point, the patient may be inoperative if the pulmonary vascular resistance is elevated and fixed (unresponsive to vasodilators), and heart-lung transplant may be the only surgical option.

Additional lesions that impose a volume load on the heart include the **regurgitant lesions** (see Chapter 477) and the **dilated cardiomyopathies** (see Chapter 488.1). Regurgitation through the AV valves is most frequently encountered in patients with partial or complete AV septal defects (AV canal or endocardial cushion defects). In these lesions, the combination of a left-to-right shunt with AV valve regurgitation increases the volume load on the heart and often leads to earlier and more severe symptoms than for isolated septal defects. Regurgitation through the tricuspid valve is seen in **Ebstein anomaly** (see Chapter 479.7). Regurgitation involving one of the semilunar (aortic or pulmonary) valves also results in a volume load but is often also associated with some degree of stenosis, leading to a combined pressure and volume load. Aortic regurgitation may be encountered in patients with a VSD directly under the aortic valve **(supracristal VSD)**, leading to two sources of volume load on the left ventricle.

In contrast to left-to-right shunts, in which intrinsic cardiac muscle contractile function is generally either normal or increased, heart muscle function can be decreased in the cardiomyopathies. **Cardiomyopathies** may affect systolic contractility (dilated cardiomyopathy) or diastolic relaxation (restrictive cardiomyopathy) or both. Decreased cardiac function results in increased atrial and ventricular filling pressure, and pulmonary edema occurs secondary to increased capillary pressure. Poor cardiac output leads to decreased end-organ blood flow, sympathetic activation, and the symptoms of poor perfusion and decreased urine output. The major causes of cardiomyopathy in infants and children include viral myocarditis,

metabolic disorders, and pathogenic gene variants in sarcomeric and other cardiac structural, functional, and energy production genes (see Chapter 488).

Lesions Resulting in Increased Pressure Load

The pathophysiologic common denominator of lesions resulting in increased pressure load is an obstruction to normal blood flow. The most frequent are **obstructions to ventricular outflow**: valvular pulmonic stenosis, valvular aortic stenosis, and coarctation of the aorta (see Chapter 476). Less common are **obstructions to ventricular inflow**: tricuspid or mitral stenosis, cor triatriatum, and obstruction of the pulmonary veins. Ventricular outflow obstruction can occur at the valve, below the valve (double-chambered right ventricle, subaortic membrane), or above the valve (branch pulmonary stenosis or supravalvular aortic stenosis). Unless the obstruction is severe, cardiac output will be maintained and the clinical symptoms of heart failure will be either subtle or absent. The heart compensates for the increased afterload by increasing wall thickness (hypertrophy), but in later stages the affected chamber develops fibrosis and will begin to dilate and can progress to ventricular failure.

The clinical picture is different when obstruction to outflow is severe, which is usually encountered in the immediate newborn period. The infant may become critically ill within several hours of birth. Severe pulmonic stenosis in the newborn period **(critical pulmonic stenosis)** results in signs of right-sided heart failure (hepatomegaly, peripheral edema) and cyanosis from right-to-left shunting across the foramen ovale. Severe aortic stenosis in the newborn period **(critical aortic stenosis)** is characterized by signs of left-sided heart failure (pulmonary edema, poor perfusion), often combined with signs of right-sided failure (hepatomegaly, peripheral edema), and may progress rapidly to total circulatory collapse. In older children, severe untreated pulmonic stenosis leads to symptoms of right-sided heart failure, but usually not to cyanosis unless a pathway persists for right-to-left shunting (e.g., patency of the foramen ovale).

Coarctation of the aorta in older children and adolescents is usually manifested as upper body hypertension and diminished pulses in the lower extremities. In the immediate newborn period, presentation of coarctation can range from decreased pulses in the lower extremities to total circulatory collapse, depending on the severity of the narrowing. The clinical presentation of coarctation may be delayed because of the normally patent ductus arteriosus in the first few days of life. In these patients, even as the ductus begins to close, the open aortic end of the ductus serves as a conduit for blood flow to partially bypass the obstruction; in more severe coarctations, blood leaving the right ventricle traverses the ductus to directly supply the descending aorta (as it did in the fetus). These infants then become symptomatic, often dramatically, when the ductus finally closes, usually within the first few weeks of life. Differential cyanosis (normal saturation in the right arm and low saturation in the foot) is a hallmark sign of this condition, and if picked up on oximetry screen before hospital discharge can be lifesaving.

CYANOTIC CONGENITAL HEART LESIONS

The cyanotic group of congenital heart lesions can also be further divided according to pathophysiology. In one major subdivision, pulmonary blood flow is *decreased,* usually from an **obstruction to right ventricular outflow** (tetralogy of Fallot, tetralogy with pulmonary atresia, or pulmonary atresia with an intact septum) or to an **obstruction to right ventricular inflow** (tricuspid atresia). In the second major subdivision, pulmonary blood flow is *increased* and oxygenated and deoxygenated blood are *mixing* (transposition of the great arteries, single ventricle, truncus arteriosus, total anomalous pulmonary venous return [TAPVR] without obstruction). In the case of TAPVR with obstruction, pulmonary flow is decreased but because there is no exit from the pulmonary veins, the lungs appear to be markedly congested. The chest radiograph is a valuable tool for initial differentiation between these two categories.

Cyanotic Lesions with Decreased Pulmonary Blood Flow

For cyanosis to occur, these lesions must include both an obstruction to pulmonary blood flow (at the tricuspid valve or pulmonary valve level) *and* a pathway by which systemic venous blood can shunt from right to left and enter the systemic circulation (via a patent foramen ovale, ASD, or VSD). Common lesions in this group include tricuspid atresia, tetralogy of Fallot, tetralogy of Fallot with pulmonary atresia, pulmonary atresia with intact septum (with atrial-level shunting), and various forms of single ventricle with pulmonary stenosis or atresia (see Chapter 457). In these lesions, the degree of cyanosis depends on the degree of obstruction to pulmonary blood flow. If the obstruction is mild, cyanosis may be absent at rest. However, these patients may have hypercyanotic (tet) spells during conditions of stress. In contrast, if the obstruction is severe, pulmonary blood flow may be totally dependent on patency of the ductus arteriosus. When the ductus closes in the first few days of life, the neonate experiences profound hypoxemia.

Cyanotic Lesions with Increased Pulmonary Blood Flow

This group of lesions is not associated with obstruction to pulmonary blood flow. Cyanosis is caused by either abnormal ventricular-arterial connections or total mixing of systemic venous (deoxygenated) and pulmonary venous (oxygenated) blood within the heart (see Chapter 480). **Transposition of the great arteries** (or **vessels**) is the most common of the former group of lesions. In this condition the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle. Systemic venous blood returning to the right atrium is pumped directly back to the body, and oxygenated blood returning from the lungs to the left atrium is pumped back into the lungs. The **persistence of fetal pathways** (foramen ovale and ductus arteriosus) allows for some degree of mixing in the immediate newborn period, keeping the systemic saturation from falling until the ductus begins to close; these infants can then become extremely cyanotic quite precipitously.

Total mixing lesions include cardiac defects with a common atrium or ventricle, TAPVR, and truncus arteriosus (see Chapter 480). In this group, deoxygenated systemic venous blood and oxygenated pulmonary venous blood mix completely at some location in the heart, and as a result, the oxygen saturation is equal in the pulmonary artery and aorta. If pulmonary blood flow is not obstructed, these infants have a combination of cyanosis and pulmonary overcirculation leading to heart failure. In contrast, if pulmonary stenosis is present, these infants may have cyanosis alone, similar to patients with tetralogy of Fallot.

Chapter 475

Acyanotic Congenital Heart Disease: Left-to-Right Shunt Lesions

475.1 Atrial Septal Defect

Daniel Bernstein

Atrial septal defects **(ASDs)** can occur in any portion of the atrial septum—**secundum**, **primum**, or **sinus venosus**—depending on which embryonic septal structure has failed to develop normally (Fig. 475.1) (see Chapter 469). Less often, the atrial septum may be almost absent, with the creation of a functional single atrium. Isolated secundum ASDs account for approximately 7% of all congenital heart defects. The majority of cases of ASD are sporadic; autosomal dominant inheritance does occur as part of **Holt-Oram syndrome** (hypoplastic or absent thumbs, radii, triphalangism, phocomelia, first-degree heart block, ASD) or in families with both secundum ASD and heart block (see Table 473.2).

An isolated valve-incompetent **patent foramen ovale (PFO)** is a common echocardiographic finding during infancy. It is usually of no hemodynamic significance and is not considered an ASD; a PFO may play an important role if other structural heart defects are present. If another cardiac anomaly is causing increased right atrial pressure (pulmonary stenosis or atresia, tricuspid valve abnormalities, right ventricular dysfunction), venous blood may shunt across the PFO into the left atrium with resultant cyanosis. Because of the anatomic structure of the PFO, left-to-right shunting is unusual outside the immediate newborn period. In the presence of a large volume load or a hypertensive left atrium (e.g., secondary to mitral stenosis), the foramen ovale may be sufficiently dilated to result in a significant atrial left-to-right shunt. A valve-competent but probe-patent (able to be pushed opened with a catheter) PFO may be present in 15–30% of adults. An isolated PFO does not require surgical treatment, although it is a risk for paradoxical (right-to-left) systemic embolization. In adults who have had a thromboembolic stroke, echocardiographic screening for a PFO is routinely performed, and device closure of the PFO is a common treatment option.

475.2 Ostium Secundum Defect

Daniel Bernstein

An ostium secundum defect in the region of the fossa ovalis is the most common form of ASD and is associated with structurally normal atrioventricular (AV) valves (see Fig. 475.1). **Mitral valve prolapse** has been described in association with this defect but is rarely an important clinical consideration. Secundum ASDs may be single or multiple (fenestrated atrial septum), and openings ≥2 cm in diameter are common in symptomatic older children. Large defects may extend inferiorly toward the inferior vena cava (IVC) and ostium of the coronary sinus, superiorly toward the superior vena cava (SVC), or posteriorly. Females outnumber males 3:1 in incidence. **Partial anomalous pulmonary venous return** (PAPVR), usually of the right upper pulmonary vein, may be an associated lesion.

PATHOPHYSIOLOGY

The degree of left-to-right shunting depends on the size of the defect, the relative compliance of the right and left ventricles, and the relative vascular resistance in the pulmonary and systemic circulations. In large defects, a considerable shunt of oxygenated blood flows from the left to the right atrium (Fig. 475.2). This blood is added to the usual venous return to the right atrium and is pumped by the right ventricle to the lungs. With large defects, the ratio of pulmonary-to-systemic blood flow (Qp:Qs) is usually between 2:1 and 4:1. The paucity of symptoms in infants with ASDs is related to the structure of the right ventricle in early life, when its muscular wall is still thick and less compliant, thus limiting the left-to-right shunt. As the infant becomes older and pulmonary vascular resistance (PVR) drops, the right ventricular (RV) wall becomes thinner, and the left-to-right shunt across the ASD increases. The increased blood flow through the right side of the heart results in enlargement of the right atrium and ventricle and dilation of the pulmonary artery. The left atrium may also be enlarged as the increased pulmonary blood flow returns to the left atrium, but the left ventricle and aorta are normal in size. Despite the large pulmonary blood flow, pulmonary arterial pressure is usually initially normal

Congenital heart disease in the adult and pediatric patient. In: Zipes DP, Libby P, Bonow RO, et al., eds. Braunwald's Heart Disease, 11th ed. Philadelphia: Elsevier; 2019, Fig 75.17, p. 1536.)*

because of the absence of a high-pressure communication between the pulmonary and systemic circulations. PVR remains low throughout childhood, although it may begin to increase in adulthood and may eventually result in reversal of the shunt and clinical cyanosis **(Eisenmenger syndrome)**.

CLINICAL MANIFESTATIONS

A child with an ostium secundum ASD is often asymptomatic; the lesion is often discovered during routine physical examination. Even an extremely large secundum ASD rarely produces clinically evident heart failure in childhood. However, on closer evaluation, younger children may show subtle signs of failure to thrive, and older children may have varying degrees of exercise intolerance. Often, the degree of limitation may go unnoticed by the family until after repair, when the child's growth or activity level greatly increases.

The physical findings of an ASD are usually characteristic but fairly subtle and require careful examination of the heart, paying special attention to the heart sounds. Examination of the chest may reveal a mild left precordial bulge. An RV systolic lift may be palpable at the left sternal border. Sometimes a pulmonic ejection click can be heard. In most patients with an ASD, the characteristic finding is that the second heart sound (S_2) is **widely split and fixed** in its splitting during all phases of respiration. Normally, the duration of RV ejection varies with respiration, with inspiration increasing RV volume and delaying closure of the pulmonary valve, widening the S_2 split. With an ASD, RV diastolic volume is constantly increased because of the shunt, and ejection time is prolonged throughout all phases of respiration. A systolic ejection murmur is heard; it is usually no greater than a grade 3/6, medium pitched, without harsh qualities, seldom accompanied by a thrill, and best heard at the left middle and upper sternal border. It is produced by the increased flow across the RV outflow tract into the pulmonary artery. Because the atria are at low pressure, flow across the ASD itself does not cause an audible murmur. A short, rumbling mid-diastolic murmur produced by the increased volume of blood flow across the tricuspid valve (see Fig. 475.2) is often audible at the lower-left sternal border. This finding, which may be subtle and is heard best with the bell of the stethoscope, usually indicates a Qp:Qs ratio of at least 2:1.

DIAGNOSIS

The chest radiograph shows varying degrees of enlargement of the right ventricle and atrium, depending on the size of the shunt. The pulmonary artery is enlarged, and pulmonary vascularity is increased. These signs vary and may not be conspicuous in mild cases. Cardiac enlargement is often best appreciated on the lateral chest radiograph because the right ventricle protrudes anteriorly as its volume increases. The **electrocardiogram** (ECG) shows RV volume overload: the QRS axis may be normal or exhibit right axis deviation, and a minor RV conduction delay (rsR′ pattern in the right precordial leads) may be present (Fig. 475.3). **Right ventricular hypertrophy** would be unusual

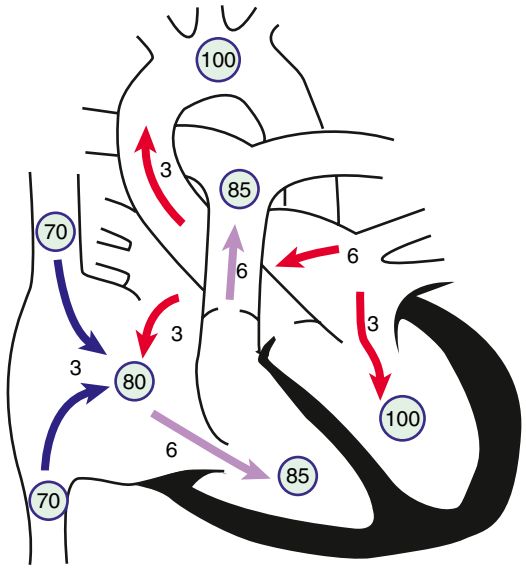

Fig. 475.2 Physiology of atrial septal defect (ASD). *Circled numbers* represent oxygen saturation (S_{O_2}) values. The *numbers next to the arrows* represent volumes of blood flow (in L/min/m^2). This illustration shows a hypothetical patient with a pulmonary-to-systemic blood flow ratio (Qp:Qs) of 2:1. Desaturated blood enters the right atrium from the vena cava at a volume of 3 L/min/m^2 and mixes with an additional 3 L of fully saturated blood shunting left to right across the ASD; the result is an increase in S_{O_2} in the right atrium. Six liters of blood flow through the tricuspid valve and cause a mid-diastolic flow rumble. S_{O_2} may be slightly higher in the right ventricle because of incomplete mixing at the atrial level. The full 6 L flow across the right ventricular outflow tract and cause a systolic ejection flow murmur. Six liters return to the left atrium, with 3 L shunting left to right across the defect and 3 L crossing the mitral valve to be ejected by the left ventricle into the ascending aorta (normal cardiac output).

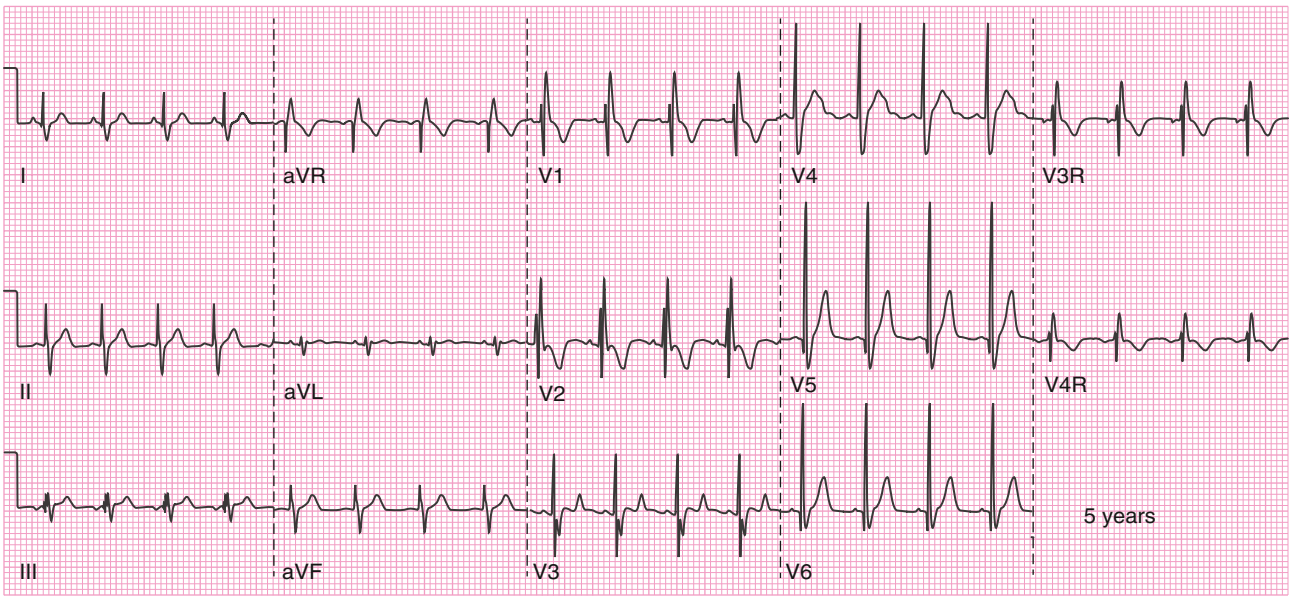

Fig. 475.3 Electrocardiogram in a child with an atrial septal defect showing rSR′ pattern (minor RV conduction delay) pattern in the right precordial leads.

in the absence of pulmonary hypertension or other lesions (e.g., valvar pulmonic stenosis).

The **echocardiogram** shows findings characteristic of RV volume overload, including an increased RV end-diastolic dimension and flattening and abnormal motion of the ventricular septum (see Fig. 475.1). A normal septum moves posteriorly during systole and anteriorly during diastole (synchronous with the left ventricular contractions). With RV overload and normal PVR, septal motion is either flattened or reversed—that is, anterior movement in systole. The location and size of the ASD are readily appreciated by two-dimensional (2D) scanning, with a characteristic brightening of the echo image seen at the edge of the defect caused by the increased reflectivity of ultrasound at the tissue-blood interface (T-artifact). The shunt is confirmed by pulsed and color flow Doppler. The normal entry of all pulmonary veins into the left atrium should be confirmed given the potential for anomalous return of the right upper pulmonary vein.

Patients with the classic features of a hemodynamically significant ASD on physical examination and chest radiography in whom echocardiographic identification of an isolated secundum ASD is made need not undergo diagnostic catheterization before repair, with the exception of an older patient, in whom PVR may be a concern. If pulmonary vascular disease is suspected, cardiac catheterization confirms the presence of the defect and allows measurement of the shunt ratio and pulmonary pressure and resistance.

If catheterization is performed, usually at the time of device closure, the oxygen content of blood from the right atrium will be much higher than that from the SVC (see Fig. 475.2). This feature is not specifically diagnostic because it may occur with PAPVR to the right atrium, with a **ventricular septal defect** (VSD) in the presence of tricuspid insufficiency, with AV septal defects associated with left ventricular–to–right atrial shunts, and with aorta–to–right atrial communications (ruptured sinus of Valsalva aneurysm). Pressure in the right side of the heart is usually normal, but small to moderate pressure gradients (<25 mm Hg) may be measured across the RV outflow tract because of functional pulmonary stenosis related to excessive blood flow. If the pressure gradient across the pulmonary valve is greater, pathologic pulmonary stenosis is likely present. In children and adolescents, PVR is almost always normal. The shunt is variable and depends on the size of the defect, but it may be of considerable volume. **Cineangiography**, performed with the catheter through the defect and in the right upper pulmonary vein, demonstrates the defect and confirms the location of the right upper pulmonary venous drainage (normal or aberrant into the SVC). **Pulmonary angiography** demonstrates the defect on the *levophase* (return of contrast to left side of the heart after passing through the lungs).

COMPLICATIONS

Secundum ASDs are usually isolated, although they may be associated with PAPVR, pulmonary valvular stenosis, VSD, pulmonary artery branch stenosis, and persistent left SVC, as well as mitral valve prolapse and insufficiency. Secundum ASDs are associated with autosomal dominant **Holt-Oram syndrome**. The gene responsible for this syndrome, situated in the region 12q21-q22 of chromosome 12, is *TBX5,* a member of the T-box transcriptional family. A **familial form of secundum ASD** associated *with* AV conduction delay has been linked to pathogenic variants in another transcription factor, Nkx2.5. Patients with **familial ASD** *without* heart block may carry a variant in the transcription factor GATA4, located on chromosome 8p22-23 (see Table 473.2).

TREATMENT

Transcatheter device or surgical closure is advised for all symptomatic patients and for asymptomatic patients with a Qp:Qs ratio of at least 2:1 and those with RV enlargement. The timing for elective closure is usually after the first year of life and before entry into school. Closure carried out at open heart surgery is associated with a mortality rate of <1%. Repair is preferred during early childhood because surgical mortality and morbidity are significantly greater in adulthood; the long-term risk of arrhythmia caused by chronic atrial dilation is also greater after ASD repair in adults. For most patients, *the procedure of choice is percutaneous catheter device closure using an atrial septal occlusion device,* implanted transvenously in the cardiac catheterization laboratory (Fig. 475.4). The results are excellent, and patients are usually discharged from the hospital the following day. The incidence of serious complications (e.g., device erosion) is very low and can be decreased by identifying high-risk patients, such as those with a deficient rim of septum in the area where the device would be anchored. Echocardiography can usually determine whether a patient is a good candidate for device closure. In patients with small secundum ASDs and minimal left-to-right shunts without RV enlargement, the consensus is that closure is usually not required. Infants with small to moderate-sized ASDs can be watched closely, because these defects will often grow smaller in the first year of life. It is unclear whether the persistence of a small ASD into adulthood increases the risk for stroke enough to warrant prophylactic closure of these defects in all patients, including those with no history of stroke.

PROGNOSIS

Small to moderate-sized ASDs detected in term infants may grow smaller or close spontaneously. Secundum ASDs are well tolerated during childhood, and significant symptoms do not usually appear until the third decade or later. Pulmonary hypertension, atrial dysrhythmias, tricuspid or mitral insufficiency, and heart failure are late manifestations; these symptoms may initially appear

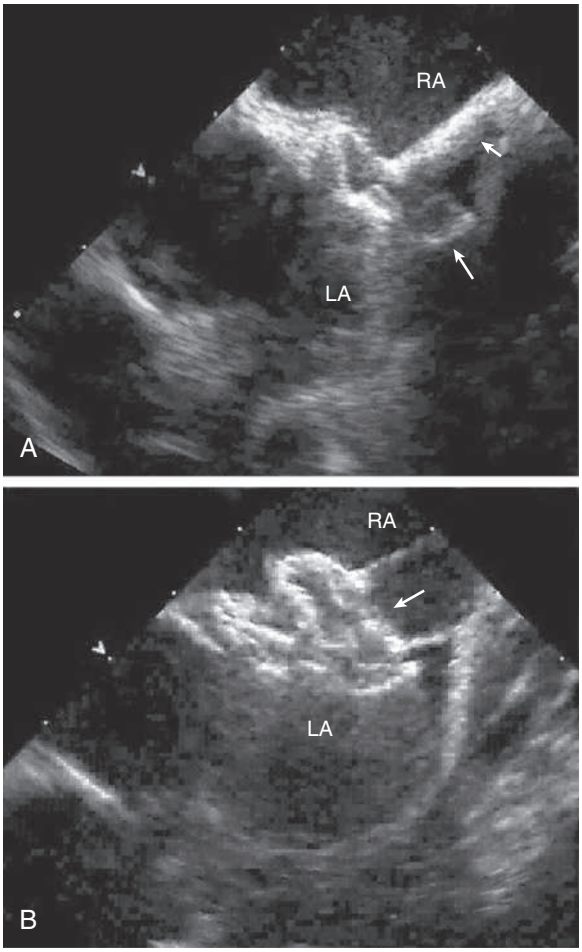

Fig. 475.4 Intravascular ultrasound imaging of transcatheter occlusion of an atrial septal defect (ASD). **A,** Catheter *(small arrow)* has been advanced across the ASD, and the left-sided disk of the device *(large arrow)* has been extruded from the sheath into the left atrium (LA). **B,** The right atrial disk *(arrow)* has now been extruded into the right atrium (RA). The two halves of the device are then locked together and the catheter detached from the occluder device and removed.

during the increased volume load of pregnancy. Infective endocarditis is extremely rare, and antibiotic prophylaxis for isolated secundum ASDs is not recommended.

The results after surgical or device closure in children with moderate-sized to large shunts are excellent. Symptoms, if present, disappear rapidly, and growth is frequently enhanced. Heart size decreases to normal, and the ECG shows decreased RV volume load. Late right-sided heart failure and arrhythmias are less common in patients who have had early repair, becoming more common in patients who undergo surgery after 20 years of age. Although early and midterm results with device closure are excellent, the long-term effects are not yet known. Reports of resolution of migraine headaches with aura in patients after device closure of an ASD or PFO suggest a possible thromboembolic etiology; however, whether to close such defects is still unclear.

475.3 Sinus Venosus Atrial Septal Defect

Daniel Bernstein

A sinus venosus ASD is situated in the upper part of the atrial septum in close relation to the entry of the superior vena cava (see Fig. 475.1). Often, one or more pulmonary veins (usually from the right lung) drain anomalously into the SVC. The SVC sometimes straddles the defect; in this case, some systemic venous blood enters the left atrium, but only rarely does it cause clinically evident cyanosis. The hemodynamic disturbance, clinical picture, ECG, and radiograph are similar to those seen in secundum ASD. The **diagnosis** can usually be made by echocardiography. If questions remain after echocardiogram regarding pulmonary venous drainage, cardiac CT or MRI is usually diagnostic. Cardiac catheterization is rarely required, except in adult patients in whom PVR assessment may be important. **Anatomic correction** generally requires surgical insertion of a patch to close the defect while incorporating the entry of any anomalous pulmonary veins into the left atrium. If the anomalous vein drains high in the SVC, the vein can be left intact and the ASD closed to incorporate the SVC mouth into the left atrium. The SVC proximal to the venous entrance is then detached and anastomosed directly to the right atrial appendage (Warden procedure). This procedure avoids direct suturing of the pulmonary vein, with less chance of future stenosis. Surgical results are generally excellent. Rarely, sinus venosus defects involve the IVC.

475.4 Partial Anomalous Pulmonary Venous Return

Daniel Bernstein

One or several pulmonary veins may return anomalously to the SVC or IVC, right atrium, or coronary sinus and produce a left-to-right shunt of oxygenated blood. *Partial* anomalous pulmonary venous return (PAPVR) usually involves some or all of the veins from only one lung, typically the right. When an associated ASD is present, it is generally of the sinus venosus type but can be secundum (see Chapters 475.2 and 475.3). When an ASD is detected by echocardiography, one must always search for associated PAPVR. The history, physical signs, and electrocardiographic and radiologic findings are indistinguishable from those of an isolated ostium secundum ASD. Occasionally, an anomalous vein draining into the IVC is visible on chest radiography as a crescentic shadow of vascular density along the right border of the cardiac silhouette **(scimitar syndrome)**; in these patients an ASD is not usually present, but **pulmonary sequestration** or **lung hypoplasia** and anomalous arterial supply to that lobe are common findings. **Total anomalous pulmonary venous return** (TAPVR) is a cyanotic lesion and is discussed in Chapter 480.7. Echocardiography generally confirms the diagnosis. MRI and CT are also useful if there is a question regarding pulmonary venous drainage or in cases of scimitar syndrome. If cardiac catheterization is performed, the presence of anomalous pulmonary veins is demonstrated by selective pulmonary arteriography, and anomalous pulmonary arterial supply to the right lung is demonstrated by descending aortography.

The prognosis for PAPVR is excellent, similar to that for ostium secundum ASDs. When a significant left-to-right shunt is present, surgical repair is performed. The associated ASD should be closed in such a way that pulmonary venous return is directed to the left atrium. A single anomalous pulmonary vein without an atrial communication may be difficult to redirect to the left atrium; if the shunt is small and the right ventricle is not enlarged, it may be left unoperated.

475.5 Atrioventricular Septal Defects (Ostium Primum and Atrioventricular Canal or Endocardial Cushion Defects)

Daniel Bernstein

The abnormalities encompassed by atrioventricular (AV) septal defects are grouped together because they represent a spectrum of a basic embryologic abnormality, a **deficiency of the AV septum**. In the normal heart, the tricuspid valve sits slightly lower (more toward the cardiac apex) than does the mitral valve, and thus a small portion of septum (the AV septum) separates the left ventricle from the right atrium. This septum is deficient in all forms of AV septal defect. When the AV septum is absent and there is also an **ostium primum** defect, the main communication is situated in the lower portion of the atrial septum and overlies the mitral and tricuspid valves. In most cases a **cleft in the anterior leaflet of the mitral valve** is also noted. The tricuspid valve is usually functionally normal, although some anatomic abnormality of the septal leaflet is present. The ventricular septum is intact.

An **AV septal defect**, formerly known as an *AV canal defect* or *endocardial cushion defect,* consists of a defect of the AV septum and contiguous atrial and ventricular septal defects with a common AV valve. The severity of the AV valve abnormality varies considerably. In a **complete AV septal defect**, a single AV valve is common to both ventricles and consists of an anterior and a posterior bridging leaflet related to the ventricular septum, with a lateral leaflet in each ventricle. The anterior bridging leaflet can be divided into right- and left-sided components or may be single and free floating over the ventricular septum. Complete AV septal defect is one of the most common forms of congenital heart disease in children with **Down syndrome**.

Transitional varieties of these defects also occur and include ostium primum defects with clefts in the anterior mitral and septal tricuspid valve leaflets and small VSDs and, less commonly, ostium primum defects with normal AV valves. In some patients the atrial septum is intact but a VSD is seen in the inlet septum, similar to that found in the complete form of AV septal defect. Sometimes, AV septal defects are associated with varying degrees of hypoplasia of one of the ventricles, known as either **left-dominant** or **right-dominant AV septal defect**. If the affected ventricular chamber is too small to establish a two-ventricle circulation, surgical palliation, aiming for an eventual Fontan procedure, is performed (see Chapters 479.4 and 480.10).

PATHOPHYSIOLOGY

In ostium primum defects, the basic abnormality is the combination of a left-to-right shunt across the atrial defect and mitral (or occasionally tricuspid) insufficiency. The shunt is usually moderate to large, the degree of mitral insufficiency is generally mild to moderate, and pulmonary artery pressure (PAP) is typically normal or only mildly increased. The physiology of this lesion is therefore similar to that of an ostium secundum ASD.

In complete AV septal defects, left-to-right shunting occurs at both the atrial and the ventricular level (Fig. 475.5). Additional shunting may occur directly from the left ventricle to the right atrium (known as a *Gerbode shunt*) because of absence of the AV septum. Pulmonary

hypertension and an early tendency to increase PVR are common. AV valvular insufficiency, which may be moderate to severe, further increases the volume load on one or both ventricles. If the defect is large enough, some right-to-left shunting may also occur at the atrial and ventricular levels and lead to mild arterial desaturation. With time, progressive pulmonary vascular disease increases the right-to-left shunt so that clinical cyanosis develops (**Eisenmenger physiology**; see Chapter 482.2). The risk for development of pulmonary vascular disease is greater in patients with Down syndrome, and therefore surgical correction is usually considered early in these patients, within the first 3-6 months of life.

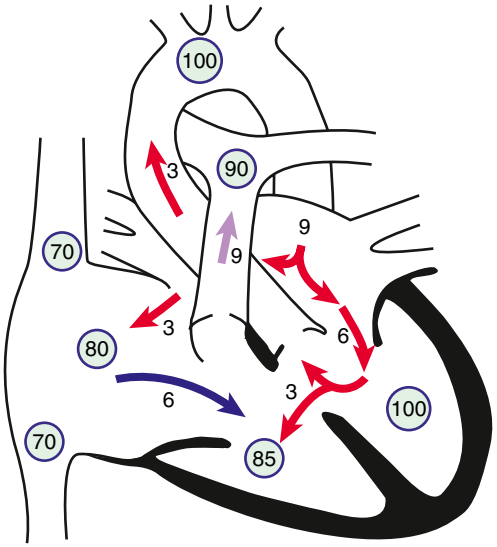

Fig. 475.5 Physiology of atrioventricular (AV) septal defect. *Circled numbers* represent oxygen saturation (S_{O_2}) values. The *numbers next to the arrows* represent volumes of blood flow (in L/min/m^2). This illustration shows a hypothetical patient with a pulmonary-to-systemic blood flow ratio (Qp:Qs) of 3:1. Desaturated blood enters the right atrium from the vena cava at a volume of 3 L/min/m^2 and mixes with 3 L of fully saturated blood shunting left to right across the atrial septal defect; the result is an increase in S_{O_2} in the right atrium. Six liters of blood flow through the right side of the common AV valve, joined by an additional 3 L of saturated blood shunting left to right at the ventricular level, further increasing S_{O_2} in the right ventricle. The full 9 L flow across the right ventricular outflow tract into the lungs. Nine liters return to the left atrium, with 3 L shunting left to right across the defect and 6 L crossing the left side of the common AV valve and causing a mid-diastolic flow rumble. Three liters of this volume shunt left to right across the ventricular septal defect, and 3 L are ejected into the ascending aorta (normal cardiac output).

CLINICAL MANIFESTATIONS

Many children with an isolated ostium primum defect are asymptomatic, and the anomaly is discovered during a general physical examination. In patients with moderate shunts and mild mitral insufficiency, the physical signs are similar to those of the secundum ASD, but with an additional apical holosystolic murmur caused by mitral insufficiency.

A history of exercise intolerance, easy fatigability, and recurrent pneumonia may be obtained, especially in infants with large left-to-right shunts and severe mitral insufficiency. In these patients, cardiac enlargement is moderate or marked and the precordium is hyperdynamic. Auscultatory signs produced by the left-to-right shunt include a normal or accentuated first heart sound (S_1); wide, fixed splitting of S_2; a pulmonary systolic ejection murmur sometimes preceded by a click; and a low-pitched, mid-diastolic rumbling murmur at the lower-left sternal edge or apex, or both, as a result of increased flow through the AV valves. **Mitral insufficiency** may be manifested by a harsh (occasionally very high-pitched) **apical holosystolic murmur** that radiates to the left axilla.

With *complete* AV septal defects, heart failure and intercurrent pulmonary infection usually appear in infancy. The liver is enlarged, and the infant often develops respiratory symptoms, feeding intolerance, and failure to thrive. Cardiac enlargement is moderate to marked, and a systolic thrill is frequently palpable at the lower-left sternal border. A precordial bulge and lift may be present as well. S_1 is normal or accentuated. S_2 is fixed and widely split if the pulmonary flow is massive. A low-pitched, mid-diastolic rumbling murmur is audible at the lower-left sternal border, indicative of increased blood flow across the right side of the common AV valve, and a pulmonary systolic ejection murmur is produced by the large pulmonary flow. The harsh apical holosystolic murmur of mitral insufficiency may also be present.

DIAGNOSIS

Chest radiographs of children with complete AV septal defects often show moderate to severe cardiac enlargement caused by the prominence of both ventricles and atria. The pulmonary artery is large, and pulmonary vascularity is increased.

The ECG in patients with a complete AV septal defect is *distinctive* and usually diagnostic. Principal abnormalities include (1) superior and rightward orientation of the mean frontal QRS axis (−90 to −180 degrees) represented by the QRS being negative in both lead I and lead aVF, (2) counterclockwise inscription of the superiorly oriented QRS vector loop (manifested by a Q wave in leads I and aVL), (3) signs of biventricular hypertrophy or isolated RV hypertrophy, (4) RV conduction delay (rSR′ pattern in leads V_3R and V_1), (5) normal or tall P waves, and (6) occasional prolongation of the P-R interval (Fig. 475.6).

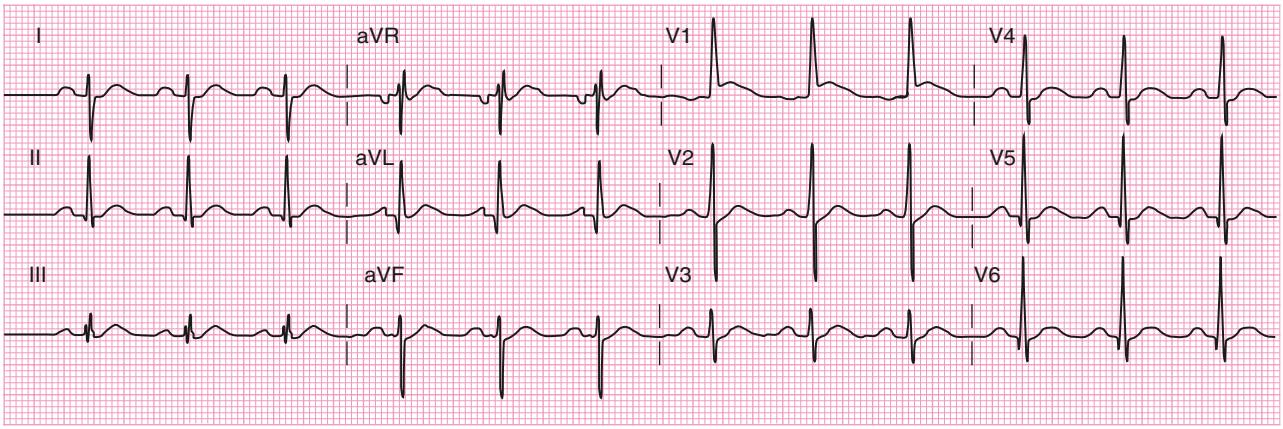

Fig. 475.6 Electrocardiogram from an infant with atrioventricular septal defect. Note that the QRS complexes are negative in both leads I and roughly equipotential in lead III, so the QRS axis is −150 degrees. There is also right ventricular hypertrophy (RVH) and a minor right ventricular conduction delay with an RSR′ pattern in aVR.

The echocardiogram is diagnostic and shows signs of RV enlargement (Fig. 475.7). There is encroachment of the mitral valve into the left ventricular outflow tract (LVOT); the abnormally low position of the AV valves results in a "gooseneck" deformity of the LVOT. In normal hearts the tricuspid valve inserts slightly more toward the apex than does the mitral valve. In AV septal defects, both valves insert at the same level because of absence of the AV septum. In complete AV septal defects, the inlet portion of the ventricular septum is also deficient, and the common AV valve is readily appreciated. Pulsed and color flow Doppler echocardiography will demonstrate left-to-right shunting at the atrial, ventricular, or left ventricular–to–right atrial levels and can be used to semiquantitate the degree of AV valve insufficiency. Echocardiography is useful for determining the insertion points of the chordae of the common AV valve, the relative size of the two ventricles, and evaluating the presence of associated lesions such as patent ductus arteriosus (PDA) or coarctation of the aorta.

Cardiac catheterization and angiocardiography are rarely required to confirm the diagnosis unless pulmonary vascular disease is suspected, as when the diagnosis has been delayed beyond early infancy, especially in patients with Down syndrome in whom the development of pulmonary vascular disease may be more rapid. Catheterization demonstrates the magnitude of the left-to-right shunt, the degree of PVR elevation, and the severity of insufficiency of the common AV valve. By oximetry, the shunt is usually demonstrable at both the atrial and the ventricular level. Arterial oxygen saturation is normal or only mildly reduced unless pulmonary vascular disease is present. Children with ostium primum defects generally have normal or only moderately elevated PAP. Conversely, complete AV septal defects are associated with RV and pulmonary arterial hypertension and, in older patients, increased PVR (see Chapter 482.2).

Selective left ventriculography will demonstrate deformity of the common AV valve and distortion of the LVOT caused by the abnormally apical position of this valve (gooseneck deformity). The abnormal anterior leaflet of the mitral valve is serrated, and insufficiency is noted. Direct shunting of blood from the left ventricle to the right atrium may also be demonstrated.

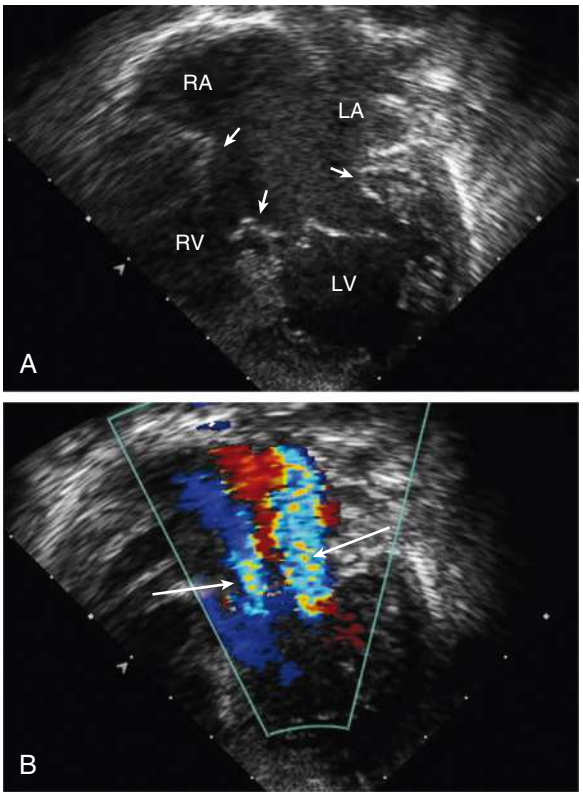

Fig. 475.7 Echocardiograms of atrioventricular (AV) septal defect. **A,** Subcostal four-chamber view demonstrating the common AV valve *(arrows)* spanning the atrial and ventricular septal defects. **B,** Doppler imaging shows two jets of regurgitation through the left side of the common AV valve *(arrows)*. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

TREATMENT

Ostium primum defects are approached surgically from an incision in the right atrium. The cleft in the mitral valve is located through the atrial defect and is repaired by direct suture. The defect in the atrial septum is usually closed by insertion of a patch prosthesis. The surgical mortality rate for ostium primum defects is very low.

Surgical treatment of complete AV septal defects is more complex, although highly successful. The postoperative course may be prolonged in infants with severe cardiac failure and in those with pulmonary hypertension. Because of the risk of **pulmonary vascular disease** developing as early as 6-12 months of age, surgical intervention must be performed during infancy. Full correction of these defects can be readily accomplished. Palliation with *pulmonary arterial banding* is uncommon now and reserved for the small subset of patients who have other associated lesions that make early corrective surgery too risky. However, banding may not be effective in patients with a large amount of AV valve regurgitation, as the higher pressure will only increase the regurgitation. The atrial and ventricular defects are patched, using either one or two separate patches, and the AV valves are reconstructed. Uncommon complications include surgically induced heart block requiring placement of a permanent pacemaker and excessive LVOT narrowing requiring surgical revision. More common long-term complications include residual tricuspid or mitral regurgitation, because full repair of very abnormal valves is often not possible. This requires long-term surveillance because these patients may require replacement with a prosthetic valve later in life.

PROGNOSIS

The prognosis for unrepaired complete AV septal defects depends on the magnitude of the left-to-right shunt, degree of PVR elevation, and severity of AV valve insufficiency. Before the advent of early corrective surgery, death from cardiac failure during infancy was common, and patients who survived without surgery usually developed pulmonary vascular disease. Most unoperated patients with ostium primum defects and minimal AV valve involvement are asymptomatic or have only minor, nonprogressive symptoms until they reach the third or fourth decade of life, similar to the course of patients with secundum ASDs. Today, long-term results after surgical repair are excellent. Late postoperative **complications** include atrial arrhythmias and heart block, progressive narrowing of the LVOT requiring surgical revision, and eventual worsening of AV valve regurgitation (usually on the left side) requiring reoperation or replacement with a prosthetic valve.

475.6 Ventricular Septal Defect

Daniel Bernstein

Ventricular septal defect is the most common cardiac malformation and accounts for 25% of cases of congenital heart disease. Defects may occur in any portion of the ventricular septum, but the most common are of the **membranous** type (Fig. 475.8). These defects are in a posteroinferior position, anterior to the septal leaflet of the tricuspid valve. VSDs between the crista supraventricularis and the papillary muscle of the conus may be associated with pulmonary stenosis and other manifestations of tetralogy of Fallot (see Chapter 479.1). VSDs superior to the crista supraventricularis **(supracristal)** are less common; these are found just beneath the pulmonary valve and may impinge on an aortic sinus and cause aortic insufficiency (see Chapter 475.7). Supracristal

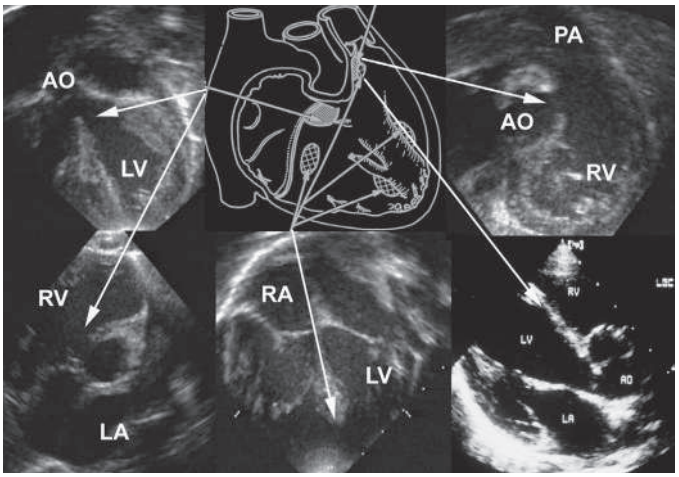

Fig. 475.8 Different types of ventricular septal defects (VSDs). The **central diagram** outlines the location of the various types of defects as seen from the right ventricle. **Two left images** show a perimembranous VSD as seen in the five-chamber and short-axis views. Note the defect is roofed by the aorta and is next to the tricuspid valve. **Bottom middle** echocardiogram shows a muscular apical defect. **Top right image** is a right anterior oblique view in a doubly committed VSD. **Bottom right image** is a short axis view showing an outlet VSD with prolapse of the right coronary cusp. AO, Aorta; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle. *(From Webb GD, Smallhorn JF, Therrien J, et al. Congenital heart disease in the adult and pediatric patient. In: Zipes DP, Libby P, Bonow RO, et al., eds. Braunwald's Heart Disease, 11th ed. Philadelphia: Elsevier; 2019, Fig 75.21, p. 1514.)*

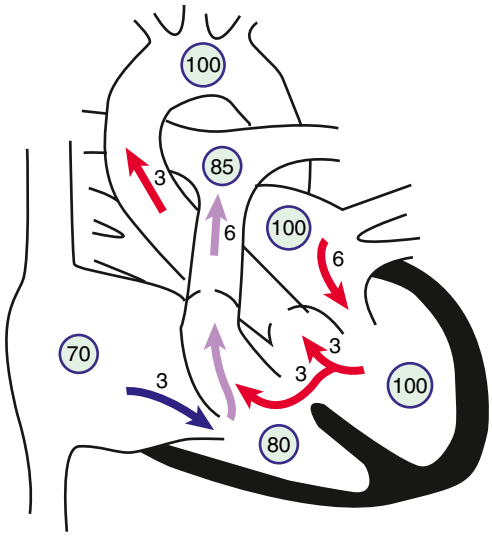

Fig. 475.9 Physiology of a moderate-to-large ventricular septal defect. *Circled numbers* represent oxygen saturation (So_2) values. The *numbers next to the arrows* represent volumes of blood flow (in L/min/m^2). This illustration shows a hypothetical patient with a pulmonary-to-systemic blood flow ratio (Qp:Qs) of 2:1. Desaturated blood enters the right atrium from the vena cava at a volume of 3 L/min/m^2 and flows across the tricuspid valve. An additional 3 L of blood shunt left to right across the VSD, resulting in increased So_2 in the right ventricle. Six liters of blood are ejected into the lungs (2:1 shunt). Pulmonary arterial saturation may be further increased because of incomplete mixing at the right ventricular level. Six liters return to the left atrium, cross the mitral valve, and cause a mid-diastolic flow rumble. Three liters of this volume shunt left to right across the VSD, and 3 L are ejected into the ascending aorta (normal cardiac output).

VSDs are more common in patients of Asian descent. VSDs in the midportion or apical region of the ventricular septum are muscular in type and may be single or multiple ("Swiss cheese" septum).

PATHOPHYSIOLOGY

The physical size of the VSD is a major determinant of the size of the left-to-right shunt. When the defect is large, the level of pulmonary vascular resistance (PVR) in relation to systemic vascular resistance (SVR) is the major determinant of the shunt's magnitude, since the large defect will essentially equalize pressure between the two ventricles. When a small communication is present (usually <5 mm), the VSD is deemed to be pressure **restrictive**, meaning that right ventricular (RV) pressure is normal or only slightly elevated. The higher pressure in the left ventricle drives the shunt left to right, and the size of the defect limits the magnitude of the shunt. In larger, **nonrestrictive** VSDs (usually >10 mm), RV and left ventricular (LV) pressures are equalized. In these defects the direction of shunting and the shunt magnitude are determined by the PVR/SVR ratio (Fig. 475.9).

After birth in patients with a large VSD, PVR may remain elevated, delaying the normal postnatal decrease, and thus the size of the left-to-right shunt may initially be limited. Because of normal involution of the media of small pulmonary arterioles, PVR begins to fall in the first few weeks after birth, and the size of the left-to-right shunt then increases. Eventually, a large left-to-right shunt develops, and clinical symptoms become apparent. In most cases during early infancy, PVR is only slightly elevated, and the major contribution to pulmonary hypertension is the large communication allowing exposure of the pulmonary circulation to systemic pressure and the large pulmonary blood flow. With continued exposure of the pulmonary vascular bed to high systolic pressure and high flow, pulmonary vascular obstructive disease eventually develops. When the PVR/SVR ratio approaches 1:1, the shunt becomes bidirectional, signs of heart failure abate, and the patient begins to show signs of cyanosis (**Eisenmenger physiology**; see Chapter 482.2), intermittent at first, but then more constant. In rare infants with a large VSD, more often in those with Down syndrome, PVR never decreases after birth, and symptoms may remain minimal until Eisenmenger physiology becomes evident.

The magnitude of intracardiac shunts is usually described by the Qp:Qs ratio. If the left-to-right shunt is small (Qp:Qs <1.5:1), the cardiac chambers are not appreciably enlarged, and the pulmonary vascular bed is probably normal. If the shunt is large (Qp:Qs >2:1), left atrial and LV volume overload occurs, and RV and pulmonary arterial hypertension may be present if the defect is large. The main pulmonary artery, left atrium, and left ventricle are enlarged.

CLINICAL MANIFESTATIONS

The clinical findings of patients with a VSD vary according to the size of the defect and pulmonary blood flow and pressure. Small VSDs with trivial left-to-right shunts and normal pulmonary artery pressure (PAP) are common. These patients are asymptomatic, and the cardiac lesion is usually found during routine physical examination. Characteristically, a loud, harsh, or blowing holosystolic murmur is present and heard best over the lower-left sternal border, and it is frequently accompanied by a thrill. In a few cases the murmur ends before the second heart sound (S_2), presumably because of closure of the defect during late systole. A short, loud, harsh systolic murmur localized to the apex in a neonate is often a sign of a tiny VSD in the apical muscular septum. These tiny defects most often close during infancy. In premature infants the murmur of a VSD may be heard early because PVR decreases more rapidly.

Large VSDs with excessive pulmonary blood flow and pulmonary hypertension are responsible for signs of congestive heart failure: dyspnea, feeding difficulties, poor growth, profuse perspiration, and recurrent pulmonary infections in early infancy. Cyanosis is usually absent, but duskiness is sometimes noted during infections or crying. Prominence of the left precordium is common, as are a palpable parasternal lift, a laterally displaced apical impulse and apical thrust, and a systolic thrill. The holosystolic murmur of a large VSD is generally less harsh than that of a small VSD and more blowing in nature because of the absence of a significant pressure gradient across the defect. It is less likely to be prominent in the newborn period before PVR drops. The

pulmonic component of S_2 may be increased as a result of pulmonary hypertension. The presence of a mid-diastolic, low-pitched rumble at the apex is caused by increased blood flow across the mitral valve and usually indicates a Qp:Qs ratio ≥2:1. This murmur is best appreciated with the bell of the stethoscope.

DIAGNOSIS

In patients with small VSDs, the chest radiograph is usually normal, although minimal cardiomegaly and a borderline increase in pulmonary vasculature may be observed. The ECG is generally normal but may suggest LV hypertrophy. The presence of RV hypertrophy on ECG is worrisome and a warning that the defect is not small and that the patient has pulmonary hypertension or an associated lesion such as pulmonic stenosis. In large VSDs the chest radiograph shows gross cardiomegaly with prominence of both ventricles, the left atrium, and the pulmonary artery (Fig. 475.10). Pulmonary vascular markings are increased, and frank pulmonary edema, including pleural effusions, may be present. The ECG shows biventricular hypertrophy; the P waves may be notched (indicative of left atrial [LA] enlargement).

The 2D echocardiogram shows the position and size of the VSD (see Fig. 475.8). In small defects, especially those of the muscular septum, the defect itself may be difficult to image and is visualized only by color Doppler examination. In defects of the **membranous septum**, a thin membrane (called a **ventricular septal aneurysm** but consisting of abnormal tricuspid valve tissue) can partially cover the defect and limit the volume of the left-to-right shunt. Echocardiography is also useful for estimating shunt size by examining the degree of volume overload of the left atrium and left ventricle; in the absence of associated lesions, the extent of their increased dimensions is a good reflection of the size of the left-to-right shunt. Pulsed Doppler examination shows whether the VSD is pressure restrictive by calculating the pressure gradient across the defect. Such calculation allows an estimation of RV pressure and helps determine whether the patient is at risk for the development of early pulmonary vascular disease. The echocardiogram can also be useful to determine the presence of aortic valve insufficiency or aortic leaflet prolapse, which can be associated especially with supracristal VSDs.

The hemodynamics of a VSD can also be demonstrated by cardiac catheterization, although catheterization currently is performed only when laboratory data do not fit well with the clinical findings or when pulmonary vascular disease is suspected. Oximetry demonstrates increased oxygen content in the right ventricle; because some defects eject blood almost directly into the pulmonary artery (streaming), the full magnitude of the oxygen saturation increase may only be apparent when pulmonary arterial blood is sampled. Small, restrictive VSDs are associated with normal right-sided heart pressures and PVR. Large, nonrestrictive VSDs are associated with equal or near-equal pulmonary and systemic systolic pressure and variable elevations in PVR. Pulmonary blood flow may be 2-4 times systemic blood flow. In patients with such "hyperdynamic pulmonary hypertension," PAP is at systemic level, but PVR is only minimally elevated because of the high pulmonary blood flow (resistance is equal to the mean pressure divided by flow). However, if left untreated until Eisenmenger syndrome is present, systolic and diastolic PAP will be elevated and the degree of left-to-right shunting minimal. In these cases, desaturation of blood in the left ventricle is usually encountered. The size, location, and number of ventricular defects can be demonstrated by left ventriculography. Contrast medium passes across the defect(s) to opacify the right ventricle and pulmonary artery. Administration of 100% oxygen with and without nitric oxide can be used to determine whether PVR, if elevated, is still reactive and therefore more likely to decrease after surgical repair.

TREATMENT

The natural course of a VSD depends to a large degree on the size of the defect. A significant number (30–50%) of small defects close spontaneously, most frequently during the first 2 years of life. Small *muscular* VSDs are more likely to close (up to 80%) than *membranous* VSDs (up to 35%). Most defects that close do so before age 4 years, although spontaneous closure has been reported in adults. VSDs that close often have ventricular septal aneurysm (accessory tricuspid valve) tissue covering them that limits the magnitude of the shunt. Most children with small restrictive defects remain asymptomatic, without evidence of an increase in heart size, PAP, or PVR; a long-term risk is infective endocarditis. Some long-term studies of adults with unoperated small VSDs show an increased incidence of arrhythmia, subaortic stenosis, and exercise intolerance. It is recommended that an isolated, small, hemodynamically insignificant VSD is not an indication for surgery. However, with the declining risk of open heart surgery, whether all VSDs should be closed electively in mid-childhood is still debated.

It is less common for moderate or large VSDs to close spontaneously, although even defects large enough to result in heart failure may become smaller, and up to 8% may close completely. More frequently, infants with large defects have repeated episodes of respiratory infection and heart failure despite optimal medical management. Heart failure may be manifested in many of these infants primarily as failure to thrive. Pulmonary hypertension occurs as a result of high pulmonary blood flow. These patients are at risk for pulmonary vascular disease if the defect is not repaired during early infancy.

Patients with VSD are also at risk for the development of **aortic valve regurgitation**, the greatest risk occurring in patients with a supracristal VSD (see Chapter 475.7), where the position of the defect undermines support for the right coronary or noncoronary leaflet of the aortic valve. A small number of patients with VSD develop **acquired infundibular pulmonary stenosis**, which then protects the pulmonary circulation from the short-term effects of pulmonary overcirculation and the long-term effects of pulmonary vascular disease. In these patients the clinical picture changes from that of a VSD with a large left-to-right shunt to a VSD with pulmonary stenosis. The shunt may diminish in

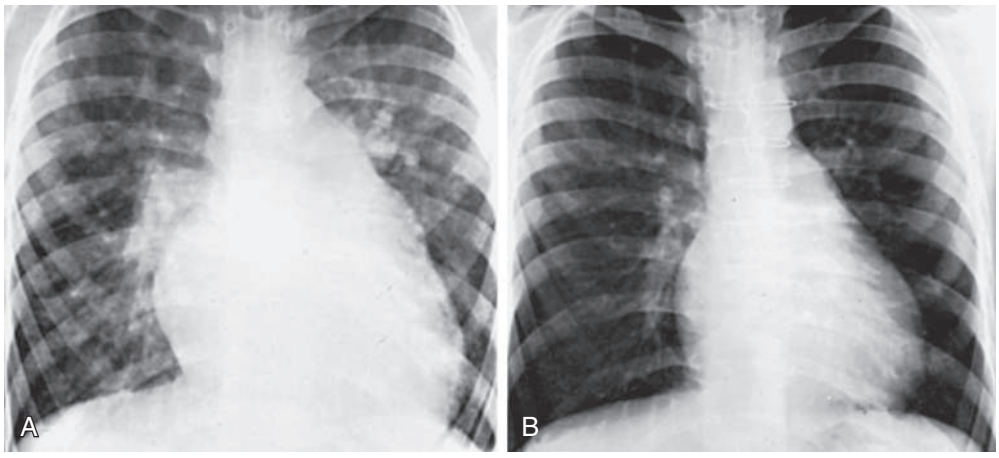

Fig. 475.10 A, Preoperative radiograph in a patient with a ventricular septal defect with a large left-to-right shunt and pulmonary hypertension. Significant cardiomegaly, prominence of the pulmonary arterial trunk, and pulmonary overcirculation are evident. B, Three years after surgical closure of the defect, heart size is greatly decreased and the pulmonary vasculature is normal.

size, become balanced, or even become a net right-to-left shunt. These patients must be carefully distinguished from those in whom an Eisenmenger physiology develops (see Chapter 482.2).

In patients with small VSDs, parents should be reassured of the relatively benign nature of the lesion, and the child should be encouraged to live a normal life, with no restrictions on physical activity. Surgical repair is not recommended; however, routine follow-up with the cardiologist is important. As protection against infective endocarditis, the integrity of primary and permanent teeth should be carefully maintained; with the latest revision of the American Heart Association (AHA) guidelines, antibiotic prophylaxis is no longer recommended for dental visits or surgical procedures (see Chapter 486). These patients can be monitored by a combination of clinical examination and noninvasive laboratory tests until the VSD has closed spontaneously. Echocardiography is used to estimate PAP, screen for the development of LVOT pathology (subaortic membrane or aortic regurgitation), and confirm spontaneous closure.

In infants with a large VSD and heart failure, management is directed at reducing symptoms and optimizing the patient's fluid status so that they are in optimal condition for surgical repair. In infants in the first year of life, if early treatment is successful, the size of the defect may sometimes diminish in size with clinical improvement. Selected patients in this group can be observed closely with echocardiographic monitoring. The clinician must be alert not to confuse clinical improvement caused by a decrease in defect size with clinical changes caused by the development of Eisenmenger physiology. Because surgical closure can be carried out at low risk in most infants, medical management should not be pursued in symptomatic infants after an initial unsuccessful trial. Because pulmonary vascular disease can usually be prevented when surgery is performed within the first year of life, even infants with well-controlled heart failure should not have surgery delayed inordinately unless there is echocardiographic evidence that the defect is becoming pressure restrictive.

Indications for surgical closure of a VSD include patients at any age with large defects in whom clinical symptoms and failure to thrive cannot be controlled medically or in whom the defect is not decreasing in size; infants between 6 and 12 months of age with moderate to large defects associated with pulmonary hypertension, even if the symptoms are controlled by medication; and patients older than 24 months with a Qp:Qs ratio greater than 2:1. Patients with a supracristal VSD of any size are usually referred for surgery because of their higher risk for developing aortic valve regurgitation (see Chapter 475.7). Severe pulmonary vascular disease nonresponsive to pulmonary vasodilators is a contraindication to closure of a VSD.

Transcatheter closure has been used successfully in treating larger muscular VSDs, which may be difficult to access by surgery. Perimembranous and intracristal VSD catheter closure is more complex because of the proximity of the defect to the tricuspid valve and conduction system; devices have been designed more specifically to address these issues and are currently being investigated. Preliminary data suggest that, for carefully selected patients (usually children beyond infancy), the results appear to be comparable to surgical repair. Hybrid methods employing a sternotomy with device placement through the anterior wall of the right ventricle under transesophageal echocardiographic and fluoroscopic visualization have also been performed in difficult-to-approach defects.

PROGNOSIS

The results of primary surgical repair are excellent, and complications leading to long-term problems (residual ventricular shunts requiring reoperation or device closure and heart block requiring a pacemaker) are rare. Surgical risks are somewhat higher for defects in the muscular septum, particularly apical defects and multiple (Swiss cheese–type) VSDs. Some of these patients may require pulmonary arterial banding if symptomatic, with subsequent debanding and repair of multiple VSDs at an older age.

After surgical closure of the left-to-right shunt, the hyperdynamic heart becomes quiet, cardiac size decreases toward normal (see Fig. 475.10), thrills and murmurs are absent, and pulmonary artery hypertension regresses. The patient's clinical status greatly improves. Most infants begin to thrive, often quite rapidly after hospital discharge, and cardiac medications are no longer required. Catch-up growth occurs in most patients within the next year. In some patients, after successful surgery, systolic ejection murmurs of low intensity persist for months. The long-term prognosis after surgery is excellent. Patients with a small VSD and those who have undergone surgical closure without residua are considered to be at standard risk for health and life insurance.

475.7 Supracristal Ventricular Septal Defect with Aortic Insufficiency

Daniel Bernstein

A supracristal VSD can be complicated by **prolapse of the aortic valve** into the defect and aortic insufficiency, which may eventually develop in 50–90% of these patients. Although supracristal VSD accounts for approximately 5% of all patients with VSD, the incidence is higher in Asian children and in males. The VSD, which may be small or moderate in size, is located anterior to and directly below the pulmonary valve in the outlet septum, superior to the muscular ridge known as the *crista supraventricularis,* which separates the trabecular body of the right ventricle from the smooth outflow portion. The right or, less often, the noncoronary aortic cusp prolapses into the defect and may partially or even completely occlude it. Such occlusion may limit the amount of left-to-right shunting and give the false impression that the defect is not large. Aortic insufficiency is most often not recognized until after 5 years of age, or even later. Although most common with supracristal VSDs, aortic insufficiency is occasionally associated with VSDs located in the membranous septum.

Early heart failure secondary to a large left-to-right shunt rarely occurs, but without surgery, moderate to severe aortic insufficiency and left ventricular failure may eventually ensue. The murmur of a supracristal VSD is usually heard at the mid- to upper-left sternal border, as opposed to the lower-left sternal border, and it is sometimes confused with that of pulmonic stenosis. A decrescendo diastolic murmur will be appreciated at the upper-right or mid-left sternal borders if there is aortic insufficiency. More advanced degrees of aortic insufficiency will be associated with a wide pulse pressure and a hyperdynamic precordium. These clinical findings must be distinguished from PDA or other defects associated with aortic runoff.

The clinical manifestations vary widely, from trivial aortic regurgitation and small left-to-right shunts in asymptomatic children to florid aortic insufficiency and massive cardiomegaly in symptomatic adolescents. Closure of all supracristal ventricular VSDs is usually recommended to prevent the development of aortic regurgitation, even in an asymptomatic child. Patients who already have significant aortic insufficiency require surgical intervention to prevent irreversible left ventricular dysfunction. Surgical options depend on the degree of damage to the valve, and for mild insufficiency, may include simple closure of the defect to bolster the valve apparatus without touching the valve itself, valvuloplasty for more significant degrees of involvement, and replacement with a prosthesis or homograft or aortopulmonary translocation (Ross procedure) for severe involvement.

475.8 Patent Ductus Arteriosus

Daniel Bernstein

During fetal life, most of the pulmonary arterial blood is shunted right to left through the ductus arteriosus into the aorta (see Chapter 470). Functional closure of the ductus normally occurs soon after birth, usually within the first week of life, but if the ductus remains patent when

PVR falls, aortic blood then is shunted left to right into the pulmonary artery. The aortic end of the ductus is just distal to the origin of the left subclavian artery, and the ductus enters the pulmonary artery at its bifurcation. Female patients with patent ductus arteriosus (PDA) outnumber males 2:1. PDA is also associated with maternal rubella infection during early pregnancy, an uncommon occurrence in the vaccination era. PDA is a common problem in premature infants because the smooth muscle in the wall of the preterm ductus is less responsive to high Po_2 and therefore less likely to constrict after birth. In these infants the shunt through a PDA can cause severe hemodynamic derangements and several major sequelae (see Chapter 131.3).

When a term infant is found to have a PDA, the wall of the ductus is deficient in both the mucoid endothelial layer and the muscular media, whereas in the premature infant, the PDA usually has a normal structure. Thus a PDA persisting beyond the first few weeks of life in a term infant rarely closes spontaneously or with pharmacologic intervention, whereas if early pharmacologic or surgical intervention is not required in a premature infant, spontaneous closure occurs in most instances. A PDA is seen in 10% of patients with other congenital heart lesions and often plays a critical role in providing a source of pulmonary blood flow when the right ventricular outflow tract is stenotic or atretic (see Chapter 479) or in providing systemic blood flow in the presence of aortic coarctation or interruption (see Chapters 476.6-476.8) or in hypoplastic left heart syndrome.

A PDA is a common finding (~90%) in patients with **smooth muscle dysfunction syndrome (SMDS)** caused by a heterozygous pathogenic variant in *ACTA2*. Additional features include congenital mydriasis, pulmonary hypertension, aortic and other arterial aneurysms, moyamoya-like cerebrovascular disease, and intestinal hypoperistalsis.

PATHOPHYSIOLOGY

Because of the higher aortic pressure postnatally, blood shunts left to right through the ductus, from the aorta to the pulmonary artery. The extent of the shunt depends on the size of the ductus and on the PVR/SVR ratio. If the PDA is small, pressures within the pulmonary artery, the right ventricle, and the right atrium are normal. If the PDA is large, PAP may be elevated to systemic levels during both systole and diastole. Thus patients with a large PDA are at high risk for the development of pulmonary vascular disease if left unoperated.

CLINICAL MANIFESTATIONS

A small PDA is usually asymptomatic and is usually diagnosed by the presence of a heart murmur. A large PDA will result in heart failure similar to that encountered in infants with a large VSD. Stunting of physical growth may be a major manifestation in infants with large shunts. A small PDA is associated with normal peripheral pulses, and a large PDA results in bounding peripheral arterial pulses and a *wide pulse pressure,* caused by runoff of blood into the pulmonary artery during diastole. Although normal in size when the ductus is small, the heart is moderately or grossly enlarged in cases with a large communication; in these patients the apical impulse is prominent and, with cardiac enlargement, is heaving. A **thrill**, maximal in the second left interspace, is often present and may radiate toward the left clavicle, down the left sternal border, or toward the apex. It is usually systolic but may also be palpated throughout the cardiac cycle. The classic continuous murmur is described as "machinery-like" in quality. It begins soon after onset of S_1, reaches maximal intensity at the end of systole, and wanes in late diastole. It may be localized to the second left intercostal space or radiate down the left sternal border or to beneath the left clavicle. When PVR is increased, the diastolic component of the murmur may be less prominent or absent. In patients with a large left-to-right shunt, a low-pitched mitral mid-diastolic murmur may be audible at the apex as a result of the increased volume of blood flow across the mitral valve.

DIAGNOSIS

If the left-to-right shunt is small, the ECG is normal; if the ductus is large, LV or biventricular hypertrophy is present. The diagnosis of an isolated, uncomplicated PDA is untenable when RV hypertrophy is present on the ECG.

Radiographic studies in patients with a large PDA show a prominent pulmonary artery with increased pulmonary vascular markings. Cardiac size depends on the degree of left-to-right shunting; it may be normal or moderately to greatly enlarged. The chambers involved are the left atrium and left ventricle. The aortic knob may be normal or prominent.

On echocardiogram the cardiac chambers will be normal in size if the ductus is small. With large shunts, LA and LV dimensions are increased. The ductus can easily be visualized directly and its size estimated. Color and pulsed Doppler examinations demonstrate systolic or diastolic (or both) retrograde turbulent flow in the pulmonary artery and aortic retrograde flow in diastole in the presence of a large shunt (Fig. 475.11).

The clinical signs and echocardiographic findings are sufficiently distinctive to allow an accurate diagnosis by noninvasive methods in most patients. In rare patients with atypical findings, cardiac catheterization may be indicated for confirmation of diagnosis. Cardiac catheterization will demonstrate either normal or increased pressure in the right ventricle and pulmonary artery, depending on the size of the ductus. The presence of oxygenated blood shunting into the pulmonary artery confirms the left-to-right shunt. The catheter may pass from the pulmonary artery through the ductus into the descending aorta. Injection of contrast medium into the ascending aorta shows opacification of the pulmonary artery from the aorta and identifies the ductus.

Other conditions can produce systolic and diastolic murmurs in the pulmonic area in an acyanotic patient (see Chapter 471). An **aortico-pulmonary window defect** may rarely be clinically indistinguishable from a patent ductus, although in most cases the murmur is only systolic and is loudest at the right rather than the left upper sternal border

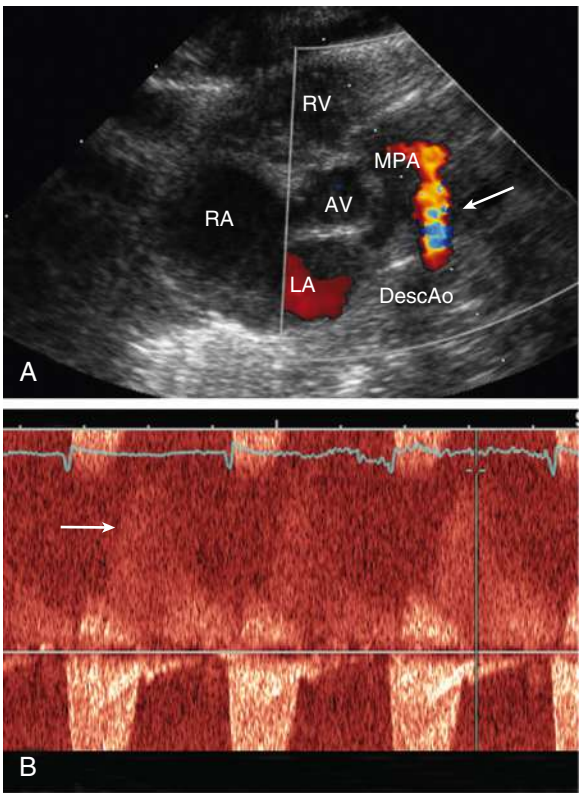

Fig. 475.11 Echocardiogram in a newborn with a small to moderate-size patent ductus arteriosus. **A,** Color Doppler evaluation in a parasternal short-axis view shows flow *(arrow)* from the aorta into the main pulmonary artery. **B,** Doppler evaluation demonstrates retrograde diastolic flow into the pulmonary artery. AV, Aortic valve; DescAo, descending aorta; LA, left atrium; MPA, main pulmonary artery; RA, right atrium; RV, right ventricle.

(see Chapter 475.9). A sinus of Valsalva aneurysm that has ruptured into the right side of the heart or pulmonary artery, a coronary AV fistula, and an aberrant left coronary artery with massive collaterals from the right coronary display dynamics similar to that of a PDA with a continuous murmur and a wide pulse pressure. Truncus arteriosus with torrential pulmonary flow also can present with aortic runoff physiology. A peripheral AV fistula also results in a wide pulse pressure, but the distinctive precordial murmur of a PDA is not present. VSD with aortic insufficiency, repaired tetralogy of Fallot, and combined aortic and mitral insufficiency (usually from rheumatic fever) may be confused with a PDA, but the murmurs should be differentiated by their to-and-fro rather than continuous nature. In a to-and-fro murmur there is a quiet segment between the systolic and diastolic components, whereas in a continuous murmur there is flow disturbance throughout the cardiac cycle (even if the murmur is louder during systole than diastole). The combination of a large VSD and a PDA result in findings more like those of an isolated VSD. Echocardiography should be able to eliminate these other diagnostic possibilities.

PROGNOSIS AND COMPLICATIONS

Spontaneous closure of the ductus after infancy is extremely rare. Patients with a small PDA may live a normal span with few or no cardiac symptoms, but late manifestations may occur. In patients with a large PDA, cardiac failure most often occurs in early infancy but may occur later in life, even with a moderate-sized communication.

Infective endarteritis may be seen at any age. Pulmonary or systemic emboli may occur. Rare complications include aneurysmal dilation of the pulmonary artery or the ductus, calcification of the ductus, noninfective thrombosis of the ductus with embolization, and paradoxical emboli. Pulmonary hypertension (Eisenmenger syndrome) usually develops in patients with a large PDA who do not undergo ductal closure (see Chapter 482.2).

TREATMENT

Irrespective of age, patients with a PDA require either catheter or surgical closure. In patients with a small PDA, the rationale for closure is prevention of bacterial endarteritis or other late complications. In patients with a moderate to large PDA, closure is accomplished to treat heart failure and prevent the development of pulmonary vascular disease. Once the diagnosis of a moderate to large PDA is made, treatment should not be unduly postponed after adequate medical therapy for cardiac failure has been instituted.

Transcatheter PDA closure is routinely performed in the cardiac catheterization laboratory (Fig. 475.12). Small PDAs are generally closed with intravascular coils. Moderate to large PDAs may be closed with an umbrella-like or pluglike device or with a catheter-introduced sac into which several coils are released. Surgical closure of a PDA can be accomplished by a standard left thoracotomy or using thoracoscopic minimally invasive techniques. The case fatality rate with interventional or surgical treatment is considerably less than 1%; thus closure of the ductus is indicated even in asymptomatic patients. Pulmonary hypertension is not a contraindication to surgery at any age if it can be demonstrated at cardiac catheterization that the shunt flow is still predominantly left to right and that severe pulmonary vascular disease is not present. After closure, symptoms of cardiac failure rapidly disappear. Infants who had failed to thrive usually have immediate improvement in physical development. The pulse and blood pressure return to normal, and the machinery-like murmur disappears. A functional systolic murmur over the pulmonary area may persist; it may represent turbulence in a persistently dilated pulmonary artery. The radiographic signs of cardiac enlargement and pulmonary overcirculation disappear over several months, and the ECG becomes normal.

PATENT DUCTUS ARTERIOSUS IN LOW BIRTHWEIGHT INFANTS

See Chapter 126.1.

475.9 Aortopulmonary Window Defect

Daniel Bernstein

An aortopulmonary window defect consists of a communication between the ascending aorta and the main pulmonary artery. The presence of pulmonary and aortic valves and an intact ventricular septum distinguishes this anomaly from **truncus arteriosus** (see Chapter 480.8). An aortopulmonary window is an associated lesion in patients with **smooth muscle dysfunction syndrome** (see Chapter 475.8). Symptoms of heart failure appear during early infancy; occasionally, minimal cyanosis is present. The defect is usually large, and the cardiac murmur is usually systolic with an apical mid-diastolic rumble as a result of the increased blood flow across the mitral valve. In the rare instance when the communication is smaller and pulmonary hypertension is absent, the findings on examination can mimic those of a PDA (wide pulse pressure and a continuous murmur at the upper sternal borders). The ECG shows either LV or biventricular hypertrophy. Radiographic studies demonstrate cardiac enlargement and prominence of the pulmonary artery and intrapulmonary

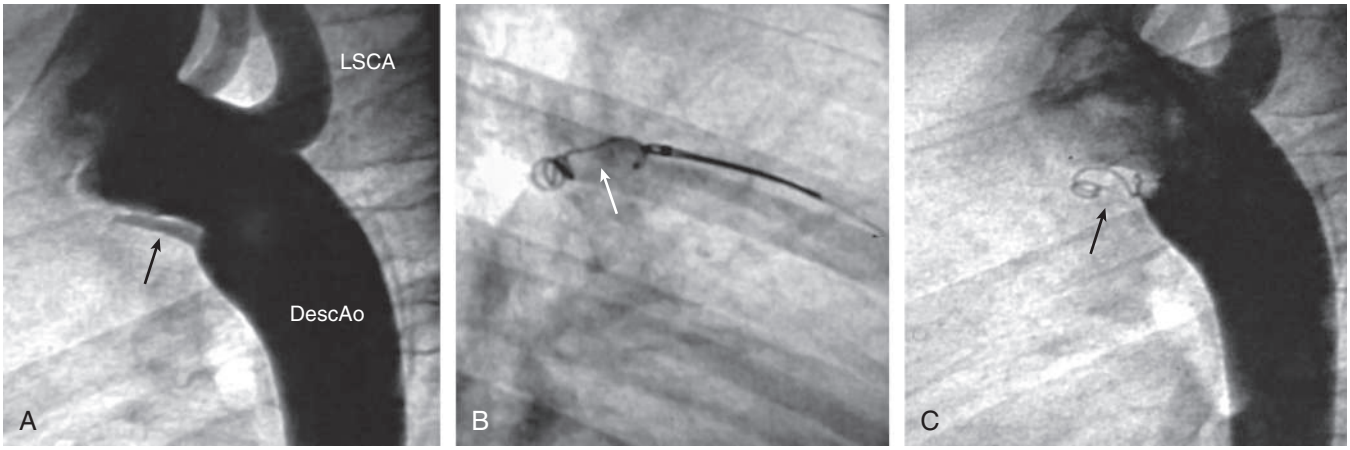

Fig. 475.12 Transcatheter closure of a small patent ductus arteriosus using a coil. **A,** Angiogram of transverse and descending aorta shows small PDA *(arrow).* **B,** Coil *(arrow)* has been extruded from the sheath and is being positioned in the ductal lumen. **C,** Angiogram demonstrating total occlusion of PDA by coil *(arrow).* DescAo, Descending aorta; LSCA, left subclavian artery.

vasculature. The echocardiogram shows enlarged left-sided heart chambers; the window defect can best be delineated with color flow Doppler. CT or MR angiography can also be used to visualize the defect (see Fig. 472.26).

Cardiac catheterization, usually performed in older children to evaluate pulmonary vascular resistance, reveals a left-to-right shunt at the level of the pulmonary artery, as well as hyperkinetic pulmonary hypertension, because the defect is almost always large. Selective aortography with injection of contrast medium into the ascending aorta demonstrates the lesion, and manipulation of the catheter from the main pulmonary artery directly to the ascending aorta is also diagnostic.

An aortopulmonary window defect is surgically corrected during infancy. If surgery is not carried out in infancy, survivors carry the risk of progressive pulmonary vascular obstructive disease, similar to that of other patients who have large intracardiac or great vessel communications.

475.10 Coronary Artery Fistula

Daniel Bernstein

A congenital fistula may exist between a coronary artery and an atrium, ventricle (especially the right), or pulmonary artery. Sometimes, multiple fistulas exist. Regardless of the recipient chamber, the clinical signs are similar to those of PDA, although the machinery-like murmur may be more diffuse. If the flow is substantial, the involved coronary artery may be dilated or aneurysmal. The anatomic abnormality is usually demonstrable by color flow Doppler echocardiography and, during catheterization, by contrast injection into the ascending aorta. Small fistulas may be hemodynamically insignificant and may even close spontaneously. If the shunt is large, treatment consists of either transcatheter coil embolization or, for lesions not amenable to catheter intervention, surgical closure of the fistula.

475.11 Ruptured Sinus of Valsalva Aneurysm

Daniel Bernstein

When one of the sinuses of Valsalva of the aorta is weakened by congenital or acquired disease, an aneurysm may form and eventually rupture, usually into the right atrium or ventricle. This condition is rare in childhood. The onset is usually sudden. The diagnosis should be suspected in a patient in whom symptoms of acute heart failure develop in association with a new, loud, to-and-fro murmur. Color Doppler echocardiography and cardiac catheterization demonstrate the left-to-right shunt at the atrial or ventricular level. Urgent surgical repair is generally required. This condition is often associated with infective endocarditis of the aortic valve.

Chapter 476
Acyanotic Congenital Heart Disease: Obstructive Lesions

476.1 Pulmonary Valve Stenosis with Intact Ventricular Septum

Daniel Bernstein

Of the various forms of right ventricular (RV) outflow obstruction with an intact ventricular septum, the most common is isolated **valvular pulmonary stenosis**, which accounts for 7–10% of all congenital heart defects. The valve cusps are deformed to various degrees and, as a result, the valve opens incompletely during systole. The valve may be bicuspid or tricuspid and the leaflets partially fused together with an eccentric outlet. This fusion may be so severe that only a pinhole central opening remains. If the valve is not severely thickened, it produces a domelike obstruction to RV outflow during systole. Isolated infundibular or subvalvular stenosis, supravalvular pulmonary stenosis, and branch pulmonary artery stenosis are also encountered. In cases where pulmonary valve stenosis is associated with a **ventricular septal defect** (VSD) but without anterior deviation of the infundibular septum and overriding aorta, this condition is better classified as pulmonary stenosis with VSD rather than as **tetralogy of Fallot** (see Chapter 479.1). Pulmonary stenosis and an **atrial septal defect** (ASD) are also occasionally seen as associated defects.

The clinical and laboratory findings reflect the dominant lesion, but it is important to rule out any associated anomalies. Pulmonary stenosis as a result of valve dysplasia is the most common cardiac abnormality in **Noonan syndrome** (see Chapter 101.1) and is associated, in approximately 50% of cases, with a pathogenic variant in *PTPN11,* encoding the protein tyrosine phosphatase SHP-2 on chromosome 12. *SOS1* gene variants cause an additional 10–15%, and *RAF1* and *RIT1* genes each account for about 5% of cases. These genes are components of the RAS/MAPK cell signaling pathway, important for cell division; however, the mechanism by which these gene changes cause pulmonic stenosis is unknown. Pulmonary stenosis can also be a component of **LEOPARD syndrome** (lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, deafness syndrome), often associated with hypertrophic cardiomyopathy. Pathogenic variants in *PTPN11, RAF1, BRAF,* and *MAP2K1* have been implicated in LEOPARD syndrome. Pulmonary stenosis, of the valve or more commonly of the branch pulmonary arteries, is a common finding in patients with arteriohepatic dysplasia, also known as **Alagille syndrome** (see Chapter 404); pathogenic variants have been found in *JAGGED1* or *NOTCH2,* components of the Notch signaling pathway.

PATHOPHYSIOLOGY

The obstruction to outflow from the right ventricle to the pulmonary artery results in increased RV systolic pressure and wall stress, which lead to hypertrophy of the right ventricle (Fig. 476.1). The severity of these abnormalities depends on the size of the restricted valve opening. In severe cases, RV pressure may be higher than systemic arterial systolic pressure, whereas with milder obstruction, RV pressure is only mildly or moderately elevated. Pulmonary artery pressure (PAP, distal to the obstruction) is either normal or decreased. Arterial oxygen saturation will be normal even in cases of severe stenosis, unless an intracardiac communication such as a VSD or ASD is allowing blood to shunt from right to left. However, when severe pulmonic stenosis occurs in a neonate, decreased RV compliance often leads to cyanosis as a result of right-to-left shunting through a **patent foramen ovale** (PFO), a condition termed **critical pulmonic stenosis**.

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

Patients with mild or moderate stenosis usually have no symptoms. Growth and development are most often normal. If the stenosis is severe, signs of RV failure such as hepatomegaly, peripheral edema, and exercise intolerance may be present. In a neonate or young infant with critical pulmonic stenosis, signs of RV failure may be more prominent; cyanosis is often present because of right-to-left shunting at the foramen ovale.

With **mild pulmonary stenosis**, central venous pressure is normal. The heart is not enlarged, the apical impulse is normal, and the RV impulse is not palpable. A sharp pulmonic ejection click (caused by doming of the valve) is heard immediately after the first heart sound (S_1) at the left upper sternal border and over the sternum, more prominently during expiration. The second heart sound (S_2) is split, with a pulmonary component of normal intensity that may be slightly

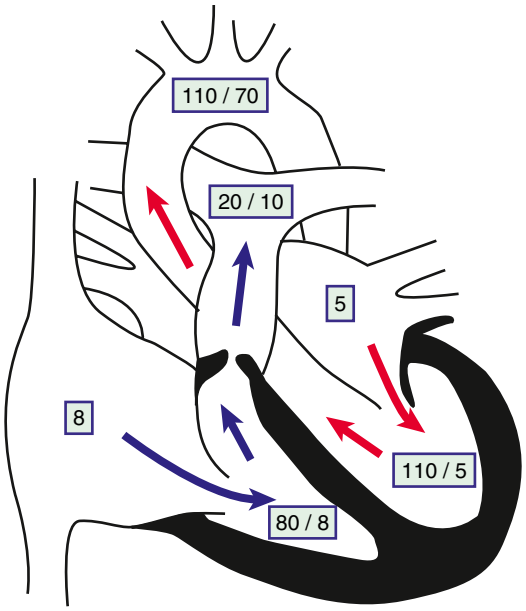

Fig. 476.1 Physiology of valvular pulmonary stenosis. *Boxed numbers* represent pressure in mm Hg. Because of the absence of right-to-left or left-to-right shunting, blood flow through all cardiac chambers is normal at 3 L/min/m^2. The pulmonary-to-systemic blood flow ratio (Qp:Qs) is 1:1. Right atrial pressure is increased slightly as a result of decreased right ventricular compliance. The right ventricle is hypertrophied, and systolic and diastolic pressures are increased. The pressure gradient across the thickened pulmonary valve is 60 mm Hg. The main pulmonary artery pressure is slightly low, and poststenotic dilation is present. Left-sided heart pressure is normal. Unless right-to-left shunting is occurring through a foramen ovale, the patient's systemic oxygen saturation will be normal.

Fig. 476.2 Radiograph of patient with valvular pulmonary stenosis and normal aortic root. The heart size is within normal limits, but poststenotic dilation of the pulmonary artery is present.

delayed. A relatively short, low- or medium-pitched systolic ejection murmur is maximally audible over the pulmonic area at the upper left sternal border and radiates minimally to the lung fields bilaterally. The electrocardiogram (ECG) is either normal or shows mild **right ventricular hypertrophy** (RVH) (e.g., slightly increased voltages in the right precordial leads); inversion of the T waves in the right precordial leads may be the only finding. Note that the T wave in lead V_1 should normally be inverted after the first week of life until at least 6-8 years of age. Therefore a positive T wave in V_1 in a young child is a sign of RVH even in the absence of voltage criteria. The only abnormality demonstrable radiographically is usually poststenotic dilation of the pulmonary artery. Two-dimensional (2D) echocardiography shows RVH and a slightly thickened pulmonic valve, which domes in systole. Doppler studies demonstrate a right ventricle–to–pulmonary artery (RV-PA) pressure gradient of ≤30 mm Hg.

In **moderate pulmonic stenosis**, central venous pressure may be slightly elevated; in older children, a prominent *a* wave may be noted in the jugular pulse. An RV lift may be palpable at the lower-left sternal border. S_2 is split, with a delayed and soft pulmonic component. As valve motion becomes more limited with more severe degrees of stenosis, both the pulmonic ejection click and the pulmonic S_2 may become inaudible. With increasing degrees of stenosis, the systolic ejection murmur becomes louder and harsher (higher frequency), the peak of the murmur is prolonged later into systole, and the murmur radiates more prominently to both lung fields, heard best over the back.

The ECG reveals RVH, sometimes with a prominent spiked P wave. Radiographically, the heart can vary from normal size to mildly enlarged with uptilting of the apex because of the prominence of the right ventricle; pulmonary vascularity is usually normal or slightly decreased. The echocardiogram shows a thickened pulmonic valve with restricted systolic motion. Doppler examination demonstrates an RV-PA pressure gradient of 30-60 mm Hg. Mild tricuspid regurgitation may be present and allows for Doppler confirmation of RV systolic pressure.

In **severe pulmonary stenosis**, mild to moderate cyanosis may be noted in patients with an interatrial communication (ASD or PFO). In the absence of any intracardiac shunt, cyanosis is absent. Hepatic enlargement and peripheral edema, if present, are an indication of RV failure. Elevation of central venous pressure is common and is identified as a large presystolic jugular *a* wave. The heart is moderately or greatly enlarged, and a conspicuous parasternal RV lift is present and frequently extends to the left midclavicular line. The pulmonic component of S_2 is usually inaudible. A loud, long, and harsh systolic ejection murmur, usually accompanied by a thrill, is maximally audible in the pulmonic area and may radiate over the entire precordium, to both lung fields, and to the back. The peak of the murmur occurs later in systole as valve opening becomes more restricted. The murmur frequently encompasses the aortic component of S_2 but is not preceded by an ejection click.

The ECG shows marked RVH, frequently accompanied by a tall, spiked P wave. Radiographic studies confirm the presence of cardiac enlargement with prominence of the right ventricle and right atrium. Prominence of the main pulmonary artery (MPA) segment may be seen as a sign of poststenotic dilation (Fig. 476.2). Intrapulmonary vascularity is decreased. The 2D echocardiogram shows severe deformity of the pulmonary valve and RVH (Fig. 476.3). In the late stages of the disease, systolic dysfunction of the right ventricle may be seen, and in these cases the ventricle becomes dilated, with prominent tricuspid regurgitation. Doppler studies demonstrate a high gradient (>60 mm Hg) across the pulmonary valve. The classic findings of severe pulmonary stenosis in older children are rarely seen today because of early intervention. In the newborn period, signs of critical pulmonic stenosis are accompanied by cyanosis.

Cardiac catheterization is not generally required for diagnostic purposes but is undertaken to perform a therapeutic **balloon valvuloplasty** procedure. Catheterization demonstrates an abrupt pressure gradient across the pulmonary valve. PAP is either normal or low. The severity of the stenosis is graded based on the ratio of RV systolic pressure to systemic systolic pressure or the RV-PA pressure gradient: 10-30 mm Hg in mild cases, 30-60 mm Hg in moderate cases, and >60 mm Hg or with RV pressure greater than systemic pressure in severe cases. If cardiac output is low or a significant right-to-left shunt exists across the atrial septum, the pressure gradient may underestimate the degree of valve stenosis. Selective right ventriculography demonstrates the

thickened, poorly mobile valve. In mild to moderate stenosis, doming of the valve in systole is readily seen. Flow of contrast medium through the stenotic valve in ventricular systole produces a narrow jet of dye that fills the dilated MPA. Subvalvular hypertrophy may be present and may intensify the obstruction.

TREATMENT

Patients with moderate or severe isolated pulmonary stenosis require relief of the obstruction. Balloon valvuloplasty is the initial treatment of choice for the majority of patients (Fig. 476.4). Patients with severely thickened pulmonic valves, especially common in those with **Noonan syndrome**, may require surgical intervention. In a neonate with critical pulmonic stenosis and cyanosis, urgent treatment by either balloon valvuloplasty or surgical valvotomy is warranted.

Excellent results are obtained in most patients. The gradient across the pulmonary valve is greatly reduced or abolished. In the early period after balloon valvuloplasty, a small to moderate residual gradient may remain because of muscular infundibular narrowing; it usually resolves with time. A short, early decrescendo diastolic murmur may be heard at the midsternal to upper left sternal border as a result of pulmonary valvular insufficiency. The degree of insufficiency is usually not clinically significant, although it can occasionally worsen over time as the child grows. No difference in patient status after valvuloplasty or surgery has been noted at late follow-up; recurrence is unusual after successful treatment except in those patients with extremely dysplastic valves. In the small minority of patients where the degree of **pulmonary regurgitation** is more severe, RV dilation may ensue, and these patients require careful follow-up and may require surgical intervention (repair or valve replacement) or placement of a transcatheter stent-valve (e.g., Melody or Harmony valve).

PROGNOSIS AND COMPLICATIONS

Heart failure occurs only in severe cases and most often during the first month of life. The development of cyanosis from a right-to-left shunt across a foramen ovale is almost exclusively seen in the neonatal period when the stenosis is severe. Infective endocarditis is a risk but is not common in childhood.

Children with mild stenosis can lead a normal life, but their progress should be evaluated at regular intervals. Patients who have small gradients rarely show progression and do not need intervention, but a significant gradient is more likely to develop in children with moderate stenosis as they grow older. Worsening of obstruction over time may also be caused by the development of secondary subvalvular muscular hypertrophy. In untreated severe stenosis, the course may abruptly worsen with the development of RV dysfunction and cardiac failure. Infants with critical pulmonic stenosis require urgent catheter balloon valvuloplasty or surgical valvotomy. Development of RV failure many years after pulmonary balloon valvuloplasty is uncommon. Nonetheless, patients should be followed serially for worsening pulmonary insufficiency and RV dilation.

476.2 Infundibular Pulmonary Stenosis and Double-Chamber Right Ventricle

Daniel Bernstein

Infundibular pulmonary stenosis is caused by muscular or fibrous obstruction in the outflow tract of the right ventricle. The site of obstruction may be close to the pulmonary valve or well below it; an

infundibular chamber may be present between the right ventricular cavity and the pulmonary valve. In many cases, a VSD may have been present initially and later closed spontaneously. When the pulmonary valve is also stenotic, the combined defect is primarily classified as valvular stenosis with secondary infundibular hypertrophy. The hemodynamics and clinical manifestations of patients with isolated infundibular pulmonary stenosis are similar, for the most part, to those described for isolated valvular pulmonary stenosis (see Chapter 476.1).

A common variation in RV outflow obstruction below the pulmonary valve is that of a **double-chambered right ventricle**. In this condition, a muscular band is present in the mid-RV region; the band divides the chamber into two parts and creates obstruction between the inlet and outlet portions. An associated VSD is often noted, and these may close spontaneously. Obstruction is not usually seen early in life but may progress rapidly in a similar manner to the progressive infundibular obstruction observed with tetralogy of Fallot (see Chapter 479.1).

The diagnosis of isolated RV infundibular stenosis or double-chambered right ventricle is usually made by echocardiography. The ventricular septum must be evaluated carefully to determine whether an associated VSD is present. When the obstruction is moderate to severe, surgery is indicated. After surgery, the pressure gradient is abolished or greatly reduced, and the long-term outlook is excellent.

476.3 Pulmonary Stenosis in Combination with an Intracardiac Shunt

Daniel Bernstein

Valvular or infundibular pulmonary stenosis, or both, may be associated with either an ASD or a VSD. In these patients the clinical features depend on the degree of pulmonary stenosis, which determines whether the net shunt is from left to right or from right to left. Neonates with severe pulmonary stenosis (termed **critical pulmonary stenosis**) usually have right-to-left shunting through the foramen ovale (see Chapter 476.1).

The presence of a large left-to-right shunt at the atrial or ventricular level is evidence that the pulmonary stenosis is mild. These patients have symptoms similar to those of patients with an isolated ASD or VSD. With increasing age, worsening of the RV outflow obstruction may limit the shunt and result in a gradual improvement in symptoms. Eventually, particularly in patients with pulmonary stenosis and VSD, a further increase in obstruction may lead to right-to-left shunting and cyanosis. When a patient with a VSD has evidence of decreasing heart failure and increased RV forces on the ECG, one must differentiate between the development of increasing pulmonary stenosis vs the onset of pulmonary vascular disease (**Eisenmenger syndrome**; see Chapter 482.2).

These anomalies are readily repaired surgically. Defects in the atrial or ventricular septum are closed, and the pulmonary stenosis is relieved by resection of infundibular muscle or pulmonary valvotomy, or both, as indicated. Patients with a predominant right-to-left shunt can have symptoms similar to those of patients with tetralogy of Fallot (see Chapter 479.1).

476.4 Peripheral Pulmonary Stenosis

Daniel Bernstein

Single or multiple constrictions may occur anywhere along the major branches of the pulmonary arteries and may range from mild to severe and from localized to extensive. Frequently, these defects are associated with other types of congenital heart disease, including valvular pulmonic stenosis, tetralogy of Fallot, patent ductus arteriosus (PDA), VSD, ASD, and supravalvular aortic stenosis. A familial tendency has been recognized in some patients with peripheral pulmonic stenosis. Peripheral pulmonary stenosis is a common cardiac sequelae of congenital rubella syndrome. The combination of supravalvular aortic stenosis with pulmonary arterial branch stenosis, idiopathic hypercalcemia of infancy, elfin facies, and intellectual disability is known as **Williams syndrome**, a condition associated with hemizygous microdeletion of ~25-27 genes (Williams-Beuren syndrome critical region: WBSCR1), including *ELN, LIMK1, GTF21,* and *GTF21RD1* in region 7q11.23 on chromosome 7. Peripheral pulmonary stenosis is also associated with **Alagille syndrome**, which may be associated with a pathogenic variant in the *JAGGED1* or *NOTCH2* genes.

A mild constriction has little effect on the pulmonary circulation. With multiple severe constrictions, pressure is increased in the right ventricle and in the pulmonary artery proximal to the site of obstruction. When the anomaly is isolated, the diagnosis is suspected by the presence of murmurs in widespread locations over the chest, either anteriorly or posteriorly. These murmurs are usually systolic ejection in quality but may be continuous. Most often, the physical signs are dominated by the associated anomaly, such as valvar pulmonary stenosis or tetralogy of Fallot (see Chapter 479.1).

In the immediate newborn period, a mild and transient form of peripheral pulmonic stenosis may be present. Physical findings are generally limited to a soft systolic ejection murmur, which can be heard over either or both lung fields. It is the absence of other physical findings of valvular pulmonic stenosis (RV lift, soft pulmonic S_2, systolic ejection click, murmur loudest at upper left sternal border) that supports this diagnosis. This murmur usually disappears by age 1-2 months.

If the stenosis is severe, the ECG shows evidence of RVH and right atrial hypertrophy, and the chest radiograph shows cardiomegaly and prominence of the MPA. The pulmonary vasculature is usually normal; in some cases, small intrapulmonary vascular shadows are seen that represent areas of poststenotic dilation. Echocardiography is limited in its ability to visualize the distal branch pulmonary arteries. Doppler examination demonstrates the acceleration of blood flow through the stenoses and, if tricuspid regurgitation is present, allows an estimation of RV systolic pressure. MRI and CT are extremely helpful in delineating distal obstructions. If moderate to severe disease is suspected, the diagnosis is usually confirmed by cardiac catheterization.

Severe obstruction of the MPA and its primary branches can be relieved during corrective surgery for associated lesions such as the tetralogy of Fallot or valvular pulmonary stenosis. If peripheral pulmonic stenosis is isolated, it may be treated by catheter balloon dilation, sometimes with placement of an intravascular stent (see Fig. 472.31).

476.5 Aortic Stenosis

Daniel Bernstein

Congenital aortic stenosis accounts for approximately 5% of cardiac malformations recognized in childhood and is more frequent in males (3:1). A bicuspid aortic valve (BAV) is one of the most common congenital heart lesions overall, identified in 1–2% of adults. If isolated, it is not even counted in the overall incidence (0.8% of live births) of congenital heart disease. There is a high incidence of family clustering, with multiple individuals affected with BAV or other left-sided heart lesions. BAV may be encountered in conjunction with other left-sided heart lesions (coarctation of the aorta, aortopathy, mitral stenosis, **Shone complex**, and hypoplastic left heart syndrome) or in conjunction with syndromes such as Loeys-Dietz, Down, Turner, and velocardiofacial (DiGeorge). Several genes have been implicated in BAV, including *NOTCH1, GATA4, GATA5,* and *SMAD6.*

In the most common form, **valvular aortic stenosis**, the leaflets are thickened and the commissures are fused to varying degrees. Left ventricular (LV) systolic pressure is increased as a result of the obstruction to outflow. The LV wall hypertrophies in compensation; as its compliance decreases, end-diastolic pressure increases as well, impairing ventricular filling in the more severe cases.

Fig. 476.5 Williams syndrome. *(From Jones KL, Smith DW. The Williams elfin facies syndrome: a new perspective. J Pediatr. 1975;86:718.)*

Subvalvular (subaortic) stenosis with a discrete fibromuscular shelf (subaortic membrane) below the aortic valve is also an important form of left ventricular outflow tract (LVOT) obstruction. This lesion is frequently associated with other forms of congenital heart disease such as mitral stenosis and coarctation of the aorta **(Shone complex)** and may progress in severity with age, sometimes rapidly. Subvalvular aortic stenosis may also become apparent after successful surgery for other congenital heart defects (coarctation of the aorta, PDA, VSD), may develop in association with mild lesions that have not been surgically repaired, or may occur as an isolated abnormality. Subvalvular aortic stenosis may also be caused by a markedly hypertrophied ventricular septum in association with hypertrophic cardiomyopathy (see Chapter 488.2).

Supravalvular aortic stenosis, the least common type, may be sporadic, familial, or associated with **Williams syndrome**, which includes developmental delay (IQ range: 41-80), elfin facies (full face, broad forehead, flattened bridge of the nose, long upper lip, and rounded cheeks) (Fig. 476.5), and idiopathic hypercalcemia of infancy. Additional features include loquacious personality, hypersensitivity to sound, spasticity, hypoplastic nails, dental anomalies (partial anodontia, microdontia enamel hypoplasia), joint hypermobility, nephrocalcinosis, hypothyroidism, and poor weight gain. Narrowing of the coronary artery ostia can occur in patients with supravalvar aortic stenosis and should be carefully evaluated. Stenosis of other arteries, particularly the branch pulmonary arteries, may also be present. Williams syndrome is caused by hemizygous microdeletion of ~25 genes in the WBSCR1 at 7q11.23 on chromosome 7 (see Chapter 476.2).

CLINICAL MANIFESTATIONS

Symptoms in patients with aortic stenosis depend on the severity of the obstruction. Severe aortic stenosis that occurs in early infancy is termed **critical aortic stenosis** and is associated with LV failure and signs of low cardiac output. Heart failure, cardiomegaly, and pulmonary edema are severe, the pulses are weak in all extremities, and the skin may be pale or grayish. Urine output may be diminished. If cardiac output is significantly decreased, the intensity of the murmur at the right upper sternal border may be minimal. The endocardial surface may be fibrotic and stiff (endocardial fibroelastosis) in the most severe cases.

Outside of the newborn period, most infants and children with less severe forms of aortic stenosis remain asymptomatic and display normal growth and development. The murmur is usually discovered during routine physical examination. Rarely, fatigue, chest pain, dizziness, or syncope with exercise may develop in an older child with previously undiagnosed severe obstruction to LV outflow. Sudden death has been reported with aortic stenosis but usually occurs in patients with severe LVOT obstruction in whom the diagnosis and surgical relief have been delayed.

The physical findings are dependent on the degree of obstruction to LV outflow. In mild stenosis, the pulses, heart size, and apical impulse are all normal. With increasing degrees of severity, the pulses become diminished in intensity and the heart may be enlarged, with an LV apical thrust. Mild to moderate valvular aortic stenosis is usually associated with an early systolic ejection click, best heard at the left sternal border and over the sternum. Unlike the click in pulmonic stenosis, its intensity does not vary with respiration. Clicks are unusual in more severe aortic stenosis or in discrete subaortic stenosis. If the stenosis is severe, S_1 may be diminished because of decreased compliance of the thickened left ventricle. Normal splitting of S_2 is present in mild to moderate obstruction. In patients with severe obstruction, the intensity of the aortic component of S_2 is diminished, and S_2 may be split paradoxically (becoming wider in expiration). A fourth heart sound (S_4) may be audible as a result of decreased LV compliance.

The intensity, pitch, and duration of the systolic ejection murmur are other indications of severity. The louder, harsher (higher pitch), and longer the murmur, the greater the degree of obstruction. The murmur will also peak later in systole with increase severity. The typical murmur is audible maximally at the right upper sternal border and radiates to the neck and the left midsternal border. It is usually accompanied by a thrill in the suprasternal notch and, in older patients, over the carotids. In patients with subvalvular aortic stenosis, the murmur may be maximal along the left sternal border or even at the apex. A soft, decrescendo diastolic murmur is present in patients who also have aortic insufficiency, not uncommon with a bicuspid aortic valve or in patients who have had surgery or balloon valvuloplasty. Occasionally, an apical short mid-diastolic rumbling murmur is audible; this murmur should raise suspicion of associated mitral valve stenosis. Careful attention to both upper- and lower-extremity peripheral pulses is essential. Patients with mild aortic stenosis will have normal pulses; as the severity increases, the pulses will become more diminished. Discrepancy between upper- and lower-extremity pulses or a delay in femoral pulses (radio-femoral delay) suggests associated coarctation of the aorta. Discrepancy between the right and left arm pulses in the presence of normal femoral pulses is a sign of possible supravalvar aortic stenosis.

LABORATORY FINDINGS AND DIAGNOSIS

The diagnosis can usually be made on the basis of the physical examination, and the severity of obstruction confirmed by laboratory tests. If the pressure gradient across the aortic valve is mild, the ECG is likely to be normal. The ECG may occasionally be normal even with mild to moderate obstruction, but evidence of left ventricular hypertrophy (LVH) and LV strain (inverted T waves in left precordial leads) is generally present if moderate to severe stenosis is long-standing. The chest radiograph frequently shows a prominent ascending aorta. Heart size is typically normal or slightly increased. Valvular calcification is noted only in older children and adults. Echocardiography identifies both the site and the severity of the obstruction. Two-dimensional imaging shows LVH and the thickened and abnormally moving aortic valve (Fig. 476.6). The echocardiogram will also demonstrate the number of valve leaflets and their morphology, which leaflets are fused, and the presence of a subaortic membrane or supravalvar stenosis. Associated anomalies of the mitral valve or aortic arch (coarctation of the aorta) or a VSD or PDA are present in up to 20% of cases. In the absence of LV failure, the shortening fraction of the left ventricle may be increased because the ventricle is hypercontractile. In infants with critical aortic

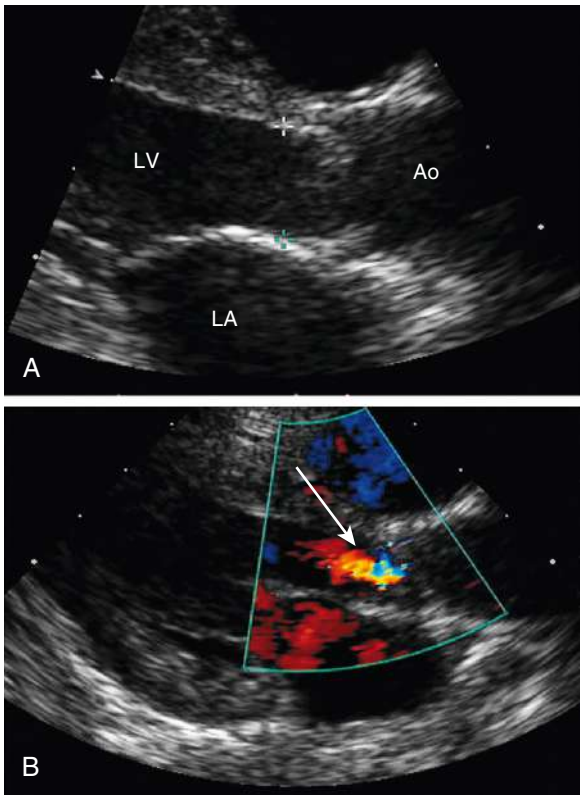

Fig. 476.6 Echocardiogram showing valvar aortic stenosis with regurgitation. **A,** In this parasternal long-axis view, the stenotic aortic valve can be seen doming in systole. The *crosshatch* marks delineate the aortic annulus. **B,** Doppler study shows the presence of aortic regurgitation *(arrow)*. Ao, Aorta; LA, left atrium; LV, left ventricle.

stenosis, the LV shortening fraction is often decreased and may be quite poor. The endocardium may appear bright, indicative of the development of endocardial fibrous scarring, known as **endocardial fibroelastosis**. Doppler studies show the specific site of obstruction and determine the peak and mean systolic LVOT gradients. When severe aortic obstruction is associated with LV dysfunction, the Doppler-derived valve gradient may greatly underestimate the severity of the obstruction because of the low cardiac output across the valve.

Cardiac catheterization is usually not required for diagnostic purposes, but it is usually performed in conjunction with aortic balloon valvuloplasty. Left heart catheterization demonstrates the magnitude of the pressure gradient from the left ventricle to the aorta. The aortic pressure curve is abnormal if the obstruction is severe. In patients with severe obstruction and decreased LV compliance, left atrial pressure is increased and pulmonary hypertension may be present. When a critically ill infant with LVOT obstruction undergoes cardiac catheterization, LV function is often greatly decreased. As with the echocardiogram, the gradient measured across the stenotic aortic valve may underestimate the degree of obstruction because of low cardiac output. Measurement of cardiac output by thermodilution and calculation of the aortic valve area may be helpful.

TREATMENT

Balloon valvuloplasty is indicated for children with moderate to severe valvular aortic stenosis to prevent progressive LV dysfunction and the risk of syncope and sudden death. Valvuloplasty should be advised when the catheter-derived peak-to-peak systolic gradient between the left ventricle and aorta exceeds 60-70 mm Hg at rest, assuming normal cardiac output, or for lesser gradients when symptoms or electrocardiographic changes are present. For more rapidly progressive subaortic obstructive lesions, a gradient of 40-50 mm Hg or the presence of aortic insufficiency is considered an indication for surgery. Balloon valvuloplasty is the procedure of choice even in the neonatal period. Surgical treatment is usually reserved for extremely dysplastic aortic valves that are not amenable to balloon therapy or in patients who also have subvalvar or *supravalvar* aortic stenosis.

Discrete subaortic stenosis can be surgically resected without damage to the aortic valve, the anterior leaflet of the mitral valve, or the conduction system. This type of obstruction is not usually amenable to catheter treatment. Relief of supravalvular stenosis is also achieved surgically, and the results are excellent if the area of obstruction is discrete and not associated with a hypoplastic aorta. In association with supravalvular aortic stenosis, one or both coronary arteries may be stenotic at their origins because of a thick supraaortic fibrous ridge. For patients who have aortic stenosis in association with severe tunnel-like subaortic obstruction, the LVOT can be enlarged by "borrowing" space anteriorly from the right ventricular outflow tract (RVOT) (the **Konno procedure**).

Regardless of whether surgical or catheter treatment has been carried out, aortic insufficiency or calcification with restenosis is likely to occur years or even decades later and eventually require reoperation and often aortic valve replacement. Thus these patients require regular follow-up with a cardiologist. When recurrence develops, it may not be associated with early symptoms. Signs of recurrent stenosis include electrocardiographic signs of LVH, an increase in the Doppler echocardiographic gradient, deterioration in echocardiographic indices of LV function, and recurrence of signs or symptoms during graded treadmill exercise. Evidence of significant aortic regurgitation includes symptoms of heart failure, cardiac enlargement on radiograph, and LV dilation on echocardiogram. The choice of reparative procedure depends on the relative degree of stenosis and regurgitation.

When **aortic valve replacement** is necessary, the choice of procedure often depends on the age of the patient. Homograft valves tend to calcify more rapidly in younger children, but they do not require chronic anticoagulation. Mechanical prosthetic valves are much longer lasting but require anticoagulation, which can be difficult to manage in young children, and they are not available in sizes appropriate for the youngest patients. In adolescent females who are nearing childbearing age, consideration of the teratogenic effects of anticoagulants may warrant the use of a homograft valve. None of these options is perfect for a younger child who requires valve replacement because neither homograft nor mechanical valves grow with the patient. An alternative operation is **aortopulmonary translocation (Ross procedure)**; it involves removing the patient's own pulmonary valve and using it to replace the abnormal aortic valve. A homograft is then placed in the pulmonary position. The potential advantage of this procedure is the possibility for growth of the translocated living "neoaortic" valve and the increased longevity of the homograft valve when placed in the lower-pressure pulmonary circulation. The long-term success of this operation, especially in young children, is still being investigated.

Transcatheter aortic valve replacement (or implantation) (TAVR) uses porcine or bovine (Melody or Sapien) valve tissue sewn into a self-expanding frame. These devices can be implanted in the cardiac catheterization laboratory using a femoral or carotid approach, or transapically through the chest wall, or in a hybrid procedure after a surgical thoracotomy. Initially used mainly in adults who were too ill to be candidates for standard surgical replacement, TAVR is gaining acceptance for carefully selected children who are not good surgical candidates. Short-term outcomes are equivalent to surgical valve replacement. Long-term complications include possible valve regurgitation or perivalvular leaks.

PROGNOSIS

Neonates with critical aortic stenosis may have severe heart failure and deteriorate rapidly to a low-output shock state. Emergency surgery or balloon valvuloplasty is lifesaving, but the mortality risk is not trivial. Neonates who die of critical aortic stenosis frequently have significant LV endocardial fibroelastosis. Those who survive may develop signs of LV diastolic dysfunction (restrictive cardiomyopathy) and eventually require cardiac transplantation (see Chapter 492).

In older infants and children with mild to moderate aortic stenosis, the prognosis is reasonably good, although disease progression over

5-10 years is common. Patients with aortic valve gradients <40-50 mm Hg are considered to have *mild* disease; those with gradients of 40-70 mm Hg have *moderate* disease. These patients usually respond well to treatment (either surgery or valvuloplasty), although reoperations on the aortic valve are often required later in childhood or in adult life, and many patients eventually require valve replacement. In unoperated patients with severe obstruction, sudden death is a significant risk and often occurs during or immediately after exercise. Subaortic stenosis secondary to hypertrophic cardiomyopathy is one of the causes of sudden cardiac death in adolescents and young adults.

Patients with moderate to severe degrees of aortic stenosis should not participate in active competitive sports. In those with milder disease, sports participation is less severely restricted. The status of each patient should be reviewed at least annually and intervention advised if progression of signs or symptoms occurs. Prophylaxis against infective endocarditis is no longer recommended unless a prosthetic or transcatheter (TAVR) valve has been inserted.

Older children and adults with isolated bicuspid aortic valve are at increased risk for developing dilation of their ascending aorta, even in the absence of significant stenosis. This risk increases with age, and the rate of increase is greatest in those with the largest aortic roots. In children, this dilation is usually mild and remains stable over many years of observation, but in young adults and older patients, the aorta can dilate substantially and progressively. Whether these patients have some undiagnosed form of connective tissue disorder remains to be determined (this form of dilation is similar to that seen in Marfan syndrome). Patients with Turner syndrome and bicuspid aortic valve also have an increased risk of aortic dilation. Although dissection and rupture are described complications of severe aortic root dilation in adults, there are not yet sufficient data to determine these risks in children, and careful monitoring with echocardiogram, CT, or MRI is warranted.

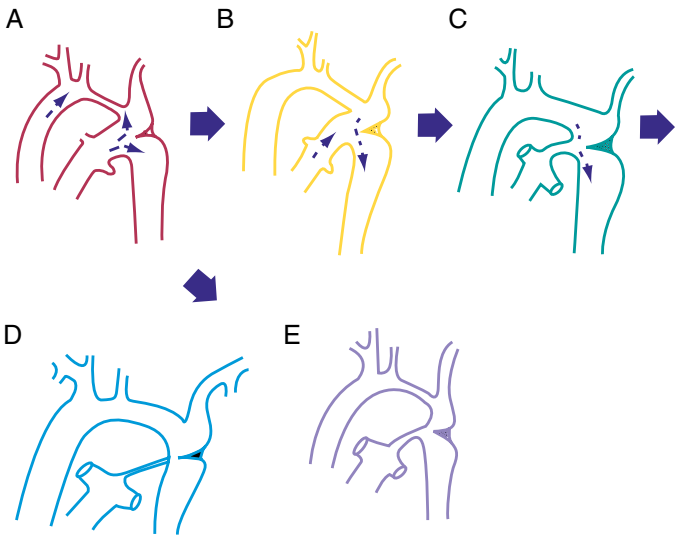

Fig. 476.7 Metamorphosis of coarctation. **A,** Fetal prototype with no flow obstruction. **B,** Late gestation. The aortic ventricle increases its output and dilates the hypoplastic segment. Antegrade aortic flow bypasses the shelf via the ductal orifice. **C,** Neonate. Ductal constriction initiates the obstruction by removing the bypass and increasing antegrade arch flow. **D,** Mature juxtaductal stenosis. The bypass is completely obliterated, and intimal hypoplasia on the edge of the shelf is aggravating the stenosis. Collaterals develop. **E,** Persistence of the infantile-type fetal prototype. An intracardiac left-sided heart obstruction precludes an increase in antegrade aortic flow before or after birth. Both isthmus hypoplasia and a contraductal shelf are present. Lower-body flow often depends on the patency of the ductus. *(From Gersony WM. Coarctation of the aorta. In: Adams FH, Emmanouilides GC, Riemenshneider T, eds. Moss Heart Disease in Infants, Children, and Adolescents, 4th ed. Baltimore: Williams & Wilkins; 1989.)*

476.6 Coarctation of the Aorta

Daniel Bernstein

Constrictions of the aorta of varying degrees may occur at any point from the transverse arch to the iliac bifurcation, but 98% occur just below the origin of the left subclavian artery at the origin of the ductus arteriosus **(juxtaductal coarctation)**. The anomaly is responsible for 5–8% of congenital heart disease and occurs twice as often in males as in females. Coarctation of the aorta is associated with a bicuspid aortic valve in >70% of patients; mitral valve abnormalities (a supravalvular mitral ring or parachute mitral valve) and subaortic stenosis are other associated lesions. When this group of left-sided obstructive lesions occurs together, they are referred to as **Shone complex**. Coarctation of the aorta is found in up to 20% of patients with **Turner syndrome** (see Chapters 99.4 and 626.1); ~5–12% of females with coarctation have Turner syndrome.

PATHOPHYSIOLOGY

Coarctation of the aorta can occur as a discrete juxtaductal obstruction or as tubular hypoplasia of the transverse aorta starting at one of the head or neck vessels and extending to the ductal area (previously referred to as *preductal* or *infantile-type coarctation;* Fig. 476.7). Often, both components are present. It is postulated that coarctation may be initiated in fetal life by the presence of a cardiac abnormality that results in decreased blood flow anterograde through the aortic valve (e.g., bicuspid aortic valve, VSD). Alternatively, it has been theorized that coarctation may be caused by abnormal extension of contractile ductal tissue into the aortic wall.

In patients with discrete juxtaductal coarctation, ascending aortic blood flows through the narrowed segment to reach the descending aorta, although LV hypertension and hypertrophy result. In the first few days of life, the PDA may serve to widen the juxtaductal area of the aorta and provide temporary relief from the obstruction. Net left-to-right ductal shunting occurs in these acyanotic infants. With more severe juxtaductal coarctation or in the presence of transverse arch hypoplasia, RV blood is ejected through the ductus to supply the descending aorta. Perfusion of the lower part of the body is then dependent on RV output. In this situation the femoral pulses are palpable, and differential blood pressures may not be helpful in making the diagnosis. However, the ductal right-to-left shunting is manifested as differential cyanosis, with the upper extremities being well oxygenated and the lower extremities cyanotic. This is one of the main reasons for performing upper- and lower-limb oxygen saturation screening in the newborn because subtle differences in saturation may not be discernable visually. Such infants may have severe pulmonary hypertension and high pulmonary vascular resistance. Signs of heart failure are prominent. Occasionally, severely hypoplastic segments of the aortic isthmus may become completely atretic and result in an interrupted aortic arch, with the left subclavian artery arising either proximal or distal to the interruption.

Blood pressure (BP) is elevated in the vessels that arise proximal to the coarctation; BP and pulse pressure are lower below the constriction. The hypertension is not caused by the mechanical obstruction alone, but also involves neurohumoral mechanisms. Unless surgically corrected in infancy, coarctation of the aorta usually results in the development of an extensive collateral circulation, chiefly from branches of the subclavian, superior intercostal, and internal mammary arteries, to create channels for arterial blood to bypass the area of coarctation. The vessels contributing to the collateral circulation may become greatly enlarged and tortuous by early adulthood.

CLINICAL MANIFESTATIONS

Coarctation of the aorta recognized after infancy may not be associated with significant symptoms, although these may be revealed on closer questioning. Some children or adolescents complain about weakness or pain/claudication (or both) in the legs after exercise, but in many cases, even patients with severe coarctation are asymptomatic. Older

children are frequently brought to the cardiologist's attention when they are found to be hypertensive on routine physical examination.

The classic sign of coarctation of the aorta is a disparity in pulsation and BP in the arms and legs. The femoral, popliteal, posterior tibial, and dorsalis pedis pulses are weak (or absent in up to 40% of patients), in contrast to bounding pulses palpated in the arms and carotid vessels. However, in patients with large numbers of collaterals, the pulse and BP may not be much diminished in the lower extremities; in these cases, diagnosis depends on palpation of the radial and femoral pulses simultaneously for the presence of a **radial-femoral delay**. Normally, the femoral pulse occurs slightly before the radial pulse. A radial-femoral delay occurs when blood flow to the descending aorta is dependent on collaterals, in which case the femoral pulse is felt after the radial pulse. In normal persons *(except neonates),* systolic BP in the legs obtained by the cuff method is usually 10-20 mm Hg higher than that in the arms. In coarctation of the aorta, BP in the legs is lower than that in the arms; frequently, it is difficult to obtain. This differential in BPs is common in patients with coarctation who are older than 1 year, approximately 90% of whom have systolic hypertension in an upper extremity >95th percentile for age. It is important to determine the BP in each arm; a BP higher in the right than the left arm suggests involvement of the left subclavian artery in the area of coarctation. Occasionally, the right subclavian may arise anomalously from below the area of coarctation and result in a left arm BP that is higher than the right. With exercise, a more prominent rise in upper arm BP occurs, and the upper- to lower-extremity pressure gradient will increase.

The precordial impulse and heart sounds are usually normal; the presence of a systolic ejection click or thrill in the suprasternal notch suggests a bicuspid aortic valve (present in 70% of cases). A short systolic murmur is often heard along the left sternal border at the third and fourth intercostal spaces. The murmur is well transmitted to the left infrascapular area and occasionally to the neck. With a bicuspid aortic valve, the typical murmur of aortic stenosis can be heard at the upper right and mid-left sternal borders. Occasionally, more significant degrees of obstruction are noted across the aortic valve. The presence of a low-pitched mid-diastolic murmur at the apex suggests mitral valve stenosis. In older patients with well-developed collateral blood flow, systolic or continuous murmurs may be heard over the left and right sides of the chest laterally and posteriorly. In these patients, a palpable thrill can sometimes be appreciated in the intercostal spaces on the back.

Neonates or infants with more severe coarctation, usually including some degree of transverse arch hypoplasia, initially have signs of lower-body hypoperfusion, acidosis, and severe heart failure. These signs may be delayed days or weeks until after closure of the ductus arteriosus. If detected before ductal closure, patients may exhibit **differential cyanosis**, best demonstrated by simultaneous oximetry of the upper and lower extremities. On physical examination the heart is large, and a systolic murmur is heard along the left sternal border.

Diagnosis

Findings on chest x-ray examination depend on the age of the patient and on the effects of hypertension and the collateral circulation. Cardiac enlargement and pulmonary congestion are noted in infants with severe coarctation. In patients with less severe forms of coarctation, the findings may not be that striking until after the first decade, when the heart tends to be mildly or moderately enlarged because of LV prominence. The enlarged left subclavian artery typically produces a prominent shadow in the left superior mediastinum. **Notching of the inferior border of the ribs** from pressure erosion by enlarged collateral vessels is common by late childhood. In most patients the descending aorta has an area of poststenotic dilation.

The ECG is usually normal in young children with milder degrees of coarctation but demonstrates LV hypertrophy in older patients. Neonates and young infants display right or biventricular hypertrophy. The segment of coarctation can generally be visualized by 2D echocardiography (Fig. 476.8); associated anomalies of the mitral and aortic valve can also be demonstrated. The descending aorta is hypopulsatile, and color Doppler demonstrates the specific site of the obstruction. Pulsed and continuous wave Doppler studies determine the pressure gradient directly at the area of coarctation; in the presence of a PDA, however, the severity of the narrowing may be underestimated. CT and MRI

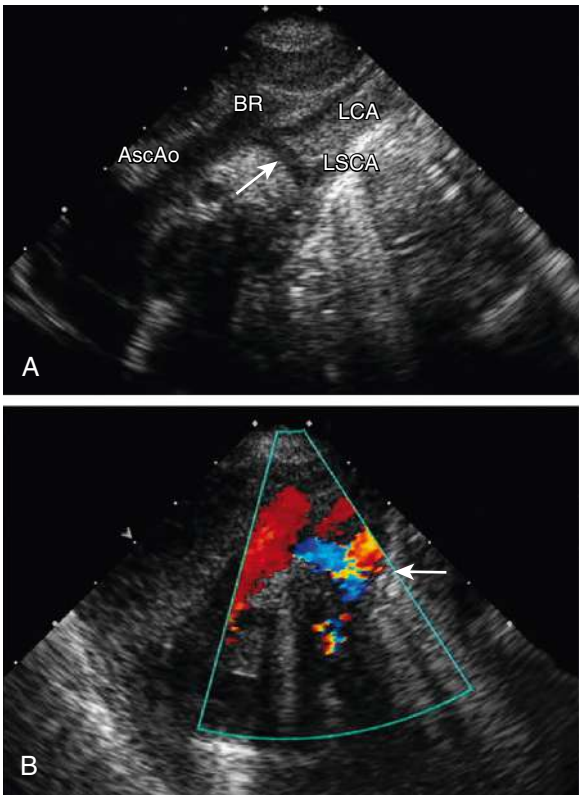

Fig. 476.8 Echocardiogram demonstrating coarctation of the aorta with hypoplastic transverse arch. **A,** Suprasternal notch 2D echocardiogram showing marked narrowing beginning just distal to the brachiocephalic artery. **B,** Color Doppler demonstrates turbulent flow in the juxtaductal area *(arrow).* AscAo, Ascending aorta; BR, brachiocephalic artery; LCA, left carotid artery; LSCA, left subclavian artery.

are valuable noninvasive tools for evaluation of coarctation when the echocardiogram is equivocal (Fig. 476.9). Cardiac catheterization with selective left ventriculography and aortography is useful in occasional patients with additional anomalies and as a means of visualizing collateral blood flow. In cases that are well defined by echocardiography, CT, or MRI, diagnostic catheterization is not usually required before surgery.

TREATMENT

In **neonates** with severe coarctation of the aorta, closure of the ductus often results in hypoperfusion, acidosis, and rapid deterioration. These patients should be given an infusion of prostaglandin E_1 to reopen the ductus and reestablish adequate lower-extremity blood flow. Once a diagnosis has been confirmed and the patient stabilized, surgical repair should be performed. **Older infants** with heart failure but good perfusion should be managed with anticongestive measures to improve their clinical status in preparation for surgical intervention. There is usually no reason to delay surgical repair waiting for patient growth; successful repairs have been performed even in small premature infants.

Older children with significant coarctation of the aorta should be treated relatively soon after diagnosis. Delay is unwarranted, especially after the second decade of life, when there may be decreased LV function and degenerative changes in the aortic wall. For patients with significant left ventricular dysfunction, relief of the obstruction can improve function as afterload on the ventricle is dramatically decreased; however, if fibrosis has occurred, patients can have residual left ventricular dysfunction. If cardiac function is normal, satisfactory repair and long-term outcome are possible well into mid-adult life.

Surgery remains the treatment of choice for isolated juxtaductal coarctation of the aorta in neonates, infants, and young children at most centers; several surgical techniques are used. The area of coarctation can be excised and a primary reanastomosis performed. Most often, the transverse aorta is opened and an "extended end-to-end" anastomosis performed to increase the effective cross-sectional area of the repair. The subclavian

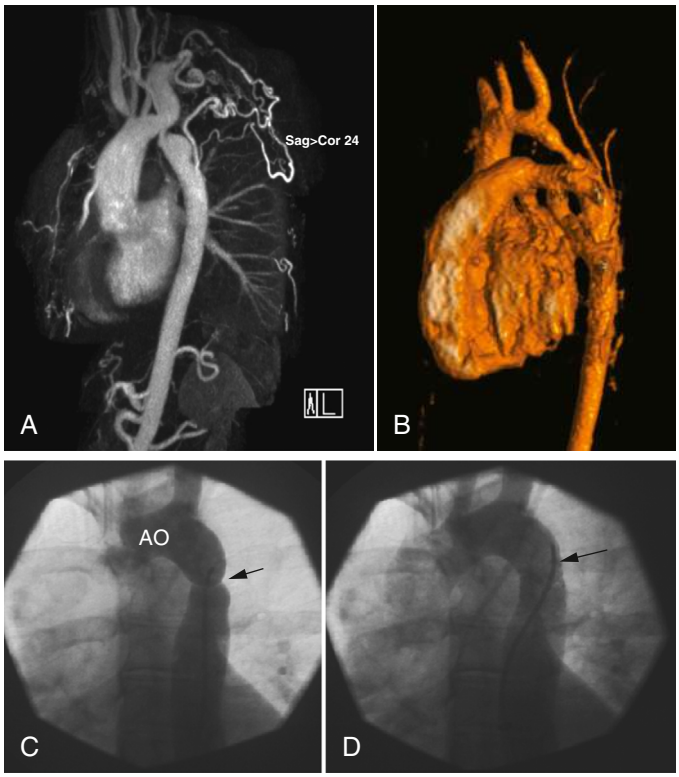

Fig. 476.9 Coarctation of the aorta. A, CT angiogram of coarctation. B, 3D reconstruction. Angiograms of the coarctation before (C) and after (D) stenting *(arrows)*. AO, Aorta. *(Adapted from Webb GD, Smallhorn JF, Therrien J, et al. Congenital heart disease in the adult and pediatric patient. In: Zipes DP, Libby P, Bonow RO, et al., eds. Braunwald's Heart Disease, 11th ed. Philadelphia: Elsevier; 2019: Fig. 75.41, p. 1561.)*

flap procedure, which involves division of the left subclavian artery and its incorporation into the wall of the repaired coarctation, has fallen out of favor because of a higher degree of residual stenosis. Some centers favor a patch aortoplasty, in which the area of coarctation is enlarged with a roof of prosthetic material. The use of **primary angioplasty** for native coarctation has been effective in older children and adults. In infants ≥3 months of age, balloon angioplasty has been as effective as surgery but is associated with higher rates of recoarctation requiring intervention (repeat angioplasty or surgery) and aortic aneurysm formation. Surgery is the treatment of choice for the symptomatic neonate. Angioplasty is the treatment of choice for recoarctation. **Primary stent placement** in the catheterization laboratory is considered in older children, where the stent can be expanded if needed to keep up with patient growth and for young adults (see Fig. 476.9). For patients who present with severe LV dysfunction, where surgical intervention may be associated with increased risk, catheter-based treatments are often considered.

After surgery, a striking increase in the amplitude of the pulse in the lower extremities is noted. In the immediate postoperative course, *rebound hypertension* can occur and requires medical management. This exaggerated acute hypertension gradually subsides, and in most patients, antihypertensive medications can be discontinued. Residual murmurs are common and may result from associated cardiac anomalies, a residual flow disturbance across the repaired area, or collateral blood flow. Rare operative problems include spinal cord injury from aortic cross-clamping (if collaterals are poorly developed), chylothorax, diaphragm injury, and laryngeal nerve injury. If a left subclavian flap approach is used, the radial pulse and BP in the left arm are diminished or absent.

POSTCOARCTECTOMY SYNDROME

Postoperative **mesenteric arteritis** may be associated with acute hypertension and abdominal pain in the immediate postoperative period. The pain varies in severity and may occur in conjunction with anorexia, nausea, vomiting, leukocytosis, intestinal hemorrhage, bowel necrosis, and small bowel obstruction. Relief is usually obtained with antihypertensive drugs (e.g., nitroprusside, esmolol, captopril) and intestinal decompression; surgical exploration is rarely required for bowel obstruction or infarction.

PROGNOSIS

Although restenosis in older patients after coarctectomy is rare, a significant number of infants operated on before 1 year of age require revision later in childhood. All patients should be monitored carefully for the development of recoarctation and for aortic aneurysm at the anastomotic site. Should recoarctation occur, **balloon angioplasty** is the procedure of choice. In these patients, scar tissue from a previous surgery may make reoperation more difficult, yet it makes balloon angioplasty safer because of the lower incidence of aneurysm formation. Relief of obstruction with this technique is usually excellent. **Intravascular stents** are typically used, especially in adolescents and young adults, with generally excellent results.

Repair of coarctation in the second decade of life or beyond may be associated with a higher incidence of premature cardiovascular disease, even in the absence of residual cardiac abnormalities. Early onset of **adult-type chronic hypertension** may occur, even in patients with adequately resected coarctation.

Abnormalities of the aortic valve are present in a majority of patients. Bicuspid aortic valves are common but do not generally produce clinical signs unless the stenosis is significant. The association of a PDA with coarctation of the aorta is also common. VSDs and ASDs may be suspected by signs of a left-to-right shunt; they are exacerbated by the increased resistance to flow through the left side of the heart. Mitral valve abnormalities are also occasionally seen, as is subvalvular aortic stenosis.

Severe neurologic damage or even death may rarely occur from associated cerebrovascular disease. Subarachnoid or intracerebral hemorrhage may result from rupture of congenital aneurysms in the circle of Willis, rupture of other vessels with defective elastic and medial tissue, or rupture of normal vessels; these events are secondary to hypertension. Children with **PHACE syndrome** (posterior brain fossa anomalies, facial hemangiomas, arterial anomalies, cardiac anomalies and aortic coarctation, eye anomalies syndrome) may have strokes (see Table 691.5). Abnormalities of the subclavian arteries may include involvement of the left subclavian artery in the area of coarctation, stenosis of the orifice of the left subclavian artery, and anomalous origin of the right subclavian artery.

Untreated, the great majority of older patients with coarctation of the aorta would succumb between ages 20 and 40 years; some live well into middle life without serious disability. The common serious complications are related to systemic hypertension, which may result in premature coronary artery disease, heart failure, hypertensive encephalopathy, or intracranial hemorrhage. Heart failure may be worsened by associated anomalies. Infective endocarditis or endarteritis is a significant complication in these adult patients. Aneurysms of the descending aorta or the enlarged collateral vessels may develop.

476.7 Coarctation with Ventricular Septal Defect

Daniel Bernstein

In most cases, coarctation is the major anomaly causing the severe symptoms, and resection of the coarcted segment results in striking improvement. Repair of both the VSD and coarctation is usually performed at the same operation through a midline sternotomy using cardiopulmonary bypass.

476.8 Coarctation with Other Cardiac Anomalies and Interrupted Aortic Arch

Daniel Bernstein

Coarctation often occurs in infancy in association with other major cardiovascular anomalies, including hypoplastic left heart, severe mitral or aortic valve disease, transposition of the great arteries, and variations of

double-outlet or single-ventricle. The clinical manifestations depend on the effects of the associated malformations and on the coarctation itself.

Coarctation of the aorta associated with severe **mitral** and **aortic valve disease** may have to be treated within the context of hypoplastic left heart syndrome (see Chapter 480.10), even if the LV chamber is not severely hypoplastic. Such patients usually have a long segment of narrow, transverse aortic arch in addition to an isolated coarctation at the site of the ductus arteriosus. Coarctation of the aorta with **transposition of the great arteries** or **single ventricle** may be repaired alone or in combination with other corrective or palliative measures.

Complete interruption of the aortic arch is the most severe form of coarctation and is usually associated with other intracardiac pathology. Interruption may occur at any level, although it is most often seen between the left subclavian artery and the insertion of the ductus arteriosus **(type A)**, followed in frequency by those between the left subclavian and left carotid arteries **(type B)**, or between the left carotid and brachiocephalic arteries **(type C)**. In newborns with an interrupted aortic arch, the ductus arteriosus provides the sole source of blood flow to the descending aorta, and differential oxygen saturations between the right arm (normal saturation) and the legs (decreased saturation) is noted. When the ductus begins to close, severe congestive heart failure, lower-extremity hypoperfusion, and anuria usually develop, progressing to shock. Patients with an interrupted aortic arch can be supported with prostaglandin E_1 to keep the ductus open before surgical repair. As one of the **conotruncal malformations**, an interrupted aortic arch, especially type B, can be associated with **DiGeorge syndrome** (cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia). Cytogenetic analysis using fluorescence in situ hybridization demonstrates deletion of a segment of chromosome 22q11, known as the **DiGeorge critical region**.

476.9 Congenital Mitral Stenosis

Daniel Bernstein

Congenital mitral stenosis is a rare anomaly that can be either isolated or associated with other defects, the most common being subvalvar and valvar aortic stenosis and coarctation of the aorta **(Shone complex)**. The mitral valve may be funnel shaped, with thickened leaflets and chordae tendineae that are shortened and deformed. Other mitral valve anomalies associated with stenosis include **parachute** mitral valve, caused by a single papillary muscle, and **double-orifice** mitral valve.

If the stenosis is moderate to severe, symptoms usually appear within the first 2 years of life. These infants have failure to thrive and various degrees of dyspnea and pallor. In some patients, wheezing may be a dominant symptom, and a misdiagnosis of bronchiolitis or reactive airway disease may have been made. Heart enlargement because of dilation and hypertrophy of the right ventricle and left atrium is common. Most patients have rumbling apical diastolic murmurs, but because the pressure gradients in diastole are not very high, the auscultatory findings may be relatively obscure. S_2 is split with a loud P_2 if pulmonary hypertension is present. An opening snap of the mitral valve may be present. The ECG reveals RVH and may show bifid or spiked P waves indicative of left atrial enlargement. Radiographs usually show left atrial and RV enlargement and pulmonary congestion in a perihilar or venous pattern. The echocardiogram is diagnostic and shows thickened mitral valve leaflets, a significant reduction of the mitral valve orifice, abnormal papillary muscle structure (or a single papillary muscle), and an enlarged left atrium with a normal or small left ventricle. A **double-orifice mitral valve** is one variant that can usually be seen on echocardiogram. Doppler studies demonstrate a mean pressure gradient across the mitral orifice during diastole. Associated anomalies such as aortic stenosis and coarctation can be evaluated. Cardiac catheterization is often performed to confirm the transmitral pressure gradient before surgery. An increase in RV, pulmonary artery, and pulmonary capillary wedge pressure can be noted. Angiocardiography shows delayed emptying of the left atrium and the small mitral orifice.

The results of surgical treatment depend on the anatomy of the valve, but if the mitral orifice is significantly hypoplastic, reduction of the gradient may be difficult. In some patients, a mitral valve prosthesis is required, and if the valve orifice is too small, the prosthesis may be placed in the supramitral position. However, whatever prosthesis is used, it must be replaced serially as the child grows. These patients must be anticoagulated, usually with warfarin, and although manageable in older children, complications of excessive and insufficient anticoagulation are more common in infancy. Transcatheter balloon valvuloplasty has been used as a palliative procedure with mixed results, except in the situation of rheumatic mitral stenosis. Recent experience using the percutaneous Melody stent-valve in selected patients in the mitral position is encouraging.

476.10 Pulmonary Venous Hypertension

Daniel Bernstein

A variety of lesions may give rise to chronic pulmonary venous hypertension, which, when extreme, may result in pulmonary arterial hypertension and right-sided heart failure. These lesions include congenital **mitral stenosis**, **mitral insufficiency**, **total anomalous pulmonary venous return with obstruction**, **left atrial myxomas**, **cor triatriatum**, individual **pulmonary vein stenosis**, and **supravalvular mitral rings**. Early symptoms can be confused with chronic pulmonary disease such as asthma because of a lack of specific cardiac findings on physical examination. Subtle signs of pulmonary hypertension may be present. The ECG shows RVH with spiked P waves. Radiographic studies demonstrate prominence of the pulmonary veins in the hilar region and enlargement of the right ventricle and atrium and the main pulmonary artery; the left atrium is normal in size or only slightly enlarged.

The echocardiogram may demonstrate left atrial myxoma, cor triatriatum, stenosis of one or more pulmonary veins, or a mitral valve abnormality (e.g., supravalvar mitral ring). Cardiac catheterization excludes the presence of a shunt and demonstrates pulmonary hypertension with elevated pulmonary arterial wedge pressure. Left atrial pressure is normal if the lesion is at the level of the pulmonary veins, but it is elevated if the lesion is at the level of the mitral valve. Selective pulmonary arteriography usually delineates the anatomic lesion. Cor triatriatum, left atrial myxoma, and supravalvular mitral rings can all be successfully managed surgically.

The differential diagnosis includes **pulmonary venoocclusive disease**, an idiopathic process that produces obstructive lesions in one or more pulmonary veins. The cause is uncertain, and disease that begins in one vein can spread to others. Although it is usually encountered in patients after repair of obstructed total anomalous pulmonary venous return (see Chapter 480.7), it can occur sporadically or in families in the absence of congenital heart disease. Pathogenic variants in *BMPR2* may be seen in the familial or sporadic cases. The patient initially presents with symptoms similar to left-sided heart failure on the basis of congested lungs with apparent pulmonary edema. Dyspnea, fatigue, and pleural effusions are common. Left atrial pressure is normal, but pulmonary arterial wedge pressure is usually elevated. A normal wedge pressure may be encountered if collaterals have formed, or the wedge recording is performed in an uninvolved segment. Angiographically, the pulmonary veins return normally to the left atrium, but one or more pulmonary veins are narrowed, either focally or diffusely. Sporadic or familial cases present with a primary pulmonary hypertension phenotype, with dyspnea and cyanosis. However, treatment with a primary pulmonary hypertension regimen will precipitate pulmonary edema.

Studies using lung biopsy have demonstrated pulmonary venous and, occasionally, arterial involvement. Pulmonary veins and venules demonstrate fibrous narrowing or occlusion, and pulmonary artery thrombi may be present. Attempts at surgical repair, balloon dilation, and transcatheter stenting have not significantly improved the generally poor prognosis of these patients. Use of antiproliferative agents with imatinib with or without bevacizumab has demonstrated success in preliminary studies. Combined heart-lung transplantation is often the only alternative therapeutic option (see Chapter 492.2).

Chapter 477

Acyanotic Congenital Heart Disease: Regurgitant Lesions

477.1 Pulmonary Valvular Insufficiency and Congenital Absence of the Pulmonary Valve

Daniel Bernstein

Pulmonary valvular insufficiency most often accompanies other cardiovascular diseases (surgical repair of pulmonary valve stenosis) or may be secondary to severe **pulmonary hypertension**. Some degree of incompetence of the valve is an expected result after surgery for right ventricular outflow tract (RVOT) obstruction, including pulmonary valvotomy in patients with **valvular pulmonic stenosis** or valvotomy with infundibular resection in patients with **tetralogy of Fallot**. Isolated congenital insufficiency of the pulmonary valve is rare, and these patients are usually asymptomatic because the insufficiency is generally mild.

The prominent physical sign is a decrescendo diastolic murmur at the upper and mid-left sternal border, which has a lower pitch than the murmur of aortic insufficiency because of the lower pressure involved. Radiographs of the chest show prominence of the main pulmonary artery and, if the insufficiency is severe, right ventricular (RV) enlargement. The electrocardiogram (ECG) is normal or shows an rSR′ pattern in the right precordial leads (V_1, V_2) and minimal or no RV hypertrophy. Pulsed and color Doppler studies demonstrate retrograde flow from the pulmonary artery into the right ventricle during diastole. Echocardiography can give qualitative measures of RV volume; cardiac magnetic resonance angiography (MRA) is the best method for quantifying RV volume, the regurgitant fraction, and RV systolic function (ejection fraction). Mild pulmonary valvular insufficiency is generally well tolerated and does not require surgical treatment. When pulmonary insufficiency is moderate to severe and the right ventricle becomes significantly dilated and/or if tricuspid insufficiency has begun to develop, re-repair, replacement with a homograft valve, or transcatheter stent-valve placement may become necessary to preserve RV function.

Congenital absence of the pulmonary valve is usually associated with a ventricular septal defect (VSD), often in the context of tetralogy of Fallot (see Chapter 479.1). In many of these neonates, the pulmonary arteries become widely dilated and compress the bronchi, resulting in recurrent episodes of wheezing, pulmonary collapse, and pneumonitis. The presence and degree of cyanosis are variable. Florid pulmonary valvular incompetence may not be well tolerated, and death may occur from a combination of bronchial compression, hypoxemia, and heart failure. Correction involves plication of the massively dilated pulmonary arteries, closure of the VSD, and placement of a homograft across the RVOT.

477.2 Congenital Mitral Insufficiency

Daniel Bernstein

Congenital mitral insufficiency is rare as an isolated lesion and is more often associated with other anomalies. It is most frequently encountered in combination with an **atrioventricular septal defect**, either an ostium primum defect or a complete atrioventricular septal defect (see Chapter 475.5) where the insufficient jet is through a cleft in the mitral valve. Mitral insufficiency is also seen in patients with dilated cardiomyopathy (see Chapter 488.1) when the left ventricular (LV) function deteriorates, the chamber dilates, and the valve ring is stretched. In adults, mitral insufficiency can be the result of ischemic injury to a papillary muscle; this is uncommon in children. Mitral insufficiency may also be encountered in conjunction with coarctation of the aorta, VSD, corrected transposition of the great vessels, anomalous origin of the left coronary artery from the pulmonary artery, or Marfan syndrome. In the absence of other congenital heart disease, endocarditis or rheumatic fever should be suspected in a patient with isolated mitral insufficiency.

In mitral insufficiency caused by a congenitally malformed valve, the mitral valve annulus may be dilated, the chordae tendineae short and may insert anomalously, and the valve leaflets are deformed. When mitral insufficiency is severe enough to cause clinical symptoms, the left atrium enlarges as a result of the regurgitant flow, and the left ventricle becomes dilated and mildly hypertrophied. Pulmonary venous pressure is increased, and the increased pressure can ultimately result in pulmonary hypertension and RV hypertrophy and dilation. Mild lesions produce no symptoms; the only abnormal sign is an apical holosystolic murmur of mitral regurgitation. In contrast, moderate to severe regurgitation results in symptoms that can appear at any age, including poor growth, frequent respiratory infections, fatigue on exertion, and episodes of pulmonary edema or congestive heart failure. Often, a diagnosis of reactive airways disease will have been made because of the similarity in pulmonary symptoms, including wheezing, which may be a dominant finding in infants and young children. The presence of a murmur helps distinguish these two etiologies.

The typical murmur of mitral insufficiency is a moderately high-pitched, apical blowing, holosystolic murmur. The murmur radiates from the apex toward the mid-left sternal border. If the insufficiency is moderate to severe, it is usually associated with a low-pitched, apical mid-diastolic rumbling murmur indicative of increased diastolic flow across the mitral valve (physiologic mitral stenosis). The pulmonic component of the second heart sound will be accentuated if there is pulmonary hypertension. The ECG usually shows bifid P waves consistent with left atrial enlargement, signs of LV hypertrophy, and sometimes signs of RV hypertrophy. Radiographic examination shows enlargement of the left atrium, which at times can be massive. The left ventricle is also enlarged and pulmonary vascularity prominent, especially in the perihilar areas. The echocardiogram demonstrates the enlarged left atrium and left ventricle and defines the structure of the valve, the presence or absence of a cleft, and the chordal apparatus. 3D echocardiography is especially useful for this imaging. Color Doppler demonstrates the extent of the insufficiency, and pulsed Doppler of the pulmonary veins detects retrograde flow when mitral insufficiency is severe. Cardiac catheterization shows elevated left atrial pressure and left ventricular end-diastolic pressure. Pulmonary artery hypertension of varying severity may be present. Selective left ventriculography demonstrates the severity of mitral regurgitation.

Surgical **mitral valvuloplasty** can result in striking improvement in symptoms and heart size, but in some patients, installation of a prosthetic mechanical mitral valve may be necessary. Before surgery, associated anomalies must be identified, as they will need to be addressed at the time of valve repair. If the valve requires replacement, several alternatives are available, including mechanical (used mainly for older children) and bioprosthetic, as well as the use of the Melody stent-valve. These can be inserted during a **hybrid procedure** (surgery and catheterization). A cardiac catheter laboratory–inserted device (MitraClip), used mostly in adults, has been used in a few selected pediatric patients to cinch together the anterior and posterior mitral valve leaflets, reducing insufficiency by creating a double-orifice mitral valve.

477.3 Mitral Valve Prolapse

Daniel Bernstein

Mitral valve prolapse (MVP) results from an abnormal mitral valve mechanism that causes billowing of one or both mitral leaflets, especially the posterior cusp, into the left atrium toward the end of ventricular systole. The abnormality is predominantly congenital but may not be recognized until adolescence or adulthood. Primary mitral valve prolapse is common, is present in 2–3% of the population, is more common in females, and may be sporadic or inherited as an autosomal dominant trait (less often X-linked) with variable expression. Pathogenic variants in *DCHS1, LMCD1, TNS1,* and *DZIP1* are possible genes associated with nonsyndromic MVP. It is a common finding in patients with Marfan syndrome, Loeys-Dietz syndrome, mitral-aortic-skeleton-skin (MASS) phenotype, familial myxomatous valvular degeneration, fragile X syndrome, mucopolysaccharidoses, Stickler syndrome, straight back syndrome, pectus excavatum, scoliosis, Ehlers-Danlos syndrome, osteogenesis imperfecta, and pseudoxanthoma elasticum and can also be associated with hyperthyroidism. Fibromyxomatous degeneration of the valve leaflets causes them to be thickened and elongated.

The abnormal signs are auscultatory, although occasional patients may have chest pain and/or palpitations. The apical murmur is late systolic and may be preceded by a click, but these signs may vary in the same patient, and at times, only the click is audible. Sudden standing, or the strain phase of the Valsalva maneuver, decreases LV volume, so the click moves closer to S_1 and the murmur becomes longer. Squatting (or the release phase of the Valsalva maneuver) increases LV volume, so that the click moves away from S_1 and the murmur is shortened. Arrhythmias may occur, primarily unifocal or multifocal premature ventricular contractions. In young adults, MVP has been associated with sudden cardiac death secondary to ventricular arrhythmias.

The ECG is usually normal but may show biphasic T waves, especially in leads II, III, aVF, and V_6; the T-wave abnormalities may vary at different times in the same patient. The chest radiograph is normal. The echocardiogram shows a characteristic posterior movement of the posterior mitral leaflet during mid- or late ventricular systole or demonstrates pansystolic prolapse of both the anterior and posterior mitral leaflets. These echocardiographic findings must be interpreted cautiously because the appearance of minimal mitral prolapse may be a normal variant. Prolapse is more precisely defined by single or bileaflet prolapse of >2 mm beyond the long-axis annular plane of the valve with or without leaflet thickening. Prolapse with valve thickening >5 mm is "classic"; a lesser degree is "nonclassic." Two-dimensional echocardiography shows that both the free edge and the body of the mitral leaflets move posteriorly in systole toward the left atrium. Doppler is then used to assess the presence and severity of mitral regurgitation.

This lesion is not progressive in childhood, and specific therapy is not indicated. Antibiotic prophylaxis is not recommended during surgery and dental procedures (see Chapter 486). This recommendation is controversial because certain features (regurgitation, thickened redundant leaflets) may increase the risk of endocarditis.

Adults (males more often than females) with MVP are at increased risk for cardiovascular complications (sudden death, arrhythmia, cerebrovascular accident, progressive valve dilation, heart failure, and endocarditis) if they have thickened (>5 mm) and redundant mitral valve leaflets. Risk factors for morbidity also include poor LV function, moderate to severe mitral regurgitation, and left atrial enlargement. MVP with severe valve regurgitation, or heart failure, or significant arrhythmias may require initial valve repair or replacement. Beta-blocking agents have been used for patients with palpitations and some arrhythmias. Most patients are asymptomatic and require no treatment.

477.4 Tricuspid Regurgitation

Daniel Bernstein

Isolated congenital tricuspid regurgitation is most often associated with **Ebstein anomaly of the tricuspid valve** (see Chapter 479.7). Ebstein anomaly may occur either without cyanosis or with varying degrees of cyanosis, depending on the severity of the tricuspid regurgitation and the presence of an atrial-level communication (patent foramen ovale or atrial septal defect). Older children tend to have the acyanotic form or only develop cyanosis with exercise, whereas if detected in the newborn period, Ebstein anomaly is usually associated with severe cyanosis.

In pediatric patients, tricuspid regurgitation is most often associated with congenital heart disease and/or RV dysfunction. When the right ventricle becomes dilated because of volume overload (e.g., pulmonary insufficiency) or intrinsic myocardial disease (dilated cardiomyopathy), the tricuspid annulus also enlarges, with separation of the leaflets and resultant valve insufficiency. This form of regurgitation may improve if the cause of the RV dilation is corrected, or it may require surgical plication of the valve annulus. Tricuspid regurgitation can also be encountered in patients with congenitally corrected transposition of the great arteries (see Chapter 479) and in patients with hypoplastic left heart syndrome after surgical palliation; in both of these situations the RV is pumping at systemic pressure. Isolated tricuspid regurgitation is also encountered in newborns with perinatal asphyxia. The cause may be related to an increased susceptibility of the papillary muscles to ischemic damage and subsequent transient papillary muscle dysfunction. Lastly, tricuspid regurgitation is seen in up to 30% of children after heart transplantation, which can be a risk factor for graft dysfunction, but is also seen as a result of valve injury caused by endomyocardial biopsy.

Chapter 478

Cyanotic Congenital Heart Disease: Evaluation of the Critically Ill Neonate with Cyanosis and Respiratory Distress

Daniel Bernstein

See also Chapter 124.

A severely ill neonate with cardiorespiratory distress and cyanosis is a diagnostic challenge. The clinician must perform a rapid evaluation to determine whether congenital heart disease (CHD) is a cause so that potentially lifesaving measures can be instituted. The differential diagnosis of neonatal cyanosis is presented in Table 121.2.

477.3 Mitral Valve Prolapse

Daniel Bernstein

Mitral valve prolapse (MVP) results from an abnormal mitral valve mechanism that causes billowing of one or both mitral leaflets, especially the posterior cusp, into the left atrium toward the end of ventricular systole. The abnormality is predominantly congenital but may not be recognized until adolescence or adulthood. Primary mitral valve prolapse is common, is present in 2–3% of the population, is more common in females, and may be sporadic or inherited as an autosomal dominant trait (less often X-linked) with variable expression. Pathogenic variants in *DCHS1, LMCD1, TNS1,* and *DZIP1* are possible genes associated with nonsyndromic MVP. It is a common finding in patients with Marfan syndrome, Loeys-Dietz syndrome, mitral-aortic-skeleton-skin (MASS) phenotype, familial myxomatous valvular degeneration, fragile X syndrome, mucopolysaccharidoses, Stickler syndrome, straight back syndrome, pectus excavatum, scoliosis, Ehlers-Danlos syndrome, osteogenesis imperfecta, and pseudoxanthoma elasticum and can also be associated with hyperthyroidism. Fibromyxomatous degeneration of the valve leaflets causes them to be thickened and elongated.

The abnormal signs are auscultatory, although occasional patients may have chest pain and/or palpitations. The apical murmur is late systolic and may be preceded by a click, but these signs may vary in the same patient, and at times, only the click is audible. Sudden standing, or the strain phase of the Valsalva maneuver, decreases LV volume, so the click moves closer to S_1 and the murmur becomes longer. Squatting (or the release phase of the Valsalva maneuver) increases LV volume, so that the click moves away from S_1 and the murmur is shortened. Arrhythmias may occur, primarily unifocal or multifocal premature ventricular contractions. In young adults, MVP has been associated with sudden cardiac death secondary to ventricular arrhythmias.

The ECG is usually normal but may show biphasic T waves, especially in leads II, III, aVF, and V_6; the T-wave abnormalities may vary at different times in the same patient. The chest radiograph is normal. The echocardiogram shows a characteristic posterior movement of the posterior mitral leaflet during mid- or late ventricular systole or demonstrates pansystolic prolapse of both the anterior and posterior mitral leaflets. These echocardiographic findings must be interpreted cautiously because the appearance of minimal mitral prolapse may be a normal variant. Prolapse is more precisely defined by single or bileaflet prolapse of >2 mm beyond the long-axis annular plane of the valve with or without leaflet thickening. Prolapse with valve thickening >5 mm is "classic"; a lesser degree is "nonclassic." Two-dimensional echocardiography shows that both the free edge and the body of the mitral leaflets move posteriorly in systole toward the left atrium. Doppler is then used to assess the presence and severity of mitral regurgitation.

This lesion is not progressive in childhood, and specific therapy is not indicated. Antibiotic prophylaxis is not recommended during surgery and dental procedures (see Chapter 486). This recommendation is controversial because certain features (regurgitation, thickened redundant leaflets) may increase the risk of endocarditis.

Adults (males more often than females) with MVP are at increased risk for cardiovascular complications (sudden death, arrhythmia, cerebrovascular accident, progressive valve dilation, heart failure, and endocarditis) if they have thickened (>5 mm) and redundant mitral valve leaflets. Risk factors for morbidity also include poor LV function, moderate to severe mitral regurgitation, and left atrial enlargement. MVP with severe valve regurgitation, or heart failure, or significant arrhythmias may require initial valve repair or replacement. Beta-blocking agents have been used for patients with palpitations and some arrhythmias. Most patients are asymptomatic and require no treatment.

477.4 Tricuspid Regurgitation

Daniel Bernstein

Isolated congenital tricuspid regurgitation is most often associated with **Ebstein anomaly of the tricuspid valve** (see Chapter 479.7). Ebstein anomaly may occur either without cyanosis or with varying degrees of cyanosis, depending on the severity of the tricuspid regurgitation and the presence of an atrial-level communication (patent foramen ovale or atrial septal defect). Older children tend to have the acyanotic form or only develop cyanosis with exercise, whereas if detected in the newborn period, Ebstein anomaly is usually associated with severe cyanosis.

In pediatric patients, tricuspid regurgitation is most often associated with congenital heart disease and/or RV dysfunction. When the right ventricle becomes dilated because of volume overload (e.g., pulmonary insufficiency) or intrinsic myocardial disease (dilated cardiomyopathy), the tricuspid annulus also enlarges, with separation of the leaflets and resultant valve insufficiency. This form of regurgitation may improve if the cause of the RV dilation is corrected, or it may require surgical plication of the valve annulus. Tricuspid regurgitation can also be encountered in patients with congenitally corrected transposition of the great arteries (see Chapter 479) and in patients with hypoplastic left heart syndrome after surgical palliation; in both of these situations the RV is pumping at systemic pressure. Isolated tricuspid regurgitation is also encountered in newborns with perinatal asphyxia. The cause may be related to an increased susceptibility of the papillary muscles to ischemic damage and subsequent transient papillary muscle dysfunction. Lastly, tricuspid regurgitation is seen in up to 30% of children after heart transplantation, which can be a risk factor for graft dysfunction, but is also seen as a result of valve injury caused by endomyocardial biopsy.

Chapter 478

Cyanotic Congenital Heart Disease: Evaluation of the Critically Ill Neonate with Cyanosis and Respiratory Distress

Daniel Bernstein

See also Chapter 124.

A severely ill neonate with cardiorespiratory distress and cyanosis is a diagnostic challenge. The clinician must perform a rapid evaluation to determine whether congenital heart disease (CHD) is a cause so that potentially lifesaving measures can be instituted. The differential diagnosis of neonatal cyanosis is presented in Table 121.2.

CARDIAC DISEASE LEADING TO CYANOSIS

CHD produces cyanosis when obstruction to right ventricular inflow or outflow causes intracardiac right-to-left shunting or when complex anatomic defects cause an admixture of pulmonary (deoxygenated) and systemic (oxygenated) venous return somewhere in the heart. Cyanosis from pulmonary edema may also develop in patients with heart failure caused by left-to-right shunts, although the degree of desaturation is usually less severe. In general, right ventricular outflow obstruction without an intracardiac shunt (e.g., isolated valvar pulmonary stenosis) does not cause cyanosis; however, in the newborn period, cyanosis may be caused by right-to-left shunting across the foramen ovale in the presence of elevated right-sided filling pressures. **Persistent pulmonary hypertension of the newborn (PPHN)** is another cause of right-to-left shunting at the atrial level in the newborn period (see Chapter 130).

DIFFERENTIAL DIAGNOSIS

The **hyperoxia test** is one method of distinguishing cyanotic CHD from pulmonary disease. This test is based on the premise that neonates with cyanotic CHD usually are unable to significantly raise their arterial blood partial pressure of oxygen (Pao_2) during administration of 100% oxygen, whereas in infants with pulmonary disease, high levels of intraalveolar Po_2 will overcome at least some of the ventilation-perfusion abnormalities and reverse the hypoxia. This test is performed using a hood rather than nasal cannula or face mask to guarantee delivery of almost 100% oxygen to the patient. False-positive tests can occur if this is not done correctly. In a healthy newborn, the Pao_2 should rise above 300 mm Hg; if between 150 and 300 mm Hg, noncardiac etiologies (pulmonary disease, central nervous system disorders, methemoglobinemia) are most likely. This is not 100% confirmative, however, because some patients with cyanotic CHD may be able to increase their Pao_2 to >150 mm Hg because of favorable intracardiac streaming patterns. In infants with cyanosis from a central nervous system disorder, the Pao_2 usually normalizes completely during artificial ventilation. If the Pao_2 is between 100 and 150 mmHg, then cyanotic congenital heart lesions, increased pulmonary blood flow (mixing lesions, see Chapter 480), or PPHN are more likely. If the Pao_2 is less than 100 mm Hg, then CHD with decreased pulmonary blood flow (see Chapter 479) is more likely. Another clue to etiology is that hypoxia in many heart lesions is relatively constant, whereas in respiratory disorders and in PPHN, Pao_2 often varies with time or changes in ventilator management. For example, hyperventilation may improve the hypoxia in neonates with PPHN but only occasionally in those with cyanotic CHD.

Although a significant heart murmur usually suggests a cardiac basis for the cyanosis, several of the more severe cardiac defects (e.g., transposition of the great vessels) may not initially be associated with a murmur. The chest radiograph may be helpful in the differentiation of pulmonary and cardiac disease; in the latter, it also indicates whether pulmonary blood flow is increased, normal, or decreased (Fig. 478.1) as well as shows alterations in cardiac size.

Two-dimensional echocardiography with Doppler is the definitive noninvasive test to determine the presence of CHD. With today's high-quality echocardiography, cardiac catheterization is less often used for diagnostic purposes and is usually performed to examine structures that are less well visualized by echocardiography, such as distal branch pulmonary arteries and aortopulmonary collateral arteries in patients with tetralogy of Fallot with pulmonary atresia (see Chapter 479.2) or coronary arteries and right ventricular sinusoids in patients with pulmonary atresia and intact ventricular septum (see Chapter 479.3). If echocardiography is not immediately available to confirm a diagnosis of cyanotic CHD, the clinician caring for a newborn with possible cyanotic CHD should not hesitate to start a prostaglandin infusion (for a possible ductal-dependent lesion). Because of the risk of hypoventilation associated with prostaglandins, a practitioner skilled in neonatal endotracheal intubation must be available.

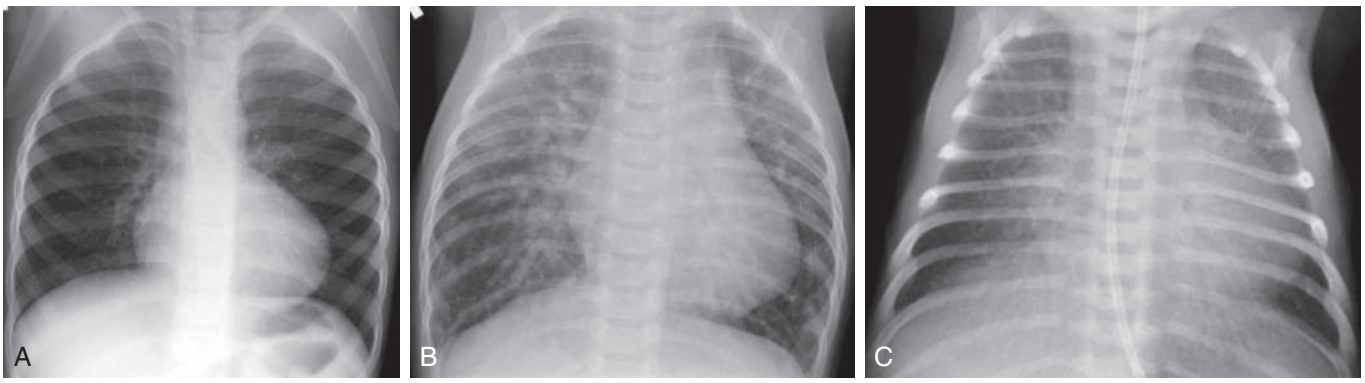

Fig. 478.1 Physiology of congenital heart disease delineated by chest radiography. **A,** Mild cardiomegaly with an upturned cardiac apex, a concave main pulmonary artery segment, and symmetric, severely diminished pulmonary blood flow in a 4-yr-old child with tetralogy of Fallot/pulmonary atresia. **B,** Moderate cardiomegaly and symmetric, increased pulmonary blood flow in a 3-mo-old infant with a large atrial septal defect and ventricular septal defect. **C,** Moderate cardiomegaly with interstitial edema in an 8-day-old newborn with critical aortic stenosis. *(From Frost JL, Krishnamurthy R, Sena L. Cardiac imaging. In: Walters MM, Robertson RL, eds. Pediatric Radiology—The Requisites, 4th ed. Philadelphia: Elsevier; 2017: Fig. 3.9, p. 68.)*

Chapter 479

Cyanotic Congenital Heart Disease: Lesions Associated with Decreased Pulmonary Blood Flow

479.1 Tetralogy of Fallot

Daniel Bernstein

Tetralogy of Fallot is one of the **conotruncal** family of heart lesions in which the primary defect is an anterior deviation of the *infundibular septum* (the muscular septum that separates the aortic and pulmonary outflows during division of the truncus arteriosus). The consequences of this deviation are the four components that Fallot initially described: (1) obstruction to right ventricular (RV) outflow (pulmonary stenosis); (2) a malalignment type of ventricular septal defect (VSD); (3) dextroposition of the aorta so that it overrides the ventricular septum; and (4) right ventricular hypertrophy (RVH; Fig. 479.1). Obstruction to pulmonary artery blood flow is usually at both the RV infundibulum (subpulmonic area) and the pulmonary valve. The main pulmonary artery (MPA) may also be small, and various degrees of branch pulmonary artery stenosis may be present. Complete obstruction of RV outflow (tetralogy with pulmonary atresia) is classified as an *extreme* form of tetralogy of Fallot (see Chapter 479.2) and may be associated with various degrees of hypoplasia of the branch pulmonary arteries. The degree of pulmonary outflow obstruction and whether the ductus arteriosus is open or closed determine the degree of the patient's cyanosis and the age at first presentation.

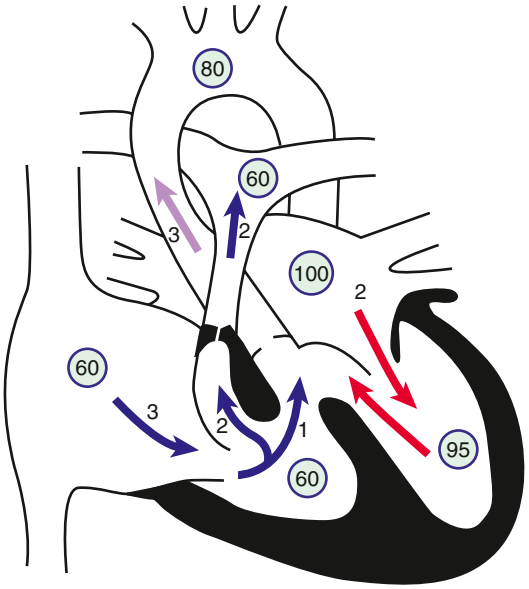

Fig. 479.1 Physiology of tetralogy of Fallot. *Circled numbers* represent oxygen saturation values. The *numbers next to the arrows* represent volumes of blood flow (in L/min/m^2). Atrial (mixed venous) oxygen saturation is decreased because of the systemic hypoxemia. A volume of 3 L/min/m^2 of desaturated blood enters the right atrium and traverses the tricuspid valve. Two liters flow through the right ventricular outflow tract into the lungs, whereas 1 L shunts right to left through the ventricular septal defect (VSD) into the ascending aorta. Thus pulmonary blood flow is two-thirds normal (Qp:Qs [pulmonary-to-systemic blood flow ratio] of 0.7:1). Blood returning to the left atrium is fully saturated. Only 2 L of blood flow across the mitral valve. Oxygen saturation in the left ventricle may be slightly decreased because of right-to-left shunting across the VSD. Two liters of saturated left ventricular blood mixing with 1 L of desaturated right ventricular blood are ejected into the ascending aorta. Aortic saturation is decreased, and cardiac output is normal.

PATHOPHYSIOLOGY

The pulmonary valve annulus may range from being nearly normal in size to being severely hypoplastic. The valve itself is often bicuspid or unicuspid and, occasionally, is the only site of stenosis. More often, the subpulmonic or infundibular muscle, known as the *crista supraventricularis,* is hypertrophic, which contributes to the subvalvar stenosis and results in an infundibular chamber of variable size and contour. When the right ventricular outflow tract (RVOT) is completely obstructed **(pulmonary atresia)**, the anatomy of the branch pulmonary arteries is extremely variable. An MPA segment may be in continuity with RV outflow, separated by a fibrous but imperforate pulmonary valve; the MPA may be moderately or severely hypoplastic but still supply part or all of the pulmonary bed; or the entire main pulmonary artery segment may be absent. Occasionally, the branch pulmonary arteries may be discontinuous. In these extreme cases, pulmonary blood flow may be supplied by a **patent ductus arteriosus** (PDA) or by multiple **major aortopulmonary collateral arteries (MAPCAs)** arising from the ascending and/or descending aorta or aortic branches and supplying various lung segments.

The VSD is usually nonrestrictive and large, is located just below the aortic valve, and is related to the posterior and right aortic cusps. Rarely, the VSD may be in the inlet portion of the ventricular septum (tetralogy with atrioventricular septal defect). The normal fibrous continuity of the mitral and aortic valves is usually maintained, and if not (because of the presence of a subaortic muscular conus), the defect is classified as a **double-outlet right ventricle** (DORV) instead of tetralogy of Fallot (see Chapter 479.5). The aortic arch is right sided in 20% of cases, and the aortic root is usually large and overrides the VSD to varying degrees. When the aorta overrides the VSD by >50% (in which case it may also be a subaortic conus), this defect is also classified as a form of DORV; however, the circulatory dynamics and the method of repair for these types of DORV are the same as for tetralogy of Fallot.

Systemic venous return to the right atrium and right ventricle is normal. When the right ventricle contracts in the presence of marked pulmonary stenosis, blood is shunted into the overriding aorta or across the VSD into the aorta. Persistent arterial desaturation and cyanosis result, with the degree of desaturation dependent on the severity of the pulmonary obstruction. Pulmonary blood flow, when severely restricted by the obstruction to RV outflow, is often supplemented by a PDA during the immediate newborn period. Peak systolic and diastolic pressures in each ventricle are similar and at the systemic level. A large pressure gradient occurs across the obstructed RVOT, and pulmonary artery pressure is either normal or lower than normal. The degree of RV outflow obstruction determines the timing of the onset of symptoms and the severity of cyanosis. When obstruction to RV outflow is mild to moderate and a balanced shunt is present across the VSD, the patient may not be visibly cyanotic (**acyanotic** or "pink" tetralogy of Fallot). When obstruction is severe, cyanosis will be present from birth and worsen dramatically when the ductus arteriosus begins to close.

CLINICAL MANIFESTATIONS

Infants with mild degrees of RV outflow obstruction may initially even have symptoms of heart failure caused by a ventricular-level left-to-right shunt. In these patients, cyanosis is not present at birth, but with increasing hypertrophy of the RV infundibulum as the patient grows, cyanosis occurs later in the first few months of life. In contrast, in infants with more severe degrees of RV outflow obstruction, neonatal cyanosis is noted immediately. In these infants, pulmonary blood flow

may be partially or almost totally dependent on flow through the ductus arteriosus. When the ductus begins to close in the first few hours or days of life, severe cyanosis and circulatory collapse may occur. All degrees of variation exist between these two clinical extremes. Older children with long-standing cyanosis who have not undergone surgery may have dusky blue skin, mucous membranes, and nailbeds (the latter two are key to diagnosing cyanosis in children with darker skin color). Patients may have gray sclerae with engorged blood vessels and (usually after 2 years of age) clubbing of the fingers and toes. Chapter 483 describes the extracardiac manifestations of long-standing cyanotic congenital heart disease.

In older children with unrepaired tetralogy, dyspnea occurs on minimal exertion. They may play actively for a short time and then sit or lie down or walk a block or so before stopping to rest. Characteristically, children assume a **squatting** position for the relief of dyspnea caused by physical effort; squatting increases venous return to the right side of the heart and also increases systemic vascular resistance, both serving to increase flow through the obstructed RV outflow. The child is usually able to resume physical activity after a few minutes of squatting.

Paroxysmal hypercyanotic attacks (hypoxic, "blue," or "tet" spells) may develop during the first year of life. The infant becomes hyperpneic and restless, cyanosis increases, gasping respirations ensue, and syncope may follow. The spells occur most frequently in the morning on initially awakening or after episodes of vigorous crying. Temporary disappearance or a decrease in intensity of the typical systolic ejection murmur occurs as flow across the RVOT diminishes during the spell. Tet spells may last from a few minutes to a few hours. Short episodes are followed by generalized weakness and sleep. Severe spells may progress to unconsciousness and occasionally to convulsions, stroke, and death. The onset of these spells is usually spontaneous and unpredictable. They are associated with reduction of an already compromised pulmonary blood flow, which, when prolonged, results in severe systemic hypoxia and metabolic acidosis. Infants who are only mildly cyanotic at rest may be more prone to the development of hypoxic spells because they have not acquired the homeostatic mechanisms that would allow them to better tolerate rapid lowering of arterial oxyhemoglobin saturation (Sao_2), such as polycythemia.

Depending on the frequency and severity of hypercyanotic attacks, one or more of the following procedures should be instituted in sequence: (1) placement of the infant on the abdomen in the knee-chest position while making certain that the infant's clothing is not constrictive; (2) administration of oxygen (although increasing inspired oxygen will not reverse cyanosis caused by intracardiac shunting); (3) injection of morphine subcutaneously or intranasal fentanyl or intranasal midazolam; (4) administer propranolol or esmolol; and (5) begin a phenylephrine intravenous infusion. Calming and holding the infant in a knee-chest position may abort progression of an early spell. Premature attempts to obtain blood samples may cause further agitation and may be counterproductive; transcutaneous oxygen saturation monitoring is helpful in these cases but is limited in not measuring the degree of acidosis if the spell is prolonged.

Because metabolic acidosis develops when arterial oxygen tension (Pao_2) is <40 mm Hg, rapid correction (within several minutes) with intravenous (IV) administration of sodium bicarbonate is necessary if the spell is unusually severe and the child shows a lack of response to the foregoing therapy. Recovery from the spell is usually rapid once the pH has returned to normal. Repeated blood pH measurements may be necessary because rapid recurrence of acidosis may ensue. For spells that are resistant to this therapy, intubation and anesthetic sedation are often sufficient to break the spell. Drugs that increase systemic vascular resistance, such as IV phenylephrine, can improve RV outflow, decrease the right-to-left shunt, and improve symptoms. β-Adrenergic blockade by the IV administration of propranolol (0.15-0.25 mg/kg/dose given slowly; can be repeated once in 15 minutes) has also been used. Spells are quite rare because most infants with tetralogy of Fallot undergo reparative surgery in early infancy.

Growth and development may be delayed in patients with severe untreated tetralogy of Fallot, particularly when their Sao_2 is chronically <70%. Puberty may also be delayed in patients who have not undergone surgery.

The peripheral pulses are usually normal, as are central venous and arterial pressures. In older infants and children, the left anterior hemithorax may bulge anteriorly because of long-standing RVH. A substernal RV impulse can usually be detected. A systolic thrill may be felt along the left sternal border in the third and fourth parasternal spaces. The systolic murmur is usually loud and harsh; it may be transmitted widely, especially to the lungs, but is most intense at the mid- and upper-left sternal border. The murmur is generally ejection in quality at the upper-left sternal border, but it may sound more holosystolic toward the lower-left sternal border. It may be preceded by a click at the upper sternal border or over the sternum. The murmur is caused by turbulence through the RVOT. It tends to become louder, longer, and harsher as the severity of pulmonary stenosis increases from mild to moderate; however, it can become less prominent with severe obstruction, especially during a hypercyanotic spell, because of shunting of blood away from the RV outflow through the overriding aortic valve. Either the second heart sound (S_2) is single or the pulmonic component is soft because of the decreased excursion of the stenotic valve. Infrequently, a continuous murmur may be audible, especially if prominent MAPCAs are present.

DIAGNOSIS

The typical radiologic configuration as seen in the anteroposterior (AP) view consists of a narrow base, concavity of the left heart border in the area usually occupied by the pulmonary artery, and normal overall heart size. The hypertrophied right ventricle causes the rounded apical shadow to be uptilted so that it is situated higher above the diaphragm than normal and pointing horizontally to the left chest wall. The cardiac silhouette has been likened to that of a *boot* ("coeur en sabot") (Fig. 479.2). The hilar areas and lung fields are relatively clear because of diminished pulmonary blood flow or the small size of the pulmonary arteries, or both. The aorta is usually large, and in approximately 20% of patients it arches to the right, which results in an indentation of the leftward-positioned air-filled tracheobronchial shadow in the AP view.

The electrocardiogram (ECG) demonstrates right-axis deviation and evidence of RVH; because prominent right-sided forces are normal in the newborn period, the ECG may be technically normal at this time. A dominant R wave appears in the right precordial chest leads (V_1, V_2) or an RSR′ pattern. In some cases, the only sign of RVH may initially

Fig. 479.2 Chest radiograph of 8-yr-old child with tetralogy of Fallot. Note the normal heart size, some elevation of the cardiac apex, concavity in the region of the main pulmonary artery, right-sided aortic arch, and diminished pulmonary vascularity.

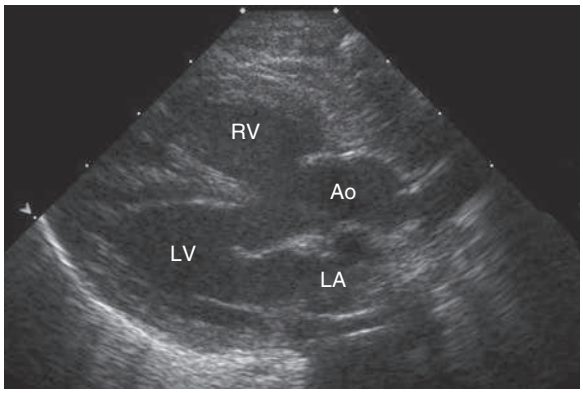

Fig. 479.3 Echocardiogram of patient with tetralogy of Fallot. This parasternal long-axis 2D view demonstrates anterior displacement of the outflow ventricular septum that resulted in stenosis of the subpulmonic right ventricular outflow tract, overriding of the aorta, and an associated ventricular septal defect. Ao, Overriding aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

be a positive T wave in leads V_3R and V_1. The P wave may be tall and peaked, suggesting right atrial enlargement (see Fig. 472.6).

Two-dimensional (2D) echocardiography with Doppler establishes the diagnosis (Fig. 479.3) and provides information about the extent of aortic override of the septum, the location and degree of the RVOT obstruction, the size of the pulmonary valve annulus and main and proximal branch pulmonary arteries, and the side of the aortic arch. The echocardiogram is also useful in determining whether a PDA is supplying a portion of the pulmonary blood flow. In a patient with tetralogy of Fallot without pulmonary atresia, echocardiography usually obviates the need for catheterization before surgical repair. However, in patients with pulmonary atresia, catheterization and CT angiography are usually necessary to image the size and source of blood supply (native pulmonary arteries or MAPCAs) to each lung vascular segment.

Cardiac catheterization demonstrates a systolic pressure in the right ventricle equal to the systemic pressure because the right ventricle is connected directly to the overriding aorta. If the pulmonary artery is entered, the pressure is greatly decreased, although crossing the RVOT, especially in severe cases, may precipitate a tet spell. Pulmonary artery pressure is usually lower than normal, in the range of 5-10 mm Hg. The Sao_2 level depends on the magnitude of the right-to-left shunt; in "pink tets," the systemic So_2 may be normal, whereas in a moderately cyanotic patient at rest, it is usually 75–85%.

Selective right ventriculography will demonstrate all the anatomic features. Contrast medium outlines the heavily trabeculated right ventricle. The infundibular stenosis varies in length, width, contour, and distensibility (Fig. 479.4). The pulmonary valve is usually thickened, and the annulus may be small. In patients with tetralogy and pulmonary atresia, echocardiography alone is not adequate to assess the anatomy of the true pulmonary arteries and collateral MAPCAs. Cardiac CT is extremely helpful, and cardiac catheterization with injection into each arterial collateral is usually indicated. Complete and accurate information regarding the size and peripheral distribution of the main pulmonary arteries and any collateral vessels (MAPCAs) is important when evaluating these children for complex reparative surgery.

Aortography or coronary arteriography outlines the course of the coronary arteries. In 5–10% of patients with the tetralogy of Fallot, coronary artery abnormalities may be present, most often an aberrant coronary artery crossing over the RVOT; care must be taken not to cut this artery during surgical repair. Verification of normal coronary arteries is important when considering surgery in young infants, who may need a patch across the pulmonary valve annulus. Echocardiography can usually delineate the coronary artery anatomy; angiography is reserved for cases in which questions remain.

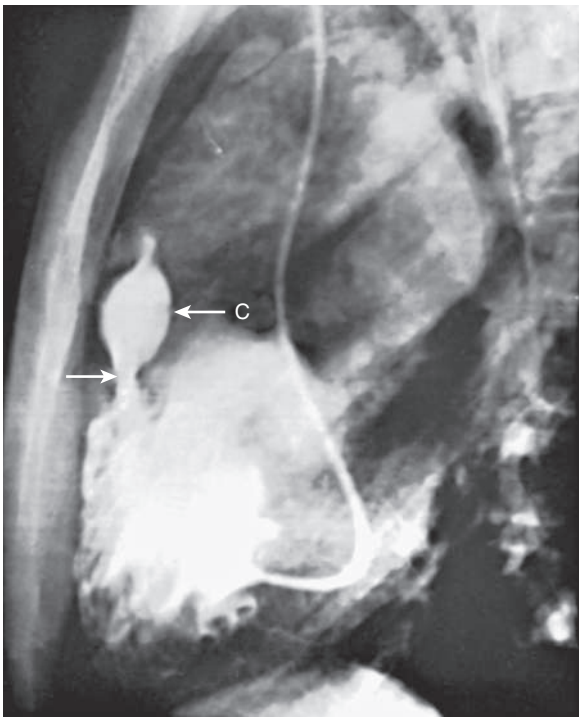

Fig. 479.4 Lateral view of selective right ventriculogram in patient with tetralogy of Fallot. The *left arrow* points to an infundibular stenosis that is below the infundibular chamber (C). The narrowed pulmonary valve orifice is seen at the distal end of the infundibular chamber.

COMPLICATIONS

Before the advent of corrective surgery, patients with tetralogy of Fallot were susceptible to several serious complications. For this reason, most children undergo complete repair (or in rare situations palliation) in the first few months of life; consequently, these complications are now rare. **Cerebral thromboses**, usually occurring in the cerebral veins or dural sinuses and occasionally in the cerebral arteries, are sequelae of extreme polycythemia and dehydration. Thromboses occur most often in patients younger than 2 years. These patients may have iron-deficiency anemia, frequently with hemoglobin and hematocrit levels in the normal range (but too low for cyanotic heart disease). Therapy consists of adequate hydration and supportive measures. Phlebotomy and volume replacement with albumin or saline are indicated in extremely polycythemic patients who are symptomatic.

Brain abscess is less common than cerebrovascular events and extremely rare today. Patients with a brain abscess are usually older than 2 years. The onset of the illness is often insidious and consists of low-grade fever or a gradual change in behavior, or both. Some patients have an acute onset of symptoms that may develop after a recent history of headache, nausea, and vomiting. Seizures may occur; localized neurologic signs depend on the site and size of the abscess and the presence of increased intracranial pressure. Head CT or MRI confirms the diagnosis. Antibiotic therapy may help keep the infection localized, but surgical drainage of the abscess is usually necessary (see Chapter 644).

Bacterial endocarditis may occur in the RV infundibulum or on the pulmonic, aortic, or rarely, tricuspid valve. Endocarditis may complicate palliative shunts or, in patients with corrective surgery, any residual pulmonic stenosis or VSD. Heart failure is not a usual feature in patients with tetralogy of Fallot, with the exception of some young infants with "pink" or acyanotic tetralogy of Fallot. When the degree of pulmonary obstruction worsens with age, the symptoms of heart failure resolve, and eventually the patient experiences cyanosis, usually by 4-6 months of age. These patients are at increased risk for hypercyanotic spells at this time.

ASSOCIATED ANOMALIES

A PDA may be present, and defects in the atrial septum are occasionally seen. A right aortic arch occurs in approximately 20% of patients, and other anomalies of the pulmonary arteries and aortic arch may also be seen. Persistence of a left superior vena cava draining into the coronary sinus is common but not a concern. Multiple VSDs are occasionally present and should be diagnosed before corrective surgery. Coronary artery anomalies are present in 5–10% and can complicate surgical repair. Tetralogy of Fallot may also occur with an atrioventricular septal defect, often associated with Down syndrome.

Congenital absence of the pulmonary valve produces a distinct syndrome that is usually marked by signs of upper airway obstruction (see Chapter 477.1). Cyanosis may be absent, mild, or moderate; the heart is large and hyperdynamic; and a loud to-and-fro murmur is present. Marked aneurysmal dilation of the main and branch pulmonary arteries results in compression of the bronchi and then produces stridulous or wheezing respirations and recurrent pneumonia. If the airway obstruction is severe, reconstruction of the trachea at the time of corrective cardiac surgery may be required to alleviate the symptoms.

Absence of a branch pulmonary artery, most often the left, should be suspected if the radiographic appearance of the pulmonary vasculature differs between the right and left sides; absence of a pulmonary artery is often associated with hypoplasia of the affected lung. It is important to recognize the absence of a pulmonary artery because occlusion of the remaining pulmonary artery during surgery seriously compromises the already reduced pulmonary blood flow.

As one of the conotruncal malformations, tetralogy of Fallot can be associated with **DiGeorge syndrome** or **velocardiofacial syndrome**, also known by the acronym **CATCH 22** (cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia). Cytogenetic analysis using fluorescence in situ hybridization (FISH) demonstrates deletions of a large segment of **chromosome 22q11.2** known as the **DiGeorge critical region**. Deletion or pathogenic variants in *Tbx1* have been implicated as a possible cause of DiGeorge syndrome, although several other genes have been identified as possible candidates or as modifier genes (see Chapter 473).

TREATMENT

Treatment of tetralogy of Fallot depends on the severity of the RVOT obstruction. Infants with severe tetralogy require urgent medical treatment and surgical intervention in the neonatal period. Therapy is aimed at providing an immediate increase in pulmonary blood flow to prevent the sequelae of severe hypoxia. Prolonged, severe hypoxia may lead to shock, respiratory failure, and intractable acidosis and will significantly reduce the chance of survival, even when surgically amenable lesions are present. It is critical that normal body temperature be maintained during the transfer because cold increases oxygen consumption, which places additional stress on a cyanotic infant, whose oxygen delivery is already limited. Blood glucose levels should be monitored because hypoglycemia is more likely to develop in infants with cyanotic heart disease.

Neonates with marked RVOT obstruction may deteriorate rapidly because as the ductus arteriosus begins to close, pulmonary blood flow is further compromised. The IV administration of **prostaglandin E_1** (PGE_1; 0.05-0.1 μg/kg/min), a potent and specific relaxant of ductal smooth muscle, causes dilation of the ductus arteriosus and usually provides adequate pulmonary blood flow until a surgical procedure can be performed. This agent should be administered intravenously as soon as cyanotic CHD is clinically suspected and continued through the preoperative period and during cardiac catheterization. Because prostaglandin can cause apnea, an individual skilled in neonatal intubation should be readily available.

Infants with less severe RVOT obstruction who are stable and awaiting surgical intervention require careful observation. Acyanotic patients can progress fairly quickly to having cyanotic episodes. Prevention or prompt treatment of dehydration is important to avoid hemoconcentration and possible thrombotic episodes. In the past, oral propranolol (0.5-2 mg/kg every 6 hours) was used to decrease the frequency and severity of hypercyanotic spells, but with the excellent surgical results available today, surgical treatment is indicated, usually before spells begin.

Infants with symptoms and severe cyanosis in the first month of life usually have marked obstruction of the RVOT. Two options are available in these infants. The first option is **corrective open heart surgery** performed in early infancy (or even in the newborn period in critically ill infants). This approach has widespread acceptance with excellent short- and long-term results and has supplanted palliative shunts (see later) for most cases. Early total repair carries the theoretical advantage that early physiologic correction allows for improved growth of the branch pulmonary arteries. In infants with less severe cyanosis who can be maintained with good growth and absence of hypercyanotic spells, primary repair is performed electively in the first few months.

Corrective surgical therapy consists of relief of the RVOT obstruction by resecting obstructive muscle bundles and by patch closure of the VSD. If the pulmonary valve is stenotic, as it usually is, a valvotomy is performed. If the pulmonary valve annulus is too small or the valve is extremely thickened, a valvectomy may be performed, the pulmonary valve annulus split open, and a transannular patch placed across the pulmonary valve ring. The advantage of a patch that is not circumferential is that it preserves part of the normal valve annulus and leaflets, allowing for future growth. A right ventriculotomy was once the standard approach; a transatrial-transpulmonary approach is routinely performed to reduce the long-term risks of a large right ventriculotomy. In the past, surgeons placed large transannular patches with the goal of eliminating any possibility of residual pulmonary stenosis, even if these resulted in wide-open pulmonary insufficiency. Currently, surgeons use smaller patches and are more accepting of small RVOT gradients if the degree of valve insufficiency can be minimized. In tetralogy patients, pulmonary valve insufficiency is one of the main reasons for reoperation long-term.

The second option, rarely used today, is a palliative systemic-to-pulmonary artery shunt **(Blalock-Taussig or B-T shunt)** performed to augment pulmonary artery blood flow. The B-T shunt augmented pulmonary blood flow, decreasing hypoxia, improving linear growth, and augmenting growth of the branch pulmonary arteries. Initially performed via direct anastomosis of the subclavian artery to the pulmonary artery, today, the modified B-T shunt consists of a Gore-Tex conduit anastomosed side to side from the subclavian artery to the homolateral branch of the pulmonary artery (Fig. 479.5). Sometimes the shunt is brought directly from the ascending aorta to the MPA; in this case it is called a *central shunt*. Postoperative complications after a B-T shunt include chylothorax, diaphragmatic paralysis, and Horner syndrome. Rarely, postoperative pulmonary overcirculation leading to symptoms of cardiac failure may be caused by too large a shunt. Long-term problems associated with the original B-T shunt (absent radial pulse and arm length discrepancy) are rarely seen with the current procedure.

B-T shunts are usually reserved for patients with comorbidities, such as other major congenital anomalies or prematurity, that would make full repair a higher-risk option. Many surgeons still recommend full repair in these situations, being preferable to the combined risks of a staged procedure, and successful complete repairs have been done even in small premature infants.

PROGNOSIS

After successful total correction, patients are generally asymptomatic and are able to lead unrestricted lives. Uncommon immediate postoperative problems include RV failure, transient heart block, residual VSD with left-to-right shunting, and (rarely) myocardial infarction from interruption of an aberrant coronary artery. The long-term effects of isolated, surgically induced pulmonary valvular insufficiency or of insufficiency and mild stenosis (as is more typical with modern-era smaller transannular patches) are still being defined as more patients with repaired tetralogy of Fallot reach adulthood, but pulmonary insufficiency is generally well tolerated through childhood and early adolescence. Many patients after tetralogy repair, and all those with transannular patch repairs, have a to-and-fro murmur at the left sternal border, usually indicative of mild outflow obstruction and mild

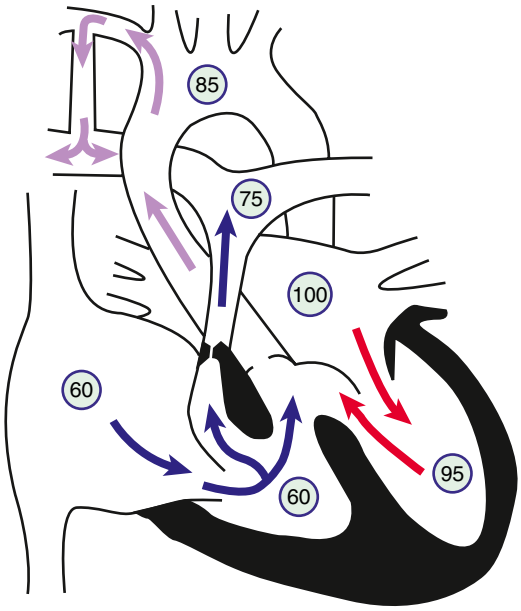

Fig. 479.5 Physiology of Blalock-Taussig shunt in patient with tetralogy of Fallot. *Circled numbers* represent oxygen saturation values. The intracardiac shunting pattern is as described for Figure 479.1. Blood shunting left to right across the shunt from the right subclavian artery to the right pulmonary artery increases total pulmonary blood flow and results in a higher oxygen saturation than would exist without the shunt.

to moderate pulmonary insufficiency. Patients with more marked or long-standing pulmonary valve insufficiency may also have moderate to more severe degrees of RV enlargement and may develop tricuspid regurgitation as the tricuspid valve annulus dilates. These patients will develop a holosystolic murmur at the lower-left and -right sternal borders. Patients with a moderate to severe residual gradient (stenosis) across the RVOT usually require balloon angioplasty or catheter placement of a stent or reoperation, but milder degrees of residual obstruction usually do not require reintervention.

Follow-up of patients 5-20 years after surgery indicates generally excellent outcomes, with minimal symptoms and good exercise tolerance. Despite being asymptomatic, many patients may have lower-than-normal exercise capacity and maximal heart rate on formal cardiopulmonary exercise testing. These abnormal findings are more common in patients who underwent placement of a transannular outflow tract patch and may be less frequent when surgery is performed at an early age. When these children move into adolescence and adulthood, some (more often those with transannular patches) will develop RV dilation as a result of long-term pulmonary regurgitation. Careful surveillance for excessive RV dilation and early signs of RV dysfunction is critical. After reaching adulthood, lifelong follow-up by a specialist in adult congenital heart disease (CHD) is important. Serial echocardiography and the more quantitative magnetic resonance angiography (MRI/MRA) are valuable tools for assessing the degree of RV dilation, identifying the presence of early stages of RV dysfunction, and quantifying the regurgitant fraction. A significant portion of patients with tetralogy of Fallot have been found to have some degree of fibrosis within the right ventricle by MRI. Valve repair or replacement is indicated for those patients with increasing RV dilation and if tricuspid regurgitation is more than mild. For patients requiring valve replacement, nonsurgical (transcatheter) options are available. Several stent-valves can be delivered in the cardiac catheterization laboratory, and these have been used successfully in patients with repaired tetralogy of Fallot. The initial versions of these devices (the Melody valve) were designed to be used predominantly in patients who have previously had a homograft or other artificial conduit placed between the RV and pulmonary arteries; often stent-valves (the Harmony valve) have been designed to be inserted into the native RVOT.

Conduction disturbances can occur after surgery. The atrioventricular node and the bundle of His and its divisions are close to the VSD and may be injured during surgery; however, permanent complete heart block after tetralogy repair is rare. When present, it should be treated by placement of a permanently implanted pacemaker. Even transient complete heart block in the immediate postoperative period is rare; it may be associated with an increased incidence of late-onset complete heart block and sudden death. In contrast, right bundle branch block is extremely common on the postoperative ECG. The duration of the QRS interval has been shown to predict both the presence of residual hemodynamic derangement and the long-term risk of arrhythmia (mainly ventricular tachycardia) and sudden death. Biventricular pacing (in which a pacemaker is used to resynchronize the activation of the right and left ventricles) has been shown to improve hemodynamics in patients with RV dysfunction and long ventricular conduction delays on ECG.

Many children have **premature ventricular beats** after repair of the tetralogy of Fallot. These beats, if isolated and infrequent, may be benign but are of particular concern in patients with residual hemodynamic abnormalities. Approximately 10% of patients with repaired tetralogy are at risk of life-threatening ventricular arrhythmias, and 30% are at risk of atrial arrhythmias as they reach adulthood. Long-duration electrocardiographic monitoring studies, such as Holter (24-48 hours) or ZioPatch (1-2 weeks), should be performed on a regular basis to ensure that occult episodes of ventricular tachycardia are not occurring. Exercise studies may be useful in provoking cardiac arrhythmias that are not apparent at rest. In the presence of complex ventricular arrhythmias or severe residual hemodynamic abnormalities, prophylactic antiarrhythmic drug therapy or an implantable defibrillator is warranted. Surgical or transcatheter intervention is indicated if significant residual RVOT obstruction or severe pulmonary insufficiency is present because arrhythmia risk may improve after hemodynamics are restored to a more normal level.

479.2 Tetralogy of Fallot with Pulmonary Atresia

Daniel Bernstein

Tetralogy of Fallot with pulmonary atresia is the most extreme form of the tetralogy of Fallot. The pulmonary valve is atretic (absent), and the pulmonary trunk may be hypoplastic or atretic as well. The entire RV output is ejected into the aorta. Pulmonary blood flow is then dependent on multiple **major aortopulmonary collateral arteries (MAPCAs)** arising from the ascending and/or descending aorta or aortic branches and supplying various lung segments or, rarely, on a PDA. The ultimate prognosis depends on the presence or absence of true branch pulmonary arteries and, if present, the degree of development. This is best assessed by a combination of CT and cardiac catheterization. If repair is approached early in life and performed at a center with expertise in this highly complex surgery, the mid-term outcomes are good. However, if the pulmonary arteries are severely hypoplastic and surgical intervention fails to establish low pulmonary vascular pressures, lung or heart-lung transplantation may be the only therapy (see Chapter 492.2). Tetralogy of Fallot with pulmonary atresia is also associated with the 22q11.2 deletion and DiGeorge syndrome. The association of severe **tracheomalacia** or **bronchomalacia** with these severe forms of tetralogy/pulmonary atresia may complicate postoperative recovery.

CLINICAL MANIFESTATIONS

Patients with tetralogy of Fallot/pulmonary atresia have findings similar to those in patients with severe tetralogy of Fallot. Cyanosis usually appears within the first few hours or days after birth; however, the prominent systolic murmur associated with tetralogy is usually absent. The first heart sound (S_1) may be followed by an ejection click caused

by the enlarged aortic root, S_2 is single and loud, and continuous murmurs of collateral flow may be heard over the entire precordium and over the back. Most patients are moderately cyanotic and are initially stabilized with a PGE_1 infusion pending cardiac catheterization and/or CT scan to further delineate the anatomy. Patients with several large MAPCAs may be less cyanotic and, once the diagnosis is confirmed, can be taken off prostaglandin while awaiting palliative surgical intervention. Some patients may even develop symptoms of heart failure caused by increased pulmonary blood flow via these collateral vessels.

DIAGNOSIS

The chest radiograph demonstrates a varying heart size, depending on the amount of pulmonary blood flow, a concavity at the position of the pulmonary arterial segment, and often the reticular pattern of bronchial collateral flow. The ECG shows RVH. The echocardiogram identifies aortic override, a thick RV wall, and atresia of the pulmonary valve. Pulsed and color Doppler echocardiographic studies show an absence of forward flow across the pulmonary valve, with pulmonary blood flow being supplied by MAPCAs, which can usually be seen using color Doppler arising from the descending aorta. At cardiac catheterization, right ventriculography reveals a large aorta, opacified immediately by passage of contrast medium through the VSD but with no dye entering the lungs through the RVOT. It is important in planning surgical repair to delineate carefully the often diminutive native pulmonary arteries, if present, to determine whether they are continuous or discontinuous and whether they arborize to all lung segments. The location and arborization of all MAPCAs and the presence of any localized stenosis, which become more common as the patient grows older, are determined by selective contrast injection into each vessel from its origin in the aorta. CT angiography is extremely valuable in mapping the extent of MAPCA arborization.

TREATMENT

The surgical procedure of choice depends on whether the MPA segment is present and, if so, on the size and branching pattern of the branch pulmonary arteries. If these arteries are well developed, a one-stage surgical repair with a homograft conduit inserted between the right ventricle and pulmonary arteries and closure of the VSD is usually feasible. If the pulmonary arteries are hypoplastic, extensive reconstruction may be required. This may involve several staged surgical procedures. If the native pulmonary artery is present but small, a connection made between the aorta and the hypoplastic native pulmonary artery **(aortopulmonary window)** can be performed in the newborn period to induce growth of the native pulmonary arteries. At 3-4 months of age, the multiple MAPCAs are gathered together **(unifocalization procedure)** and eventually incorporated into the final repair along with the native pulmonary arteries. This series of operations may be accomplished through successive right and left lateral thoracotomies or through a single midline sternotomy if the anatomy is favorable.

To be a candidate for full repair, the pulmonary arteries must be of adequate size to accept the full volume of RV output. Complete repair includes closure of the VSD and placement of a homograft conduit from the right ventricle to the pulmonary artery. At the time of reparative surgery, previous shunts are taken down. Because of patient growth and homograft narrowing caused by proliferation of intimal tissue and calcification, replacement of the homograft conduit replacement is usually required in later life, and multiple replacements may be needed. Some of these patients are candidates for placement of a transcatheter stent-valve in the pulmonary position. Patients with obstruction of the very distal branches of the pulmonary arteries may undergo repeat surgical procedures or transcatheter balloon dilation and stenting of the multibranch pulmonary arterial stenosis. Careful follow-up is warranted for these patients, with a combination of echocardiogram, catheterization, and CT or MRI, to ensure maximal chance of growth of all pulmonary artery segments. Serial radionuclide lung perfusion scans can be used to assess pulmonary perfusion to each lung segment and the percentage of flow to the right vs the left lung.

479.3 Pulmonary Atresia with Intact Ventricular Septum

Daniel Bernstein

Pulmonary atresia with an intact ventricular septum presents in the newborn period with severe cyanosis. The pulmonary valve leaflets are completely fused to form a membrane, and the RVOT is atretic. Because no VSD is present, no egress of blood from the right ventricle can occur. Any blood that enters the right ventricle will regurgitate back across the tricuspid valve into the right atrium. Right atrial pressure increases, and blood shunts via the foramen ovale into the left atrium, where it mixes with pulmonary venous blood and enters the left ventricle (Fig. 479.6). The combined left and right ventricular output is pumped solely by the left ventricle into the aorta. In a newborn with pulmonary atresia, the only source of pulmonary blood flow occurs via a PDA. The right ventricle and tricuspid valve are usually hypoplastic, although the degree of hypoplasia varies considerably. Patients who have a small RV cavity also tend to be those with the smallest tricuspid valve annulus, which limits RV inflow. Patients with pulmonary atresia and intact ventricular septum may have **coronary sinusoidal channels** within the RV wall that communicate directly with the coronary arterial circulation. The high RV pressure results in desaturated blood flowing retrograde through these channels into the coronary arteries. Sometimes there are also stenoses of the coronary arteries proximal to where the sinusoids enter, so that distal coronary artery flow is dependent on flow from the right ventricle (known as *right ventricle–dependent coronary circulation*). The prognosis in patients with these sinusoids and proximal stenosis of the coronary arteries is more guarded than in those patients without sinusoids or with sinusoids but no coronary stenoses. Rarely, the proximal coronary artery may be totally absent.

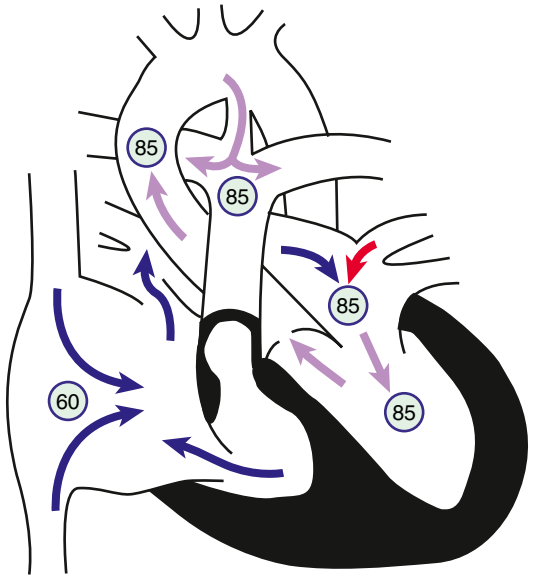

Fig. 479.6 Physiology of pulmonary atresia with intact ventricular septum. *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. A small amount of the blood entering the right atrium may cross the tricuspid valve, which is often stenotic as well. The right ventricular cavity is hypertrophied and may be hypoplastic. No outlet from the right ventricle exists because of the atretic pulmonary valve; thus any blood entering the right ventricle returns to the right atrium via tricuspid regurgitation. Most of the desaturated blood shunts right to left via the foramen ovale into the left atrium, where it mixes with fully saturated blood returning from the lungs. The only source of pulmonary blood flow is via the patent ductus arteriosus. Aortic and pulmonary arterial oxygen saturation will be identical (definition of a total mixing lesion).

CLINICAL MANIFESTATIONS

When the ductus arteriosus closes in the first hours or days of life, infants with pulmonary atresia and an intact ventricular septum become markedly cyanotic because their only source of pulmonary blood flow is removed. Untreated, most patients die within the first week of life. Physical examination reveals severe cyanosis and respiratory distress. S_2, representing only aortic closure, is single and loud. Often, no murmurs are audible; sometimes a systolic or continuous murmur can be heard secondary to ductal blood flow. A harsh holosystolic murmur may be heard at the lower left and right sternal borders if there is significant tricuspid regurgitation.

DIAGNOSIS

The ECG shows a frontal QRS axis between 0 and +90 degrees, the amount of leftward shift reflecting the degree of RV hypoplasia. Tall, spiked P waves indicate right atrial enlargement. QRS voltages are consistent with left ventricular dominance or hypertrophy; RV forces are usually decreased in proportion to the decreased size of the RV cavity. Because the normal newborn ECG shows increased right-sided forces, if a normal "adult" ECG R-wave progression is seen, it suggests RV hypoplasia of some degree. Most patients with small right ventricles have decreased RV forces, but occasionally, patients with larger, thickened RV cavities may have evidence of RVH. The chest radiograph shows decreased pulmonary vascularity, the degree depending on the size of the branch pulmonary arteries and the patency of the ductus. Unlike in patients with pulmonary atresia and tetralogy of Fallot, the presence of MAPCAs is rare.

The 2D echocardiogram is useful in estimating RV dimensions and the size of the tricuspid valve annulus, which have been shown to be of prognostic value. Echocardiography can often suggest the presence of sinusoidal channels but cannot be used to evaluate coronary stenoses. Thus cardiac catheterization is necessary for complete evaluation. Pressure measurements reveal right atrial and RV hypertension. Ventriculography demonstrates the size of the RV cavity, the atretic RVOT, the degree of tricuspid regurgitation, and the presence or absence of intramyocardial sinusoids filling the coronary vessels. Aortography shows filling of the pulmonary arteries by the PDA and is helpful in determining the size and branching patterns of the pulmonary arterial bed. An aortogram or, if necessary, selective coronary angiography is performed to evaluate for the presence of proximal coronary artery stenosis (RV-dependent coronary circulation) or proximal coronary artery atresia.

TREATMENT

Infusion of PGE_1 (0.05-0.1 μg/kg/min) is usually effective in keeping the ductus arteriosus open before intervention, thus reducing hypoxemia and acidemia before surgery. The choice of surgical procedure depends on whether there is an RV-dependent coronary circulation and on the size of the RV cavity. In patients with only mild to moderate RV hypoplasia without sinusoids, or in patients with sinusoids but no evidence of coronary stenoses, a surgical pulmonary valvotomy is carried out to relieve outflow obstruction. Often, the RVOT is widened with a patch. To provide adequate pulmonary blood flow, an aortopulmonary (Blalock-Taussig) shunt may also be performed during the same procedure. An alternative approach uses interventional catheterization, in which the imperforate pulmonary valve is first punctured either with a wire or a radiofrequency ablation catheter, followed by a balloon valvuloplasty. If this course is taken, it may take days to weeks before the RV muscle regresses enough for the patient to be weaned from prostaglandin, and many of these patients will still require surgical intervention.

The aim of surgery or interventional catheterization is to encourage growth of the RV chamber by allowing some forward flow through the pulmonary valve while using the shunt to ensure adequate pulmonary blood flow. Later, if the tricuspid valve annulus and RV chamber grow to adequate size, the shunt is taken down and any remaining atrial-level shunt can be closed. If the RV chamber remains too small for use as a pulmonary ventricle, the patient is treated as having a single-ventricle circulation, with a **Glenn procedure** followed by a modified **Fontan procedure** (see Chapter 479.4), allowing blood to bypass the hypoplastic right ventricle by flowing to the pulmonary arteries directly from the venae cavae. When coronary artery stenoses are present and retrograde coronary perfusion occurs from the right ventricle through myocardial sinusoids, the prognosis is more guarded because of a higher risk of arrhythmias, coronary ischemia, and sudden death. It is important for these patients not to try to open the RVOT, because dropping the RV pressure rapidly will reduce coronary perfusion, leading to ischemia. These patients are usually treated with an aortopulmonary shunt, followed by the Glenn and Fontan procedure. Although at higher risk than those without coronary stenoses, recent reports show good success with this approach; however, long-term complications are higher than in other groups of single-ventricle patients. A small number of these infants (e.g., those with atresia of a proximal coronary artery) are best referred for heart transplantation.

479.4 Tricuspid Atresia

Daniel Bernstein

In tricuspid atresia, there is no outlet from the right atrium to the right ventricle; the entire systemic venous return leaves the right atrium and enters the left side of the heart through the foramen ovale or, most often, an atrial septal defect (ASD) (Fig. 479.7). The physiology of the circulation and the clinical presentation will depend on the presence and type of other congenital heart defects, most notably on whether the great arteries are normally related or are transposed (aorta arising from the right ventricle, pulmonary artery from the left ventricle). In patients with normally related great arteries, left ventricular (LV)

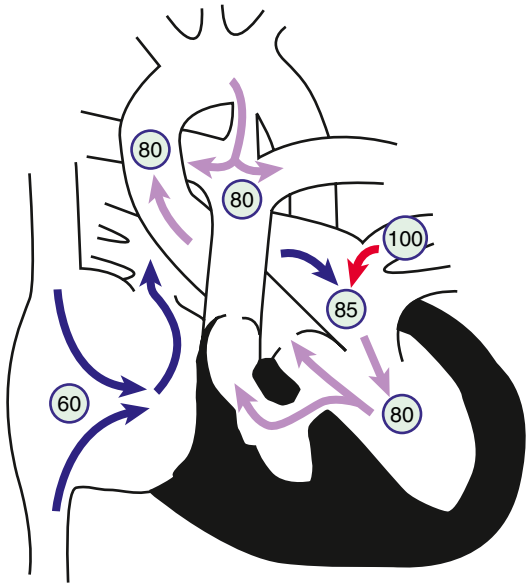

Fig. 479.7 Physiology of tricuspid atresia with normally related great vessels. *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. The tricuspid valve is nonpatent, and the right ventricle may manifest varying degrees of hypoplasia. The only outlet from the right atrium involves shunting right to left across an atrial septal defect or patent foramen ovale to the left atrium. There, desaturated blood mixes with saturated pulmonary venous return. Blood enters the left ventricle and is ejected either through the aorta or via a ventricular septal defect (VSD) into the right ventricle. In this example, some pulmonary blood flow is derived from the right ventricle and the rest from a patent ductus arteriosus (PDA). In patients with tricuspid atresia, the PDA may close or the VSD may grow smaller and result in a marked decrease in systemic oxygen saturation.

blood supplies the systemic circulation through the aorta. Blood also flows into the right ventricle through a VSD (if the ventricular septum is intact, the right ventricle will be completely hypoplastic and pulmonary atresia will also be present [see Chapter 479.3]). *Pulmonary blood flow (and thus the degree of cyanosis) depends on the size of the VSD and the presence and severity of any associated pulmonic stenosis.* Pulmonary blood flow may be augmented by or be totally dependent on a PDA. The inflow portion of the right ventricle is always missing, but the outflow portion can be of variable size. The clinical presentation of patients with tricuspid atresia and *normally related great arteries* will depend on the degree of obstruction to pulmonary blood flow. Patients with a smaller VSD or moderate degrees of pulmonary stenosis are recognized in the early days or weeks of life by decreased pulmonary blood flow and cyanosis, especially after the PDA begins to close. Alternatively, in those with a large VSD and minimal or no RVOT obstruction, pulmonary blood flow may be normal or increased; these patients have only mild cyanosis and can present with signs of pulmonary overcirculation and heart failure.

In patients with tricuspid atresia and **transposition of the great arteries (TGA)**, LV blood flows directly into the pulmonary artery, whereas systemic blood must traverse the VSD and right ventricle to reach the aorta. In these patients, pulmonary blood flow is usually massively increased, and heart failure develops early. If the VSD is restrictive, systemic blood flow may be compromised and the patient may present with signs of decreased perfusion. **Coarctation of the aorta** is often noted in this setting.

CLINICAL MANIFESTATIONS

Some degree of cyanosis is usually evident at birth, with the extent depending on the degree of limitation to pulmonary blood flow. Unique to tricuspid atresia, an increased LV impulse may be noted, in contrast to most other causes of cyanotic heart disease, in which an increased RV impulse is usually present. Most patients have holosystolic murmurs audible along the left sternal border; S_2 is usually single. Pulses in the lower extremities may be weak or absent in the presence of transposition and with coarctation of the aorta. Patients with tricuspid atresia are at risk for spontaneous narrowing or even closure of the VSD, which can occasionally occur rapidly and lead to a marked increase in cyanosis.

DIAGNOSIS

Radiologic studies show either pulmonary undercirculation (most often in patients with normally related great arteries) or overcirculation (most often in patients with transposed great arteries). Left-axis deviation and LV hypertrophy are generally noted on the ECG (except in patients with TGA), and these unique features are a hallmark of tricuspid atresia, distinguishing it from most other cyanotic heart lesions, which are associated with right-axis deviation and RV hypertrophy. In the right precordial leads, the normally prominent R wave is replaced by an rS complex. The left precordial leads show a qR complex, followed by a normal, flat, biphasic, or inverted T wave. RV_6 is normal or tall, and SV_1 is generally deep. The P waves are usually biphasic, with the initial component tall and spiked in lead II. 2D echocardiography reveals the presence of a fibromuscular membrane in place of a tricuspid valve, a variably small right ventricle, variably sized VSD, and a slightly to moderately enlarged left ventricle (Fig. 479.8). The relationship of the great vessels (normal or transposed) can be determined. The degree of obstruction at the level of the VSD or at the RVOT can be determined by Doppler examination. Blood flow through a patent ductus can be evaluated by color flow and pulsed Doppler.

Cardiac catheterization, indicated usually only if questions remain after echocardiography, shows normal or slightly elevated right atrial pressure with a prominent *a* wave. If the right ventricle is entered through the VSD, the pressure may be lower than on the left if the VSD is restrictive in size. Right atrial angiography shows immediate opacification of the left atrium from the right atrium, followed by left ventricular filling and visualization of the aorta. Absence of direct flow to the right ventricle results in an angiographic filling defect between the right atrium and the left ventricle.

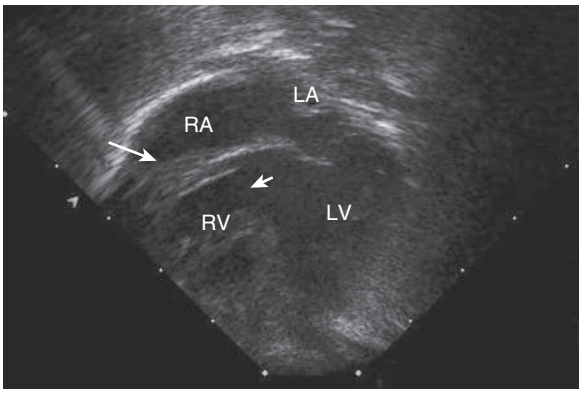

Fig. 479.8 Echocardiogram demonstrating tricuspid atresia. The floor of the right atrium consists of a fibromuscular membrane *(longer arrow)* instead of the normal tricuspid valve apparatus. The large secundum atrial septal defect can be seen between the right and left atria. The *short arrow* shows the ventricular septal defect. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

TREATMENT

Management of patients with tricuspid atresia depends on the adequacy of pulmonary blood flow. Moderately or severely cyanotic neonates (most often those with normally related great arteries) should be maintained on an IV infusion of PGE_1 (0.05-0.1 μg/kg/min) until a surgical aortopulmonary shunt procedure can be performed to increase pulmonary blood flow. The Blalock-Taussig procedure (see Chapter 479.1) or a variation is the preferred anastomosis. Rare patients with restrictive atrial-level communications also benefit from a Rashkind balloon atrial septostomy (see Chapter 480.2) or surgical septectomy.

Infants with increased pulmonary blood flow because of an unobstructed pulmonary outflow tract (more often patients with TGA) may require early surgery or pulmonary arterial banding (especially for patients in the first 1-2 months of life) to decrease the symptoms of heart failure and protect the pulmonary bed from the development of pulmonary vascular disease. Infants with just adequate pulmonary blood flow who are well balanced between cyanosis and pulmonary overcirculation can be watched closely for the development of increasing cyanosis, which may occur as the VSD begins to get smaller or the pulmonary outflow becomes narrower and is an indication for surgery.

The next stage of palliation for patients with tricuspid atresia involves the creation of an anastomosis between the superior vena cava and the pulmonary arteries (**bidirectional Glenn shunt**; Fig. 479.9A). This procedure is performed at usually between 2 and 6 months of age. The Glenn shunt provides a stable source of pulmonary blood flow as well as reducing the volume load on the left ventricle.

The **modified Fontan operation** is the preferred approach for longer-term palliation. It is usually performed between 2 and 3 years of age, after the patient is ambulatory. Initially, this procedure was performed by anastomosing the right atrium or atrial appendage directly to the pulmonary artery. The procedure used most often now is a modification of the Fontan procedure, known as a **cavopulmonary isolation procedure**, which involves anastomosing the inferior vena cava directly to the pulmonary arteries using a homograft or Gore-Tex tube running outside the heart (external-conduit Fontan; Fig. 479.9C). An older version of this procedure uses an internal baffle that runs along the lateral wall of the right atrium (lateral-tunnel Fontan; see Fig. 479.9B). In a completed Fontan repair, desaturated blood flows from both venae cavae directly into the pulmonary arteries. Oxygenated blood returns to the left atrium, enters the left ventricle, and is ejected into the systemic circulation. The volume load is completely removed from the left ventricle, and the right-to-left shunt is abolished. Because of the reliance on passive filling of the pulmonary circulation, the Fontan procedure is contraindicated in patients with elevated pulmonary vascular resistance, in those with pulmonary artery hypoplasia, and in patients with LV dysfunction. The patient also must not have significant mitral insufficiency. Patients who are not in normal sinus rhythm

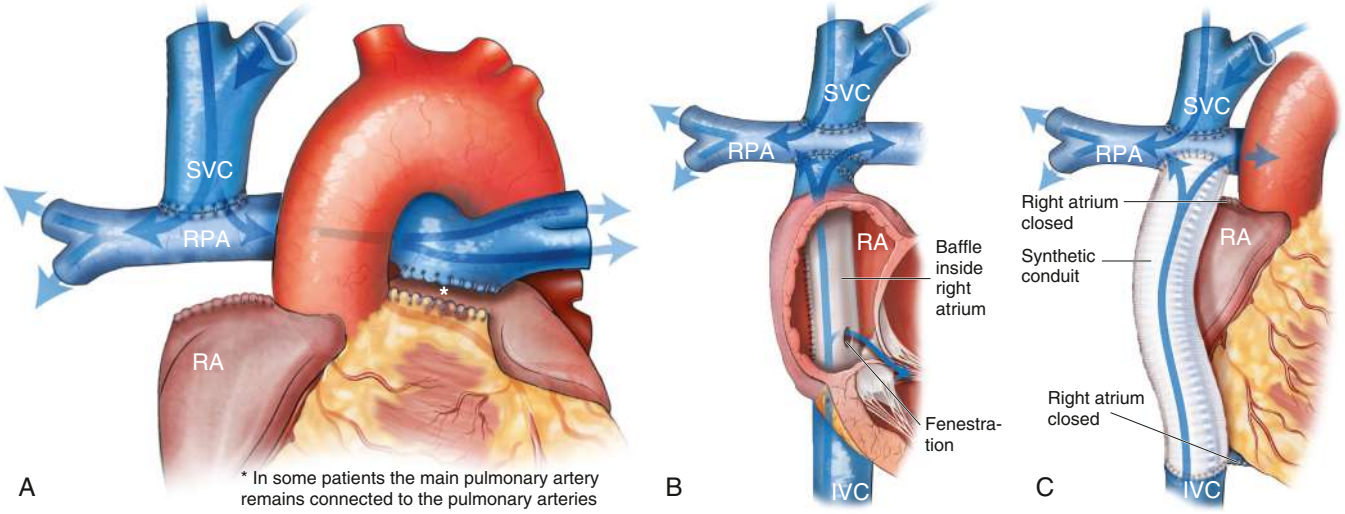

Fig. 479.9 Staged surgical approach to palliation of the patient with a single-ventricle circulation. **A,** Bidirectional Glenn shunt. The superior vena cava (SVC) is divided and detached from the right atrium (RA) and anastomosed end-to-side to the pulmonary artery, which has also been divided and detached from the right ventricle. **B,** Lateral tunnel Fontan. Inferior vena caval flow is directed upward through a synthetic or pericardial baffle sutured to the RA wall. The lower portion of the SVC (previously divided during the Glenn shunt) is now sutured directly to the right pulmonary artery. Thus blood flows from the upper body via the SVC directly into the lungs via the previous Glenn shunt and from the lower body via the baffle, through the RA but not emptying into the RA, directly into the lungs. The only remaining blood flow entering into the RA is from the coronary sinus, which represents the small amount of venous return coming directly from the left ventricle. The RA is thus excluded from the Fontan circuit. **C,** Extracardiac Fontan. The inferior vena cava (IVC) is detached from the RA, and an extracardiac synthetic conduit or homograft is used to direct that flow, outside the heart, to the inferior aspect of the right pulmonary artery (RPA). Both Fontan approaches achieve the same endpoint in isolating the venous circulation (blue blood) from the arterial circulation (red blood). The external conduit Fontan procedure is more common today because of concerns about atrial arrhythmias and/or blood clots related to the baffle in the RA. Many surgeons orient the connection from the IVC more centrally on the pulmonary arteries than shown in (**C**) to avoid a "collision" of flow from the upper and lower bodies, which in flow dynamic modeling studies has been shown to reduce the efficiency of the Fontan circulation, especially during exercise. *(Adapted from Burchill LJ, Wald RM, Mertens L. Single ventricles: echocardiographic assessment after the Fontan operation. In Otto CM, ed. The Practice of Clinical Echocardiography, 5th ed. Philadelphia: Elsevier; 2017, Figs. 49-6, 8, and 9.)*

are at increased risk, and if a pacemaker is required in these patients, dual-chamber pacing is the preferred approach.

Postoperative problems after the Fontan procedure are most often related to the increase in central venous pressure that occurs when the vena cavae are connected directly to the pulmonary arteries. Normal central venous pressure is 0-5 mm Hg, whereas after the Fontan operation, central venous pressure can rise to 10-15 mm Hg, and occasionally even more. In the immediate postoperative period, this elevation of systemic venous pressure can lead to fluid retention and pleural or pericardial effusions. The occurrence of these effusions has been markedly reduced with the cavopulmonary isolation procedure now in use, although prolonged chest tube drainage can still occur, but eventually resolves. Some centers use a fenestration at the time of the Fontan, consisting of a small communication between the inferior vena cava and the pulmonary artery conduit and the left atrium. This serves as a "pop-off" during early postoperative recovery and may hasten hospital discharge. The fenestration will result in some amount of right-to-left shunting and is therefore usually closed with a catheter closure device after the immediate postoperative period.

Late complications of the Fontan procedure include stenosis of the superior or inferior vena cava anastomosis, vena cava or pulmonary artery thromboembolism, protein-losing enteropathy, plastic bronchitis, renal dysfunction, immune deficiency, supraventricular arrhythmias (atrial flutter, paroxysmal atrial tachycardia), and hepatic injury, referred to as **Fontan-associated liver disease (FALD)**, as a result of persistently elevated central venous pressures. Rarely liver disease may predispose to the development of hepatocellular carcinoma. As more patients survive into young and middle adult years, the occurrence of these complications increases, and these patients require careful follow-up in a center skilled at caring for **adults with congenital heart disease (ACHDs)**. Oral budesonide or sildenafil has been used with varying success to treat protein-losing enteropathy associated with the Fontan procedure. MRI lymphangiography followed by thoracic duct ligation, decompression, or embolization is used to treat plastic bronchitis and other complications of a Fontan procedure. LV dysfunction may be a late occurrence, usually not until adolescence or young adulthood. Heart transplantation is a successful treatment option for pediatric patients with "failed" Fontan circuits but is a somewhat riskier procedure when performed in older adults. Patients with combined heart failure and liver dysfunction have been treated with combined heart-liver transplantation with good result.

479.5 Double-Outlet Right Ventricle

Daniel Bernstein

Double-outlet right ventricle **(DORV)** is characterized when both the aorta and pulmonary artery arise from the right ventricle. The only outlet from the left ventricle occurs through a VSD emptying into the right ventricle, although some degree of override of the septum may place either the aorta or pulmonary artery partially over the left ventricle. Normally, the aortic and mitral valves are in fibrous continuity; in DORV the aortic and mitral valves are separated by a smooth muscular **conus**, like that seen under the normal pulmonary valve. In DORV the great arteries may be *normally related,* with the aorta closer to (or slightly overriding) the VSD, or the great arteries may be *malposed,* with the pulmonary artery closer to (or slightly overriding) the VSD. The degree to which the great artery closest to the VSD may override the defect is variable but must be at least 50% committed to the right ventricle to be termed DORV. When the VSD is subaortic, the defect may be viewed as part of a continuum with the **tetralogy of Fallot**, and the physiology, history, physical examination, ECG, and radiography depend on the degree of pulmonary stenosis, like the situation in tetralogy of Fallot (see Chapter 479.1). If the VSD is subpulmonic, there may be subvalvar, valvar, or supravalvar aortic stenosis, and

coarctation is a possibility as well. This is known as the **Taussig-Bing malformation**. The clinical presentation of these patients will depend on the degree of aortic obstruction, but because the pulmonary artery is usually wide open, the presentation will usually include some degree of pulmonary overcirculation and heart failure. If the aortic obstruction is severe or there is a coarctation, poor pulses, hypoperfusion, and cardiovascular collapse are possible presenting signs, especially when the PDA begins to close.

The 2D echocardiogram demonstrates both great vessels arising from the right ventricle and mitral-aortic valve discontinuity. The relationships between the aorta and pulmonary artery to the VSD can be delineated, and the presence of either pulmonary obstruction or aortic obstruction can be evaluated. The aortic arch is imaged to evaluate for coarctation. Cardiac catheterization is not necessarily required if the echocardiogram is straightforward. Angiography will show that the aortic and pulmonary valves lie in the same horizontal plane and that both arise predominantly or exclusively from the right ventricle.

Surgical correction depends on the relationship of the great vessels to the VSD. If the VSD is *subaortic,* the repair will be like that used for tetralogy of Fallot with patch closure of the VSD so that the left ventricle ejects blood into the aorta. In cases where the aorta is more distant from the left ventricle, repair may consist of creating an intraventricular tunnel so that the left ventricle ejects blood through the VSD, into the tunnel, and into the aorta. The pulmonary obstruction is relieved either with an outflow patch or with a right ventricle–to–pulmonary artery homograft conduit **(Rastelli operation)**. If the VSD is *subpulmonic,* the great vessels can be switched (see Chapter 479.6) and the Rastelli operation performed. However, if there is substantial aortic obstruction or if one of the ventricles is hypoplastic, a Norwood-style single-ventricle repair may be necessary (see Chapter 480.10). In selected small infants, palliation with an aortopulmonary shunt can provide symptomatic improvement and allow for adequate growth before corrective surgery is performed.

479.6 Transposition of the Great Arteries with Ventricular Septal Defect and Pulmonary Stenosis

Daniel Bernstein

The combination of TGA with VSD and pulmonary stenosis may mimic tetralogy of Fallot in its clinical features (see Chapter 479.1). However, because of the transposed great vessels, the site of obstruction is in the left as opposed to the right ventricle. The obstruction can be either valvular or subvalvular; the latter type may be *dynamic,* related to the interventricular septum or atrioventricular valve tissue, or *acquired,* as in patients with transposition and VSD after pulmonary arterial banding.

The age at which clinical manifestations initially appear varies from soon after birth to later infancy, depending on the degree of pulmonic stenosis. Clinical findings include cyanosis, decreased exercise tolerance, and poor physical development, like those described for tetralogy of Fallot; the heart is usually more enlarged. The pulmonary vasculature as seen on radiograph depends on the degree of pulmonary obstruction. The ECG usually shows right-axis deviation, right and left ventricular hypertrophy, and sometimes tall, spiked P waves. Echocardiography confirms the diagnosis and is useful in sequential evaluation of the degree and progression of the LV outflow tract obstruction. Cardiac catheterization, if necessary, shows that pulmonary arterial pressure is low and that oxygen saturation in the pulmonary artery exceeds that in the aorta, since pulmonary blood flow is coming directly from the left ventricle. Selective right and left ventriculography demonstrates the origin of the aorta from the right ventricle, the origin of the pulmonary artery from the left ventricle, the VSD, and the site and severity of the pulmonary stenosis.

An infusion of PGE_1 (0.05-0.1 μg/kg/min) should be started in neonates who present with cyanosis. When necessary, **balloon atrial septostomy** is performed to improve atrial-level mixing and to decompress the left atrium (see Chapter 480.2). Cyanotic infants may be palliated with an aortopulmonary shunt (see Chapter 479.1), followed by a Rastelli operation when older, as the preferred corrective procedure. The Rastelli procedure achieves physiologic and anatomic correction by (1) closure of the VSD using an intraventricular tunnel so that LV blood flow is directed to the aorta and (2) connection of the right ventricle to the distal pulmonary artery by an extracardiac homograft conduit (Fig. 479.10). These conduits will eventually become stenotic with patient growth and require replacement. Patients with milder degrees of pulmonary stenosis amenable to simple valvotomy may be able to undergo complete correction with an **arterial switch procedure** (see Chapter 480.2) and closure of the VSD. Surgical correction by the **Mustard or Senning operation** (see Chapter 480.2) with simultaneous closure of the VSD and relief of LV outflow obstruction may be an alternative when the position of the VSD is not suitable for a Rastelli operation; however, this procedure leaves the right ventricle as the systemic pumping chamber and has fallen out of favor.

479.7 Ebstein Anomaly of the Tricuspid Valve

Daniel Bernstein

Ebstein anomaly consists of downward displacement of an abnormal tricuspid valve into the right ventricle. The defect arises from failure of the normal process by which the tricuspid valve is separated from the RV myocardium (see Chapter 469). The anterior cusp of the valve retains some attachment to the valve ring, but the other leaflets are adherent to the wall of the right ventricle. The right ventricle is thus divided into two parts by the abnormal tricuspid valve: the first, a thin-walled "atrialized" portion, is continuous with the cavity of the right atrium; the second, often smaller, portion consists of normal ventricular myocardium. The right atrium is enlarged as a result of tricuspid valve regurgitation, although the degree is extremely variable. In more severe forms of Ebstein anomaly, the effective output from the right side of the heart is decreased because of a combination of the poorly functioning small right ventricle, tricuspid valve regurgitation, and RVOT obstruction produced by the large, sail-like, anterior tricuspid valve leaflet. The severity of tricuspid valve displacement has been grouped into four degrees (A through D), known as the *Carpentier classification.* In newborns, RV function may be so compromised that it is unable to generate enough force to open the pulmonary valve in systole, thus producing "functional" pulmonary atresia. Some infants have true anatomic pulmonary atresia. The increased volume of right atrial blood shunts through the foramen ovale (or through an associated ASD) to the left atrium and produces cyanosis (Fig. 479.11).

CLINICAL MANIFESTATIONS

The severity of symptoms and the degree of cyanosis are highly variable and depend on the extent of displacement of the tricuspid valve and the severity of RVOT obstruction. In many patients with milder forms of tricuspid valve displacement, symptoms are mild and may be delayed until the teenage years or young adult life; the patient may initially have fatigue, exercise intolerance, or palpitations as a result of cardiac dysrhythmias. The atrial right-to-left shunt is responsible for cyanosis, which may only be evident during exercise and, if long-standing, polycythemia. Jugular venous pulsations, an index of central venous pressure, may be normal or increased in those with tricuspid insufficiency. On palpation, the precordium is quiet. A holosystolic murmur caused by tricuspid regurgitation is audible over most of the anterior left side of the chest. A gallop rhythm is common and often associated with multiple clicks at the lower-left sternal border. A scratchy diastolic murmur may also be heard at the left sternal border. This murmur may mimic a pericardial friction rub.

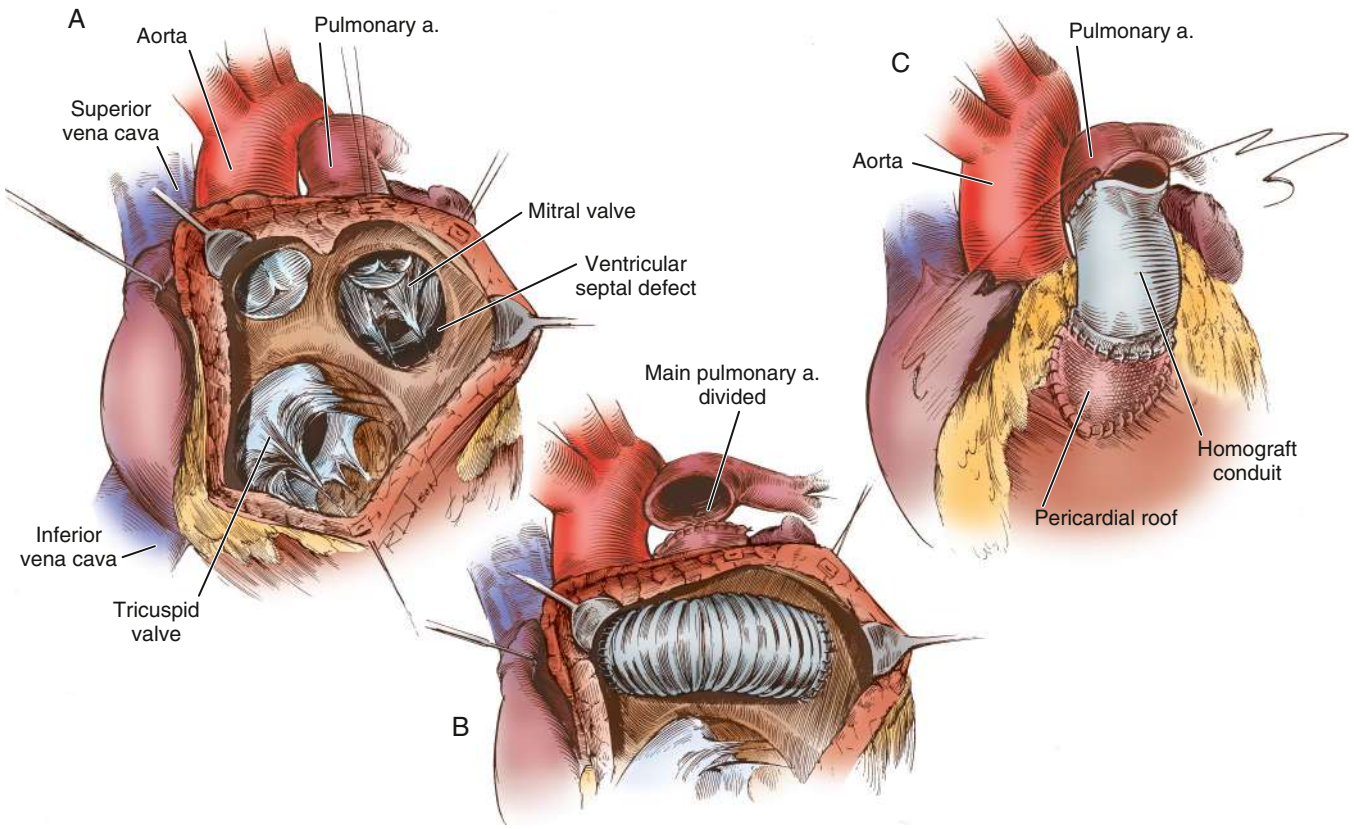

Fig. 479.10 A, Taussig-Bing type of double-outlet right ventricle with subpulmonary stenosis necessitating repair by the Rastelli technique. B, The main pulmonary artery is divided and oversewn proximally. The pulmonary valve lies within the baffle pathway. C, Completion of the Rastelli repair with a right ventricle–pulmonary artery allograft conduit. *(From Castañeda AR, Jonas RA, Mayer JE Jr, et al. Single-ventricle tricuspid atresia. In: Castañeda AR, Jonas RA. Mayer JE Jr, Hanley FL, eds. Cardiac Surgery of the Neonate and Infant. Philadelphia: Saunders; 1994.)*

Newborns with severe forms of Ebstein anomaly have marked cyanosis, massive cardiomegaly, and long holosystolic murmurs. Death may result from cardiac failure, hypoxemia, and pulmonary hypoplasia, the result of severe long-standing intrauterine right atrial enlargement. Spontaneous improvement may occur in some neonates as pulmonary vascular resistance falls and improves the ability of the right ventricle to provide pulmonary blood flow. The majority are dependent on a PDA, and thus on a prostaglandin infusion, for pulmonary blood flow. Fetuses diagnosed with Ebstein anomaly on fetal ultrasound can be particularly challenging. Severe leakage of the tricuspid valve is one of the few congenital heart lesions that cannot be bypassed by the parallel fetal circulation (see Chapter 470), and thus cardiac enlargement and fetal heart failure may supervene. When the heart enlarges, particularly the right atrium, compression of the lungs can result and the fetus is at risk for development of pulmonary hypoplasia.

DIAGNOSIS

The ECG usually shows a right bundle branch block without increased right precordial voltage, normal or tall and broad P waves, and a normal or prolonged P-R interval. **Wolff-Parkinson-White syndrome** may be present, and these patients may have episodes of supraventricular tachycardia (see Chapter 484). On radiographic examination, heart size varies from slightly enlarged to massive, box-shaped cardiomegaly caused by enlargement of the right atrium. *In newborns with severe Ebstein anomaly, the heart may be so enlarged as to totally obscure the pulmonary fields* (Fig. 479.12). Echocardiography is diagnostic and shows the degree of displacement of the tricuspid valve leaflets, a dilated right atrium, and any RVOT obstruction (Fig. 479.13). Pulsed and color Doppler examination demonstrates the degree of tricuspid regurgitation. In severe cases the pulmonary valve may appear immobile, and pulmonary blood flow may come solely from the ductus arteriosus. It may be difficult to distinguish true from functional pulmonary valve atresia. Cardiac catheterization, which is not usually necessary, confirms the presence of a large right atrium, an abnormal tricuspid valve, and any right-to-left shunt at the atrial level. The risk of arrhythmia is significant during catheterization and angiographic studies.

TREATMENT

Neonates with milder degrees of cyanosis can sometimes be managed medically, waiting to see how they do once their pulmonary vascular resistance decreases over the first few weeks of life. Those with moderate to severe hypoxia are initially treated with prostaglandins, mechanical ventilation and inhaled nitric oxide in an attempt to enhance pulmonary blood flow by reducing pulmonary vascular resistance. Surgical options for these patients include an aortopulmonary (Blalock-Taussig) shunt, tricuspid valve replacement (most often with a bioprosthetic valve), or surgical repair of the tricuspid valve (cone procedure). In the critically ill neonate, closure of the valve (creating tricuspid atresia physiology) with an aortopulmonary shunt (Starnes procedure), with eventual single-ventricle repair using the Fontan palliation (see Chapter 479.4) is

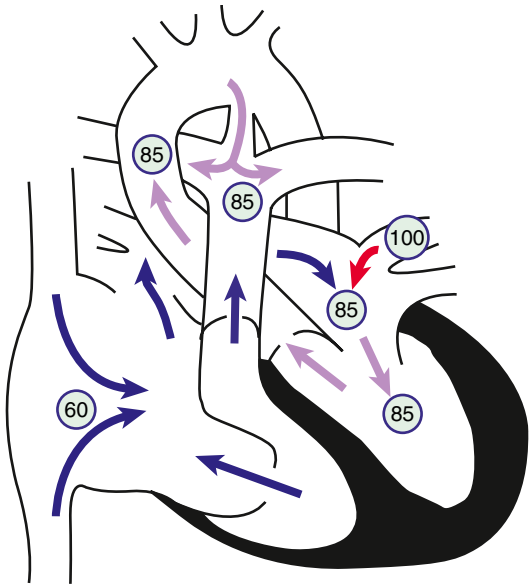

Fig. 479.11 Physiology of Ebstein anomaly of the tricuspid valve. *Circled numbers* represent oxygen saturation values. Inferior displacement of the tricuspid valve leaflets into the right ventricle has resulted in a thin-walled, low-pressure "atrialized" segment of right ventricle. The tricuspid valve is grossly insufficient. Right atrial blood flow is shunted right to left across an atrial septal defect or patent foramen ovale into the left atrium. Some blood may cross the right ventricular outflow tract and enter the pulmonary artery; however, in severe cases, the right ventricle may generate insufficient force to open the pulmonary valve, and "functional pulmonary atresia" results. In the left atrium, desaturated blood mixes with saturated pulmonary venous return. Blood enters the left ventricle and is ejected via the aorta. In this example, some pulmonary blood flow is derived from the right ventricle, the rest from a patent ductus arteriosus (PDA). Severe cyanosis will develop in neonates with a severe Ebstein anomaly when the PDA closes.

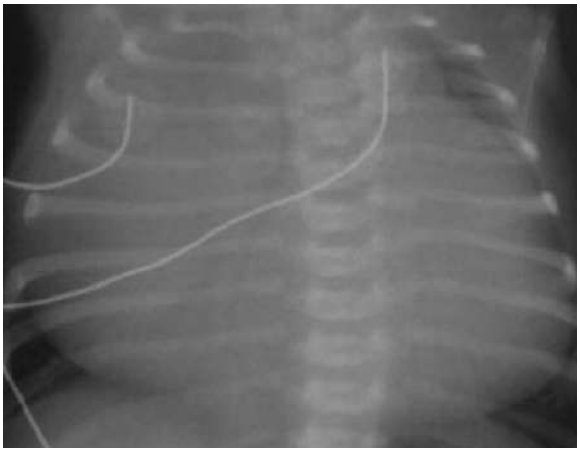

Fig. 479.12 Massive cardiomegaly in a newborn infant with severe Ebstein anomaly. The heart is so enlarged (in part because of a massive right atrium) that lung hypoplasia is a major concern.

an option. Many infants with Ebstein anomaly who have undergone valve repair will also have a bidirectional Glenn shunt performed to reduce the volume load on the right ventricle and reduce the amount of tricuspid regurgitation (see Chapter 479.4). In older children with mild or moderate disease, control of supraventricular dysrhythmias (medications or radiofrequency ablation), if present,

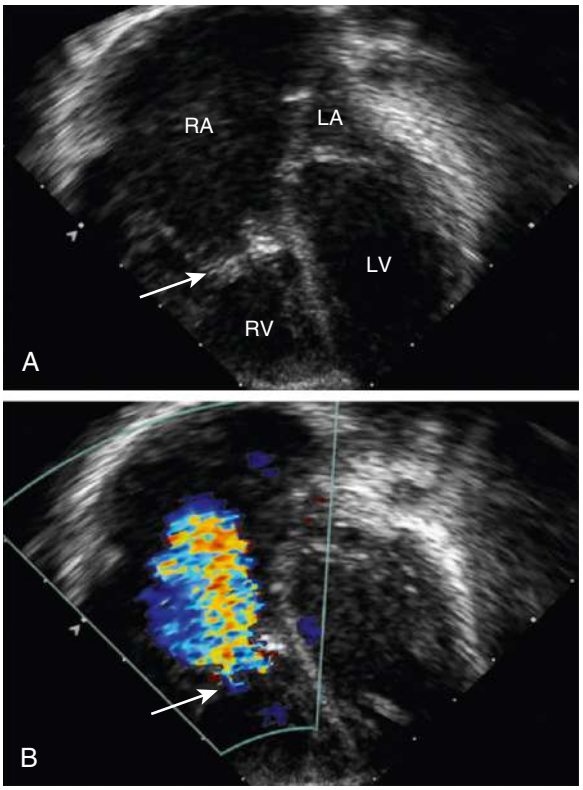

Fig. 479.13 Echocardiographic demonstration of Ebstein anomaly of the tricuspid valve. **A,** Subcostal, four-chamber, 2D view showing severe displacement of the tricuspid valve leaflets *(arrow)* inferiorly into the right ventricle. The location of the tricuspid valve annulus is outlined by the arrow. The portion of the right ventricle between the valve annulus and the valve leaflets is the "atrialized" component. **B,** Color Doppler examination showing severe regurgitation of the dysplastic tricuspid valve. Note that the regurgitant turbulent flow *(arrow)* begins halfway into the right ventricular chamber, at the location of the displaced valve leaflets. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

is of primary importance; surgical treatment may not be necessary until adolescence or young adulthood. Older patients with severe tricuspid regurgitation can undergo repair or replacement of the abnormal tricuspid valve along with closure of the ASD. In some patients, a bidirectional Glenn shunt is also performed, with the superior vena cava anastomosed to the pulmonary arteries. This procedure reduces the volume of blood that the dysfunctional right side of the heart has to pump, thus creating a "one-and-one-half ventricle repair."

PROGNOSIS AND COMPLICATIONS

The prognosis in Ebstein anomaly is extremely variable and depends on the severity of the defect. The prognosis is more guarded for neonates or infants with cyanosis. Patients with milder degrees of Ebstein anomaly usually survive well into adult life. An associated form of left ventricular cardiomyopathy, **isolated left ventricular noncompaction (LVNC)**, is seen in up to 18% of patients with Ebstein anomaly, and the severity of the LV dysfunction directly affects the prognosis.

Chapter 480

Cyanotic Congenital Heart Disease: Lesions Associated with Increased Pulmonary Blood Flow

480.1 d-Transposition of the Great Arteries

Daniel Bernstein

d-Transposition of the great arteries or vessels (d-TGA or d-TGV) accounts for approximately 5% of all congenital heart disease. In this anomaly, the systemic veins return, as normal, to the right atrium and the pulmonary veins return to the left atrium. The connections between the atria and ventricles are also normal (i.e., **atrioventricular concordance**). The aorta arises from the right ventricle and the pulmonary artery from the left ventricle (Fig. 480.1). In normally related great vessels (i.e., in the normal heart) the aorta is posterior and to the right of the pulmonary artery. Whereas in d-TGA the aorta is anterior and to the right of the pulmonary artery (the *d* indicates a dextropositioned aorta, *transposition* indicates that the aorta arises from the right ventricle and the pulmonary artery from the left ventricle). Desaturated blood returning from the body to the right side of the heart goes inappropriately out via the aorta and back to the body again, whereas oxygenated pulmonary venous blood returning to the left side of the heart is returned directly to the lungs. Thus the systemic and pulmonary circulations exist as two parallel circuits. Survival in the immediate newborn period is provided by the foramen ovale and the ductus arteriosus, which permit some mixture of oxygenated and deoxygenated blood. Approximately 50% of patients with d-TGA also have a ventricular septal defect (VSD), which usually provides for better mixing. The clinical findings and hemodynamics vary in relation to the presence or absence of associated defects (e.g., VSD or pulmonary stenosis). d-TGA is more common in infants of diabetic mothers and in males (a ratio of 3:1). When accompanied by other cardiac defects such as pulmonic stenosis or right aortic arch, d-TGA can be associated with deletion of chromosome 22q11.2 (**DiGeorge syndrome**; see Chapter 473).

480.2 d-Transposition of the Great Arteries with Intact Ventricular Septum

Daniel Bernstein

d-TGA with an intact ventricular septum is also referred to as **simple TGA** or **isolated TGA**. Before birth, oxygenation in the upper and lower body fetal circulation is only slightly abnormal, given that oxygenated blood enters the heart from the placenta, umbilical vein, and inferior vena cava. After birth, once the ductus arteriosus begins to close, the minimal mixing of systemic and pulmonary blood by the patent foramen ovale is usually insufficient and severe hypoxemia ensues, generally within the first few days of life.

CLINICAL MANIFESTATIONS

Cyanosis and tachypnea are most often recognized within the first hours or days of postnatal life. Untreated, most of these infants would not survive the neonatal period. Hypoxemia is usually moderate to severe, depending on the degree of atrial-level shunting and whether the ductus is partially open or totally closed. This condition is a medical emergency, and only early diagnosis and appropriate intervention can avert the development of prolonged severe hypoxemia and acidosis, which lead to death. Physical findings, other than cyanosis, may be remarkably nonspecific. The precordial impulse may be normal, or a parasternal heave may be present. The second heart sound (S_2) is usually single and loud, although it may be split. Murmurs may be absent, or a soft systolic ejection murmur may be noted at the mid-left sternal border.

DIAGNOSIS

The electrocardiogram (ECG) is usually normal, showing the expected neonatal right-sided dominant pattern. Chest radiographs may show mild cardiomegaly and a narrow mediastinum (the classic "egg-shaped heart"). In the early newborn period, the pulmonary blood flow is generally normal. As pulmonary vascular resistance (PVR) drops during the first several weeks of postnatal life, evidence of increased pulmonary blood flow becomes apparent. Arterial blood partial pressure of oxygen (Pao_2) is low and does not rise appreciably after the patient breathes 100% oxygen (hyperoxia test), although this test may not be totally reliable. Echocardiography is diagnostic and confirms the transposed ventricular-arterial connections (Fig. 480.2). The size of the interatrial communication and the ductus arteriosus can be visualized and the degree of mixing assessed by pulsed and color Doppler examination. The presence of any associated lesion, such as left ventricular outflow tract obstruction or a VSD, can also be assessed. The origins of the coronary arteries can be imaged, although echocardiography is not as accurate as catheterization for

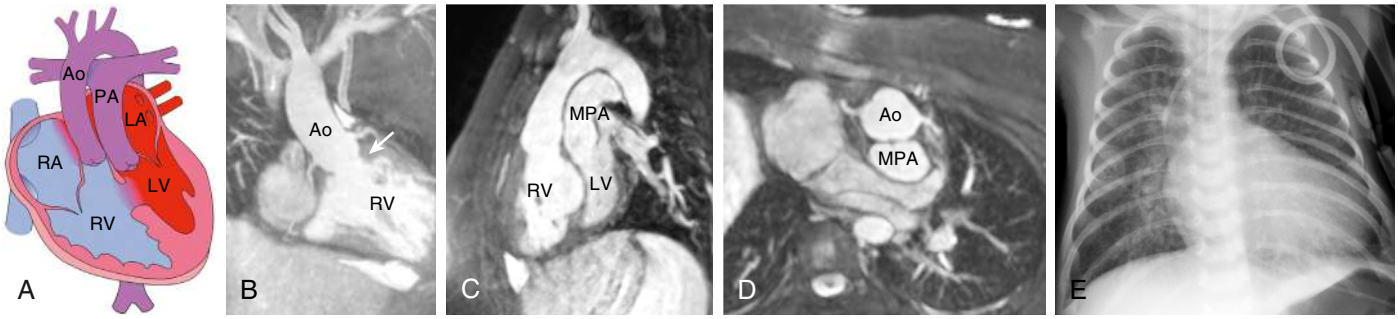

Fig. 480.1 d-Looped transposition of the great arteries (TGA). **A,** Diagram of d-TGA, with the main pulmonary artery (MPA) arising from the left ventricle (LV) and the aorta (Ao) arising from the right ventricle (RV). The degree of cyanosis is variable and depends on the presence of intracardiac shunts such as an atrial septal defect or a ventricular septal defect (VSD) to get oxygenated blood into the systemic circulation. LA, Left atrium; PA, pulmonary artery; RA, right atrium. **B** and **C,** Oblique reformatted images from a 3D steady-state free-precession sequence show (**B**) the Ao arising from the anterior RV with a subaortic conus *(arrow),* and (**C**) the MPA arising from the posterior LV. **D,** The Ao and MPA have a parallel "back-to-front" arrangement. **E,** This parallel back-to-front arrangement contributes to the narrow mediastinum and "egg on a string" appearance seen on chest radiography. This patient has a large VSD with increased pulmonary blood flow. *(From Frost JL, Krishnamurthy R, Sena L. Cardiac imaging. In: Walters MM, Robertson RL, eds. Pediatric Radiology: The Requisites, 4th ed. Philadelphia: Elsevier; 2017, Fig 3-20, p. 75.)*

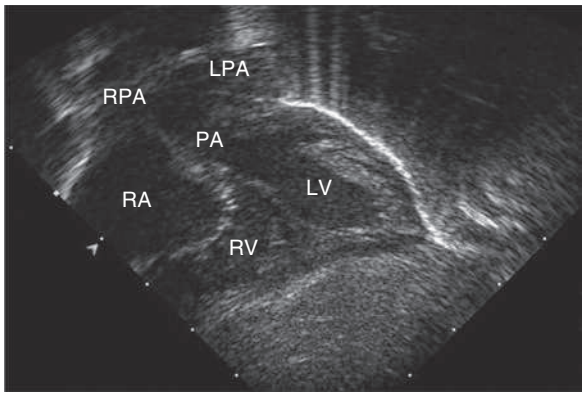

Fig. 480.2 Subcostal four-chamber 2D echocardiographic demonstration of d-transposition of the great arteries. The pulmonary artery (PA) can be seen arising directly from the left ventricle (LV). The immediate bifurcation of this great vessel into the branch pulmonary arteries differentiates it from the aorta, which branches more distally from the heart. LPA, Left pulmonary artery; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle.

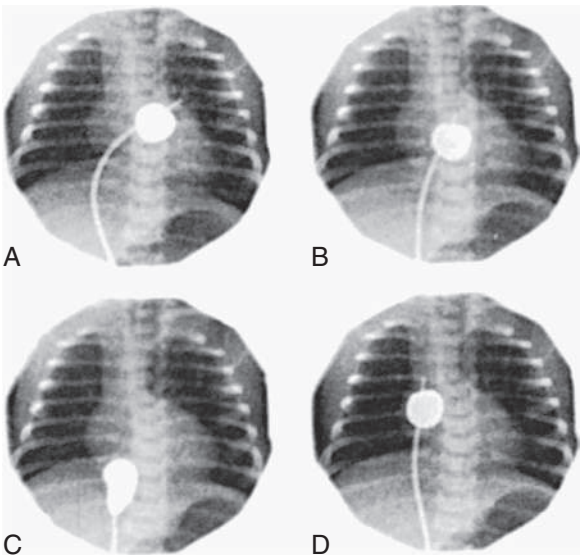

Fig. 480.3 Rashkind balloon atrial septostomy. Four frames from a continuous cineangiogram show the creation of an atrial septal defect in a hypoxemic newborn infant with transposition of the great arteries and an intact ventricular septum. **A**, Balloon inflated in the left atrium. **B**, The catheter is jerked suddenly so that the balloon ruptures the foramen ovale. **C**, Balloon in the inferior vena cava. **D**, Catheter advanced to the right atrium to deflate the balloon. The time from **A** to **C** is <1 sec.

this purpose. Cardiac catheterization may be performed in patients for whom noninvasive imaging is diagnostically inconclusive, where an unusual coronary artery anomaly is suspected, or in patients who require emergency **balloon atrial septostomy (i.e., the Rashkind procedure)**. Catheterization will show right ventricular pressure to be at a systemic level because this ventricle is supporting the systemic circulation. The blood in the left ventricle (LV) and pulmonary artery has a higher oxygen saturation than that in the aorta. Depending on the age at catheterization, LV and pulmonary artery pressure can vary from a systemic level to <50% of systemic-level pressure. Right ventriculography demonstrates the anterior and rightward aorta originating from the right ventricle (RV), as well as the intact ventricular septum. Left ventriculography shows that the pulmonary artery arises exclusively from the LV.

Anomalous coronary arteries are noted in 10–15% of patients and can be defined by an aortic root injection or by selective coronary arteriography.

TREATMENT

When transposition is suspected, an infusion of prostaglandin E_1 (PGE_1, 0.05-0.1 μg/kg/min) should be initiated immediately to maintain patency of the ductus arteriosus and improve oxygenation. Because of the risk of apnea associated with prostaglandin infusion, an individual skilled in neonatal endotracheal intubation should be available. Hypothermia intensifies the metabolic acidosis resulting from hypoxemia, and thus the patient should be kept warm. Prompt correction of acidosis and hypoglycemia is essential.

Infants who remain severely hypoxic or acidotic despite prostaglandin infusion should undergo **Rashkind balloon atrial septostomy** (Fig. 480.3). A Rashkind atrial septostomy is also usually performed in patients in whom any significant delay in surgery is expected. If surgery is planned during the first 2 weeks of life and the patient is stable, catheterization and atrial septostomy may often be avoided.

A successful Rashkind atrial septostomy should result in a rise in Pao_2 to 35-50 mm Hg and elimination of any pressure gradient across the atrial septum. Some patients with TGA and VSD (see Chapter 480.3) may require balloon atrial septostomy because of poor mixing, even though the VSD is large. Others may benefit from decompression of the left atrium to alleviate the symptoms of increased pulmonary blood flow and left-sided heart failure.

The **arterial switch (Jatene) procedure** is the surgical treatment of choice for neonates with d-TGA and an intact ventricular septum and is usually performed within the first 2 weeks of life. The reason for this time frame is that as PVR declines after birth, pressure in the LV (connected to the pulmonary vascular bed) also declines. This pressure drop results in a decrease in LV mass over the first few weeks of life. If the arterial switch operation is attempted after LV pressure (and mass) has declined too far, the LV will be unable to generate adequate pressure to pump blood to the high-pressure systemic circulation. The arterial switch operation involves dividing the aorta and pulmonary artery just above the sinuses and reanastomosing them in their correct anatomic positions. The coronary arteries are removed from the old aortic root along with a button of aortic wall and reimplanted in the old pulmonary root (now called the **neoaorta**). By using a button of great vessel tissue, the surgeon avoids having to suture directly onto the coronary artery (Fig. 480.4); this is the major innovation that has allowed the arterial switch to replace previous atrial switch operations for d-TGA. Rarely, a two-stage arterial switch procedure, with initial placement of a pulmonary artery band, may be used in patients presenting late who already have had a reduction in LV muscle mass and pressure. The arterial switch procedure has a survival rate of >95% for uncomplicated d-TGA. It restores the normal physiologic relationships of systemic and pulmonary arterial blood flow and eliminates the long-term complications of the previously used atrial switch procedure.

Previous operations for d-TGA consisted of some form of **atrial switch procedure** (**Mustard** or **Senning** operation). These procedures produced excellent early survival (85–90%) but had significant long-term morbidities. Atrial switch procedures reverse blood flow at the atrial level by creating an interatrial baffle that directs systemic venous blood returning from the venae cavae to the left atrium, where it will enter the LV, the pulmonary artery, and the lungs. The same baffle also permits oxygenated pulmonary venous blood to cross over to the right atrium, RV, and aorta. Atrial switch procedures involve significant atrial surgery and have been associated with the late development of atrial conduction disturbances, sick sinus syndrome with bradyarrhythmia and tachyarrhythmia, atrial flutter, sudden death, superior or inferior vena cava syndrome, edema, ascites, and protein-losing enteropathy. The atrial switch procedure also leaves the RV as the systemic pumping chamber, and this "systemic" RV often begins to fail in young adulthood. Atrial switch operations are currently reserved for patients whose anatomy is such that they are not candidates for the arterial switch procedure.

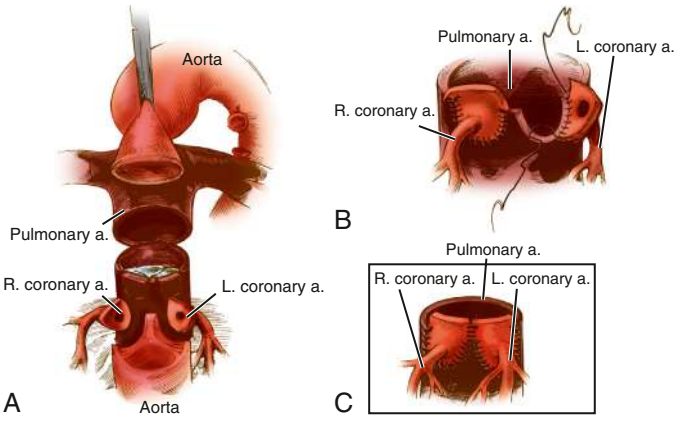

Fig. 480.4 Method for translocating the coronary arteries in the arterial switch (Jatene) procedure. **A,** The aorta (anterior) and the pulmonary artery (posterior) have been transected to allow visualization of the left and right coronary arteries. The coronaries have been excised from their respective sinuses, including a large flap (button) of arterial wall. Equivalent segments of the wall of the pulmonary artery (which will become the neoaorta) are also removed. **B,** The aortocoronary buttons are sutured into the proximal portion of the neoaorta. With this technique all sutures are placed in the button of aortic wall rather than directly on the coronary arteries. **C,** Completed anastomosis of the left and right coronary arteries to the neoaorta. *(Adapted from Castañeda AR, Jonas RA, Mayer JE Jr, et al. Cardiac Surgery of the Neonate and Infant. Philadelphia: Saunders; 1994.)*

480.3 Transposition of the Great Arteries with Ventricular Septal Defect

Daniel Bernstein

If the VSD associated with d-TGA is small, the clinical manifestations, laboratory findings, and treatment are similar to those described previously for transposition with an intact ventricular septum. A harsh systolic murmur is audible at the lower left sternal border, resulting from flow through the defect. Many of these small defects eventually close spontaneously and may not need to be addressed at the time of surgery.

When the VSD is large and not restrictive to ventricular ejection, significant mixing of oxygenated and deoxygenated blood usually occurs and clinical manifestations of cardiac failure are seen. The degree of cyanosis may be subtle and sometimes may not be recognized until an oxygen saturation measurement is performed. The murmur is holosystolic and generally indistinguishable from that produced by a large VSD in patients with normally related great arteries. The heart is usually significantly enlarged.

Cardiomegaly, a narrow mediastinal waist, and increased pulmonary vascularity are demonstrated on the chest radiograph. The ECG findings can be variable. It can show prominent P waves and isolated RV hypertrophy or biventricular hypertrophy. Occasionally, dominance of the LV is present. Usually, the QRS axis is to the right, but it can be normal or even to the left. The diagnosis is confirmed by echocardiography, and the extent of pulmonary blood flow can also be estimated by the degree of enlargement of the left atrium and ventricle. In equivocal cases, the diagnosis can be confirmed by cardiac catheterization. Right and left ventriculography indicate the presence of arterial transposition and demonstrate the site and size of the VSD. Systolic pressure is equal in the two ventricles, the aorta, and the pulmonary artery. Left atrial pressure may be much higher than right atrial pressure, a finding indicative of a restrictive communication at the atrial level. At the time of cardiac catheterization, Rashkind balloon atrial septostomy may be performed to decompress the left atrium, even when adequate mixing is occurring at the ventricular level.

Surgical treatment is advised soon after diagnosis because heart failure and failure to thrive are difficult to manage and pulmonary vascular disease can develop unusually rapidly in these patients. Preoperative management with diuretics and other anticongestive therapies (including elective intubation and positive pressure ventilation) stabilize the patient before surgery.

Patients with d-TGA and a VSD without pulmonic stenosis can be treated with an arterial switch procedure combined with VSD closure. In these patients, the arterial switch operation can be safely performed after the first 2 weeks of life because the VSD results in equal pressure in both ventricles and prevents regression of LV muscle mass. At major centers, however, there is no reason to delay repair, as results are excellent when the surgery is performed in the neonatal period.

480.4 l-Transposition of the Great Arteries (Corrected Transposition)

Daniel Bernstein

In l-transposition of the great arteries (l-TGA), both the atrioventricular and the ventriculoarterial relationships are discordant: the right atrium is connected to an LV and the left atrium to an RV, which is also known as **ventricular inversion**. The great arteries are also transposed, with the aorta arising from the RV and the pulmonary artery from the LV. In contrast to d-TGA, the aorta arises to the left of the pulmonary artery (thus the designation *l* for levo-transposition). The aorta may be anterior to the pulmonary artery, although often they are nearly side by side.

The physiology of l-TGA is quite different from that of d-TGA. Desaturated systemic venous blood returns via the vena cavae to a normal right atrium, from which it passes through a bicuspid atrioventricular (mitral) valve into a right-sided ventricle that has the architecture and smooth wall morphologic features of the normal LV (Fig. 480.5). Because transposition is also present, however, the desaturated blood ejected from this LV enters the transposed pulmonary artery and flows into the lungs, as it would in the normal circulation. Oxygenated pulmonary venous blood returns to a normal left atrium, passes through a tricuspid atrioventricular valve into a left-sided ventricle, which has the trabeculated morphologic features of a normal RV, and is then ejected into the transposed aorta. The double inversion of the atrioventricular and ventriculoarterial relationships result in desaturated right atrial blood appropriately flowing to the lungs and oxygenated pulmonary venous blood appropriately flowing to the aorta. The circulation is thus physiologically "corrected." Without other defects, the hemodynamics would be almost normal. In most patients, however, associated anomalies coexist: VSD, Ebstein-like abnormalities of the left-sided atrioventricular (tricuspid) valve, pulmonary valvular or subvalvular stenosis (or both), and atrioventricular conduction disturbances (complete heart block, accessory pathways such as Wolff-Parkinson-White syndrome).

CLINICAL MANIFESTATIONS

Symptoms and signs are widely variable and are usually determined by the associated lesions. If there is a VSD and pulmonary outflow is unobstructed, the clinical signs are similar to those of an isolated VSD. If l-TGA is associated with pulmonary stenosis and a VSD, the clinical signs are more similar to those of tetralogy of Fallot.

DIAGNOSIS

The chest radiograph may suggest the abnormal position of the great arteries; the ascending aorta occupies the upper left border of the cardiac silhouette and has a straight profile. The ECG, in addition to any atrioventricular conduction disturbances, may show abnormal P waves; absent Q waves in V_6; abnormal Q waves in leads III, aVR, aVF, and V_1; and upright T waves across the precordium. The echocardiogram is diagnostic. The characteristic echocardiographic features of the RV (moderator band, coarser trabeculations, tricuspid valve that sits more inferiorly compared with the bicuspid mitral valve, and a smooth muscular conus or infundibulum separating the atrioventricular valve

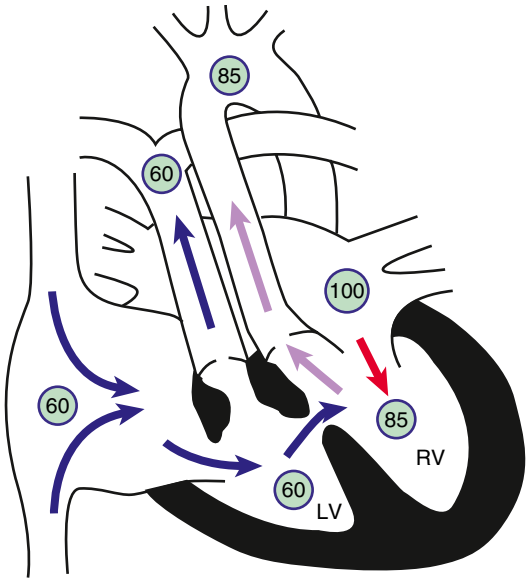

Fig. 480.5 Physiology of l-transposition or corrected transposition of the great arteries (l-TGA) with a ventricular septal defect and pulmonic stenosis (VSD + PS). *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Blood from the right atrium flows through the mitral valve into the "inverted" left ventricle (LV). The left ventricle is, however, attached to the transposed pulmonary artery. Therefore despite the anomalies, desaturated blood still winds up in the pulmonary circulation. Saturated blood returns to the left atrium, traverses the tricuspid valve into the "inverted" right ventricle (RV), and is pumped into the transposed aorta. This circulation would be totally "corrected" were it not for the frequent association of other congenital anomalies, in this case, VSD + PS. Because of the stenotic pulmonary valve, some left ventricular blood flow crosses the VSD and into the right ventricle and the ascending aorta, and systemic desaturation results.

from the semilunar valve) allow the echocardiographer to determine the presence of **atrioventricular discordance** (right atrium connected to LV; left atrium to RV) and ventriculoarterial discordance (RV connected to aorta; LV to pulmonary artery).

Surgical treatment of the associated anomalies, most often the VSD, is complicated by the position of the bundle of His, which can be injured at surgery and result in heart block. Identification of the usual course of the bundle in corrected transposition (running superior to the defect) has been accomplished by mapping the conduction system so that the surgeon can avoid the bundle of His during repair. Even without surgical injury, patients with l-TGA are at risk for developing heart block as they grow older.

Because simple surgical correction leaves the RV as the systemic pumping chamber, and thus vulnerable to late ventricular failure, surgeons have become more aggressive about trying operations that use the LV as the systemic pumping chamber. This is accomplished by performing an atrial switch operation (see Chapter 480.3) to reroute the systemic and pulmonary venous returns in combination with an arterial switch operation to reroute the ventricular outflows **(double switch procedure)**. The long-term benefit of this approach in preserving systemic ventricular function is still under investigation.

480.5 Double-Outlet Right Ventricle Without Pulmonary Stenosis

Daniel Bernstein

In double-outlet RV without pulmonary stenosis, both the aorta and the pulmonary artery arise from the RV (see Chapter 479.5). The only outlet from the LV is through a VSD. In the absence of obstruction to pulmonary blood flow, clinical manifestations are similar to those of an uncomplicated VSD with a large left-to-right shunt, although mild systemic desaturation may result from mixing of oxygenated and deoxygenated blood in the RV. The ECG usually shows biventricular hypertrophy. Echocardiography is diagnostic and shows the right ventricular origin of both great arteries, their anteroposterior relationship, and the relationship of the VSD to each of the great arteries. Surgical correction is dependent on these relationships. If the VSD is subaortic, it is accomplished by creation of an intracardiac tunnel. Blood is then ejected from the LV via the VSD into the aorta. If the VSD is subpulmonic, an arterial switch may be performed in combination with an intracardiac tunnel. If pulmonary blood flow is excessive enough to cause congestive heart failure, pulmonary arterial banding may be required in infancy, followed by surgical correction when the child is bigger. When associated pulmonary stenosis is present, cyanosis is more marked, pulmonary blood flow is decreased, and clinical presentation may be similar to that of tetralogy of Fallot.

480.6 Double-Outlet Right Ventricle with Malposition of the Great Arteries (Taussig-Bing Anomaly)

Daniel Bernstein

In double-outlet RV with malposed great arteries, the VSD is usually directly subpulmonic and the aorta distant from the LV. Sometimes both the pulmonary and the aortic valve may be located close to the VSD (**doubly committed** VSD) and sometimes neither is (**doubly uncommitted** VSD). The term *malposition* is used instead of *transposition* because both great arteries arise from the RV. Aortic obstructive lesions are common, including valvular and subvalvular aortic stenosis, coarctation of the aorta, and interruption of the aortic arch. Because pulmonary blood flow is unobstructed, patients experience cardiac failure early in infancy and are at risk for the development of pulmonary vascular disease and cyanosis. If aortic obstructive lesions are a component, patients can present with poor systemic output and cardiovascular collapse, particularly after the ductus arteriosus begins to close. Cardiomegaly is usual, and a parasternal systolic ejection murmur is audible, sometimes preceded by an ejection click and loud closure of the pulmonary valve. The ECG shows right axis deviation and right, left, or biventricular hypertrophy. The chest radiograph shows cardiomegaly and prominence of the pulmonary vasculature. The anatomic features of the anomaly and associated abnormalities are usually demonstrated by echocardiography, augmented if necessary by either cardiac catheterization, MRI, or CT. Palliation may be achieved by corrective surgery or pulmonary arterial banding in early infancy and surgical correction at a later age, which may be accomplished by an arterial switch procedure (see Chapter 480.2) combined with an intracardiac baffle or some modification of the Rastelli procedure (see Chapter 479.5).

480.7 Total Anomalous Pulmonary Venous Return

Daniel Bernstein

Abnormal development of the pulmonary veins may result in either partial or complete anomalous drainage into the systemic venous circulation. Partial anomalous pulmonary venous return (PAPVR) is usually an acyanotic lesion (see Chapter 475.4). Total anomalous pulmonary venous return (TAPVR) is associated with total mixing of systemic venous and pulmonary venous blood flow within the heart and thus produces cyanosis.

In TAPVR, there is no direct pulmonary venous connection into the left atrium (Fig. 480.6). The pulmonary veins may drain **above** the diaphragm: into the right atrium directly, into the coronary sinus, or into the superior vena cava by a "vertical vein"; or they may drain **below** the

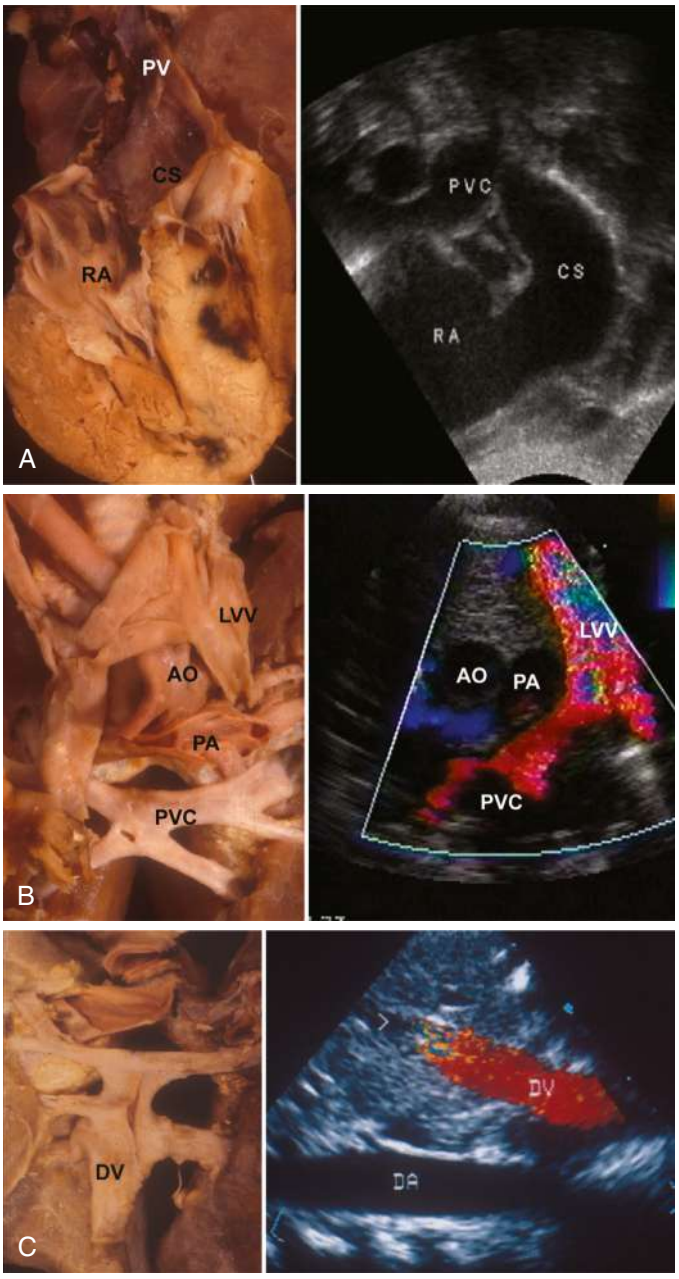

Fig. 480.6 A, Subcostal view demonstrating total anomalous pulmonary drainage to the coronary sinus. Note the dilated coronary sinus in both images. The echocardiogram also demonstrates an associated confluence that connects to the coronary sinus. B, Suprasternal view demonstrating total anomalous pulmonary venous drainage to a left vertical vein. Note the direction of flow in the vertical vein that differentiates it from a left superior vena cava. C, Total anomalous pulmonary venous drainage below the diaphragm. The specimen shows the pulmonary veins as they enter the confluence, whereas the echocardiogram demonstrates the descending veins as they enter the liver. Note that the direction of flow is away from the heart. AO, Aorta; CS, coronary sinus; DA, descending aorta; DV, descending vein; LVV, left vertical vein; PA, pulmonary artery; PV, pulmonary vein; PVC, pulmonary venous confluence; RA, right atrium. *(From Webb GD, Smallhorn, JF, Therrien J, et al. Congenital heart disease in the adult and pediatric patient. In: Zipes DP, Libby P, Bonow RO, et al., eds. Braunwald's Heart Disease, 11th ed. Philadelphia: Elsevier; 2019: Fig. 75-32, p. 1553.)*

diaphragm and join into a "descending vein" that enters the inferior vena cava or one of its major tributaries, often through the ductus venosus. This latter form of anomalous venous drainage is most often associated with *obstruction* to venous flow, usually as the ductus venosus closes soon after birth, although **supracardiac** anomalous veins may also become obstructed. Occasionally, the drainage may be **mixed**, with some veins draining above and others below the diaphragm.

Table 480.1 Total Anomalous Pulmonary Venous Return

SITE OF CONNECTION (% OF CASES)	% WITH SIGNIFICANT OBSTRUCTION
Supracardiac (50)	
Left superior vena cava (40)	40
Right superior vena cava (10)	75
Cardiac (25)	
Coronary sinus (20)	10
Right atrium (5)	5
Infracardiac (20)	95–100
Mixed (5)	

All forms of TAPVR involve mixing of oxygenated and deoxygenated blood before or at the level of the right atrium **(total mixing lesion)**. This mixed right atrial blood either passes into the RV and pulmonary artery or passes through an atrial septal defect (ASD) or patent foramen ovale into the left atrium, which will be the only source of oxygenated systemic blood flow. The right atrium and ventricle and the pulmonary artery are generally enlarged, whereas the left atrium and ventricle may be normal or small. The clinical manifestations of TAPVR depend on the presence or absence of *obstruction* of the venous channels (Table 480.1). If pulmonary venous return is obstructed, severe pulmonary congestion and pulmonary hypertension develop; rapid deterioration occurs without surgical intervention. *Obstructed TAPVR is a pediatric cardiac surgical emergency because prostaglandin therapy is usually not effective.*

CLINICAL MANIFESTATIONS

Two major clinical patterns of TAPVR are seen, depending on the presence or absence of obstruction. Those neonates with severe obstruction to pulmonary venous return, most prevalent in the **infracardiac** group (see Table 480.1), present with severe cyanosis and respiratory distress. Murmurs may not be present. These infants are severely ill and fail to respond to mechanical ventilation. Rapid diagnosis and surgical correction are necessary for survival. In contrast, those with mild or no obstruction to pulmonary venous return are usually characterized by the development of heart failure as the PVR falls, with mild to moderate degrees of desaturation. Systolic murmurs may be audible along the left sternal border, and a gallop rhythm may be present. Some infants may have mild obstruction in the neonatal period and develop worsening obstruction as time passes.

DIAGNOSIS

The ECG demonstrates RV hypertrophy (usually a qR pattern in V_3R and V_1, and P waves are frequently tall and spiked). In neonates with marked pulmonary venous obstruction, the chest radiograph demonstrates a very dramatic perihilar pattern of pulmonary edema and a small heart (Fig. 480.7A). This appearance can sometimes be confused with primary pulmonary disease, and the differential diagnosis includes persistent pulmonary hypertension of the newborn, respiratory distress syndrome, pneumonia, pulmonary lymphangiectasia, and other heart defects (hypoplastic left heart syndrome). In older children, if the anomalous pulmonary veins enter the innominate vein and persistent left superior vena cava (see Fig. 480.7B), a large supracardiac shadow can be seen, which together with the normal cardiac shadow forms a *snowman* appearance. In most cases without obstruction, the heart is enlarged, the pulmonary artery and RV are prominent, and pulmonary vascularity is increased.

The echocardiogram demonstrates a large RV and usually identifies the pattern of abnormal pulmonary venous connections

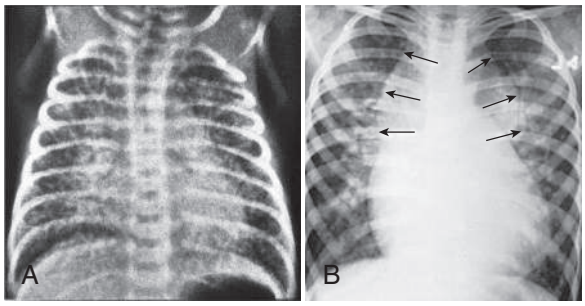

Fig. 480.7 Chest radiographs of total anomalous pulmonary venous return (TAPVR). **A,** A newborn with TAPVR to a descending vein (below the diaphragm) with obstruction, showing marked pulmonary venous congestion and normal heart size. **B,** TAPVR to the left superior vena cava (preoperative image). *Arrows* point to the supracardiac shadow, which produces the "snowman" or figure 8 configuration. Cardiomegaly and increased pulmonary vascularity are evident.

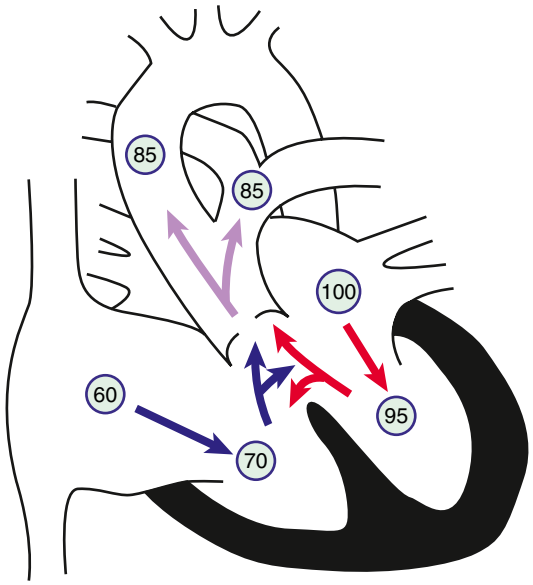

Fig. 480.8 Physiology of truncus arteriosus. *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Desaturated blood enters the right atrium, flows through the tricuspid valve into the right ventricle, and is ejected into the truncus. Saturated blood returning from the left atrium enters the left ventricle and is also ejected into the truncus. The common aortopulmonary trunk gives rise to the ascending aorta and to the main or branch pulmonary arteries. Oxygen saturation in the aorta and pulmonary arteries is usually the same (definition of a total mixing lesion). As pulmonary vascular resistance decreases in the first few weeks of life, pulmonary blood flow increases dramatically, and mild cyanosis and congestive heart failure result.

(see Fig. 480.6). The demonstration of any vein with Doppler flow away from the heart is pathognomonic of TAPVR because normal venous flow is usually toward the heart. Shunting occurs from right to left at the atrial level. The size of the left atrium and LV can be measured and the presence of any associated cardiac defects determined.

Echocardiography should be adequate to demonstrate TAPVR in most cases; however, if there is question about the drainage of one or more pulmonary veins, cardiac catheterization, MRI, or CTA is performed. Catheterization shows that the oxygen saturation of blood in both atria, both ventricles, and the aorta is similar, indicative of a **total mixing lesion**. An increase in systemic venous saturation occurs at the site of entry of the abnormal pulmonary venous channel, either above or below the diaphragm. In older patients without pulmonary venous obstruction, pulmonary arterial and RV pressure may be only moderately elevated, but in infants with pulmonary venous obstruction, pulmonary hypertension is usual. Selective pulmonary arteriography shows the anatomy of the pulmonary veins and their point of entry into the systemic venous circulation.

Fetal diagnosis of TAPVR is feasible in many, but not all, cases, with the main ultrasonographic signs being ventricular disproportion, increased area behind the left atrium, and the finding of a vertical vein. Color Doppler is key to making this diagnosis. Prenatal diagnosis can be helpful in planning for urgent surgical treatment after birth.

TREATMENT

Surgical correction of TAPVR is performed during early infancy, with emergent repair performed for those patients with venous obstruction. If surgery cannot be performed urgently, extracorporeal membrane oxygenation (ECMO) may be required to maintain oxygenation. Surgically, the pulmonary venous confluence is anastomosed directly to the left atrium, the ASD is closed, and any connection to the systemic venous circuit is interrupted. Early results are generally good, even for critically ill neonates. The postoperative period may be complicated by pulmonary artery hypertensive crises. In some patients, especially those in whom the diagnosis is delayed or the obstruction is severe, recurrent stenosis and development of pulmonary venoocclusive disease may occur. Attempts have been made to treat recurrent stenosis with surgery, balloon angioplasty, stents, and antiproliferative chemotherapy. The long-term prognosis in patients with recurrent obstruction is poor. In those with aggressive venoocclusive disease, **heart-lung transplantation** may be the only option (see Chapter 492.2).

480.8 Truncus Arteriosus

Daniel Bernstein

In truncus arteriosus, a single arterial trunk (truncus arteriosus) arises from the heart and supplies the systemic, pulmonary, and coronary circulations. A VSD is always present, with the truncus overriding the defect and receiving blood from both the RV and the LV (Fig. 480.8). The number of truncal valve cusps varies from two to as many as six, and the valve may be stenotic, regurgitant, or both. The pulmonary arteries can arise together from the posterior left side of the persistent truncus arteriosus and then divide into left and right pulmonary arteries **(type I)**. In types II and III truncus arteriosus, no main pulmonary artery is present, and the right and left pulmonary arteries arise from separate orifices on the posterior **(type II)** or lateral **(type III)** aspects of the truncus arteriosus. *Type IV truncus* is a term no longer used because, in this case, there is no identifiable connection between the heart and pulmonary arteries, and pulmonary blood flow is derived from **major aortopulmonary collateral arteries (MAPCAs)** arising from the transverse or descending aorta; this is essentially a form of pulmonary atresia (see Chapter 479.2).

Both ventricles are at systemic pressure, and both eject blood into the truncus. When PVR is relatively high immediately after birth, pulmonary blood flow may be normal; as PVR drops in the first few weeks of life, blood flow to the lungs is greatly increased and heart failure ensues. Truncus arteriosus is a **total mixing lesion** with complete admixture of pulmonary and systemic venous return. Because of the large volume of pulmonary blood flow, clinical cyanosis is usually mild. If the lesion is left untreated, PVR eventually increases, pulmonary blood flow decreases, and cyanosis becomes more prominent (**Eisenmenger physiology**; see Chapter 482.2).

CLINICAL MANIFESTATIONS

The clinical signs of truncus arteriosus vary with age and depend on the level of PVR. In the immediate newborn period, signs of heart failure are usually absent; a murmur and minimal cyanosis may be the only initial findings. If unrepaired, during the next 1-2 months of life,

pulmonary blood flow begins to become torrential and the clinical picture is dominated by heart failure, with still mild cyanosis. Runoff of blood from the truncus to the pulmonary circulation may result in a wide pulse pressure and bounding pulses. These findings will be further exaggerated if truncal valve insufficiency is present. The heart is usually enlarged, and the precordium is hyperdynamic. S_2 is loud and single. A systolic ejection murmur, sometimes accompanied by a thrill, is generally audible along the left sternal border. The murmur is frequently preceded by an early systolic ejection click caused by the abnormal truncal valve. In the presence of truncal valve insufficiency, a medium- to high-pitched early diastolic decrescendo murmur is heard at the mid-left sternal border. An apical mid-diastolic rumbling murmur caused by increased flow through the mitral valve is often audible with the bell of the stethoscope, especially as heart failure develops. Truncus arteriosus is a conotruncal malformation and may be associated with **DiGeorge syndrome**, linked to a deletion of a large region of **chromosome 22q11** (see Chapter 473).

DIAGNOSIS

The ECG shows right, left, or combined ventricular hypertrophy. The chest radiograph also shows considerable variation. Cardiac enlargement will develop over the first several weeks of life and is a result of the prominence of both ventricles. The truncus may produce a prominent shadow that follows the normal course of the ascending aorta and aortic knob; the aortic arch is right sided in 50% of patients. Sometimes a high bulge left of the aortic knob is produced by the main or left pulmonary artery. Pulmonary vascularity is increased after the first few weeks of life. Echocardiography is diagnostic and demonstrates the large truncal artery overriding the VSD and the pattern of origin of the branch pulmonary arteries (Fig. 480.9). Associated anomalies such as an interrupted aortic arch may be noted. Pulsed and color Doppler studies are used to evaluate truncal valve regurgitation. If required, cardiac catheterization shows a left-to-right shunt at the ventricular level, with right-to-left shunting into the truncus. Systolic pressure in both ventricles and the truncus is similar. Angiography reveals the large truncus arteriosus and better defines the origin of the pulmonary arteries.

TREATMENT

Most centers perform routine neonatal repair shortly after diagnosis. If surgery is delayed and PVR falls over the first several weeks of life, heart failure symptoms will worsen. Anticongestive medications can be used to better prepare these patients for surgery; however, delay of surgery much beyond this time period may increase the likelihood of developing pulmonary vascular disease. At surgery, the VSD is closed, the pulmonary arteries are separated from the truncus, and continuity is established between the RV and the pulmonary arteries with a homograft conduit. Immediate surgical results are excellent, but these conduits will develop either regurgitation or stenosis over time and must be replaced, often several times, as the child grows. If regurgitation is the primary problem, patients can now be treated with a transcatheter stent-valve (see Chapter 479.1)

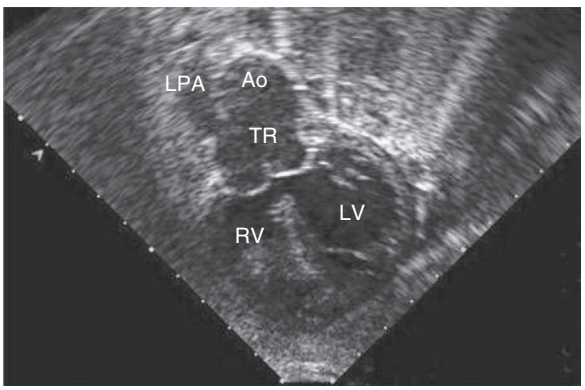

Fig. 480.9 Subcostal 2D echocardiographic demonstration of truncus arteriosus. The large truncal valve can be seen overriding the ventricular septal defect. In this case, only the left pulmonary artery (LPA) arises from the truncus (TR). The pulmonary arteries are discontinuous, and the right pulmonary artery arises from the descending aorta via the ductus arteriosus (not shown). Ao, Aorta; LV, left ventricle; RV, right ventricle.

PROGNOSIS AND COMPLICATIONS

Surgical results have been excellent, and many patients with repaired truncus are now entering mid-adulthood, with several centers reporting 30- and 40-year-old survivors. The need to replace the RV-to-pulmonary artery conduit as the child grows means that these patients will need to undergo multiple operations by the time they reach adulthood. The development of transcatheter stent-valves may reduce this in the future (see Chapter 472). When truncus arteriosus is associated with DiGeorge syndrome, the associated endocrine, immunologic, craniofacial, and airway abnormalities may complicate recovery.

480.9 Single Ventricle (Double-Inlet Ventricle, Univentricular Heart)

Daniel Bernstein

With a single ventricle, both atria empty through a common atrioventricular valve or through two separate valves into a single ventricular chamber, with total mixing of systemic and pulmonary venous return. This chamber may have left, right, or indeterminate (both right and left) ventricular morphologic characteristics. The aorta and pulmonary artery both arise from this single chamber, although one of the great vessels may originate from a rudimentary outflow chamber. The aorta may be posterior, anterior (malposition), or side-by-side with the pulmonary artery and either to the right or to the left. Pulmonary stenosis or atresia is common.

CLINICAL MANIFESTATIONS

The clinical picture is variable and depends on the associated intracardiac anomalies. If pulmonary outflow is obstructed, the findings are usually similar to those of tetralogy of Fallot: marked cyanosis without heart failure. If pulmonary outflow is unobstructed, the findings are similar to those of transposition with VSD: minimal cyanosis with increasing heart failure.

In patients with **pulmonary stenosis**, cyanosis is present in early infancy. Cardiomegaly is mild or moderate, a left parasternal lift is palpable, and a systolic thrill is common. The systolic ejection murmur is usually loud; an ejection click may be audible, and S_2 is single and loud. In patients with **unobstructed pulmonary flow**, as PVR drops, torrential pulmonary blood flow develops, and these patients present with tachypnea, dyspnea, failure to thrive, and recurrent pulmonary infections. Cyanosis is only mild or moderate. Cardiomegaly is generally marked, and a left parasternal lift is palpable. A systolic ejection murmur is present but is not usually loud or harsh, and S_2 is loud and closely split. A third heart sound (S_3) is common and may be followed by a short mid-diastolic rumbling murmur caused by increased flow through the atrioventricular valves. The eventual development of pulmonary vascular disease reduces pulmonary blood flow so that the cyanosis increases and signs of cardiac failure appear to improve (**Eisenmenger physiology**; see Chapter 482.2).

DIAGNOSIS

ECG findings are nonspecific. P waves are normal, spiked, or bifid. The precordial lead pattern suggests right ventricular hypertrophy, combined ventricular hypertrophy, or sometimes left ventricular dominance. The initial QRS forces are usually to the left and anterior. Radiographic examination confirms the degree of cardiomegaly. If present, a rudimentary outflow chamber may produce a bulge on the upper left border of the cardiac silhouette in the posteroanterior projection. In the absence of pulmonary stenosis, pulmonary vasculature is

increased, whereas in the presence of pulmonary stenosis, pulmonary vasculature is diminished. Echocardiography will confirm the absence or near-absence of the ventricular septum and can usually determine whether the single ventricle has right, left, or mixed morphologic features. The presence of a rudimentary outflow chamber under one of the great vessels can be identified, and pulsed Doppler can be used to determine whether flow through this communication (known as a **bulboventricular foramen**) is obstructed.

If cardiac catheterization is performed, the pressure in the single ventricular chamber is at systemic level; however, a gradient may be demonstrated across the entrance to the rudimentary outflow chamber. Pressure measurements and angiography demonstrate whether pulmonary stenosis is present.

TREATMENT

If pulmonary stenosis is severe, a **Blalock-Taussig aortopulmonary shunt** is performed to provide a reliable source of pulmonary blood flow (see Chapter 479.1). If pulmonary blood flow is unrestricted, pulmonary arterial banding is used to control heart failure and prevent progressive pulmonary vascular disease. The **bidirectional Glenn shunt** is usually performed at 2-4 months of age, followed by a **modified Fontan operation** (cavopulmonary isolation procedure; see Chapter 479.4) at 2-3 years. If subaortic stenosis is present because of a restrictive connection to a rudimentary outflow chamber (*restrictive* bulboventricular foramen), surgical relief can be provided by anastomosing the proximal pulmonary artery to the side of the ascending aorta **(Damus-Stansel-Kaye operation)**.

PROGNOSIS AND COMPLICATIONS

Unoperated, some patients succumb during infancy from heart failure. Others may survive to adolescence and early adult life but finally succumb to the effects of chronic hypoxemia or, in the absence of pulmonary stenosis, to the effects of pulmonary vascular disease. Patients with moderate pulmonary stenosis have the best prognosis because pulmonary blood flow, though restricted, is still adequate. Surgical palliation, eventually leading to Fontan-type circulatory physiology (see Chapter 479.4), has very good short- and intermediate-term results.

480.10 Hypoplastic Left Heart Syndrome

Daniel Bernstein

The term *hypoplastic left heart syndrome* (HLHS) is used to describe a related group of anomalies that include various degrees of underdevelopment of the left side of the heart: stenosis or atresia of the aortic and mitral valves and hypoplasia of the left ventricular cavity and ascending aorta. HLHS categories are based on anatomic characteristics: (1) mitral and aortic atresia (MA-AA), (2) mitral stenosis with aortic atresia (MS-AA), and (3) mitral and aortic stenosis (MS-AS). The LV may be only moderately hypoplastic, very small and nonfunctional, or totally atretic. The LV cavity may be slitlike, miniaturized, or small and thick walled with endocardial fibroelastosis. In patients with MS-AA, there may be anomalous connections between the ventricle and the coronary arteries, which some reports associate with an increased postoperative risk.

The etiology of HLHS may be the result of poor left-sided fetal blood flow (no flow–no grow hypothesis). Alternatively, there may be intrinsic defects of myogenic and endocardial programming affecting differentiation, proliferation, maturation, and apoptosis. Although no single gene is associated with all patients, multiple genes *(GJA1, NKX2-5, SAP130, PCDHA, Notch 1, MY46)* and pathways (transforming growth factor beta [TGF-β], Wnt) have been implicated.

In the immediate neonatal period, the RV maintains both the pulmonary circulation and the systemic circulation via the ductus arteriosus (Fig. 480.10). Pulmonary venous blood passes through an ASD (which may or may not be restrictive) or dilated foramen ovale from the left to the right side of the heart, where it mixes with systemic venous blood (total mixing lesion). Minimal (mitral stenosis subtypes)

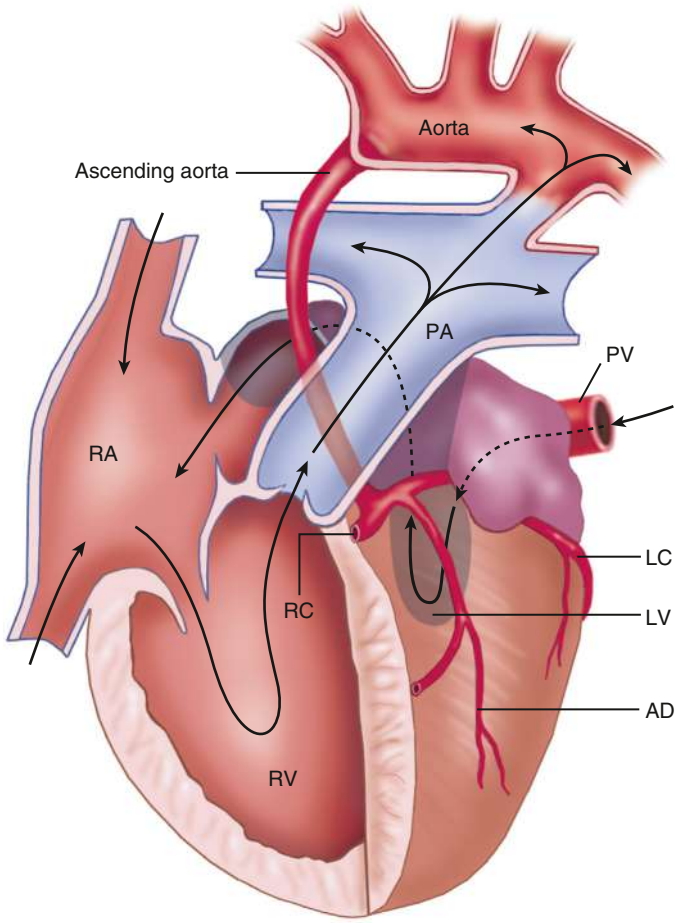

Fig. 458.10 Hypoplastic left heart with aortic hypoplasia, aortic valve atresia, and a hypoplastic mitral valve and left ventricle. AD, Anterior descending; LC, left circumflex; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RC, right coronary artery; RV, right ventricle. *(From Webb GD, Smallhorn, JF, Therrien J, et al. Congenital heart disease in the adult and pediatric patient. In: Zipes DP, Libby P, Bonow RO, et al., eds. Braunwald's Heart Disease, 11th ed. Philadelphia: Elsevier; 2019: Fig. 75-28, p. 1548. Adapted from historical illustrations in Neufeld HN, Adams P Jr, Edwards JE, et al. Diagnosis of aortic atresia by retrograde aortography. Circulation. 1962;25:278; and Edwards JE, Dry TJ, Parker RL, et al. An Atlas of Congenital Anomalies of the Heart and Great Vessels. Springfield: Charles C. Thomas; 1954.)*

or no (mitral atresia subtype) blood enters the hypoplastic LV. All the RV blood is ejected into the main pulmonary artery, where it then supplies both the descending and the ascending aorta (retrograde flow) via the ductus arteriosus. The major hemodynamic abnormalities are inadequate maintenance of the systemic circulation and, depending on the size of the atrial-level communication, either pulmonary venous hypertension (restrictive foramen ovale) or pulmonary overcirculation (moderate or large ASD).

CLINICAL MANIFESTATIONS

Although cyanosis may not always be obvious in the first 48 hours of life, a grayish-blue skin color is soon apparent and denotes a mix of cyanosis and poor perfusion. The condition is diagnosed in most infants in the first few hours or days of life. Once the ductus arteriosus begins to close, signs of poor systemic perfusion and shock predominate. All the peripheral pulses may be weak or absent. A palpable RV parasternal lift may be present along with a nondescript systolic murmur.

This lesion may be isolated or associated in 5–15% of patients with known genetic syndromes, such as Turner syndrome; trisomy 13, 18, or 21; Jacobsen syndrome (11q deletion); Holt-Oram syndrome; and Rubinstein-Taybi syndrome. In these circumstances, noncardiac

manifestations of the syndrome may be evident and influence the clinical outcomes. Occasionally, HLHS is familial and inherited as an autosomal recessive or dominant trait; there are also families with constellations of different severities of left-sided obstructive lesions, ranging from bicuspid aortic valve, to coarctation of the aorta, to Shone complex, to HLHS.

DIAGNOSIS

On chest radiograph, the heart is variable in size in the first days of life, but cardiomegaly develops rapidly and is associated with increased pulmonary vascularity. The initial ECG may show only the normal neonatal pattern of RV dominance, but later, P waves become prominent and RV hypertrophy is usual with reduced LV forces. The echocardiogram is diagnostic and demonstrates hypoplasia or atresia of the mitral valve and aortic root, a variably small left atrium and LV, and a large right atrium and RV (Fig. 480.11). The size of the atrial communication, by which pulmonary venous blood leaves the left atrium, is assessed by pulsed and color flow Doppler studies. The small ascending aorta and transverse aortic arch are identified; a discrete coarctation of the aorta in the juxtaductal area may be present, although in the presence of a large ductus, it may be difficult to identify. Doppler echocardiography demonstrates whether the mitral and aortic valves are severely stenotic or totally atretic. The presence of left ventricular–to–coronary sinusoidal connections can be identified. The diagnosis of HLHS can usually be made without the need for cardiac catheterization. If catheterization is necessary, the hypoplastic ascending aorta is demonstrated by angiography.

TREATMENT

Surgical therapy for HLHS is associated with improved survival rates, reported as high as 90–95% for the first-stage palliation in experienced centers. The first-stage repair is designed to construct a reliable source of systemic blood flow arising from the single RV using a combination of aortic and pulmonary arterial tissue and to limit pulmonary blood flow to avoid heart failure and prevent the development of pulmonary vascular disease. The surgical procedure typically used is the **Norwood procedure** (Fig. 480.12) or the **Sano procedure**. Primary heart transplantation, previously advocated by a few centers, is much less common because of the substantially improved survival rates with standard surgery and the limited supply of donor organs in this age-group.

Preoperative medical management includes maintaining ductus arteriosus patency with PGE_1 (0.05-0.1 μg/kg/min) to support systemic blood flow, avoiding excess pulmonary blood flow, and maintaining adequate flow from the left to the right atrium. Correction of acidosis and hypoglycemia and prevention of hypothermia are also key components. Excessive pulmonary blood flow, which worsens as the PVR begins to fall, can lead to both respiratory distress and systemic hypoperfusion. This can be prevented through managing ventilator settings to keep the P_{CO_2} in the 45-50 mm Hg range and avoiding supplemental oxygen (which acts as a pulmonary vasodilator) if the system arterial O_2 saturation is in the 70-80 mm Hg range. If the atrial septum is restrictive, a Rashkind balloon atrial septostomy, septal balloon dilation, or rarely, a blade septostomy of the atrial septum may be indicated.

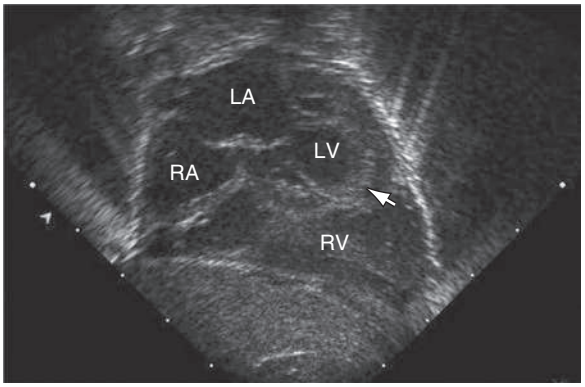

Fig. 480.11 Subcostal 2D echocardiographic diagnosis of hypoplastic left heart syndrome. The small left ventricular chamber can be seen, the apex of which *(arrowhead)* does not form the apex of the heart. The atrial septum can be seen bowing from the left to the right, indicating that the communication between the two atria is pressure restrictive. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

The Norwood or Sano procedure is usually performed in three stages. **Stage I** (see Fig. 480.12), usually performed in the first week of life, includes an atrial septectomy and transection and ligation of the distal main pulmonary artery; the proximal pulmonary artery is then connected to the transversely opened hypoplastic aortic arch to form a "neoaorta," extending through the coarcted segment of the juxtaductal aortic arch. In the Norwood operation, a synthetic aortopulmonary (Blalock-Taussig) shunt connects the aorta to the main pulmonary artery to provide controlled pulmonary blood flow. In the Sano modification, an RV–to–pulmonary artery conduit is used instead of an aortopulmonary shunt to provide pulmonary blood flow, temporarily creating a double-outlet RV. The operative risk for these first-stage procedures has improved dramatically in the past 2 decades, and the best reported results demonstrate a 90–95% survival rate. After the first stage, the patient's oxygen saturation usually ranges from 75% to 85% because of the continued admixture of oxygenated and deoxygenated blood in the right atrium. In the past, there was a high interstage mortality rate in infants discharged from the hospital between stages I and II. This has largely been prevented by performing careful interstage surveillance in home monitoring programs run by pediatric cardiac centers.

Stage II consists of a Glenn shunt anastomosis to connect the superior vena cava to the pulmonary arteries (see Chapter 480.4) at 2-6 months of age. **Stage III**, usually performed at 2-3 years, consists of a modified Fontan procedure (cavopulmonary isolation) to connect the inferior vena cava to the pulmonary arteries via either an intraatrial or external baffle. After stage III, all systemic venous return enters the pulmonary circulation directly. Pulmonary venous flow enters the left atrium and is directed across the atrial septum to the tricuspid valve and subsequently to the right (now the systemic) ventricle. Blood leaves the RV via the neoaorta, which supplies the systemic circulation. The old aortic root now attached to the neoaorta provides coronary blood flow. The risks associated with stages II and III are less than those of stage I; interstage mortality (usually between stages I and II) has been dramatically reduced with the use of home monitoring programs and interstage close follow-up. The short- and long-term benefits of using the Norwood vs the Sano procedure remain to be demonstrated.

An alternative therapeutic approach, initially developed for high-risk standard surgical candidates, is to perform a **hybrid procedure** for the first stage. This involves performing a Rashkind balloon atrial septostomy, cardiac catheter laboratory placement of a stent in the ductus arteriosus, and open chest surgical placement of bilateral pulmonary artery bands. After the hybrid procedure, patients can be weaned off prostaglandin and discharged from the hospital. However, after a hybrid procedure, patients need to undergo a more extensive second-stage procedure involving construction of a neoaorta and removal of the pulmonary artery bands.

Another alternative therapy is **cardiac transplantation**, either in the immediate neonatal period, thereby obviating stage I of the Norwood procedure, or after a successful stage I Norwood procedure is performed as a bridge to transplantation. After transplantation, patients usually have normal cardiac function and no symptoms of heart failure; however, these patients have the chronic risk of organ rejection and lifelong immunosuppressive therapy (see Chapter 492.1). The combination of donor shortage and improved results with standard surgical and hybrid procedures has caused most centers to stop recommending transplantation except when associated lesions make the Norwood operation an exceptionally high-risk procedure (e.g., significant coronary artery anomalies) or for patients who develop poor ventricular function at some time after the standard surgical approach.

PROGNOSIS AND COMPLICATIONS

Untreated patients most often succumb during the first few months of life, usually during the first or second week. Up to 30% of infants with HLHS

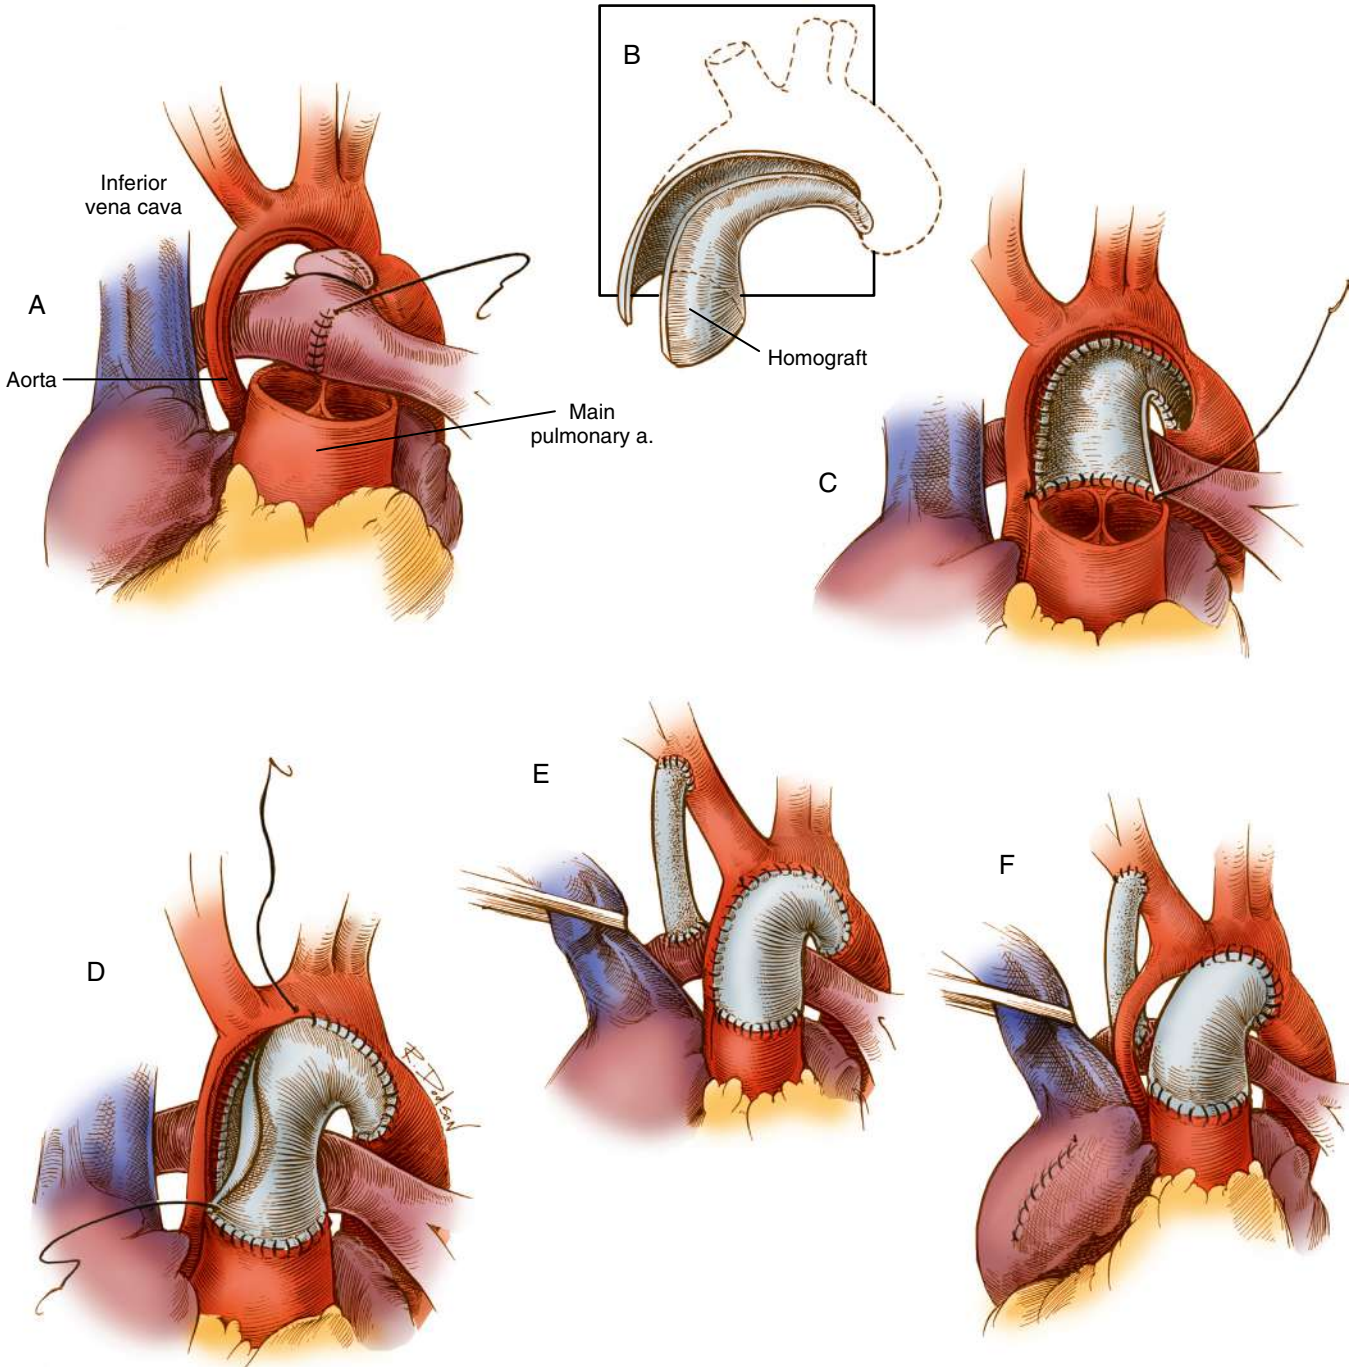

Fig. 480.12 Norwood procedure, one of the two current techniques for first-stage palliation of hypoplastic left heart syndrome. **A,** Incisions used for the procedure incorporate a cuff of arterial wall allograft. The distal divided main pulmonary artery may be closed by direct suture or with a patch. **B,** Dimensions of the cuff of the arterial wall allograft. **C,** The arterial wall allograft is used to supplement the anastomosis between the proximal divided main pulmonary artery and the ascending aorta, aortic arch, and proximal descending aorta. **D** and **E,** The procedure is completed by an atrial septectomy and a 3.5-mm modified right Blalock shunt. **F,** When the ascending aorta is particularly small, an alternative procedure involves placement of a complete tube of arterial allograft. The tiny ascending aorta may be left in situ, as indicated, or implanted into the side of the neoaorta. *(From Castañeda AR, Jonas RA, Mayer JE Jr, et al. Single-ventricle tricuspid atresia. In: Cardiac Surgery of the Neonate and Infant. Philadelphia: Saunders; 1994.)*

have evidence of either a major or a minor central nervous system abnormality. Other dysmorphic features may be found in up to 40% of patients. Thus careful preoperative evaluation (genetic, neurologic, ophthalmologic) should be performed in patients being considered for surgical therapy.

Intermediate-term follow-up after completion of all three stages of the Norwood procedure demonstrates generally good exercise capacity and long-term complications equivalent to other patients who have had the Fontan palliation (see Chapter 479.4). Some studies show that patients with HLHS have a higher risk of neurodevelopmental problems than those with other complex congenital heart lesions. Whether the poor neurodevelopmental outcome is the result of genetically associated central nervous system malformations, alteration of prenatal circulation dynamics or prenatal central nervous system injury, complications of bypass surgery, or poor preoperative and/or postoperative perfusion is unknown. Whether a specific HLHS subtype, specifically MS-AA with ventricular-coronary connections, is associated with increased postoperative mortality is still unclear, as studies have shown contradictory results.

PREVENTION

Serial fetal echocardiographic studies demonstrate that in some fetuses, HLHS may be a progressive in utero lesion, beginning with simple valvar aortic stenosis in mid-gestation. The decreased flow through the stenotic aortic valve reduces flow through the LV during development, resulting in gradual ventricular chamber hypoplasia. The potential for preventing this hypoplasia has been demonstrated by performing in utero aortic balloon valvuloplasty in mid-gestation fetuses (Fig. 480.13). Early results are encouraging, although even if the aortic valve is successfully opened, adequate ventricular growth occurs in only ~50% of patients. At present, this procedure is regarded as experimental.

Because of the high mortality of HLHS with an intact or restrictive atrial septum, in utero attempts to improve atrial mixing with either fetal atrial septoplasty or atrial stent placement are undergoing clinical investigation.

480.11 Abnormal Positions of the Heart and the Heterotaxy Syndromes (Asplenia, Polysplenia)

Daniel Bernstein

Classification and diagnosis of abnormal cardiac position are best performed through a *segmental* approach, with the position of the viscera and atria defined first, then the ventricles, followed by the great vessels (Fig. 480.14). Determination of **visceroatrial situs** can be made by radiographic demonstration of the position of the abdominal organs and the tracheal bifurcation for recognition of the right and left bronchi and by echocardiography. The atrial situs is usually similar to the situs of the viscera and lungs. In **situs solitus** the viscera are in their normal positions (stomach and spleen on the left, liver on the right), the three-lobed right lung is on the right, and the two-lobed left lung on the left; the right atrium is on the right, and the left atrium is on the left. When the abdominal organs and lung lobation are reversed, an arrangement known as **situs inversus** occurs: the left atrium is on the right and the right atrium on the left. If the visceroatrial situs cannot be readily determined, a condition known as **situs indeterminus** or **heterotaxia** exists. The two major heterotaxy syndromes are **asplenia syndrome** (right isomerism or bilateral right-sidedness), which is associated with a centrally located liver, absent spleen, and two morphologic right lungs (Figs. 480.15 and 480.16), and **polysplenia syndrome** (left isomerism or bilateral left-sidedness), which is associated with multiple small spleens, absence of the intrahepatic portion of the inferior vena cava, and two morphologic left lungs (Figs. 480.17 and 480.18). The heterotaxia syndromes are usually associated with severe congenital heart lesions: ASD, VSD, atrioventricular septal defect, hypoplasia of one of the ventricles, pulmonary stenosis or atresia, and anomalous systemic venous or pulmonary venous return (Table 480.2).

Human heterotaxia syndromes may be related to disorders in both motile and primary cilia function and in utero left-right axis development. Genes involved in heterotaxy syndromes, including *NODAL* (known asymmetric gene), and those influenced by *NODAL* such as the TGF-β superfamily *(LEFTY2)* and *Pitx2,* have been implicated in the

Table 480.2 Comparison of Cardiosplenic Heterotaxy Syndromes

FEATURE	ASPLENIA (RIGHT ISOMERISM)	POLYSPLENIA (LEFT ISOMERISM)
Spleen	Absent	Multiple
Sidedness (isomerism)	Bilateral right	Bilateral left
Lungs	Bilateral trilobar with eparterial bronchi	Bilateral bilobar with hyparterial bronchi
Sex	Male (65%)	Female ≥ male
Right-sided stomach	Yes	Less common
Symmetric liver	Yes	Yes
Partial intestinal rotation or malrotation	Yes	Yes
Risk for midgut volvulus	Yes	Yes
Dextrocardia (%)	30–40	30–40
Pulmonary blood flow	Decreased (usually)	Increased (usually)
Severe cyanosis	Yes	No
Transposition of great arteries (%)	60–75	15
Total anomalous pulmonary venous return (%)	70–80	Rare
Common atrioventricular valve (%)	80–90	20–40
Single ventricle (%)	40–50	10–15
Absent inferior vena cava with azygos continuation	No	Characteristic
Bilateral superior venae cavae	Yes	Yes
Other common defects	PA, PS, right-sided aortic arch	Partial anomalous pulmonary venous return, ventricular septal defect, double-outlet right ventricle
Risk of pneumococcal sepsis	Yes	Yes
Howell-Jolly and Heinz bodies, pitted erythrocytes	Yes	No
Risk of nosocomial infection	Yes	Yes
Absent gallbladder; biliary atresia	No	Yes

PA, Pulmonary atresia; PS, pulmonary stenosis.

development of heterotaxia syndromes (Fig. 480.19 and Table 480.3). Diagnostic gene panels are available to identify a possible genetic basis.

The next segment is localization of the **ventricles**, which depends on the direction of development of the embryonic cardiac loop. Initial protrusion of the loop to the right **(d-loop**) carries the future RV anteriorly and to the right, whereas the LV remains posterior and on the left (the normal relationship). With situs solitus, a d-loop yields normal atrioventricular connections (right atrium connecting to RV, left atrium to LV). Protrusion of the loop to the left **(l-loop)** carries the future RV to the left and the LV to the right. In this case, in the presence of situs solitus, the right atrium connects with the LV and the left atrium with the RV **(ventricular inversion)**.

The final segment is that of the **great vessels**. With each type of cardiac loop, the ventricular-arterial relationships may be regarded as either normal (RV to pulmonary artery, LV to aorta); transposed (RV to aorta, LV to pulmonary artery); or in the event of a double-outlet ventricle, either normally related or **malposed**. A further classification can be based on the position of the aorta (normally to the right and posterior) relative to the pulmonary artery. In transposition, the aorta is usually anterior and either to the right of the pulmonary artery **(d-transposition)** or to the left **(l-transposition)**.

These segmental relationships can usually be determined by echocardiographic studies demonstrating both atrioventricular and ventriculoarterial relationships. The clinical manifestations of these syndromes of abnormal cardiac position are determined primarily by their associated cardiovascular anomalies.

Dextrocardia occurs when the heart is in the right side of the chest. **Levocardia** (the normal situation) is present when the heart is in the left side of the chest. Dextrocardia without associated situs inversus or levocardia in the presence of situs inversus is most often complicated by other severe cardiac malformations. Surveys of older children and adults indicate that dextrocardia with situs inversus and normally related great arteries ("mirror-image" dextrocardia) is often associated with a functionally normal heart, although congenital heart disease of a less severe nature is common.

Anatomic or functional abnormalities of the lungs, diaphragm, and thoracic cage may result in displacement of the heart to the right **(dextroposition)**. In this case, however, the cardiac apex is pointed

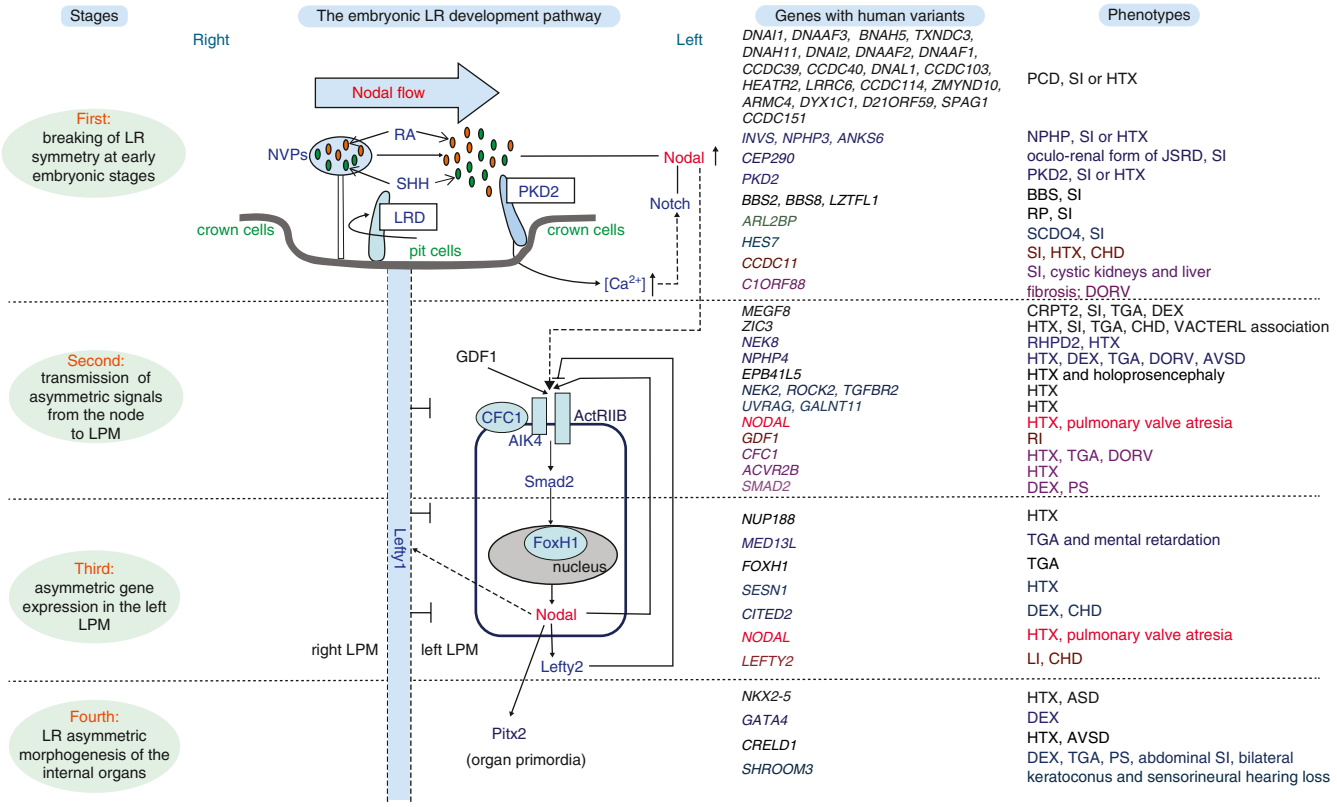

Fig. 480.19 Pathway of left-right (LR) development in the mouse embryo, list of genes associated with human LR asymmetry disorders, and corresponding phenotypes in humans. LRD-containing monocilia generate leftward nodal flow, and polycystin 2–containing cilia sense nodal flow and initiate an asymmetric calcium signal, which induces nodal expression around the node. Nodal signaling is involved in asymmetric morphogenesis by inducing expression of the nodal-responsive genes *(NODAL, LEFTY2,* and *PITX2)* in the left lateral plate mesoderm (LPM) and expression of *LEFTY1* at the midline. Pathogenic variants of genes associated with ciliopathies and nodal signal transduction pathway have been identified in human LR asymmetry disorders. *Full arrows* indicate a direct positive effect on gene expression, *dotted arrows* indicate an indirect effect, and *lines* indicate inhibition. normally to the left, as opposed to dextrocardia, where the cardiac apex is pointed to the right or anteriorly. This anatomic position is less often associated with congenital heart lesions, although hypoplasia of a lung may be accompanied by anomalous pulmonary venous return from that lung (**scimitar syndrome**; see Chapter 475.4).

The ECG is difficult to interpret in the presence of lesions with discordant atrial, ventricular, and great vessel anatomy. Diagnosis usually requires detailed echocardiographic and sometimes MRI, CT, or cardiac catheterization studies. The **prognosis** and **treatment** of patients with one of the cardiac positional anomalies are determined by the underlying defects and are covered in their respective chapters. Asplenia increases the risk of serious infections, such as bacterial (usually pneumococcal) sepsis, and thus requires daily antibiotic prophylaxis. Patients with polysplenia frequently have poor splenic function and also require prophylaxis against bacterial sepsis. Patients with heterotaxia are also at increased risk of intestinal malrotation and volvulus and of ciliary dyskinesia and associated pulmonary complications (see Chapters 101.3 and 455).

Chapter 481

Other Congenital Heart and Vascular Malformations

481.1 Anomalies of the Aortic Arch

Daniel Bernstein

RIGHT AORTIC ARCH

In this abnormality, the aorta curves to the right and, if it descends on the right side of the vertebral column, is usually associated with other cardiac malformations. It is found in 20% of cases of tetralogy of Fallot and is also common in truncus arteriosus. A right aortic arch without other cardiac anomalies is not associated with symptoms. It can often be visualized on the chest radiograph. The trachea is deviated slightly to the left of the midline rather than to the right, as in the presence of a normal left arch. On a barium esophagogram, MRI, or CT scan, the esophagus is indented on its right border at the level of the aortic arch.

VASCULAR RINGS

Congenital abnormalities of the aortic arch and its major branches result in the formation of vascular rings around the trachea and esophagus with varying degrees of compression (Table 481.1). The origin of these lesions can best be appreciated by reviewing the embryology of the aortic arch (see Fig. 469.1). The most common anomalies include (1) double aortic arch (Fig. 481.1A), (2) right aortic arch with a left ligamentum arteriosum, (3) anomalous innominate artery arising farther to the left on the arch than usual, (4) anomalous left carotid artery arising farther to the right than usual and passing anterior to the trachea, (5) anomalous right subclavian artery, and (6) anomalous left pulmonary artery **(vascular sling)**. In the latter anomaly, the abnormal vessel arises from an elongated main pulmonary artery or from the right pulmonary artery. It courses between and compresses the trachea and the esophagus. Associated congenital heart disease may be present in 5–50% of patients, depending on the vascular anomaly.

Clinical Manifestations

If the vascular ring produces compression of the trachea and/or esophagus, symptoms are frequently present during infancy. Chronic wheezing is exacerbated by crying, feeding, and flexion of the neck. Extension of the neck tends to relieve the noisy respiration. Choking on solid food and vomiting may also be symptoms. Affected infants may have a brassy cough, pneumonia, or rarely, sudden death from aspiration.

Diagnosis

Standard radiographic examination is not usually helpful. In the past, performing a barium esophagogram was the standard method of diagnosis (Fig. 481.2), which has been replaced by echocardiography in combination with either MRI or CT (Fig. 481.3). Cardiac catheterization is reserved for cases with associated anomalies or in rare cases where these other modalities are not diagnostic. Bronchoscopy is helpful in more severe cases to determine the extent of airway narrowing and whether additional surgery is required on the airway.

Treatment

Surgery is advised for symptomatic patients who have evidence of tracheal compression. The anterior vessel is usually divided in patients with a double aortic arch (see Fig. 481.1B). Compression produced by a right aortic arch and left ligamentum arteriosum is relieved by division of the latter. Anomalous innominate or carotid arteries cannot be divided; attaching the adventitia of these vessels to the sternum usually relieves the tracheal compression. An anomalous left pulmonary artery is corrected by division at its origin and reanastomosis to the main pulmonary artery after it has been brought in front of the trachea. Severe tracheomalacia, if present, may require reconstruction of the trachea as well.

481.2 Anomalous Origin of the Coronary Arteries

Daniel Bernstein

Table 481.2 provides a classification system for coronary artery anomalies. Although many of these are isolated, congenital anomalies of the coronary arteries may also be seen in patients with congenital heart disease (tetralogy of Fallot, transposition of the great arteries, congenitally corrected transposition of the great arteries, single ventricle, tricuspid atresia, truncus arteriosus, quadricuspid or bicuspid aortic valves, double-outlet ventricle). In addition, acquired lesions of the coronary arteries associated with existing congenital heart disease may develop because of alterations in blood flow or postoperative stenoses, especially in patients whose surgery involves the aortic root.

Table 481.2 Congenital Anomalies of Coronary Arteries Unassociated with Congenital Heart Disease

ANOMALOUS AORTIC ORIGIN
• Eccentric ostium within an aortic sinus
• Ectopic ostium above an aortic sinus
• Conus artery from the right aortic sinus
• Circumflex coronary artery from the right aortic sinus or from the right coronary artery
• Origin of left anterior descending and circumflex coronary arteries from separate ostia in the left aortic sinus (absence of left main coronary artery)
• Atresia of the left main coronary artery
• Origin of the left anterior descending coronary artery from the right aortic sinus or from the right coronary artery
• Origin of the right coronary artery from the left aortic sinus, from posterior aortic sinus, or from left coronary artery
• Origin of a single coronary artery from the right or left aortic sinus
• Anomalous origin from a noncardiac systemic artery
ANOMALOUS AORTIC ORIGIN WITH ANOMALOUS PROXIMAL COURSE
• Acute proximal angulation
• Ectopic right coronary artery passing between aorta and pulmonary trunk
◦ Ectopic left main coronary artery
◦ Between aorta and pulmonary trunk
◦ Anterior to the pulmonary trunk
◦ Posterior to the aorta
• Within the ventricular septum (intramyocardial)
• Ectopic left anterior descending coronary artery that is anterior, posterior, or between the aorta and pulmonary trunk
ANOMALOUS ORIGIN OF A CORONARY ARTERY FROM THE PULMONARY TRUNK
• Left main coronary artery
• Left anterior descending coronary artery
• Right coronary artery
• Both right and left coronary arteries
• Circumflex coronary artery
• Accessory coronary artery

From Perloff JK, Marelli J. *Perloff's Clinical Recognition of Congenital Heart Disease,* 6th ed. Philadelphia: Saunders; 2012: Table 32-3, p. 532.

ANOMALOUS ORIGIN OF THE LEFT CORONARY ARTERY FROM THE PULMONARY ARTERY

In anomalous origin of the left coronary artery from the pulmonary artery **(ALCAPA)**, the blood supply to the left ventricular (LV) myocardium is severely compromised. Soon after birth, as pulmonary artery pressure falls, perfusion pressure to the left coronary artery (LCA) becomes inadequate; myocardial ischemia, infarction, and fibrosis result. In some cases, interarterial collateral anastomoses develop between the right coronary artery (RCA) and LCA. Blood flow in the LCA is then reversed, and it empties into the pulmonary artery, a condition known as *myocardial steal syndrome.* The LV becomes dilated, and its performance is decreased. Mitral insufficiency is a frequent complication secondary to a dilated valve ring or infarction of a papillary muscle. Localized aneurysms may also develop in the LV free wall. Rare patients have adequate myocardial blood flow during childhood and, later in life, a continuous murmur and a small left-to-right shunt via the dilated coronary system (aorta to RCA to LCA to pulmonary artery).

Clinical Manifestations

Evidence of heart failure becomes apparent within the first few months of life and may be exacerbated by respiratory infection. Recurrent attacks of discomfort, restlessness, irritability, sweating, dyspnea, and pallor occur and represent an infantile version of **angina pectoris**. Diagnosis is often made only after a chest x-ray is obtained looking for other sources of irritability and rapid breathing. Cardiac enlargement ranges from moderate to massive. A gallop rhythm is common.

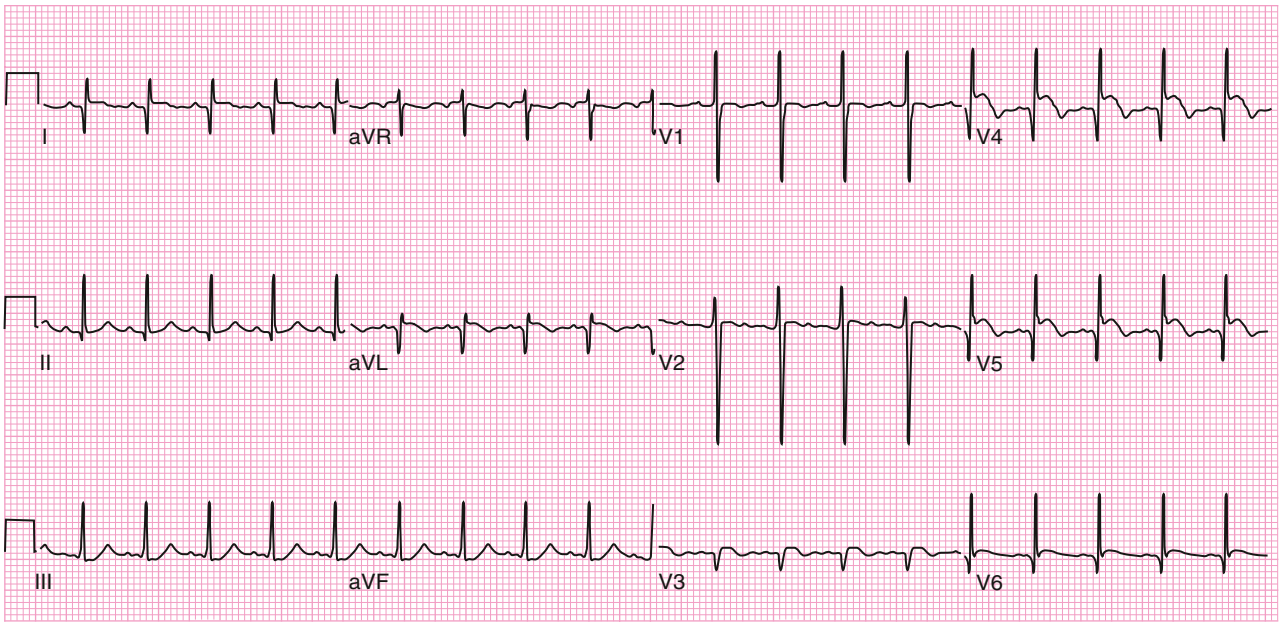

Fig. 481.4 Electrocardiogram of a 2-mo-old with anomalous origin of the left coronary artery from the pulmonary artery. Myocardial infarction is evidenced by abnormal Q waves in leads I and aVL and in the anterolateral precordial leads (V_3, V_4, V_5, V_6). There is also ST elevation in leads V_4 and V_5, a sign of ongoing ischemia. Another sign of ALCAPA is the diminution or loss of R waves in the midprecordial leads (V_2, V_3).

Murmurs may be of the nonspecific ejection type or may be holosystolic because of mitral insufficiency. Older patients with abundant intercoronary anastomoses may have continuous murmurs and less LV dysfunction. However, during older childhood and adolescence, they may experience angina during exercise. Rare patients with an anomalous RCA may also have such clinical findings, especially if the RCA supplies the inferoposterior portion of the LV (right dominant system).

Diagnosis

Radiographic examination confirms cardiomegaly. The electrocardiogram (ECG) can resemble the pattern described in anterolateral wall myocardial infarction in adults, although this pattern can vary over the first weeks of life. A QR pattern followed by flattened or inverted T waves is typically seen in leads I and aVL (Fig. 481.4). The anterolateral precordial leads (V_3-V_6) may show deep Q waves or elevated ST segments and inverted T waves (the more typical adult findings of a lateral myocardial infarction) or may be relatively normal. Decreased or absent R waves may be seen over the mid-precordial leads (V_3, V_4). Given the subtlety of these ECG findings and that an infarct pattern is not usually expected in infants, a high index of suspicion should be maintained for patients with the symptoms described earlier. Two-dimensional (2D) echocardiography with color Doppler usually confirms the diagnosis; however, in rare cases, echocardiography may not be definitive in diagnosing this condition. On 2D imaging alone, the LCA may appear as though it is arising from the aorta. Color Doppler ultrasound has improved the accuracy of diagnosis of this lesion, demonstrating the presence of retrograde flow in the LCA. If needed, CT or MRI can confirm the origin of the coronary arteries. Cardiac catheterization is also diagnostic; aortography shows immediate opacification of the RCA only. In patients who have developed collaterals, this vessel is large and tortuous. After filling of the intercoronary anastomoses, the LCA is opacified, and contrast can be seen to enter the pulmonary artery. Pulmonary arteriography should opacify the origin of the anomalous LCA. Selective left ventriculography usually demonstrates a dilated LV that empties poorly and mitral regurgitation.

Treatment and Prognosis

Untreated, death often occurs from heart failure within the first 6 months of life. Those who survive without surgery generally have abundant intercoronary collateral anastomoses. Medical management includes standard therapy for heart failure (diuretics, angiotensin-converting enzyme inhibitors, and β blockers).

Surgical treatment consists of detaching the anomalous coronary artery from the pulmonary artery and anastomosing it to the aorta to establish normal myocardial perfusion. In patients who have already sustained a significant myocardial infarction, cardiac transplantation may be the only option (see Chapter 492.1).

ANOMALOUS ORIGIN OF THE RIGHT CORONARY ARTERY FROM THE PULMONARY ARTERY

Anomalous origin of the RCA from the pulmonary artery is not usually manifested in infancy or early childhood. The LCA is enlarged, whereas the RCA is thin walled and mildly enlarged. In early infancy, perfusion of the RCA is from the pulmonary artery, whereas later, perfusion is from collaterals of the left coronary vessels. Angina and sudden death can occur in adolescence or adulthood. When recognized, this anomaly should be repaired by reanastomosis of the RCA to the aorta.

ANOMALOUS AORTIC ORIGIN OF A CORONARY ARTERY

In anomalous aortic origin of a coronary artery (AAOCA), one or both coronary arteries arise from their nonusual sinus (e.g., LCA from the right sinus of Valsalva) or high on the aorta, above the sinotubular junction. There are multiple anatomic variations, with different physiologic consequences, and therefore with different risks of coronary ischemia, arrhythmia, and potentially sudden death. Fortunately, most variants of AAOCA are benign, and the challenge for clinicians is to recognize which variants place their patient at a greater risk of a life-threatening event.

The aberrant artery may be a left, right, or major branch coronary artery. The site of origin may be the wrong sinus of Valsalva (anomalous origin of a coronary artery from the opposite sinus, **ACAOS**) or a proximal coronary artery. The ostium may be hypoplastic, slitlike, or of normal caliber. The aberrant vessel may pass anteriorly, posteriorly, or between the aorta and right ventricular outflow tract (RVOT); it may take an intramural course, tunneling in the conal or interventricular septal tissue. Obstruction resulting from hypoplasia of the ostia, tunneling between the aorta and RVOT or interventricular septum, and acute angulation produce myocardial ischemia and infarction. Although unobstructed vessels usually produce no

Table 481.3 Classification of Coronary Anomalies Based on Ischemia

ISCHEMIA	CLASSIFICATION
Absence of ischemia	Most anomalies (split RCA, ectopic RCA from right cusp; ectopic RCA from left cusp)
Episodic ischemia	Anomalous origin of a coronary artery from the opposite sinus (ACAOS); coronary artery fistulas; myocardial bridge
Typical ischemia	Anomalous left coronary artery from the pulmonary artery (ALCAPA); coronary ostial atresia or severe stenosis

RCA, Right coronary artery.
From Mehran R, Dangas GD. Coronary angiography and intravascular imaging. In: Zipes DP, Libby P, Bonow RO, et al., eds. *Braunwald's Heart Disease,* 11th ed. Philadelphia: Elsevier; 2019: Fig. 20.8, p. 385.

symptoms (Table 481.3), patients with coronary obstruction may initially present with an acute coronary event, either acute myocardial infarction, ventricular arrhythmias, angina pectoris, or syncope; sudden death may occur, especially in young athletes.

Diagnostic modalities include ECG, 2D echocardiography, CT or MRI, radionuclide perfusion scan, and cardiac catheterization with selective coronary angiography. Exercise stress testing can play an important role in assessing risk (e.g., in patients who present only with chest pain), but is usually contraindicated in those who present with a sudden cardiac arrest, documented ischemia, or ventricular arrhythmia.

Treatment is indicated for obstructed vessels, for patients with symptoms, and for those who present with a sudden cardiac event and consists of reanastomosis of the aberrant vessel to the correct aortic sinus. The management of asymptomatic patients with ectopic coronary origin without obstruction remains controversial, as the ability to predict risk is still incompletely understood. Management decisions should be based on the specific anatomy, results of laboratory investigations, and shared decision-making with patients and their families after careful explanation of risks and benefits. Surgery is not without complications and should be performed at centers experienced in AAOCA surgery.

The risk appears to be highest with anomalous LCA from the right sinus of Valsalva with interarterial course (see Table 481.3); however, there are patients with anomalous RCA who are also at risk.

481.3 Pulmonary Arteriovenous Fistula

Daniel Bernstein

Fistulous vascular communications in the lungs may be large and localized or multiple, scattered, and small. The most common form of this unusual condition is **Osler-Weber-Rendu syndrome** (hereditary hemorrhagic telangiectasia type I), which is also associated with angiomas of the nasal and buccal mucous membranes, gastrointestinal (GI) tract, or liver. Pathogenic variants in the endoglin gene, a cell surface component of the transforming growth factor (TGF)-β receptor complex, cause this syndrome. The usual communication is between the pulmonary artery and pulmonary vein; direct communication between the pulmonary artery and left atrium is extremely rare. Desaturated blood in the pulmonary artery is shunted through the fistula into the pulmonary vein, thus bypassing the lungs, and then enters the left side of the heart, *resulting in systemic arterial desaturation and sometimes clinically detectable cyanosis.* The shunt across the fistula is at low pressure and resistance, so pulmonary artery pressure is normal; cardiomegaly and heart failure are not present.

The clinical manifestations depend on the magnitude of the shunt. Large fistulas are associated with dyspnea, cyanosis, clubbing, a continuous murmur, and polycythemia. Hemoptysis is rare, but when it occurs, it may be massive. Features of Osler-Weber-Rendu syndrome are seen in approximately 50% of patients (or other family members) and include recurrent epistaxis and GI tract bleeding. Transitory dizziness, diplopia, aphasia, motor weakness, or convulsions may result from cerebral thrombosis, abscess, or paradoxical emboli. Soft systolic or continuous murmurs may be audible over the site of the fistula. The ECG is normal. Chest radiographs may show opacities produced by large fistulas; multiple small fistulas may be visualized by fluoroscopy (as abnormal pulsations), MRI, or CT. Selective pulmonary arteriography demonstrates the site, extent, and distribution of the fistulas.

Treatment consisting of excision of solitary or localized lesions by lobectomy or wedge resection results in complete disappearance of symptoms. In most patients, fistulas are so widespread that surgery is not possible. Any direct communication between the pulmonary artery and the left atrium can be obliterated.

Patients who have undergone a **Glenn cavopulmonary anastomosis** for cyanotic congenital heart disease (see Chapter 479.4) are also at risk for the development of pulmonary **arteriovenous malformations** (AVMs). In these patients the AVMs are usually multiple, and the risk increases over time after the Glenn procedure. Pulmonary AVMs rarely occur after full palliation by completion of the **Fontan operation**. This finding suggests that the pulmonary circulation requires an as-yet-undetermined hepatic factor to suppress the development of AVMs. The hallmark of the development of pulmonary AVMs is a gradual decrease in the patient's oxygen saturation, which is usually lower than normal to begin with. The diagnosis can often be made with contrast echocardiography; cardiac catheterization is the definitive test. Completion of the Fontan circuit, so that inferior vena cava blood flow (containing hepatic venous drainage) is routed through the lungs, usually results in improvement or resolution of the malformations.

481.4 Ectopia Cordis

Daniel Bernstein

In the most common thoracic form of ectopia cordis, the sternum is split and the heart protrudes outside the chest. In other forms, the heart protrudes through the diaphragm into the abdominal cavity or may be situated in the neck. Associated intracardiac anomalies are seen in 40% (tetralogy of Fallot, conotruncal lesions). **Pentalogy of Cantrell** consists of ectopia cordis, midline supraumbilical abdominal defect, deficiency of the anterior diaphragm, defect of the lower sternum, and an intracardiac defect (ventricular septal defect, tetralogy of Fallot, or diverticulum of the left ventricle). Death may occur early in life, usually from infection, cardiac failure, or hypoxemia. Surgical therapy for neonates without overwhelmingly severe cardiac anomalies consists of covering the heart with skin without compromising venous return or ventricular ejection. Repair or palliation of associated defects is also necessary.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

481.5 Diverticulum of the Left Ventricle

Daniel Bernstein

Left ventricular diverticulum is a rare anomaly in which the diverticulum protrudes into the epigastrium. The lesion may be isolated or associated with complex cardiovascular anomalies. A pulsating mass is usually visible and palpable in the epigastrium. Systolic or systolic-diastolic murmurs produced by blood flow into and out of the diverticulum may be audible over the lower part of the sternum and the mass. The ECG shows a pattern of complete or incomplete left bundle branch block. The chest radiograph may or may not show the mass. Associated abnormalities include defects of the sternum, abdominal wall, diaphragm, and pericardium (see earlier). Surgical treatment of the diverticulum and associated cardiac defects can be performed in selected cases. Occasionally, a diverticulum may be small and not associated with clinical signs or symptoms. These small diverticula are diagnosed at echocardiographic examination for other indications.

Chapter 482
Pulmonary Hypertension

482.1 Primary Pulmonary Hypertension

Daniel Bernstein and Rachel K. Hopper

Pulmonary hypertension (PH) refers to an elevated pressure in the pulmonary arteries and is associated with significant morbidity and mortality in children. The etiologies of PH are varied, but all lead to similar symptoms and can ultimately result in right-sided heart failure (Tables 482.1 and 482.2). PH is often characterized by progressive vascular disease of the pulmonary arteries (pulmonary arterial hypertension [PAH], previously called *primary PH*). PH occurs at any age, although in pediatric patients the mean age at diagnosis is 7-10 years. In patients with idiopathic or familial PAH, females outnumber males 1.7:1; in other patients, both genders are represented equally. Pathogenic variants in the *BMPR2* gene, a member of the transforming growth factor (TGF)-β receptor family, on chromosome 2q33 have been identified in 70% of patients with **familial pulmonary arterial hypertension** and in 10–20% with idiopathic sporadic PAH (see Table 482.2). Other potential disease-causing genes include *ALK1* and *ENG* (both associated with hereditary hemorrhagic telangiectasia) and *SMAD9, CAV1, KCNK3,* and *SOX17* (associated with congenital heart disease and PAH). *TBX4* is associated with developmental lung disease and PAH. Viral infection, such as with the vasculotropic human herpesvirus 8, has been suggested as a trigger factor in some patients.

PAH is associated with precapillary obstruction of the pulmonary vascular bed as a result of hyperplasia of the muscular and elastic tissues and a thickened intima of the small pulmonary arteries and arterioles (Fig. 482.1). Secondary remodeling may be found in the larger pulmonary arteries as well. **Pulmonary venoocclusive disease**, mixed precapillary and postcapillary vascular disease, may account for some cases of PAH. Before a diagnosis of PAH can be made, other causes of elevated pulmonary artery pressure must be eliminated; these include chronic pulmonary parenchymal disease, persistent obstruction of the upper airway, congenital cardiac malformations, left-sided heart disease, recurrent pulmonary emboli, developmental lung disease, liver disease, autoimmune disease, and moyamoya disease (see Table 482.1). PAH accounts for nearly half of all pediatric PH (45%), with PAH associated with congenital heart disease being the most common in pediatric patients, followed by idiopathic or familial disease. PH associated with chronic lung disease is growing to encompass a larger portion of new cases, nearly half of all pediatric PH (49%). Bronchopulmonary dysplasia related to prematurity and other developmental lung diseases are increasingly recognized as contributing to PH in children (see Table 482.2).

PH places an afterload burden on the right ventricle, which results in right ventricular hypertrophy (RVH). Dilation of the pulmonary artery is present, and pulmonary valve insufficiency may occur. In the later stages of the disease, the right ventricle dilates, tricuspid insufficiency develops as the tricuspid valve leaflets are pulled apart, and cardiac output is decreased. Arrhythmias, syncope, and sudden death are known complications.

CLINICAL MANIFESTATIONS

The predominant symptoms include exercise intolerance (dyspnea) and fatigability; occasionally, precordial chest pain, dizziness, or headaches are noted. Syncope may be noted in approximately 30% of pediatric patients. Patients often undergo an incorrect evaluation and are treated for asthma or seizures before a proper diagnosis is made. Peripheral cyanosis may be present, especially during exercise or in patients with a patent foramen ovale or other intracardiac communication through which blood can shunt from right to left. In the late stages of disease, patients may have cold extremities and a gray appearance associated with low cardiac output. Arterial oxygen-hemoglobin saturation is usually normal unless there is an associated intracardiac shunt. If right-sided heart failure has supervened, jugular venous pressure is elevated, and hepatomegaly and edema are present. Jugular venous *a* waves are present, and in those with functional tricuspid insufficiency, a conspicuous jugular *cv* wave and systolic hepatic pulsations are manifested. The heart is moderately enlarged, and a right ventricular heave can be noted. The first heart sound is often followed by an ejection click emanating from the dilated pulmonary artery. The second heart sound (S_2) is narrowly split, with a loud pulmonic component that is sometimes booming in quality; it is frequently palpable at the upper left sternal border. A presystolic (S_4) gallop rhythm may be audible at the lower left sternal border. The systolic murmur is soft and short and is sometimes followed by a blowing decrescendo diastolic murmur caused by pulmonary insufficiency. In later stages, a holosystolic murmur of tricuspid insufficiency is appreciated at the lower left sternal border.

DIAGNOSIS

Chest radiographs reveal a prominent pulmonary artery and right ventricle (Fig. 482.2). The pulmonary vascularity in the hilar areas may be prominent, in contrast to the peripheral lung fields in which pulmonary markings are decreased. The electrocardiogram (ECG) shows RVH, often with spiked P waves. Echocardiography is used to screen for any congenital cardiac malformations and assess right ventricular size and function. Doppler evaluation of the tricuspid valve, if insufficiency is present, will allow estimation of the right ventricular (and thus pulmonary arterial) systolic pressure.

At cardiac catheterization, the presence of left-sided obstructive lesions (pulmonary venous stenosis, mitral stenosis, restrictive cardiomyopathy) that result in pulmonary venous hypertension can be evaluated (see Chapters 476.9, 480.7, and 488.3). Elevated pulmonary artery pressures with a normal pulmonary capillary wedge pressure and high vascular resistance is diagnostic of PAH. If the wedge pressure is elevated and left ventricular end-diastolic pressure (LVEDP) is normal, obstruction at the level of the pulmonary veins, left atrium, or mitral valve should be suspected. If LVEDP is also elevated, the diagnosis of restrictive cardiomyopathy should be entertained. The risks associated with cardiac catheterization are increased in severely ill patients with PAH and should occur at centers with expertise in pediatric PH.

PROGNOSIS AND TREATMENT

Many forms of PAH are progressive, and no cure is currently available. Figure 482.3 provides a general treatment approach to PH. Current medical therapies are pulmonary vasodilatory agents, which relieve symptoms, improve quality of life, and delay clinical worsening; however, they do not stop the progression of the disease. Some success has been reported with oral **calcium channel blockers (CCBs)** such as nifedipine in children who demonstrate pulmonary vasoreactivity when these agents are administered during catheterization. Continuous intravenous infusion of the arachidonic acid metabolite **prostacyclin** (epoprostenol) provides relief as long as the infusion is continued and has been shown to improve survival in children with PAH. **Treprostinil**, a prostacyclin analog with a longer half-life, has also been shown to be effective. Nebulized and oral forms of prostacyclin, as well as other oral pulmonary vasodilators, such as endothelin receptor antagonists and phosphodiesterase type 5 inhibitors, have been used with success in adults and in a small number of clinical studies in children (Table 482.3). In patients with PH secondary to left-sided heart disease or lung disease, pulmonary vasodilators should only be considered after optimization of the underlying condition and in consultation with a PH expert.

Anticoagulation may be of value in patients with previous pulmonary thromboemboli; some of these patients may respond to balloon angioplasty of narrowed pulmonary artery segments. Riociguat, a soluble guanylate cyclase stimulator, with vasorelaxation, antiproliferation, and antifibrotic properties, has proved effective in adults with chronic thromboembolic or idiopathic PH. Diuretics are often used to manage right heart failure. Despite many advances, definitive therapy is still lung transplantation (see Chapter 492.2). Palliative interventions may

Table 482.1 Classification of Pulmonary Hypertension (PH)*

1. Pulmonary arterial hypertension (PAH)
   - 1.1 Idiopathic PAH
   - 1.2 Heritable PAH
   - 1.3 Drug- and toxin-induced PAH
   - 1.4 PAH associated with:
     - 1.4.1 Connective tissue disease
     - 1.4.2 HIV infection
     - 1.4.3 Portal hypertension
     - 1.4.4 Congenital heart disease
     - 1.4.5 Schistosomiasis
   - 1.5 PAH long-term responders to calcium channel blockers
   - 1.6 PAH with overt features of venous/capillaries (PVOD/PCH) involvement
   - 1.7 Persistent PH of the newborn syndrome
2. Pulmonary hypertension due to left heart disease
   - 2.1 PH due to heart failure with preserved LVEF
   - 2.2 PH due to heart failure with reduced LVEF
   - 2.3 Valvular heart disease
   - 2.4 Congenital/acquired cardiovascular conditions leading to postcapillary PH
3. Pulmonary hypertension due to lung diseases and/or hypoxia
   - 3.1 Obstructive lung disease
   - 3.2 Restrictive lung disease
   - 3.3 Other lung disease with mixed restrictive/obstructive pattern
   - 3.4 Hypoxia without lung disease
   - 3.5 Developmental lung disorders
4. PH due to pulmonary artery obstructions
   - 4.1 Chronic thromboembolic pulmonary hypertension
   - 4.2 Other pulmonary artery obstructions
5. Pulmonary hypertension with unclear and/or multifactorial mechanisms
   - 5.1 Hematologic disorders
   - 5.2 Systemic and metabolic disorders
   - 5.3 Others
   - 5.4 Complex congenital heart disease.

Pediatric pulmonary hypertension. *J Amer Coll Cardiol.* 2013;62(25):Suppl D, D118–D126, 2013.

include atrial septostomy or a surgical Potts shunt to create a right-to-left shunt as a pop-off to allow decompression of the right ventricle (see Fig. 482.3). In patients with severe PH and low cardiac output, the terminal event is often sudden and related to a lethal arrhythmia. Patients with PH diagnosed in infancy, especially those in premature infants with chronic lung disease, have a high risk of early mortality, but PH generally improves over time if lung growth and protection from infection and injury are achieved. Infants with PH caused by pulmonary vein stenosis often have rapid progression and high mortality.

482.2 Pulmonary Vascular Disease (Eisenmenger Syndrome)

Daniel Bernstein and Rachel K. Hopper

The term *Eisenmenger syndrome* refers to patients with an intracardiac defect or aortopulmonary connection through which blood is shunted

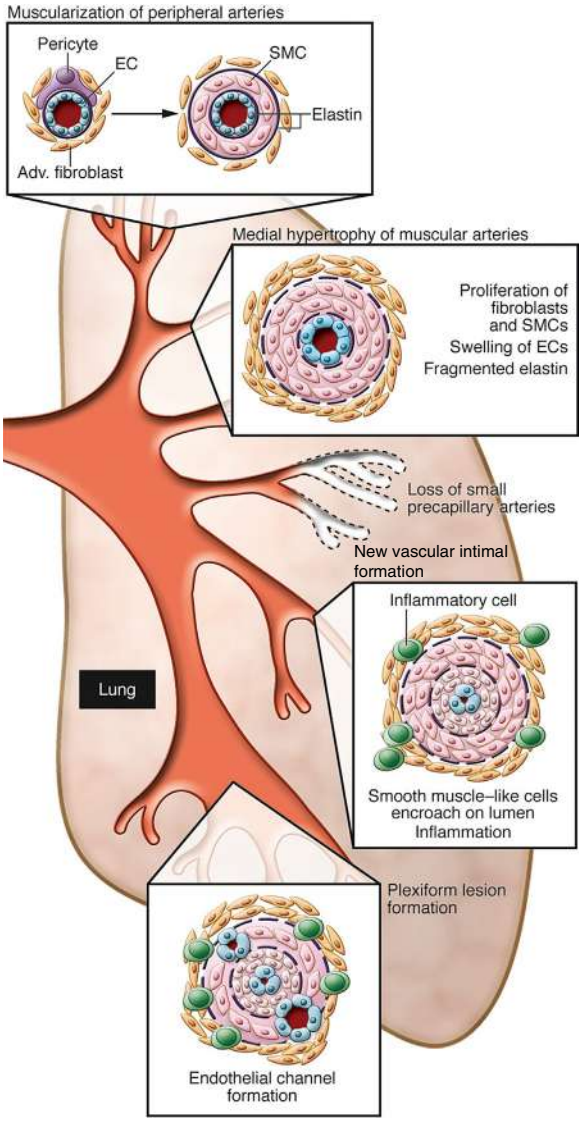

Fig. 482.1 Vascular abnormalities associated with pulmonary arterial hypertension: abnormal muscularization of distal and medial precapillary arteries, loss of precapillary arteries, thickening of large pulmonary arterioles, and new vascular intimal formation that is occlusive in vessels <500-100 μM and in plexiform lesions therein. partially or totally from right to left as a result of the development of pulmonary vascular disease. This physiologic abnormality can occur with unrepaired ventricular or atrioventricular septal defects, patent ductus arteriosus, aortopulmonary window, or any other communication between the aorta and pulmonary artery and in many forms of complex congenital heart disease with unrestricted pulmonary blood flow. Pulmonary vascular disease with an isolated atrial septal defect can occur, but this is less common and usually does not occur until late in adulthood.

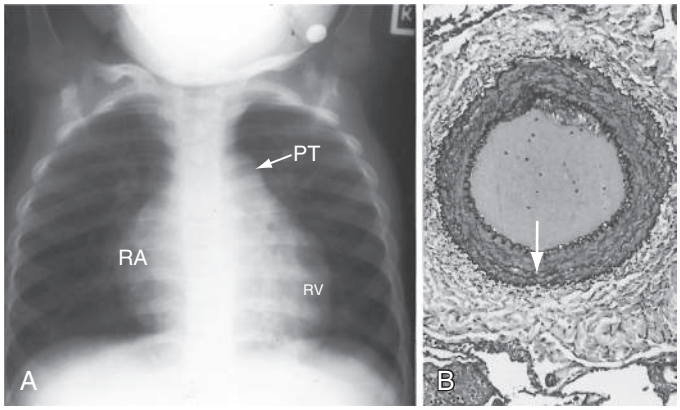

Fig. 482.2 A, Radiograph from a 3-yr-old child with pulmonary arterial hypertension. Pulmonary vascularity is reduced. The pulmonary trunk (PT), right atrium (RA), and right ventricle (RV) are considerably enlarged. B, Histology of an intrapulmonary artery at necropsy shows medial hypertrophy *(arrow). (From Perloff JK, Marelli AJ. Perloff's Clinical Recognition of Congenital Heart Disease, 6th ed. Philadelphia: Saunders; 2012: Fig. 14-17, p. 207.)*

In Eisenmenger syndrome, pulmonary vascular resistance (PVR) after birth either remains high or, after having decreased during early infancy, rises thereafter because of chronic increased shear stress on pulmonary arterioles. Factors playing a role in the rapidity of development of pulmonary vascular disease include increased pulmonary artery pressure, increased pulmonary blood flow, and the presence of hypoxia or hypercapnia. Early in the course of disease, PH is the result of markedly increased pulmonary blood flow (*hyperkinetic* PH). This form of PH decreases with the administration of pulmonary vasodilators such as nitric oxide, or oxygen, or both. With the development of Eisenmenger syndrome, PH is the result of pulmonary vascular disease (obstructive pathologic changes in the pulmonary vessels). This form of PH is usually only minimally responsive to pulmonary vasodilators or oxygen or may be totally unresponsive.

PATHOLOGY AND PATHOPHYSIOLOGY

The pathologic changes of Eisenmenger syndrome occur in the small pulmonary arterioles and muscular arteries (<300 μm) and are graded on the basis of histologic characteristics **(Heath-Edwards classification)**:

- **Grade I** change involves medial hypertrophy alone.
- **Grade II** consists of medial hypertrophy and intimal hyperplasia.
- **Grade III** involves near-obliteration of the vessel lumen.
- **Grade IV** includes arterial dilation.
- **Grades V and VI** include plexiform lesions, angiomatoid formation, and fibrinoid necrosis.

Grades IV-VI indicate irreversible pulmonary vascular obstructive disease. Eisenmenger physiology is usually defined by an absolute elevation in pulmonary arterial resistance to >12 Wood units (resistance units indexed to body surface area) or by a ratio of pulmonary-to-systemic vascular resistance of ≥1.0.

Pulmonary vascular disease occurs more rapidly in patients with trisomy 21 who have left-to-right shunts. It also complicates the natural history of patients with elevated pulmonary venous pressure secondary to mitral stenosis or left ventricular dysfunction,

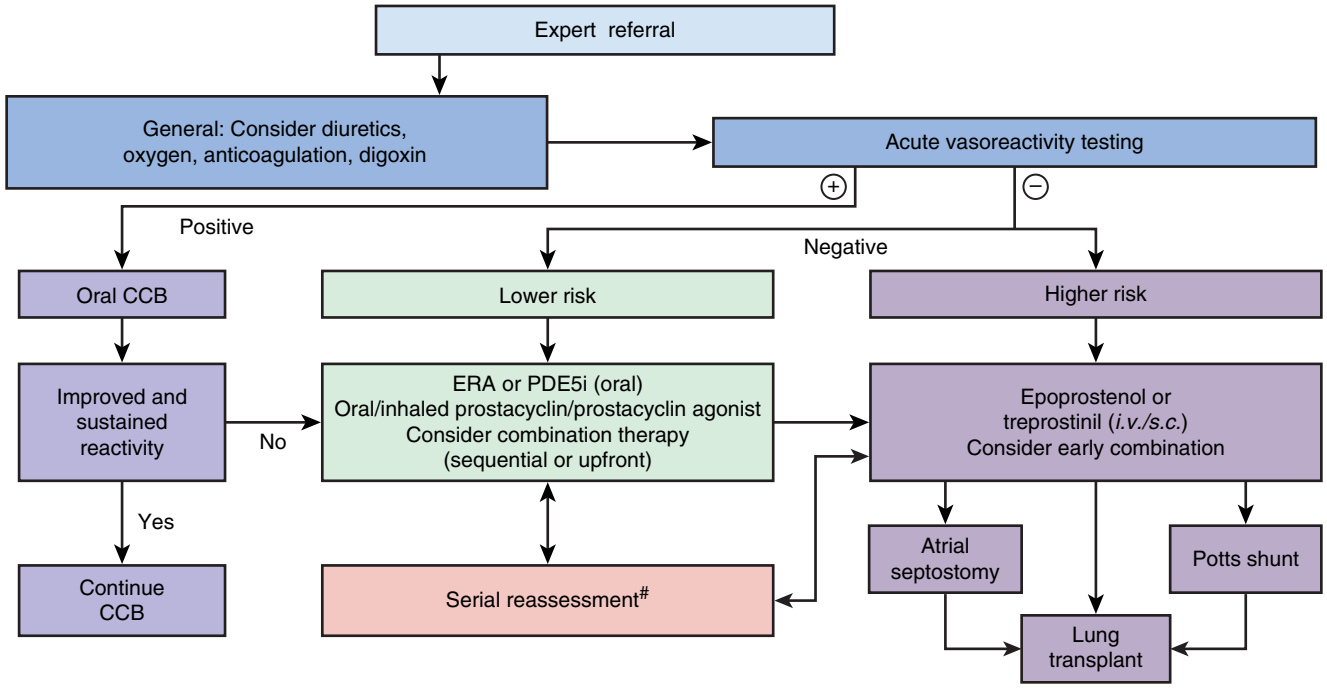

Fig. 482.3 6th World Symposium on Pulmonary Hypertension Consensus pediatric idiopathic/familial PAH treatment algorithm. Use of all agents is considered off-label in children aside from sildenafil in Europe and bosentan in age >3 yr in the United States. CCB, Calcium channel blocker; ERA, endothelin receptor antagonist; PAH, pulmonary arterial hypertension; IV, intravenous; PDE-5i, phosphodiesterase-5 inhibitor; SC, subcutaneous; PO, by mouth; #, deterioration or not meeting treatment goals. *(From Rosenzweig EB, Abman SH, Adatia I, et al. Paediatric pulmonary arterial hypertension: updates on definition, classification, diagnostics and management. Eur Respir J. 2019;53[1]:1801916.)*

Table 482.3 Summary of Drugs Used to Treat Pulmonary Hypertension*

DRUG AND MECHANISM OF ACTION	DOSES USED IN PEDIATRIC STUDIES	COMMON SIDE EFFECTS
Epoprostenol (prostacyclin [PGI_2], a potent vasodilator; also inhibits platelet aggregation)	1-2 ng/kg/min initially Increase based on clinical course and tolerance to 5-80 ng/kg/min Some patients may require even higher doses Must be given by continuous infusion that is not interrupted	Flushing, headache, nausea, diarrhea, hypotension, chest pain, jaw pain, foot and bone pain
Iloprost (synthetic analog of PGI_2)	2.5-5.0 μg 6-9 times daily (limited data in children) via inhalation	Flushing, headache, diarrhea, hypotension, jaw pain, exacerbation of pulmonary symptoms (cough, wheezing)
Treprostinil (synthetic analog of PGI_2)	1-2 ng/kg/min initially Target dose ranges from 20-80 ng/kg/min Given either IV or SC via continuous infusion Longer half-life than epoprostenol *Inhaled:* 6-54 mcg (1-9 patient activated breaths) every 6 hr *Oral:* initially 0.125 mg 3 times daily Target dose ranges from 1 to 10 mg 3 times daily	Flushing, headache, diarrhea, hypotension, jaw pain Pain at infusion site when given SC Inhaled form can exacerbate reactive airway symptoms Increased gastrointestinal side effects with oral formulation
Selexipag (prostacyclin IP receptor agonist)	50-1600 mcg PO twice daily; limited data in children	Headache, pain in jaw, joints or limbs, myalgias, nausea, vomiting, diarrhea, flushing
Ambrisentan (selective endothelin EtA receptor antagonist)	Target dose ranges from 1.25 to 10 mg daily; use ½ dose for first mo	Flushing, headache, hypotension, fluid retention/edema, nasopharyngitis/congestion, vomiting; teratogenicity risk
Bosentan (nonselective endothelin receptor EtA and EtB antagonist)	Starting dose: 0.3-1 mg/kg/dose twice daily PO for first mo For patients <10 kg: max. 2 mg/kg/dose twice daily; 10-20 kg: max. 2 mg/kg/dose twice daily (32 mg tablets); 20-40 kg: 62.5 mg/dose twice daily; >40 kg: 125 mg/dose twice daily	Flushing, headache, hypotension, nasopharyngitis/congestion, fluid retention, edema, vomiting, anemia, elevated transaminases (monthly LFTs required); teratogenicity risk. Caution in concomitant use of CYP3A4 inducers and inhibitors
Macitentan (nonselective endothelin receptor EtA and EtB antagonist)	5-10 mg daily PO; limited data in children	Flushing, headache, fluid retention/edema, anemia, nasopharyngitis/congestion; teratogenicity risk.
Sildenafil (phosphodiesterase type 5 inhibitor)	0.5-1 mg/kg/dose given 3-4 times daily PO For 10-20 kg, use 10 mg 3 times daily; >20 kg, 20 mg 3 times daily Initial dosing should be ½ final target dose to evaluate for hypotension	Flushing, headache, dyspepsia, diarrhea, hypotension, priapism, visual disturbance (blue coloration), tinnitus
Tadalafil (phosphodiesterase type 5 inhibitor)	1 mg/kg/dose given daily PO Maximum adult dose 40 mg daily Initial dosing should be ½ final target dose to evaluate for hypotension	Similar to sildenafil
Riociguat (soluble guanylate cyclase stimulator)	Limited pediatric data Starting adult dose 1 mg tid, can increase to maximum 2.5 mg tid	Hypotension, headache, dizziness, dyspepsia Use with PDE5 inhibitors contraindicated
Calcium channel blockers (amlodipine, diltiazem, nifedipine)	Previously widely used, now indicated only for patients who show a strong response to nitric oxide during cardiac catheterization	Flushing, headache, edema, arrhythmia, headache, hypotension, rash, nausea, constipation, elevated LFTs

*Modified as compared with the Nice 2013 classification.
Note: These medications should only be administered under the direction of a specialist in pulmonary hypertension.
cGMP, Cyclic guanosine monophosphate; IV, Intravenously; LFT, liver function test; SC, subcutaneously.

especially in those with restrictive cardiomyopathy (see Chapter 488.3). Pulmonary vascular disease can also occur in any patient with transmission of systemic pressure to the pulmonary circulation via a shunt at the interventricular or great vessel level and in patients chronically exposed to low partial pressure of oxygen (because of high altitude). Patients with cyanotic congenital heart lesions associated with unrestricted pulmonary blood flow are at particularly high risk.

CLINICAL MANIFESTATIONS

Symptoms do not usually develop until the second or third decade of life, although a more fulminant course may occur. Intracardiac or extracardiac communications that would normally shunt from left to right are converted to right-to-left shunting as PVR exceeds systemic vascular resistance. Cyanosis becomes apparent, and dyspnea, fatigue, and a tendency toward dysrhythmias begin to occur. In the late stages of the disease, heart failure, chest pain, headaches,

syncope, and hemoptysis may be seen. Physical examination reveals a right ventricular heave and a narrowly split S_2 with a loud pulmonic component. Palpable pulmonary artery pulsation may be present at the left upper sternal border. A holosystolic murmur of tricuspid regurgitation may be audible along the left sternal border. An early decrescendo diastolic murmur of pulmonary insufficiency may also be heard along the left sternal border. The degree of cyanosis depends on the stage of the disease. Clubbing of the distal digits may be seen in late disease as a result of chronic hypoxia.

DIAGNOSIS

On chest radiograph, the heart varies in size from normal to greatly enlarged; the latter usually occurs late in the course of the disease. The main pulmonary artery is generally prominent, similar to other causes of PAH (see Fig. 482.2A). The pulmonary vessels are enlarged in the hilar areas and taper rapidly in caliber in the peripheral branches. The right ventricle and atrium are prominent. The ECG shows marked RVH. The P wave may be tall and spiked. Cyanotic patients have various degrees of polycythemia that depend on the severity and duration of hypoxemia.

The echocardiogram shows a thick-walled right ventricle and demonstrates the underlying congenital heart lesion. 2D echocardiography assists in eliminating from consideration lesions such as obstructed pulmonary veins, supramitral membrane, mitral stenosis, and restrictive cardiomyopathy. Doppler studies demonstrate the direction of the intracardiac shunt and the presence of a typical hypertension waveform in the main pulmonary artery. Tricuspid and pulmonary regurgitation can be used in the Doppler examination to estimate pulmonary artery systolic and diastolic pressures.

Cardiac catheterization usually shows a bidirectional shunt at the site of the defect. Systolic pressure is generally equal in the systemic and pulmonary circulations. Pulmonary capillary wedge pressure is normal unless a left-sided heart obstructive lesion or left ventricular failure is the cause of the PAH. Arterial oxygen-hemoglobin saturation is decreased depending on the magnitude of the right-to-left shunt. The response to vasodilator therapy (oxygen, prostacyclin, nitric oxide) may identify patients with less severe disease. Selective pulmonary artery injections may be necessary if pulmonary venous obstruction is suspected because of high wedge pressure and low LVEDP.

TREATMENT

The best management for patients who are at risk for the development of late pulmonary vascular disease is prevention by early surgical elimination of large intracardiac or great vessel communications during infancy. Some patients may be missed because they have not shown early clinical manifestations. Rarely, PVR never decreases at birth in these infants, and therefore they never acquire enough left-to-right shunting to become clinically apparent. Such delayed recognition is a particular risk in patients with congenital heart disease who live at high altitude. It is also a risk in infants with trisomy 21, who have a propensity for earlier development of pulmonary vascular disease. Because of the high incidence of congenital heart disease associated with trisomy 21, routine echocardiography is recommended at the time of initial diagnosis, even in the absence of other clinical findings.

Medical treatment of Eisenmenger syndrome is primarily symptomatic. Many patients benefit substantially from either oral **(CCBs, endothelin antagonist**, **phosphodiesterase inhibitors)** or chronic continuous intravenous **(prostacyclin)** therapy. Combined heart-lung or bilateral lung transplantation is the only surgical option for many of these patients (see Chapter 492.2). Heart-lung transplantation may be the option if there is associated complex congenital heart disease.

Chapter 483

General Principles of Treatment of Congenital Heart Disease

Daniel Bernstein

Most patients who have minor congenital heart lesions do not require treatment. The parents and child should be made aware that a normal life is expected and that no restriction of the child's activities is necessary. Overprotective parents may use the presence of a minor congenital heart lesion or even a functional heart murmur as a means to exert excessive control over their child's activities. Although fears may not be expressed overtly, the child may become anxious regarding early death or debilitation, especially when an adult member of the family acquires unrelated symptomatic heart disease. The family may have an unexpressed fear of sudden death, and the rarity of this manifestation should be emphasized in discussions directed at improving their understanding of the child's congenital heart defect. General health maintenance, including a well-balanced "heart-healthy" diet, aerobic exercise, and avoidance of smoking, should be encouraged.

Even patients with moderate to severe congenital heart disease (CHD) need not be restricted from all physical activity, although many will tend to limit their own activities. Physical education should be modified appropriately to the child's capacity to participate; the extent of such modification can be guided by formal exercise testing in an appropriately equipped pediatric exercise laboratory. Although competitive sports for some patients may need to be discouraged, decisions are made on an individual basis. The influence of coach and peer pressure should be considered when recommending competitive vs noncompetitive athletics. Many cardiologists will also prohibit certain high-impact activities ("collision sports") such as tackle football or contact martial arts in patients who have had prior open heart surgery.

Routine immunizations should be given, with the inclusion of influenza vaccine during the appropriate season. Vaccination against the SARS-CoV-2 virus has been recommended for children with heart disease who are eligible based on age. Prophylaxis against respiratory syncytial virus (RSV) is recommended during RSV season in young infants with unrepaired CHD and significant hemodynamic abnormalities or in those with cardiomyopathy and heart failure. Careful consideration of the timing of administration of live-virus vaccination is required in patients who are potential candidates for heart or heart-lung transplantation, and these patients cannot receive live-virus vaccines after they have received their transplant.

Bacterial infections should be treated vigorously. **Prophylaxis against bacterial endocarditis** should be carried out during dental procedures for appropriate patients (see Chapter 486).

Cyanotic patients need to be monitored for noncardiac manifestations of oxygen deficiency (Table 483.1); however, it is rare today for a patient to remain significantly cyanotic beyond the first few years of life, although mild degrees of cyanosis may be seen in patients with a single ventricle (e.g., hypoplastic left heart) who have a fenestration in their Fontan conduits allowing right-to-left shunting. These patients should be carefully observed for excessive **polycythemia**. Cyanotic patients should avoid situations where dehydration may occur, which leads to increased viscosity and increases the risk of stroke. Diuretics may need to be decreased or temporarily discontinued during episodes of acute gastroenteritis or during excessively hot weather. High altitudes and sudden changes in the thermal environment should also be avoided. Treatment of iron deficiency is important in cyanotic patients, who

Table 483.1 Extracardiac Complications of Cyanotic Congenital Heart Disease and Eisenmenger Physiology

PROBLEM	ETIOLOGY	THERAPY
Polycythemia	Persistent hypoxia	Phlebotomy if symptomatic
Relative anemia	Nutritional deficiency	Iron replacement
CNS abscess	Right-to-left shunting	Antibiotics, drainage
CNS thromboembolic stroke	Right-to-left shunting or polycythemia	Anticoagulation, phlebotomy
Low-grade DIC, thrombocytopenia	Polycythemia	None for DIC unless bleeding, then phlebotomy
Hemoptysis	Pulmonary infarct, thrombosis, or rupture of pulmonary artery plexiform lesion	Embolization
Plastic bronchitis	Fontan procedure	Bronchoscopy, vascular coiling, lymphatic ablation
Gum disease	Polycythemia, gingivitis, bleeding	Dental hygiene
Gout	Polycythemia, diuretic agent	Allopurinol
Arthritis, clubbing	Hypoxic osteoarthropathy	None
Pregnancy complications: miscarriage, fetal growth retardation, prematurity increase, maternal illness	Poor placental perfusion, poor ability to increase cardiac output	Pregnancy prevention counseling, high-risk obstetric management
Infections	Associated asplenia, DiGeorge syndrome, endocarditis	Antibiotics
	Fatal RSV pneumonia with pulmonary hypertension	RSV monoclonal antibodies* (prevention)
Failure to thrive	Increased oxygen consumption, decreased nutrient intake	Treat heart failure; correct defect early; increase caloric intake
Protein-losing enteropathy	s/p Fontan; high right-sided pressures	Oral budesonide or sildenafil
Chylothorax	Injury to thoracic duct	Medium-chain triglyceride diet Octreotide Surgical ligation of thoracic duct
Neurodevelopmental disabilities	Chronic hypoxia, cardiac surgery, genetic	Early school-based evaluation and intervention
Psychosocial adjustment	Limited activity, cyanotic appearance, chronic disease, multiple hospitalizations	Counseling

*Palivizumab, nirsevimab.
CNS, Central nervous system; DIC, disseminated intravascular coagulation; RSV, respiratory syncytial virus; s/p, status post (after).

may have a low mean corpuscular hemoglobin concentration despite polycythemia. The risk of stroke for these patients can be reduced if the red blood cells are not microcytic. Phlebotomy with partial exchange transfusion is carried out only in symptomatic patients with severe polycythemia (usually those with hematocrit >65%).

Patients with moderate to severe forms of CHD or a history of rhythm disturbance should be carefully monitored during anesthesia for even routine surgical or dental procedures. Consultation with an anesthesiologist experienced in the care of children with CHD is recommended even if the surgical procedure is not cardiac related.

Females with unrepaired severe CHD should be counseled on the risks associated with childbearing and on the use of contraceptives and other methods to prevent pregnancy (see Chapter 483.1). Females with mild to moderate CHD and many who have had corrective surgery can have normal pregnancies, although those with residual hemodynamic derangements or with systemic right ventricles (RVs) should be followed by a high-risk perinatologist and a cardiologist with expertise in caring for adults with CHD. Pregnancy may be highly dangerous to both mother and fetus for patients with palliated (rather than repaired) complex CHD, chronic cyanosis, or pulmonary arterial hypertension; for patients with a Fontan circulation, the miscarriage rate has been reported as ranging from 27% to 50% and the rate of prematurity at 69%. Risks to the mother include heart failure, thromboembolism, and arrhythmia. Several risk stratification schemes have been developed for pregnant women with CHD, including the Cardiac Disease in Pregnancy **(CARPREG)** score, the Zwangerschap bij Aangeboren HARtAfwijkingen **(ZAHARA)** score, and the World Health Organization (WHO) classification. Based on the WHO system, patients for whom pregnancy is associated with increased risk of mortality or morbidity include those with a systemic RV (e.g., corrected transposition with good function), Fontan circulation, repaired coarctation of the aorta bicuspid aortic valve with enlarged aortic root of 45-50 mm, **Marfan syndrome** with enlarged aortic root of 40-45 mm, atrioventricular septal defects, moderate mitral stenosis, severe aortic stenosis, and mechanical valve replacement. Patients for whom pregnancy is considered contraindicated include those with pulmonary arterial hypertension, Ehlers-Danlos syndrome, severe recoarctation of the aorta, Fontan circulation with any complications, severe aortic or mitral stenosis, severe aortic dilation, and systemic ventricular dysfunction with ejection fraction <30%.

POSTOPERATIVE MANAGEMENT

After successful open heart surgery, the severity of the congenital heart defect, the age and condition (nutritional status) of the patient before surgery, the events in the operating room (OR), and the quality of the postoperative care influence the patient's course. **Intraoperative** factors that influence survival and that should be noted when a patient returns from the OR include the duration of **cardiopulmonary bypass** (CPB), duration of **aortic cross-clamping** (time the heart is not being perfused), and duration of **profound hypothermia** (used in some newborns; time the entire body is not being perfused). Surgical techniques to provide ongoing perfusion to the upper body and brain even during surgery on the aortic arch (e.g., in hypoplastic left heart syndrome [HLHS]) have eliminated the use of profound hypothermia in many centers.

Immediate postoperative care should be provided in an intensive care unit (ICU) staffed by a team of physicians, nurses, and technicians experienced with the unique problems encountered after open heart surgery in childhood. In most major centers, this occurs in a dedicated pediatric cardiovascular ICU. Preparation for postoperative monitoring begins in the OR, where the anesthesiologist or surgeon places an arterial catheter to allow direct arterial pressure measurements and arterial sampling for blood gas determination. A central venous catheter is also placed for measuring central venous pressure and for infusions of cardioactive medications. In more complex cases, right or left atrial or pulmonary artery catheters may be inserted directly into these cardiac structures and used for pressure monitoring purposes. Temporary pacing wires are placed on the atrium or ventricle, or both, in case temporary postoperative heart block occurs. Transcutaneous oximetry provides for continuous monitoring of arterial oxygen saturation. Near-infrared spectroscopy is used to monitor cerebral and other end-organ perfusion in the perioperative period.

Functional failure of one organ system may cause profound physiologic and biochemical changes in another. Respiratory insufficiency, for example, leads to hypoxia, hypercapnia, and acidosis, which in turn compromise cardiac, vascular, and renal function. The latter problems cannot be managed successfully until adequate ventilation is reestablished. Thus it is essential that the primary source of each postoperative problem be identified and treated.

Respiratory failure is a serious postoperative complication encountered after open heart surgery. CPB performed in the presence of pulmonary congestion results in decreased lung compliance, copious tracheal and bronchial secretions, atelectasis, and increased breathing effort. Because fatigue and subsequently hypoventilation and acidosis may rapidly ensue, mechanical positive pressure endotracheal ventilation is usually continued after open heart surgery for a minimum of several hours in relatively stable patients and for up to 2-3 days or longer in severely ill patients, especially infants. Protocols for early extubation have been successfully used in older children with uncomplicated intraoperative courses. Patients with certain congenital heart lesions, particularly those with **DiGeorge syndrome**, may also have airway abnormalities (micrognathia, tracheomalacia, bronchomalacia) that can make both ventilation and extubation more difficult.

The electrocardiogram (ECG) should be monitored continuously during the postoperative period. A change in heart rate, even without arrhythmia, may be the first indication of a serious complication such as hemorrhage, hypothermia, hypoventilation, or heart failure. **Cardiac rhythm disorders** must be diagnosed quickly because a prolonged untreated arrhythmia may add a severe hemodynamic burden to the heart in the critical early postoperative period (see Chapter 484). Injury to the heart's conduction system during surgery can result in postoperative complete heart block. This complication is usually temporary and is treated with surgically placed pacing wires that can later be removed. Occasionally, complete heart block is permanent. If heart block persists beyond 10-14 days postoperatively, insertion of a permanent pacemaker is required. Tachyarrhythmias are a common problem in postoperative patients. Junctional ectopic tachycardia (JET) can be a particularly troublesome rhythm to manage, although it usually responds to antiarrhythmic medications such as intravenous amiodarone.

Heart failure with poor cardiac output after cardiac surgery may be secondary to respiratory failure, serious arrhythmias, myocardial injury, blood loss, hypovolemia, a significant residual hemodynamic abnormality, or any combination of these factors. Treatment specific to the cause should be instituted. Catecholamines, phosphodiesterase inhibitors, nitroprusside and other afterload-reducing agents, and diuretics are the cardioactive agents most often used in patients with myocardial dysfunction in the early postoperative period (see Chapter 491). Postoperative pulmonary hypertension can be managed with hyperventilation and inhaled nitric oxide (iNO). In the rare patients who are unresponsive to standard pharmacologic treatment, various ventricular assist devices are available, depending on the patient's size. If pulmonary function is adequate, a **left ventricular assist device (LVAD)** may be used. If pulmonary function is inadequate, **biventricular assist devices (BVAD)** or **extracorporeal membrane oxygenation (ECMO)** may be used. These extraordinary measures are helpful in maintaining the circulation until cardiac function improves, usually within 2-5 days. They have also been used as a bridge to transplantation in patients with severe nonremitting postoperative cardiac failure.

Acidosis secondary to low cardiac output, renal failure, or hypovolemia must be prevented or, if present, promptly corrected. Serial monitoring of arterial blood gases (ABGs) and lactate concentrations is performed. A low arterial pH may be a sign of decreased perfusion, and acidosis can worsen cardiac function and may be the forerunner of arrhythmias or cardiac arrest.

Renal function may be compromised by congestive heart failure and further impaired by prolonged CPB. Blood and fluid replacement, cardiac inotropic agents, and vasodilators will usually reestablish normal urine flow in patients with hypovolemia or cardiac failure. Renal failure secondary to tubular injury contributes to postoperative fluid overload and may require temporary peritoneal or hemodialysis or hemofiltration. With attention paid to renal injury during the perioperative period, the incidence and severity of chronic renal failure can be reduced.

Neurologic abnormalities can develop after CPB, especially in the neonatal period. Seizures may occur when the patient awakens from sedation and can usually be controlled with anticonvulsant medications. In the absence of other neurologic signs, self-limited isolated seizures in the immediate postoperative period usually carry a good long-term prognosis. Thromboembolism and stroke are rarer but serious complications of open heart surgery. In the long term, both subtle and more substantial learning disabilities may develop. Patients who have undergone surgery entailing CPB, especially in the newborn period, should be watched carefully during their early school years for signs of mild to moderate learning disabilities or attention deficit disorders, which are often amenable to early remedial intervention. The risk is higher in patients who have undergone repair using hypothermic total circulatory arrest than in those where systemic blood flow is maintained using CPB. With the increased recognition of the genetic link between CHD and moderate or greater neurodevelopmental delay, many of these cases may have multifactorial etiologies.

Postpericardiotomy syndrome may occur toward the end of the first postoperative week or may sometimes be delayed until weeks or months after surgery (Table 483.2). This febrile illness is characterized by fever, decreased appetite, listlessness, nausea, and vomiting. Chest pain is not always present, so a high index of suspicion should be maintained in any recently postoperative patient. Echocardiography is diagnostic. In most instances, postpericardiotomy syndrome is self-limited; when pericardial fluid accumulates rapidly, the potential danger of cardiac tamponade should be recognized (see Chapter 489).

Table 483.2 Postpericardiotomy Syndrome (PPS) Findings

FINDING	PERCENTAGE
SYMPTOMS	
Pleuritic or pericarditic chest pain	>50
Intermittent, low-grade fever	~50
CLINICAL FINDINGS	
Pericardial friction rub	20–30
Elevated C-reactive protein (CRP)	80–90
Elevated erythrocyte sedimentation rate (ESR)	80–90
Leukocytosis	80–90
Electrocardiogram (ECG): low voltage of the QRS, T-wave inversion, ST elevation or depression	~50
IMAGING	
Chest x-ray: pleural effusion	>90
Heart echocardiography: pericardial effusion	~90
Mild (<10 mm)	~75*
Moderate (10-20 mm)	~10*
Large (>20 mm)	~5
Pleuropericardial involvement	>80

*Of all PPS patients

From Lehto J, Kiviniemi T. Postpericardiotomy syndrome after cardiac surgery. *Ann Med.* 2020;52(6):243–264, Table 1.

Rarely, arrhythmias may also occur. Symptomatic patients usually respond to salicylates, indomethacin, or colchicine and bed rest. Occasionally, corticosteroid therapy or pericardiocentesis is required. Late recurrences are rare and can lead to chronic pericarditis.

Hemolysis of mechanical origin is seen, although rarely, after repair of certain cardiac defects, for example, atrioventricular septal defects (AVSDs), or after the insertion of a mechanical prosthetic valve. It is caused by unusual turbulence of blood at increased pressure. Reoperation may be necessary in rare patients with severe and progressive hemolysis who require frequent blood transfusions, but in most cases the problem slowly regresses.

Infection is another potentially serious postoperative problem. Patients usually receive a broad-spectrum antibiotic for the initial postoperative period. Potential sites of infection include the lungs (generally related to postoperative atelectasis), the subcutaneous tissues at the incision site, the sternum, and the urinary tract (especially after an indwelling catheter has been in place). Sepsis with infective endocarditis is an infrequent complication and can be difficult to manage, especially if prosthetic material was placed at surgery (see Chapter 486). Patients who undergo CPB during a viral infection, even if mild, can develop severe complications; therefore many anesthesiologists will postpone elective surgery if a child presents with a viral infection, either upper respiratory or gastrointestinal.

INTERSTAGE MANAGEMENT

One group of infants at particularly high risk for both morbidity and mortality are those who have completed their first-stage **Norwood** or **Sano** palliation for HLHS and are awaiting the next stage **(Glenn shunt)** of their three-stage palliation. Mortality in this group of infants had been reported as high as 10–15%, motivating the National Pediatric Cardiology Quality Improvement Collaborative **(NPC-QIC)** to develop an **interstage home monitoring program** that has been successful in reducing interstage mortality by 44%.

LONG-TERM MANAGEMENT

Patients who have undergone surgery for CHD can be divided into three major categories: lesions for which total repair has been achieved; lesions for which both anatomic and physiologic corrections have been achieved; and lesions for which only palliation, although potentially long term, has been achieved. There is some disagreement among cardiologists as to exactly in which category a particular congenital heart lesion might fall, and to some degree every case should be considered individually. Many argue that only for isolated patent ductus arteriosus (PDA) is total repair really achieved, with no requirement for long-term follow-up. Patients who are able to undergo anatomic and physiologic correction include many of the left-to-right shunt lesions (atrial and ventricular septal defects) and milder forms of obstructive lesions (e.g., valvar pulmonic stenosis, some forms of valvar aortic stenosis, coarctation of aorta) and some forms of cyanotic heart disease (e.g., uncomplicated tetralogy of Fallot, simple transposition of great arteries). These patients usually have achieved total or near-total physiologic correction of their lesion; however, they are still at some risk of long-term sequelae, including late heart failure or arrhythmia, or recurrence of a significant physiologic abnormality (e.g., recoarctation of aorta, worsening mitral regurgitation in patients with AVSDs, long-standing pulmonary regurgitation in patients with tetralogy of Fallot repaired with transannular patch). These patients require regular follow-up with a pediatric cardiologist (and, when old enough, with an **adult congenital heart disease specialist**; see Chapter 483.1); however, their long-term prognosis is generally very good, although some will require repeat surgeries or catheter-based interventions. Patients with more complex lesions, such as those with single-ventricle physiology (e.g., hypoplastic left or right heart syndrome), are at much higher risk of long-term sequelae and require even closer follow-up. These patients, particularly those who have undergone the Fontan procedure, are at risk long-term for arrhythmia, thrombosis, protein-losing enteropathy, plastic bronchitis, hepatic dysfunction (Fontan-associated liver disease or FALD), renal dysfunction, and heart failure. Some may eventually require heart, heart-liver, or heart-kidney transplantation.

Physical limitations in patients with CHD are variable, ranging from minimal to none in patients with physiologic correction to mild to moderate in patients with palliative procedures. The extent to which a patient should be allowed to participate in athletics, both recreational and competitive, can best be determined by the cardiologist, often with formal cardiopulmonary exercise testing (see Chapter 472.5).

Long-term morbidities affecting neurologic function and behavior are influenced by many factors, including the effects of any genetic alterations on the developing central nervous system (CNS). There may be a greater role for prenatal CNS abnormalities (anatomic, genetic, or secondary lesions caused by alterations in fetal cerebral blood flow or oxygenation); these include microcephaly, cerebral atrophy, and altered cerebral biochemistry. Chronic hypoxemia and failure to thrive may also influence the developing brain, and there is evidence that the type of intervention required (CPB, hypothermic total circulatory arrest, catheter-based therapy) plays a substantial role. Data from the **Pediatric Cardiac Genomics Consortium** have shown that there is also a genetic component to these learning disabilities. Performing exome sequencing on patients and their parents (trios), de novo gene variants were found in 2% of patients with CHD but in 20% of patients with CHD and neurodevelopmental delay. The identity of these gene variants and their mechanism of action is under study. In general, in the absence of a significant genetic syndrome or major perioperative complication, most children function at a fairly high level after repair of congenital heart defects and are able to attend regular school. Group mean scores on standard cognitive tests are no different from the general population; however, some areas appear to be more at risk than others, including certain aspects of motor function, speech, visual-motor tracking, and phonologic awareness. Awareness of these potential issues is critical to obtaining prompt remedial assistance if a child is found to be struggling in school.

483.1 Congenital Heart Disease in Adults

Salil Ginde and Michael G. Earing

Approximately 90% of children with CHD survive to adulthood. More adults than children are living with CHD in the United States, with a 5% increase every year. In the past decade, 35% of hospitalizations for CHD were patients older than 18 years (mean age: 55 years).

LONG-TERM MEDICAL CONSIDERATIONS

Approximately 25% of adults with CHD have a mild form that has allowed them to survive into adulthood without surgical or interventional cardiac catheterization. The most common lesions in this category include mild aortic valve stenosis (usually in the setting of a bicuspid aortic valve), small restrictive ventricular septal defects (VSDs), mild pulmonary valve stenosis, and mitral valve prolapse (Table 483.3). These patients need less frequent follow-up to assess for progression of disease and to identify associated complications. Many adults with CHD living in the United States are patients who have had previous intervention (Table 483.4). Although most children who undergo surgical intervention will survive to adulthood, with few exceptions, *total correction is not the rule.* The few exceptions include PDA, VSDs, and atrial septal defects (ASDs); this is true only if they are closed early, before the development of irreversible pulmonary vascular changes, and if no residual lesions exist.

It has become apparent that even the simplest congenital heart lesions can be associated with long-term complications, including both cardiac and noncardiac problems (Tables 483.5 and 483.6 and Fig. 483.1). *Cardiac* complications include arrhythmias and conduction defects, ventricular dysfunction, residual shunts, valvular lesions (regurgitation and stenosis), hypertension, and aneurysms. *Noncardiac* sequelae **(comorbidities)** include pulmonary, renal, and hepatic dysfunction that is caused either directly or indirectly by the underlying CHD. Abnormal pulmonary function most often presents as restrictive lung physiology and likely results

Table 483.3 Congenital Heart Defects Associated with Survival into Adulthood Without Surgery or Interventional Cardiac Catheterization

Mild pulmonary valve stenosis
Bicuspid aortic valve
Small to moderate-sized atrial septal defect
Small ventricular septal defect
Small patent ductus arteriosus
Mitral valve prolapse
Partial atrioventricular canal (ostium primum atrial septal defect and cleft mitral valve)
Marfan syndrome
Ebstein anomaly
Congenitally corrected transposition (atrioventricular and ventriculoarterial discordance)

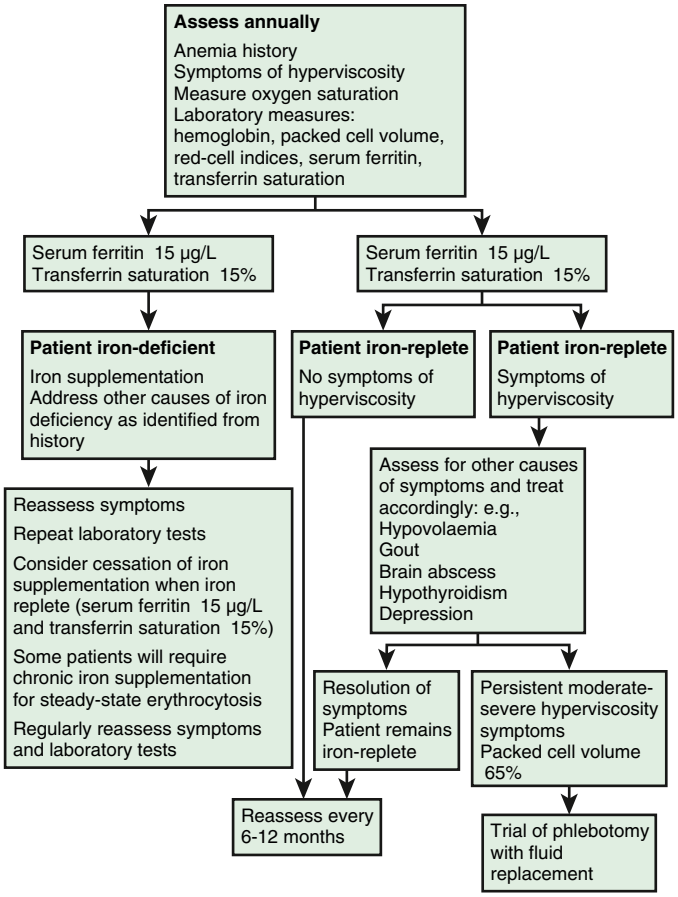

Fig. 483.1 Algorithm detailing crucial issues to address at transition to adulthood in patients with cyanotic congenital heart disease. *(From Spence MS, Balaratnam MS, Gatzoulis MA. Clinical update: cyanotic adult congenital heart disease. Lancet. 2007;370:1531.)*

from prior sternotomy or thoracotomy, scoliosis, diaphragmatic dysfunction, or parenchymal lung disease. Reduced pulmonary function contributes to reduced exercise tolerance and is a risk factor for mortality in adults with CHD. Renal dysfunction may result from chronic cyanosis, multiple surgeries requiring CPB, or from other comorbid conditions, such as hypertension and diabetes mellitus. Hepatic injury from chronic liver congestion in patients with elevated central venous pressures, particularly patients palliated with the Fontan procedure, can result in hepatic fibrosis, cirrhosis, hepatic dysfunction, and rarely, hepatocellular carcinoma. Adults with CHD are at risk for developmental abnormalities such as intellectual impairment, somatic abnormalities such as facial dysmorphism (cleft palate/lip), CNS abnormalities such as seizure disorders from previous thromboembolic events or cerebrovascular accidents, and impairments of hearing or vision loss. Psychosocial problems involving employment, life and health insurance, participation in sports, sexual activity, and contraception are common. Mental health issues, such as anxiety and depression, are common in adults with CHD and are often underrecognized and significantly affect quality of life. As a result of these long-term complications, the majority of adults with CHD need lifelong follow-up, ideally in an integrated, collaborative, and multidisciplinary program. When adults with CHD are hospitalized, it is usually for heart failure or an arrhythmia; others may require catheterization or another cardiac surgical procedure.

SPECIFIC LESIONS

Left-to-Right Shunts

In general, the long-term outcomes of adults with a history of shunt lesions that underwent repair early in life are good with near-normal life expectancy and relatively low risk for cardiac complications. However, if the initial lesion has a shunt that is large and nonrestrictive (allowing transmission of near-systemic pressure to the pulmonary arteries) and is unrepaired, irreversible pulmonary vascular changes can occur, resulting in pulmonary hypertension at systemic levels with reversed or bidirectional shunting at the level of the defect (**Eisenmenger syndrome**; see Chapter 482.2).

Atrial Septal Defects

See Chapter 475.1.

Although most individuals with an ASD are diagnosed during childhood after a murmur is noted, a minority of patients present with symptoms for the first time as adults. Most patients are asymptomatic during the first and second decades of life. In the third decade, an increasing number of patients then develop exercise intolerance, palpitations from atrial arrhythmias, and cardiac enlargement. If untreated, survival into adulthood is the rule; life expectancy is reduced, however, and there is significant long-term morbidity. After age 40 the mortality rate increases by 6% per year, and >20% of patients will have developed atrial fibrillation (AF). By age 60 the number of patients with AF increases to >60%.

Late Outcome After Closure of Atrial Septal Defect

Most patients who have undergone early ASD closure will have excellent long-term survival with low morbidity if repair is undertaken before age 25 years. Older age at repair is associated with decreased late survival with an associated increased risk for the development of atrial arrhythmias, thromboembolic events, and pulmonary hypertension. Long-term late complications and survival after transcatheter device closure remain unknown; early and intermediate results are excellent, with a high rate of ASD closure and few major complications.

Ventricular Septal Defects

See Chapter 475.6.

Although isolated VSDs are among the most common forms of CHD, the diagnosis of a VSD in an adult is rare. The primary reason is that most patients with a hemodynamically significant VSD will have undergone repair in childhood or will have died earlier in life. As result, the spectrum of isolated VSD in adults is limited to (1) those with small restrictive defects, (2) those with Eisenmenger syndrome, and (3) those who had their defects closed in childhood.

For patients with **small restrictive VSD**, long-term survival is excellent, with estimated 25-year survival of 96%. In addition, the long-term morbidity for patients with a restrictive VSD also appears to be low. Their clinical course is not completely benign. Reported long-term complications include endocarditis, progressive aortic regurgitation secondary to prolapse of the aortic valve into the defect (highest risk is with supracristal type but also can occur in setting of perimembranous defect), and the development of both right and left outflow tract obstruction from a double-chamber RV or a subaortic membrane. For patients who develop **Eisenmenger syndrome**, survival into the third decade is common. With increasing age, the long-term complications of right-sided heart failure, paradoxical emboli, and polycythemia usually result in progressive decline in survival, with death at an average age of 37 years.

Adults with **previous VSD closure**, without pulmonary hypertension or residual defects, live a normal life expectancy. Because patients with small VSDs are asymptomatic, these patients should be managed conservatively. Given the long-term risks, they do need intermittent follow-up for life to monitor for the development of late complications. The exception to this rule is patients with small supracristal or perimembranous VSD with associated prolapse of the aortic cusp into the defect resulting in progressive aortic regurgitation. These patients should be considered for surgical repair at diagnosis to prevent progressive aortic valve damage.

Complete Atrioventricular Canal

See Chapter 475.5.

The natural history for patients with complete AVSD is characterized by the early development of pulmonary vascular disease, leading to irreversible damage often by age 1 year (especially in children with Down syndrome). Thus patients who present in adulthood can be categorized into two groups: those with Eisenmenger syndrome and those who had their defects closed in childhood.

Overall, for those patients who underwent early repair before the development of pulmonary vascular disease, the long-term prognosis is good. The most common long-term complication is **left atrioventricular valve regurgitation**, with approximately 5–10% of patients requiring surgical revision for left atrioventricular valve repair or replacement during follow-up. The second most common long-term complication for this patient group is **subaortic stenosis**, occurring in up to 5% of patients after repair. Other long-term complications include residual atrial- or ventricular-level shunts, complete heart block, atrial and ventricular arrhythmias, and endocarditis.

For patients who have developed Eisenmenger syndrome, all are symptomatic with exertional dyspnea, fatigue, palpitations, edema, and syncope. Survival is similar to other forms of Eisenmenger syndrome, with a mean age at death of 37 years. Strong predictors for death include syncope, age at presentation of symptoms, poor functional class, low oxygen saturation (<85%), elevated serum creatinine and uric acid concentrations, and Down syndrome.

Patients who underwent previous repair and develop significant left atrioventricular valve regurgitation causing symptoms, atrial arrhythmias, or deterioration in ventricular function should undergo elective valve repair or replacement. Those previously repaired patients who develop significant subaortic stenosis (defined as a peak cardiac catheterization or echo gradient of >50 mm Hg) should undergo surgical repair.

Patent Ductus Arteriosus

See Chapter 475.8.

A PDA is usually an isolated lesion in the adult patient. The size of the defect is the primary determinant of clinical course in the adult patient. These clinical courses can be grouped into five main categories: silent PDAs; small, hemodynamically insignificant PDAs; moderate-size PDAs; large PDAs; and previously repaired PDAs.

A **silent** PDA is a tiny defect that cannot be heard by auscultation and is only detected by other means such as echocardiography. Life expectancy is always normal in this population, and the risk for endocarditis is extremely low.

Patients with a **small** PDA have an audible long-ejection or continuous murmur heard best at the left upper sternal border that radiates to the back. In addition, they have normal peripheral pulses. Because there is negligible left-to-right shunting these patients have normal left atrial and left ventricle (LV) size and normal pulmonary artery pressure by echocardiography and chest x-ray film. These patients, like those with silent PDAs, are asymptomatic and live a normal life expectancy. They have a higher risk for endocarditis.

Patients with **moderate-size** PDAs may present during adulthood. These patients often will have wide, bounding peripheral pulses and an audible continuous murmur. These patients all have significant volume overload and develop some degree of left atrial and LV enlargement and some degree of pulmonary hypertension. These patients are symptomatic with dyspnea, palpitations, and heart failure.

Patients with **large** PDAs typically present with signs of severe pulmonary hypertension and Eisenmenger syndrome. By adulthood, the continuous murmur is typically absent and there is differential cyanosis (lower-extremity saturations lower than the right arm saturation). These patients have a similar prognosis as other patients with Eisenmenger syndrome.

Patients who underwent **repair** of a PDA before the development of pulmonary hypertension have a normal life expectancy without restrictions.

All patients with *clinical evidence* of a PDA are at increased risk for endocarditis. As result, all PDAs except for small silent PDAs and those patients with severe irreversible pulmonary hypertension should be considered for closure. Catheter device closure is the preferred method in most centers today. Surgical closure is reserved for patients with PDA too large for device closure or when the anatomy is distorted, as in the setting of a large ductal aneurysm.

Cyanotic Heart Disease

See Chapters 478, 479, and 480.

Unlike the acyanotic forms of CHD, the majority of patients with cyanotic CHD will have had at least one and often several previous interventions before adulthood. The most frequent defects seen in the outpatient adult CHD setting are tetralogy of Fallot, complete transposition of the great arteries (TGA, also known as *d-transposition*), pulmonary valve stenosis, and various forms of functional single ventricles. Other defects include total anomalous pulmonary venous return, truncus arteriosus, and double-outlet RV.

Tetralogy of Fallot

See Chapter 479.1.

In the developed world, the unoperated adult patient with tetralogy of Fallot is a rarity because the majority of patients will have undergone palliation or, more often, repair in childhood. Only 11% of unoperated patients are alive by age 20 and only 3% by age 40.

Late survival after repair of tetralogy of Fallot is excellent. Repair is typically performed at 3-12 months of age and consists of patch closure of the VSD and relief of the pulmonary outflow tract obstruction by patch augmentation of the right ventricular outflow tract, pulmonary valve annulus, or both. Survival rates at age 32 and 35 years have been reported to be 86% and 85%, respectively, compared with 95% in age- and sex-matched controls. Most patients live an unrestricted life. Many patients do develop late symptoms that include exertional dyspnea, palpitations, syncope, and sudden cardiac death. Late complications include endocarditis, aortic regurgitation with or without aortic root dilation (typically caused by damage to the aortic valve during VSD closure or secondary to an intrinsic aortic root abnormality), left ventricular dysfunction (secondary to inadequate myocardial protection during previous repair or chronic LV volume overload caused by long-standing palliative arterial shunts), residual pulmonary valve obstruction, residual pulmonary valve regurgitation, RV dysfunction (as a result of pulmonary regurgitation or pulmonary stenosis), atrial arrhythmias (typically atrial flutter), ventricular arrhythmias, and heart block.

Reintervention is necessary in approximately 10% of patients after reparative surgery at 20-year follow-up. With longer follow-up, the incidence of reintervention continues to increase. The most common indication for reintervention is pulmonary valve replacement for severe pulmonary valve regurgitation. Pulmonary valve replacement, either surgical or transcatheter, is indicated when severe pulmonary valve regurgitation is associated with RV or LV systolic dysfunction, severe RV dilation, and/or progressive reduction in objective exercise tolerance. Although pulmonary valve replacement is associated with improved functional status, it has not been shown to improve mortality or risk for ventricular arrhythmias and sudden cardiac death in adults with tetralogy of Fallot. Implantable cardioverter defibrillators may be considered in patients with a history of recurrent ventricular arrhythmias or other risk factors such as ventricular dysfunction.

Transposition of the Great Arteries

See Chapter 480.1.

The natural history of patients with unrepaired TGA is so poor that very few patients survive past childhood without intervention. The first definitive operations for TGA was the **atrial switch** procedure, where the systemic and pulmonary venous returns are rerouted in the atrium by constructing baffles. The systemic venous return from the superior and inferior venae cavae is directed through the mitral valve and into the left ventricle (connected to the pulmonary artery). The pulmonary venous return is then directed through the tricuspid valve into the RV (connected to the aorta). The procedure results in physiologic correction and can be performed with low mortality but leave the left as the pulmonary ventricle and the right as the systemic ventricle. Long-term follow-up studies after the *atrial switch* procedure show a small but ongoing attrition rate with numerous other intermediate- and long-term complications. Two specific problems are most concerning: loss of sinus rhythm with development of atrial arrhythmias, occurring in 50% of TGA patients by age 25, and development of systemic ventricular dysfunction, occurring in 50% by age 35. Other long-term complications include endocarditis, baffle leaks, baffle obstruction, tricuspid valve regurgitation, and sinus node dysfunction requiring pacemaker placement.

The **arterial switch** operation is the procedure of choice to treat TGA. The great arteries are transected and reanastomosed to the correct ventricle (LV to aorta, RV to pulmonary artery) with coronary artery transfer. Operative survival after the arterial switch procedure in the current surgical era is very good, with a surgical mortality rate of 2–5%. Long-term data on survival and complications are not available, but intermediate results are promising. Reported intermediate complications include endocarditis, pulmonary outflow tract obstruction (at the supravalvular level or at the takeoff of the peripheral pulmonary arteries), aortic valve regurgitation, and coronary artery compromise (ranging from minor stenosis to complete occlusion).

The **Rastelli operation** represents a third type of repair for TGA, typically when there is associated VSD and pulmonary outflow tract obstruction. This operation involves the creation of an intracardiac baffle that closes the VSD in a way that directs flow from the LV to the aorta. The pulmonary valve is oversewn, and a valved conduit placed between the RV and pulmonary artery. Operative mortality is low, but patients require multiple reoperations for replacement of the pulmonary conduit during long-term follow-up. Other complications include complete heart block and left ventricular outflow tract obstruction.

Because of the high incidence of observed and potential medical problems, all patients who have had atrial, arterial, or Rastelli repair of TGA should have lifelong follow-up by a cardiologist at a center specializing in adult CHD.

Pulmonary Valve Stenosis

See Chapter 476.1.

Most patients with pulmonary valve stenosis are asymptomatic and present with a cardiac murmur. Survival into adult life and the need for intervention, however, are directly correlated to the degree of obstruction. Patients with **trivial** stenosis (defined as a peak gradient <25 mm Hg) followed for 25 years remain asymptomatic and have no significant progression of obstruction over time. For those patients with **moderate** pulmonary valve stenosis (defined as a peak gradient of 25-49 mm Hg), there is an approximately 20% chance of requiring intervention by age 25. For those patients with severe stenosis (defined as a peak gradient >50 mm Hg), the majority ultimately require an intervention, either surgery or balloon valvuloplasty, by age 25.

After surgical valvotomy for isolated pulmonary stenosis, long-term survival is excellent. With longer follow-up, the incidence of late complications and the need for reintervention do increase. The most common indication for reintervention is pulmonary valve replacement for severe pulmonary regurgitation. Other long-term complications include recurrent atrial arrhythmias, endocarditis, and residual right ventricular outflow tract obstruction.

Patients with **moderate to severe** pulmonary stenosis (defined as a peak gradient >50 mm Hg) should be considered for intervention even in the absence of symptoms. Percutaneous balloon valvuloplasty has been the accepted treatment for patients of all ages. Previously, surgical valvotomy had been the gold standard. Surgical valvotomy is reserved for patients who are unlikely to have successful results from balloon valvuloplasty, such as those with an extremely dysplastic or calcified valve.

Left-Sided Obstructive Lesions

Coarctation of the Aorta

See Chapter 476.6.

The clinical presentation of coarctation of the aorta depends on the severity of obstruction and the associated anomalies. Unrepaired coarctation typically presents with symptoms before adulthood. These symptoms include headaches related to hypertension, leg fatigue or cramps, exercise intolerance, and systemic hypertension (may be asymptomatic). Those untreated patients surviving to adulthood thus typically have only mild coarctation of the aorta. In the era before surgery, without treatment, the mean age of death was 32 years. Causes of death included left ventricular failure, intracranial hemorrhage, endocarditis, aortic rupture/dissection, and premature coronary artery disease (CAD).

After surgical repair, long-term survival is good but is directly correlated with the age at repair, with those repaired after age 14 years having a lower 20-year survival than those who were repaired earlier: 91% vs 79%. With longer follow-up, the incidence of long-term complications

continues to rise. The most common long-term complication is persistent or new systemic hypertension at rest or during exercise. Other long-term complications include aneurysms of the ascending or descending aorta, recoarctation at the site of previous repair, CAD, aortic stenosis or regurgitation (in the setting of an associated bicuspid aortic valve), rupture of an intracranial aneurysm, and endocarditis.

Patients with significant native or residual coarctation of the aorta (symptomatic patients with a peak gradient across the coarctation >20 mm Hg) should be considered for intervention, either surgery or catheter intervention with balloon angioplasty, with or without stent placement. Surgical repair in the adult patient is technically difficult and is associated with high morbidity. Catheter-based intervention is the preferred method in most experienced adult CHD centers.

Aortic Valve Stenosis

See Chapter 476.5.

The natural history of aortic valve stenosis in adults is quite variable but is characterized by progressive stenosis over time. By age 45 years, approximately 50% of bicuspid aortic valves will have some degree of stenosis.

Most patients with aortic valve stenosis are asymptomatic and are diagnosed after a murmur is detected. The severity of obstruction at diagnosis correlates with the pattern of progression. Symptoms are rare until patients have severe aortic valve stenosis (mean gradient by echocardiography >40 mm Hg). Symptoms include chest pain, exertional dyspnea, near-syncope, and syncope. When any of these symptoms is present, the risk of sudden cardiac death is quite high, so surgical intervention is mandated. For patients requiring surgical valvotomy to relieve the stenosis before adulthood, the majority of patients do well. However, at 25-year follow-up, up to 40% of patients will have required a second operation for residual stenosis or regurgitation.

Patients with symptoms and severe aortic valve stenosis should be considered for intervention. Treatment involves manipulating the valve to reduce stenosis. This can be accomplished by balloon dilation of the valve, open surgical valvotomy, or valve replacement. In absence of significant aortic regurgitation, most centers favor balloon dilation or surgical valvotomy for children and young adults who have pliable valves with fusion of commissures. In older adults, aortic valve replacement is the treatment of choice. Typically, surgery is performed for aortic valve replacement in younger adults with congenital aortic valve stenosis; however, transcatheter aortic valve replacement is increasingly commonly performed in older adults who may be higher-risk surgical candidates.

Endocarditis Prophylaxis

See Chapter 486.

Only patients with cardiac conditions associated with the highest risk for adverse outcomes should continue antibiotic prophylaxis before surgery: previous endocarditis, prosthetic valves (biological and mechanical), unrepaired cyanotic CHD, including palliative shunts and conduits, completely repaired congenital heart defects with prosthetic material or device, surgically placed or by catheter intervention during the first 6 months after the procedure, and repaired CHD with residual defects at or adjacent to the site of a prosthetic patch or prosthetic device (which inhibits endothelialization). Except for the conditions just listed, antibiotic prophylaxis is no longer recommended for other forms of CHD.

PREGNANCY AND CONGENITAL HEART DISEASE

CHD is the most common form of heart disease encountered during pregnancy in developed countries. Heart disease does not preclude a successful pregnancy but increases the risk to both the mother and the baby. During pregnancy, substantial hemodynamic changes occur. The hemodynamic changes in pregnancy result in a steady increase in cardiac output during pregnancy until the 32nd week of gestation, at which time the cardiac output reaches a plateau at 30–50% above the prepregnancy level. At delivery, with uterine contractions, an additional 300-500 mL of blood enters the circulation. This, in conjunction with increased blood pressure and heart rate during labor, increases the cardiac output at delivery to 80% of the prepregnancy level.

Despite these hemodynamic changes, the outcome of pregnancy is favorable in most women with CHD, provided that functional class and systemic ventricular function are good. The WHO modified categorization of risk stratification is shown in Figures 483.2 and 483.3. Pulmonary artery hypertension presents a serious risk during pregnancy, particularly when the pulmonary pressure exceeds 70% of systemic pressure, regardless of functional class. Other contraindications to pregnancy include severe obstructive left-sided lesions (coarctation of the aorta, aortic valve stenosis, mitral valve stenosis, hypertrophic cardiomyopathy), Marfan syndrome with coexisting dilated ascending aorta (defined as >4 cm), persistent cyanosis, and systemic ventricular dysfunction (ejection fraction of ≤40%). The need for full anticoagulation during pregnancy, although not a contraindication, poses an increased risk to both mother and fetus. The relative risks and benefits of the different anticoagulant approaches need to be discussed fully with the mother.

Pregnancy counseling should begin early in adolescence and should be part of the routine cardiac follow-up visit. Counseling should include a discussion about the risk of CHD in the offspring. In the general population, the incidence of CHD is 1%. In the offspring of a mother with CHD, the risk increases to 5–6%. Often the cardiac lesion in the offspring is not the same as that in the mother, except in the case of a syndrome with autosomal dominant inheritance (i.e., Marfan syndrome, hypertrophic cardiomyopathy). Risk stratification should include the specific CHD lesion but also needs to consider the maternal functional class. Although the specific CHD lesion is important, multiple studies demonstrate that the maternal functional class before pregnancy is highly predictive of both maternal and fetal outcomes, with those in the best functional class having the best outcomes. A cardiopulmonary exercise test performed before conception can predict maternal and neonatal outcomes in pregnant women with CHD. A blunted heart rate response to exercise is associated with a higher risk for adverse maternal and neonatal events. It is recommended that women with CHD at higher risk for pregnancy-related complications based on anatomy, functional status, and exercise testing be managed collaboratively during pregnancy by adult CHD cardiologists, obstetricians, and anesthesiologists with specialized experience in adults with CHD.

	Predictors of cardiac event during pregnancy	OR in study cohort	Event rate in study cohort
CARPREG II	Prior cardiac event or arrhythmia	5.9	33%
	NYHA III or IV or cyanosis	4.9	46%
	Mechanical valve	4.2	38%
	Ventricular dysfunction	2.3	30%
	High risk left-sided valve disease/left ventricular outflow tract obstruction	2.1	22%
	Pulmonary hypertension	3.3	32%
	Coronary artery disease	3.0	29%
	High risk aortopathy	2.7	18%
	No prior cardiac intervention	1.6	18%
	Late pregnancy assessment	1.6	20%
ZAHARA	Cardiac medication, other than anticoagulation	4.2	26%
	Atrioventricular valve regurgitation	2.0–2.3	17%
ROPAC	Atrial fibrillation at pre-pregnancy visit	5.1	52%
	Signs of heart failure at pre-pregnancy visit	3.3–4.2	63%

Fig. 483.2 Risk tools modified WHO (mWHO), CARdiac disease in PREGnancy (CARPREG), Zwangerschap bij Aangeboren HARtAfwijking (ZAHARA), Registry of Pregnancy and Cardiac disease (ROPAC). ORs and rates are derived from cohorts consisting of approximately 60% of patients with congenital heart disease (63% in CARPREG II and 58% in ROPAC). OR, Odds ratio. *(From van Hagen IM, Roos-Hesselink JW. Pregnancy in congenital heart disease: risk prediction and counselling. Heart. 2020;106:1853–1861, Fig. 1.)*

CONTRACEPTION

A critical part of caring for adults with CHD is to provide (or make available) advice on contraception. Unfortunately, data are limited on the safety of various contraceptive techniques in adult CHD patients. The estrogen-containing oral contraceptives (OCs) can be used in many adult CHD patients but are not recommended in adult CHD patients at risk for thromboembolism, such as those with cyanosis, prior Fontan procedure, AF, or pulmonary artery hypertension. In addition, OCs may disrupt anticoagulation control. Although slightly less effective than OCs containing combined estrogen/progesterone, medroxyprogesterone, the progesterone-only pills, and levonorgestrel are good options for most adult CHD patients. Medroxyprogesterone and levonorgestrel, however, can cause fluid retention and thus need to be used with caution in patients with heart failure. These medications are also associated with depression and often breakthrough bleeding. Tubal ligation, although the most secure method of contraception, can be a high-risk procedure in patients with complex CHD or those with pulmonary hypertension. Hysteroscopic sterilization (Essure) may be reasonable for high-risk patients. In the past, intrauterine devices (IUDs) were seldom used in cardiac patients because of the associated risk of bacteremia, pelvic inflammatory disease, and endocarditis. IUDs such as Mirena appear to be safe and effective and are rapidly becoming one of the most common forms of contraception in the adult CHD population.

ADOLESCENT TRANSITION

It is well recognized that as part of the process of obtaining independence, adolescents or young adults must develop a forward-looking, independent approach to their medical care. For children with heart disease, the transition process must begin during early adolescence and should be encouraged by both the primary care provider and the pediatric cardiologist, who must identify an appropriate adult CHD program to which transition and transfer will be made at an appropriate time (see Table 483.6).

A successful transition program includes the following elements:

- Development of a written transition plan that should begin by age 14 years
- Because adolescents and young adults are frequently unaware of the details of their cardiac diagnosis and history, a complete, concise, portable medical record, including all pertinent aspects of cardiac care, should be shared with adolescents and their family and prepared for transmittal to the eventual adult care destination.
- The primary care provider and cardiologist must address unique adolescent medical issues as they affect the cardiovascular system. In addition to medical problems, education, vocational planning, psychosocial issues, and access to medical care should be discussed with adolescents and their families.

Young adults tend to avoid medical care because of lack of education, denial, or difficulty with access to the medical care system. Thus a critical goal of the adolescent transition process is to identify an appropriate site for ongoing medical care and ensure maintenance of the medical record and continuity of care for the young adult. The site of care for a young adult with CHD may be a pediatric program or facility or a specialized center or program for the adult with CHD. The critical issues are the continuity of care, the preparation of the patient, and the patient's participation in the process.

HEART FAILURE AND TRANSPLANT

Heart failure is increasingly prevalent in adults with CHD and is associated with increased morbidity and mortality. Causes for heart failure in this population include unrepaired or residual valve dysfunction, shunts, arrhythmias, venous obstruction, and systolic and/or diastolic ventricular dysfunction. Data on medical and device therapy to treat heart failure in adults with CHD are limited because of the relatively small study populations and heterogenous heart defects. Concomitant failure of noncardiac organs, such as lung, kidney, and liver failure, is common in adult CHD patients with heart failure and further complicates the management. Currently, management of symptomatic CHD patients with systolic ventricular dysfunction is primarily extrapolated from data in adults with heart failure in the setting of acquired heart disease and includes:

- Medical therapy that includes angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, β blockers, aldosterone antagonists, and diuretics
- Electrical device therapies such as implantable cardioverter defibrillators to reduce the risk for sudden cardiac death and permanent pacemaker placement for cardiac resynchronization therapy to improve symptoms of heart failure
- Mechanical circulatory support, such as ventricular assist devices, for patients with severe, refractory heart failure symptoms
- Referral to adult CHD heart failure/transplant specialist and center

Proper timing for heart transplantation in adults with CHD is unclear and may vary for individual lesions. Patients with single ventricle anatomy and complex anatomy often have lower priority with the current transplant allocation system, and therefore often have longer wait times before receiving a heart transplant. Early posttransplant mortality is higher in adults with CHD compared with adults with acquired heart disease because of increased perioperative mortality. However, once beyond the perioperative period, patients with ACHD do as well as or better than those with acquired heart disease, with expected 10-year survival equivalent to or better than that of adults without CHD.

Section 4

Cardiac Arrhythmias

Chapter 484

Disturbances of Rate and Rhythm of the Heart

Aarti S. Dalal and George F. Van Hare

The term *arrhythmia* refers to a disturbance in heart rate or rhythm. Such disturbances can lead to heart rates that are abnormally fast, slow, or irregular. They may be transient or incessant; congenital or acquired; or caused by infection, a toxin, or drugs. They may be associated with particular forms of congenital heart disease (CHD), may be a complication after surgical repair of CHD, may be a result of genetic causes, or may be the result of a maternal connective tissue disease. Arrhythmias, either slow or fast, may lead to acutely decreased cardiac output. If incessant, they may lead to a cardiomyopathy. Initially stable and organized arrhythmias can degenerate into a more dangerous arrhythmia such as ventricular fibrillation. Arrhythmias may lead to syncope or to sudden death (see Chapter 485). When a patient has an arrhythmia, it is important to determine whether the rhythm is likely to lead to symptoms or to deteriorate into a life-threatening condition. Rhythm abnormalities such as single premature atrial and ventricular beats are common, and in children without heart disease, usually pose no risk to the patient.

A number of **pharmacologic agents** are available for treating arrhythmias; many have not been studied extensively in children. Insufficient data are available regarding pharmacokinetics, pharmacodynamics, and efficacy in the pediatric population, and therefore the selection of an appropriate agent is based on the judgement and experience of the clinician. Fortunately, most rhythm disturbances in children can be reliably controlled with a single agent (Table 484.1). **Transcatheter ablation** is acceptable therapy not only for life-threatening or drug-resistant arrhythmias but also for the cure of arrhythmias. For patients with bradycardia, **implantable pacemakers** are small enough for use in all ages, even in premature infants. Implantable cardioverter-defibrillators are available for use in high-risk patients with malignant ventricular arrhythmias and an increased risk of sudden death.

484.1 Principles of Antiarrhythmic Therapy

Aarti S. Dalal and George F. Van Hare

Many antiarrhythmic agents are available for rhythm control. The majority are not approved by the U.S. Food and Drug Administration (FDA) for use in children; their use is therefore considered "off-label." Pediatric cardiologists have experience with these drugs, with well-recognized standards for dosing.

With the availability of potentially curative ablation procedures, medical therapy has become less important. Intolerable drug side effects, as well as the potential for an arrhythmia induced by an antiarrhythmic drug, can seriously limit medical therapy and will lead the physician and family toward a potentially curative ablation procedure.

Antiarrhythmic drugs are frequently categorized using the **Vaughan-Williams classification**. This system comprises four classes: **class I** includes agents that primarily block the sodium channel, **class II** drugs are the β blockers, **class III** includes agents that prolong repolarization by blocking potassium channels, and **class IV** drugs are the calcium channel blockers. Class I is further divided by the strength of the sodium channel blockade (see Table 484.1).

484.2 Sinus Arrhythmias and Extrasystoles

Aarti S. Dalal and George F. Van Hare

Phasic sinus arrhythmia represents a normal physiologic variation in impulse discharges from the sinus node related to respirations. The heart rate slows during expiration and accelerates during inspiration. Occasionally, if the sinus rate becomes slow enough, an **escape beat** arises from the atrioventricular (AV) junction region (Fig. 484.1). Normal phasic sinus arrhythmia is caused by the activity of the parasympathetic nervous system and can be quite prominent in healthy children. It may mimic frequent premature contractions, but the relationship to the phases of respiration can be appreciated with careful auscultation. Drugs that increase vagal tone, such as digoxin, may exaggerate sinus arrhythmia; it is usually abolished by exercise. Other irregularities in sinus rhythm, especially bradycardia associated with periodic apnea, are common in premature infants.

Sinus bradycardia is a result of slow discharge of impulses from the sinus node, the heart's "natural pacemaker." A sinus rate <90 beats/min in neonates and <60 beats/min in older children is considered sinus bradycardia. Sinus bradycardia is commonly seen in highly conditioned athletes. In healthy individuals without symptoms, it has no clinical significance. Sinus bradycardia may occur in systemic disease (hypothyroidism, anorexia nervosa), and it resolves when the disorder is under control. It may also be seen in association with conditions in which there is high vagal tone, such as gastrointestinal obstruction or intracranial processes. Low birthweight infants display great variation in sinus rate. Sinus bradycardia is common in these infants, in conjunction with apnea, and may be associated with junctional escape beats; premature atrial contractions are also frequent. These rhythm changes, especially bradycardia, appear more often during sleep and are not associated with symptoms. Usually, no therapy is necessary.

A **wandering atrial pacemaker** is defined as an intermittent shift in the pacemaker of the heart from the sinus node to another part of the atrium. It is not uncommon in childhood and usually represents a normal variant. It may also be seen in association with sinus bradycardia in which the shift in atrial focus is an escape phenomenon.

Extrasystoles are produced by the premature discharge of an ectopic focus that may be situated in the atrium, the AV junction, or the ventricle. Usually, isolated extrasystoles are of no clinical or prognostic significance. Under certain circumstances, however, premature beats may be caused by organic heart disease (inflammation, ischemia, fibrosis) or drug toxicity.

Atrial extrasystoles, also known as **premature atrial contractions** or **complexes (PACs)**, are common in childhood, usually in the absence of cardiac disease. Depending on the degree of prematurity of the beat (coupling interval) and the preceding R-R interval (cycle length), PACs may result in a normal, a prolonged (aberrancy), or an absent (blocked PAC) QRS complex. Blocked PACs occur when the premature impulse cannot conduct to the ventricle because of refractoriness of the AV node or distal conducting system (Fig. 484.2). Atrial extrasystoles must be distinguished from premature ventricular contractions. Careful scrutiny of the electrocardiogram (ECG) for a premature P wave preceding the QRS will show either a premature P wave superimposed on and deforming the preceding T wave or a P wave that is premature and has a different contour from that of the other sinus P waves. PACs usually reset the sinus node pacemaker, leading to an incomplete compensatory pause, but this feature is not always present and so is not regarded as a completely reliable means of differentiating atrial from ventricular premature complexes in children.

Ventricular extrasystoles, also known as **premature ventricular contractions** or **complexes (PVCs)**, may arise in any region of either ventricle. PVCs are characterized by premature, widened, bizarre QRS complexes that are not preceded by a premature P wave (Fig. 484.3). When all premature beats have identical contours, they are classified

Table 484.1 Antiarrhythmic Drugs Commonly Used in Pediatric Patients, by Class

DRUG	INDICATIONS	DOSING	SIDE EFFECTS	DRUG INTERACTIONS	DRUG LEVEL
CLASS IA: INHIBITS NA^+ FAST CHANNEL, PROLONGS REPOLARIZATION					
Quinidine	SVT, atrial fibrillation, atrial flutter, VT; in atrial flutter, an AV node–blocking drug (digoxin, verapamil, propranolol) must be given first to prevent 1:1 conduction	Oral: 30-60 mg/kg/24 hr divided q6h (sulfate) or q8h (gluconate) 200 mg q6 (1-1.5 g/day divided q6), sulfate; 324 mg q8-12h (1.5 g/day divided q8-12h), gluconate Max dose: 2.4 g/24 hr	Nausea, vomiting, diarrhea, fever, cinchonism, QRS and QT prolongation, AV nodal block, asystole, syncope, thrombocytopenia, hemolytic anemia, SLE, blurred vision, convulsions, allergic reactions, exacerbation of periodic paralysis	Enhances digoxin, may increase PTT when given with warfarin	2-6 µg/mL
Procainamide	SVT, atrial fibrillation, atrial flutter, VT	Oral: 15-50 mg/kg/day divided q3-6h Max dose: 4 g/24 hr IV: 10-15 mg/kg over 30-60 min load followed by 20-80 µg/kg/min Max dose: 2 g/24 hr	PR, QRS, QT interval prolongation, anorexia, nausea, vomiting, rash, fever, agranulocytosis, thrombocytopenia, Coombs-positive hemolytic anemia, SLE, hypotension, exacerbation of periodic paralysis, proarrhythmia	Toxicity increased by amiodarone and cimetidine	4-8 µg/mL With NAPA <40 µg/mL
Disopyramide	SVT, atrial fibrillation, atrial flutter	Oral (immediate release): <1 yr: 10-30 mg/kg/day divided q6h 1-4 yr: 10-20 mg/kg/day divided q6h >4-12 yr: 10-15 mg/kg/day divided q6h >12- ≤18 yr: 6-15 mg/kg/day divided q6h Max dose: 1.6 g/day Adults: <50 kg: 100 mg q6h; >50kg:150 mg q6h Long-acting dosing is 200-300 q12h	Anticholinergic effects, urinary retention, blurred vision, dry mouth, QT and QRS prolongation, hepatic toxicity, negative inotropic effects, agranulocytosis, psychosis, hypoglycemia, proarrhythmia		2-7 µg/mL
CLASS IB: INHIBITS NA^+ FAST CHANNEL, SHORTENS REPOLARIZATION					
Lidocaine	VT, VF	IV: 1 mg/kg repeat q 5 min 2 times followed by 20-50 µg/kg/min (max dose: 3 mg/kg) Adult infusion rate: 1-4 mg/min	CNS effects, confusion, convulsions, high-grade AV block, asystole, coma, paresthesias, respiratory failure	Propranolol, cimetidine, increases toxicity	1.5-5.0 µg/mL
Mexiletine	VT	Oral: 6-15 mg/kg/24 hr divided q8h Max dose: 15 mg/kg/day or 1.2 g/day. Adults: 150-300 mg q8-12h (max 1.2 g/day)	GI upset, skin rash, neurologic	Cimetidine	0.5-2 mcg/mL
Phenytoin	Digitalis intoxication	Oral: 4-8 mg/kg/24 hr divided q12h Max dose: 300-600 mg/day IV: 10-15 mg/kg over 1 hr load	Rash, gingival hyperplasia, ataxia, lethargy, vertigo, tremor, macrocytic anemia, bradycardia with rapid push	Amiodarone, oral anticoagulants, cimetidine, nifedipine, disopyramide, increase toxicity	10-20 µg/mL
CLASS IC: INHIBITS NA^+ CHANNEL					
Flecainide	SVT, atrial tachycardia, VT	BSA dosing: 50-200 mg/m^2/day divided q8-12h Weight based: 3-6 mg/kg/day divided q8h Max dosing: 8 mg/kg/day Max adult dosing: 400 mg/day	Blurred vision, nausea, decrease in contractility, proarrhythmia	Amiodarone increases toxicity	0.2-1 µg/mL

Table 484.1 Antiarrhythmic Drugs Commonly Used in Pediatric Patients, by Class—cont'd

DRUG	INDICATIONS	DOSING	SIDE EFFECTS	DRUG INTERACTIONS	DRUG LEVEL
Propafenone	SVT, atrial tachycardia, atrial fibrillation, VT	Oral: 150-300 mg/m^2/24 hr divided q8h	Hypotension, decreased contractility, hepatic toxicity, paresthesia, headache, proarrhythmia	Increases digoxin levels	0.2-1 μg/mL
CLASS II: β BLOCKERS					
Propranolol	SVT, long QT	Oral: 1-4 mg/kg/24 hr divided q6h Max dose 60 mg/24 hr IV: 0.01-0.15 mg/kg/dose SLOW over 5-10 min Max dose: 1-3 mg/dose	Bradycardia, loss of concentration, school performance problems, bronchospasm, hypoglycemia, hypotension, heart block, CHF	Co-administration with disopyramide, flecainide, or verapamil may decrease ventricular function	
Atenolol	SVT	Oral: 0.5-1 mg/kg/24 hr once daily or divided q12h	Bradycardia, loss of concentration, school performance problems	Co-administration with disopyramide, flecainide, or verapamil may decrease ventricular function	
Nadolol	SVT, long QT	Oral: 1-2 mg/kg/24 hr given once daily	Bradycardia, loss of concentration, school performance problems, bronchospasm, hypoglycemia, hypotension, heart block, CHF	Co-administration with disopyramide, flecainide, or verapamil may decrease ventricular function	
CLASS III: PROLONGS REPOLARIZATION					
Amiodarone	SVT, JET, VT	Oral: 10-15 mg/kg/day IV: 2.5-5 mg/kg over 30-60 min, may repeat 3 times, then 5-20 mg/kg/day continuous infusion Max daily dose: 2.2 g/day	Hypothyroidism or hyperthyroidism, elevated triglycerides, hepatic toxicity, pulmonary fibrosis	Digoxin (increases levels), flecainide, procainamide, quinidine, warfarin, phenytoin	1-2.5 mg/L
CLASS IV AND MISCELLANEOUS MEDICATIONS					
Digoxin	SVT (not WPW), atrial flutter, atrial fibrillation	Oral/load instructions: Premature: 20 μg/kg Newborn: 30 μg/kg >6 mo: 40 μg/kg Give 1/2 total dose followed by 1/4 q8-12h × 2 doses Maintenance: 10 μg/kg/24 hr divide q12h Max dose: 0.5 mg IV: 3/4 PO dose Max dose: 0.5 mg	PAC, PVC, bradycardia, AV block, nausea, vomiting, anorexia, prolongs PR interval	Quinidine Amiodarone, verapamil, increase digoxin levels	1-2 mg/mL
Verapamil	SVT (not WPW)	Oral: 2-8 mg/kg/day divided q8h Max dose: 480 mg/day IV: 0.1-0.3 mg/kg/dose Max dose: 5-10 mg/dose	Bradycardia, asystole, high-degree AV block, PR prolongation, hypotension, CHF	Use with β blocker or disopyramide exacerbates CHF, increases digoxin level and toxicity	
Adenosine	SVT	IV: 50-300 μg/kg by need rapid IV push Begin with 50 μg/kg and increase by 50-100 μg/kg/dose Max dose: 18 mg	Chest pain, flushing, dyspnea, bronchospasm, atrial fibrillation, bradycardia, asystole		

AV, Atrioventricular; CHF, congestive heart failure; CNS, central nervous systems; GI, gastrointestinal; IV, intravenous; JET, junctional ectopic tachycardia; NAPA, *N*-acetyl procainamide; PAC, premature atrial contraction; PTT, partial thromboplastin time; PVC, premature ventricular contraction; SLE, systemic lupus erythematosus–like illness; SVT, supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia; WPW, Wolff-Parkinson-White syndrome.

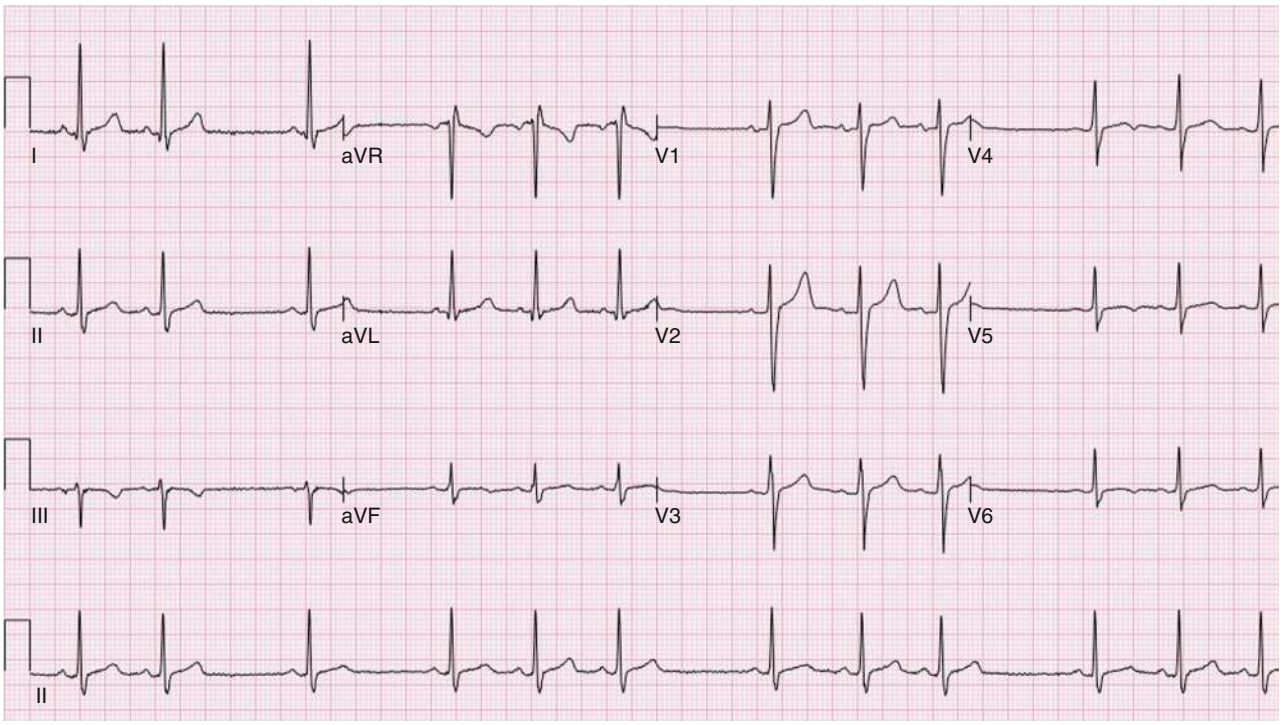

Fig. 484.1 Phasic sinus arrhythmia. Note the variation in P-P interval with no significant change in P-wave morphology or PR interval. This rhythm is normal.

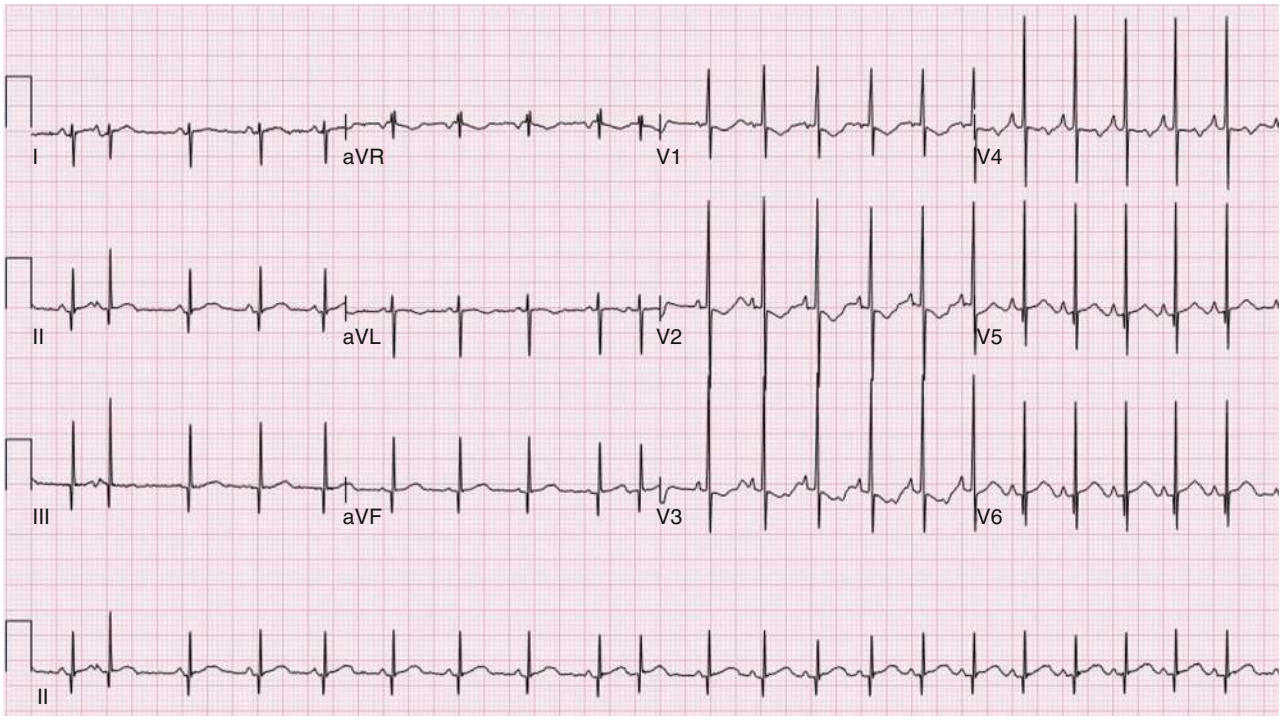

Fig. 484.2 Premature atrial contraction (PAC). The second and tenth beats are premature, and deformation of the previous T wave identifies the presence of a premature atrial contraction.

as *uniform or monomorphic,* suggesting origin from a common site. When PVCs vary in contour, they are designated as *multiform or polymorphic,* suggesting origin from more than one ventricular site. Ventricular extrasystoles are often, but not always, followed by a full compensatory pause because of a lack of resetting of the sinus node. The presence of **fusion beats**, that is, complexes with morphologic features that are intermediate between those of normal sinus beats and those of PVCs, proves the ventricular origin of the premature beat. Extrasystoles produce a smaller stroke and pulse volume than normal and, if quite premature, may not be audible with a stethoscope or palpable at the radial pulse. When frequent, extrasystoles may assume a definite rhythm, for example, alternating with normal beats **(bigeminy)** or occurring after two normal beats **(trigeminy)**. Most patients are unaware of single PVCs, although some may be aware of a "skipped beat" over the precordium. This sensation is caused by the increased stroke volume of the normal beat after a compensatory pause. Anxiety,

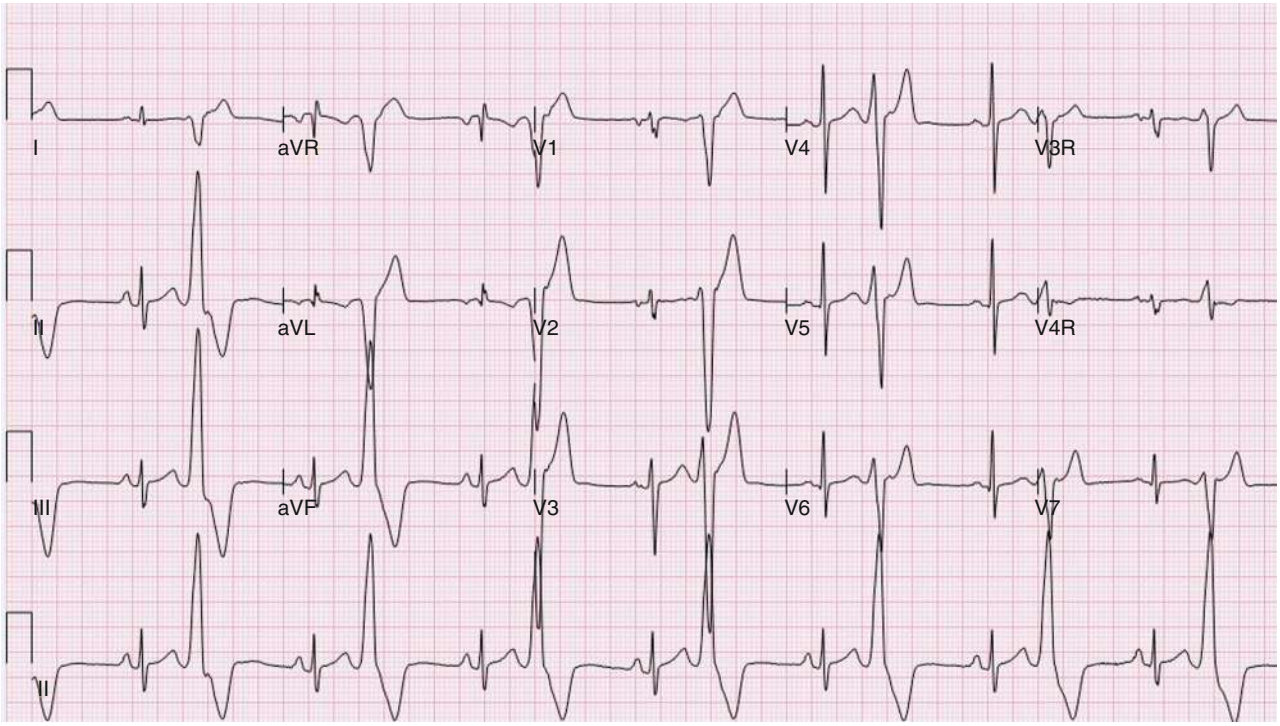

Fig. 484.3 Premature ventricular contractions in a bigeminal rhythm. Note that the premature beat is wide and has a completely different morphology from that of the sinus beat. The premature beat is not preceded by a discernible premature P wave or any appreciable deformation of the preceding T wave.

a febrile illness, or ingestion of various drugs or stimulants may make PVCs more frequent.

It is important to distinguish PVCs that are benign from those that are likely to lead to more severe arrhythmias. The former usually disappear (or are "suppressed) at higher sinus rates, as seen during exercise. If they persist or become more frequent during exercise, the arrhythmia may have greater significance. The following criteria are indications for further investigation of PVCs that could require **suppressive therapy**: (1) ≥2 PVCs in a row; (2) multiform PVCs; (3) increased ventricular ectopic activity with exercise; (4) R-on-T phenomenon (premature ventricular depolarization occurs on the T wave of the preceding beat); (5) extreme frequency of beats (e.g., >20% of total beats on Holter monitoring); and (6) most importantly, the presence of underlying heart disease, a history of heart surgery, or both. The best therapy for benign PVCs is reassurance that the arrhythmia is not life threatening, although highly symptomatic individuals may benefit from suppressive therapy.

Malignant PVCs are usually secondary to another medical problem (electrolyte imbalance, hypoxia, drug toxicity, cardiac injury, or a channelopathy). Successful treatment includes correction of the underlying abnormality if possible. An intravenous **lidocaine** bolus and drip is the first line of therapy, with more effective drugs such as **amiodarone** reserved for refractory cases or for patients with underlying ventricular dysfunction or hemodynamic compromise.

484.3 Supraventricular Tachycardia

Aarti S. Dalal and George F. Van Hare

Supraventricular tachycardia (SVT) is a general term that includes essentially all forms of paroxysmal or incessant tachycardia except ventricular tachycardia. The category of SVT can be divided into three major subcategories: reentrant tachycardias using an accessory pathway, reentrant tachycardias without an accessory pathway, and ectopic or automatic tachycardias. **Atrioventricular reciprocating tachycardia (AVRT)** involves an accessory pathway and is the most common mechanism of SVT in infants. **Atrioventricular node reentry tachycardia (AVNRT)** is rare in infancy but increases during childhood and into adolescence. **Atrial flutter** is rarely seen in children with normal hearts, whereas intraatrial reentry tachycardia (also known as *atrial flutter*) is sometimes seen in patients after cardiac surgery. Atrial and junctional ectopic tachycardias are more often associated with abnormal hearts (cardiomyopathy) and the immediate postoperative period after surgery for CHD.

CLINICAL MANIFESTATIONS

Reentrant SVT is characterized by an abrupt onset and termination; it may occur when the patient is at rest or exercising, and in infants it may be precipitated by an acute infection. Attacks may last only a few seconds or may persist for hours. The heart rate usually exceeds 180 beats/min in older children and adolescents and 220 bpm in infants and younger children. Rates of SVT are often as high as 300 beats/min in newborns and infants. The only complaint may be awareness of the rapid heart rate.

Many older children tolerate these episodes extremely well, and it is unlikely that short paroxysms are a danger to life. If heart rate is exceptionally rapid or the episode is prolonged, precordial discomfort and heart failure may occur. In children, SVT may be exacerbated by exposure to caffeine, nonprescription decongestants, or bronchodilators.

In young patients, the diagnosis may be more obscure because of their inability to communicate their symptoms. The heart rate during infancy is normally higher than in older children and increases greatly with crying. Occasionally, infants with SVT initially present with heart failure because the tachycardia may go unrecognized for a long time, **leading to tachycardia-induced cardiomyopathy**. The heart rate during SVT episodes is frequently in the range of 240-300 beats/min. If the episode lasts 6-24 hours or more, heart failure may be recognized, and the infant may present with poor feeding; an ashen color; and will be restless and irritable, with tachypnea, poor pulses, and hepatomegaly. When tachycardia occurs in the fetus, it can cause **hydrops fetalis**, the in utero manifestation of heart failure.

In neonates, SVT is usually manifested as a narrow QRS complex (<0.08 second). The P wave is visible on a standard ECG in only 50–60%

of neonates with SVT, but it is detectable with a transesophageal lead in most patients. *Differentiation from sinus tachycardia* may be difficult but is important because sinus tachycardia requires treatment of the underlying problem (e.g., sepsis, hypovolemia) rather than antiarrhythmic medication. If the rate is >230 beats/min with an abnormal P-wave axis (a normal P wave is positive in leads I and aVF), sinus tachycardia is *not* likely. The heart rate in SVT also tends to be *relatively fixed,* whereas in sinus tachycardia the heart rate *varies* with changes in parasympathetic and sympathetic tone. AVRT uses a bypass tract that may be able to conduct bidirectionally **(Wolff-Parkinson-White [WPW] syndrome)** or may be retrograde only **(concealed accessory pathway)**. Patients with WPW syndrome have a small but real risk of sudden death. If the accessory pathway rapidly conducts in antegrade fashion, the patient is at risk for atrial fibrillation begetting ventricular fibrillation. Risk stratification, including 24-hour Holter monitoring and exercise study, may help differentiate patients at higher risk for sudden death from WPW. However, it is important to note that intermittent preexcitation may not decrease a patient's risk profile. Syncope is an ominous symptom in WPW, and any patient with syncope and WPW syndrome should have an **electrophysiology study** (EPS) and consideration for catheter ablation.

The typical electrocardiographic features of WPW syndrome are seen when the patient is not having tachycardia. These features include a short P-R interval and slow upstroke of a widened QRS (delta wave) (Fig. 484.4). This may not be evident in every lead on an ECG. Although most often presenting in patients with a normal heart, WPW syndrome may also be associated with **Ebstein anomaly** of the tricuspid valve, congenitally corrected transposition of the great

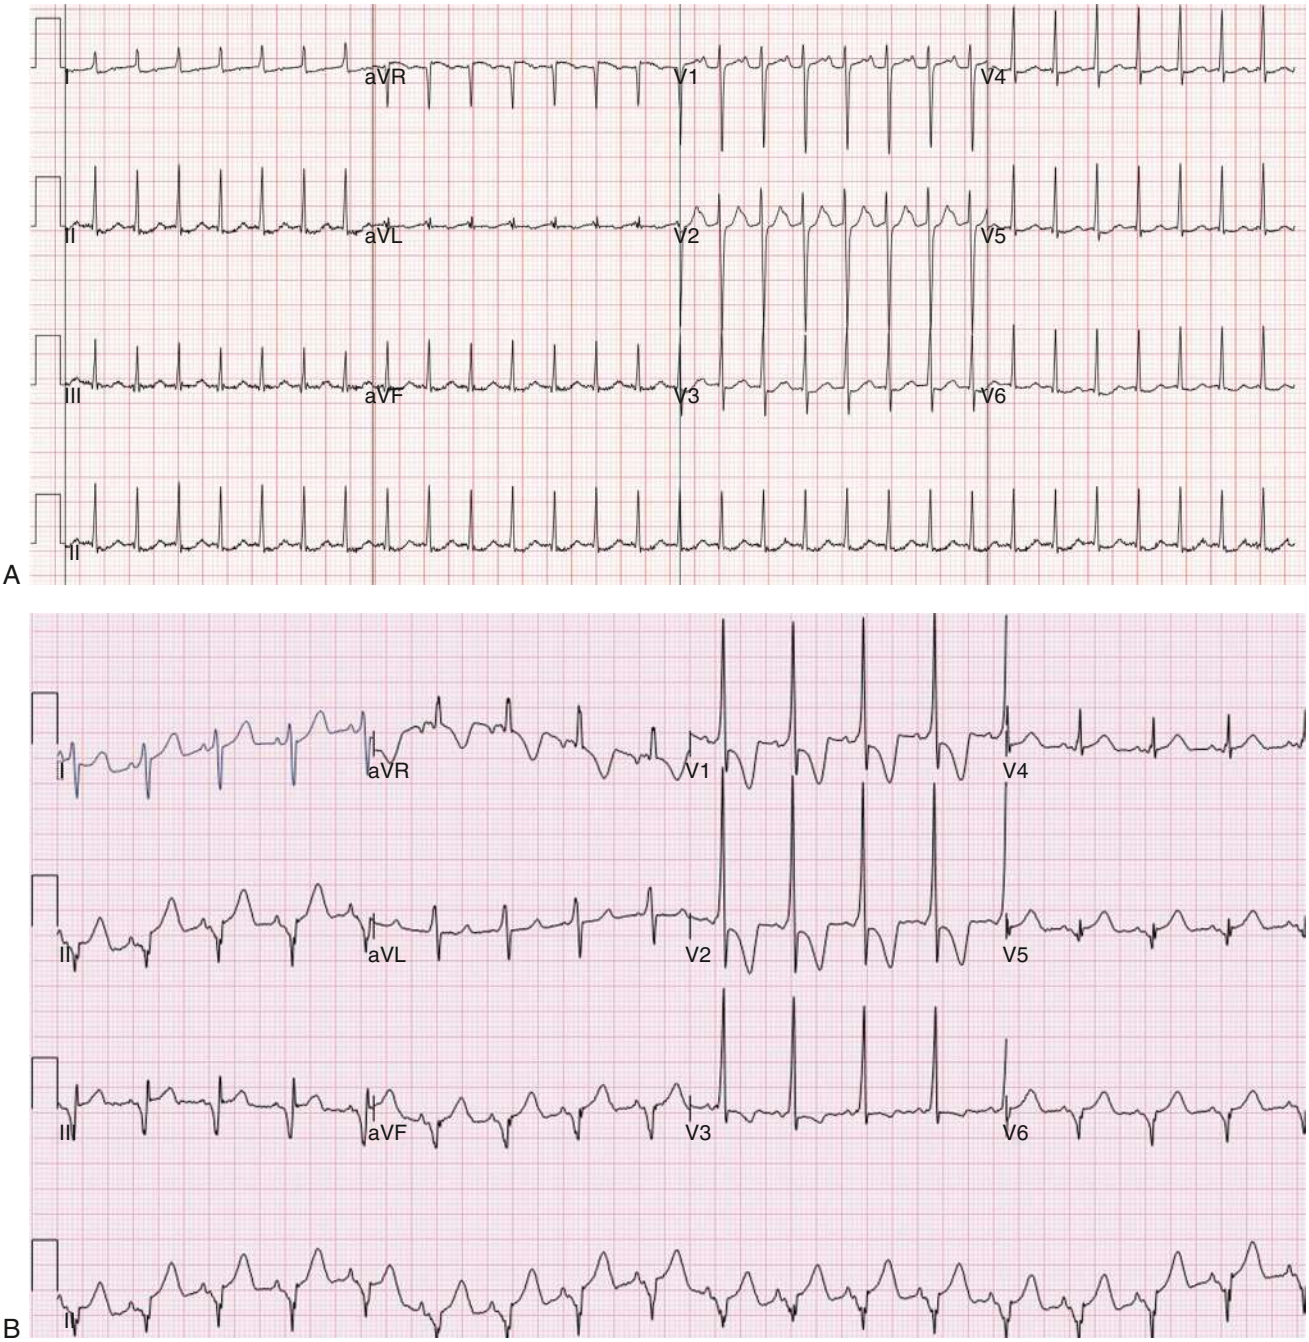

Fig. 484.4 A, Supraventricular tachycardia in a child with Wolff-Parkinson-White (WPW) syndrome. Note the normal QRS complexes during the tachycardia, as well as clear retrograde P waves seen on the upstroke of the T waves. B, Later, the typical features of WPW syndrome are apparent (short P-R interval, wide QRS with slurred upstroke known as a *delta wave*).

arteries, or certain forms of hypertrophic cardiomyopathy. WPW may also be associated with hypokalemic periodic paralysis, Danon disease, tuberous sclerosis, and rarely with pathogenic variants in *PRKAG2*.

The critical anatomic structure is an accessory pathway consisting of an electrically active myocardial fiber connecting atrium to ventricle on either the right or the left side of the AV ring (Fig. 484.5). During sinus rhythm, the impulse is carried over both the AV node and the accessory pathway; it produces some degree of fusion of the two depolarization fronts that results in an abnormal QRS complex. During AVRT, an impulse is carried in *antegrade* fashion through the AV node **(orthodromic tachycardia)**, which results in a normal QRS complex, and in *retrograde* fashion through the accessory pathway to the atrium, thereby perpetuating the tachycardia. In these cases, only after cessation of the tachycardia is the typical ECG features of WPW syndrome recognized (see Fig. 484.4). When rapid antegrade conduction occurs through the accessory pathway during tachycardia and the retrograde reentry pathway to the atrium is by the AV node **(antidromic tachycardia)**, the QRS complexes are wide and the potential for more serious arrhythmias (ventricular fibrillation) is greater, especially if atrial fibrillation occurs.

AVNRT involves the use of two functional pathways within the AV node: the *slow* and *fast* AV node pathways. This arrhythmia is more often seen in adolescence and young adulthood. It is one of the few forms of SVT that is occasionally associated with syncope. This arrhythmia is often seen in association with exercise.

TREATMENT

In infants, **vagal stimulation** can be induced by transiently placing an ice bag over the entire face to abort the attack for 15-30 seconds (this can be repeated if needed). Older children may be taught **vagal maneuvers** such as the Valsalva maneuver, straining, breath holding, or standing on their head. *Ocular pressure must never be performed, and carotid sinus massage is rarely effective*. When these measures fail, several pharmacologic alternatives are available (see Table 484.1). In stable patients, **adenosine** by rapid intravenous push is the treatment of choice (0.1 mg/kg, up to 6 mg) because of its rapid onset of action and minimal effects on cardiac contractility. The dose may need to be increased (0.2 mg/kg, up to 12 mg) if no effect on the tachycardia is seen. Because of the potential for adenosine to initiate atrial fibrillation, it should never be administered without a means for direct current **(DC) cardioversion** near at hand. Calcium channel blockers such as **verapamil** have also been used in the initial treatment of SVT in older children. Verapamil may reduce cardiac output and produce hypotension and cardiac arrest in infants younger than 1 year and therefore is contraindicated in this age-group. In urgent situations when symptoms of severe heart failure have already occurred, *synchronized* DC cardioversion (0.5-2 J/kg) is recommended as the initial management (see Chapter 79). Pace termination using esophageal pacing catheter is also an option.

Once the patient has been converted to sinus rhythm, a longer-acting agent is selected for maintenance therapy. In patients without an antegrade accessory pathway (non-WPW), the β-**adrenergic blockers** are the mainstay of drug therapy. **Digoxin** has been used for decades and may be effective in infants, but less so in older children. In children with WPW, digoxin or calcium channel blockers may *increase* the rate of antegrade conduction of impulses through the bypass tract, with the possibility of ventricular fibrillation, and are therefore contraindicated. These patients are usually managed with β blockers. In patients with resistant tachycardias, flecainide, propafenone, sotalol, and amiodarone are all acceptable next-line agents. Most antiarrhythmic agents have the potential of causing new dangerous arrhythmias (**proarrhythmia**) and decreasing heart function. Flecainide and propafenone should be limited to use in patients with hearts having otherwise normal cardiac function.

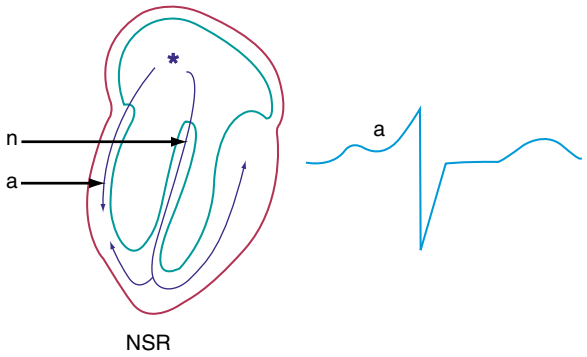

Fig. 484.5 Schematic representation of the heart with a right-sided accessory pathway (WPW syndrome). The *asterisk* indicates initiation of the sinus beat. The *arrows* indicate the direction and spread of excitation. The electrocardiographic complex shown represents a fusion beat that combines activation over the normal *(n)* and accessory *(a)* pathways. The latter inscribes the delta wave. NSR, Normal sinus rhythm.

If cardiac failure occurs because of prolonged tachycardia in an infant with a normal heart, cardiac function usually returns to normal after sinus rhythm is reinstituted, although it may take days to weeks. Infants with SVT diagnosed within the first 3-4 months of life have a lower incidence of recurrence than those initially diagnosed at a later age. These patients have up to an 80% chance of resolution by the first year of life, although approximately 30% will have recurrences later in childhood; if medical therapy is required, it can be tapered by 12-18 months and the patient watched for signs of recurrence. Parents should be taught to measure the heart rate in their infants, so that prolonged asymptomatic episodes of SVT may be detected before heart failure occurs.

The use of **24-hour electrocardiographic (Holter) monitoring** assists in following the course of therapy and detecting brief runs of asymptomatic tachycardia, particularly in younger children and infants. Direct-to-consumer heart monitoring devices ("wearables") are beginning to replace traditional monitors as newer technology allows for miniaturization and improved accuracy of at-home monitoring devices. These devices have helped identify asymptomatic tachycardia in infants and young children. Some centers use **transesophageal pacing** to evaluate the effects of therapy in infants. More detailed electrophysiology studies performed in the cardiac catheterization laboratory are often indicated in patients with refractory SVT who are candidates for catheter ablation. During an EPS, multiple electrode catheters are placed transvenously in different locations in the heart. Pacing is performed to evaluate the conduction characteristics of the accessory pathway and to initiate the tachyarrhythmia, and mapping is performed to locate the accessory pathway. **Catheter ablation** of an accessory pathway is frequently used in children and teenagers and in patients who require multiple agents or find drug side effects intolerable or for whom arrhythmia control is poor. Ablation may be performed either by **radiofrequency ablation**, which creates tissue heating, or **cryoablation**, in which tissue is frozen (Fig. 484.6). The overall initial success rate for catheter ablation in experienced pediatric laboratories ranges from 90% to 98%, depending on the location of the accessory pathway. Surgical ablation of bypass tracts is rarely done and proposed only in carefully selected patients.

The management of SVT caused by AVNRT is almost identical to that for AVRT. Children with AVNRT are not at increased risk of sudden death because they do not have a manifest accessory pathway. In practice, their episodes are more likely to be brought on by exercise or other forms of stress, and the heart rates can be quite fast, leading to chest pain, dizziness, and occasionally syncope. If chronic antiarrhythmic medication is desired, β blockers are the drugs of choice; acutely, AVNRT responds to adenosine. Less is known about the natural history, but patients with AVNRT are seen quite frequently in adulthood, so spontaneous resolution seems unlikely. Patients are quite amenable to catheter ablation, either using radiofrequency energy or cryoablation, with high success rates and low complication rates.

Atrial ectopic tachycardia is an uncommon tachycardia in childhood. It is characterized by a variable rate (seldom >200 beats/min), identifiable P waves with an abnormal axis, and either a sustained or incessant nonsustained tachycardia (Fig. 484.7). This form of atrial tachycardia has a single automatic focus. Identification of this mechanism is aided by monitoring the ECG while initiating vagal or pharmacologic therapy. Unlike reentrant tachycardias, which "break" suddenly, automatic tachycardias such as atrial tachycardia tend to

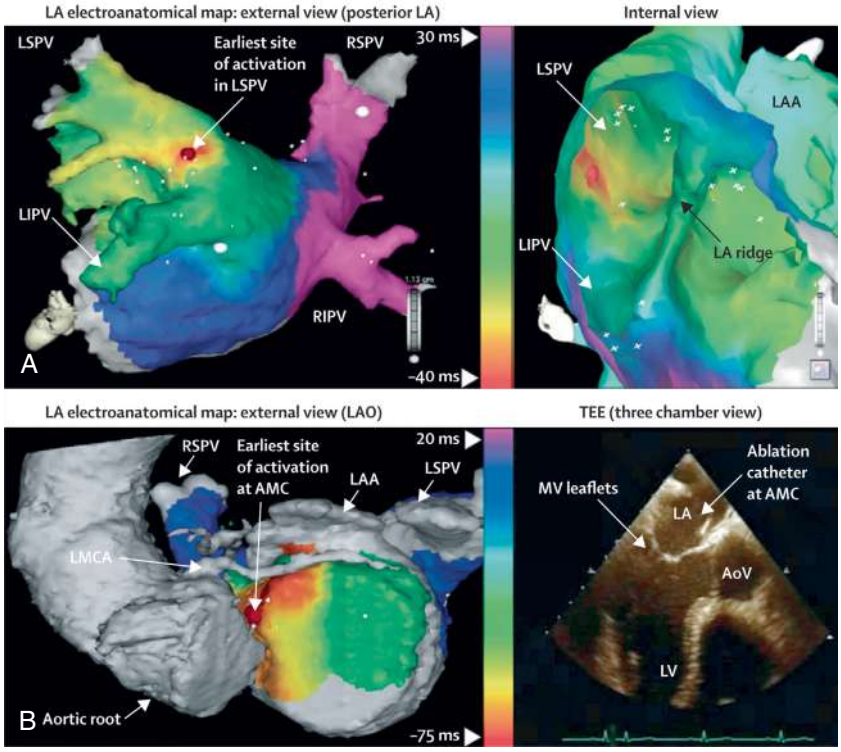

Fig. 484.6 Three-dimensional electroanatomic map of focal atrial tachycardias. Focal site of early activation *(red)* is shown, with radial propagation away from that central site. The activation map was superimposed onto the patient's cardiac CT scan, taken the day before the procedure and imported into the mapping system. This patient had two separate atrial foci. **A**, Tachycardia #1: Earliest site of activation, mapped to the posterior aspect of the LSPV ostium. Posterior external view *(left side)* and endoluminal or internal view looking posterior to anterior from within the left atrium into the mouth of the LSPV *(right side)* are shown. **B**, Tachycardia #2: Earliest site mapped to the aortomitral continuity. The anatomic relation between the mitral annulus and the aortic root can be clearly appreciated *(left side)*. The location of the ablation catheter at the site of earliest atrial activation during atrial tachycardia is shown on the TEE image *(right side)*. AMC, Aortomitral continuity; AoV, aortic valve; LA, left atrium; LAA, left atrial appendage; LAO, left anterior oblique; LIPV, left inferior pulmonary vein; LMCA, left main coronary artery; LSPV, left superior pulmonary vein; LV, left ventricle; MV, mitral valve; RIPV, right inferior pulmonary vein; RSPV, right superior pulmonary vein; TEE, transesophageal echocardiogram. *(From Lee G, Sanders P, Kalman JM. Catheter ablation of atrial arrhythmias: state of the art. Lancet. 2012;380:1509–1518, Fig 3.)*

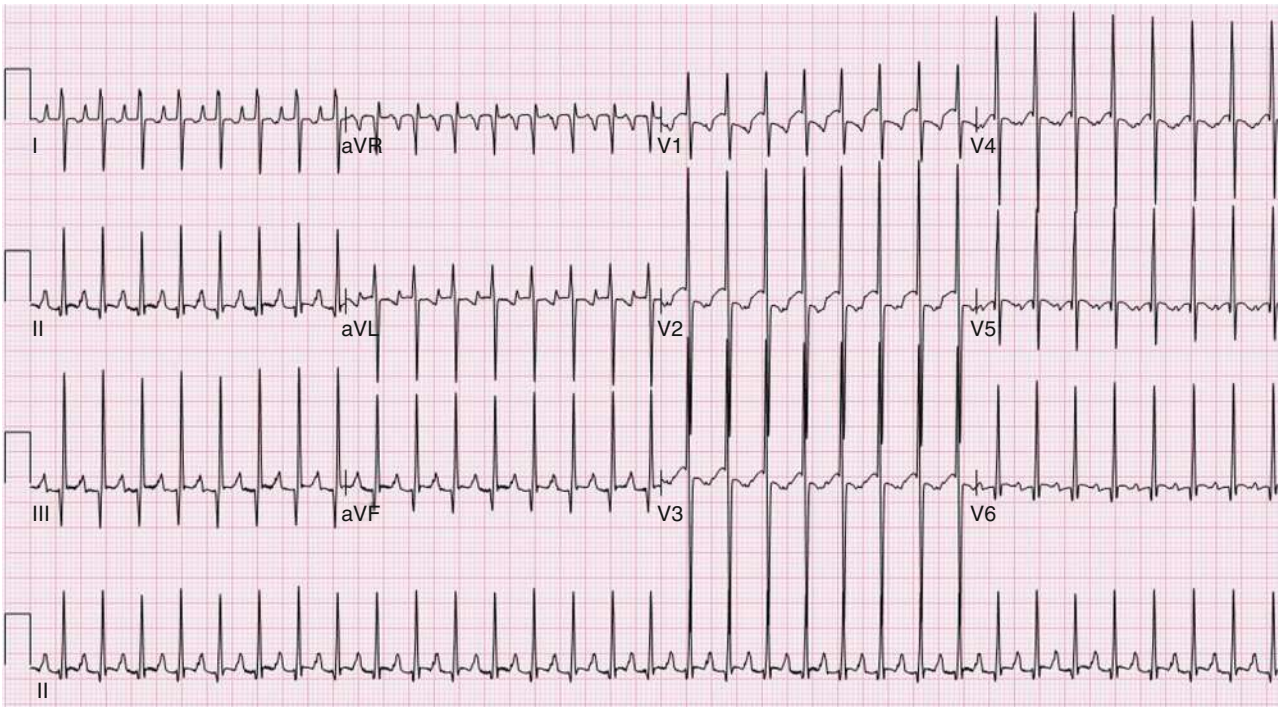

Fig. 484.7 Atrial ectopic tachycardia. Note the abnormal P waves and relative prolongation of the PR interval.

"warm up" and "cool down" (i.e., rates tend to gradually increase and decrease). Atrial ectopic tachycardias are usually more difficult to control pharmacologically than the more common reentrant tachycardias. If pharmacologic therapy with a single agent is unsuccessful, catheter ablation is suggested and has a high success rate, usually >90%. Long-term treatment or ablation may not be necessary in some cases, as atrial ectopic tachycardia may resolve spontaneously in some patients.

Chaotic or multifocal atrial tachycardia is defined as atrial tachycardia with ≥3 ectopic P-wave morphologies, frequent blocked P waves, and varying P-R intervals of conducted beats. This arrhythmia occurs most often in infants younger than 1 year of age, usually without concomitant cardiac disease, although some evidence suggests an association with viral myocarditis or pulmonary disease. The goal of drug treatment is rate control, or slowing of the ventricular rate, because conversion to sinus rhythm may not be possible. Multiple agents are often required. When this arrhythmia occurs in infancy, it usually terminates spontaneously by 3 years of age.

Accelerated junctional ectopic tachycardia (JET) is an automatic (non-reentry) arrhythmia in which the junctional rate exceeds that of the sinus node and AV dissociation may result. This arrhythmia is most often recognized in the early postoperative period after cardiac surgery and may be extremely difficult to control. Reduction of the infusion rate of exogenous catecholamines and mitigating causes of endogenous catecholamines such as fever and pain are important adjuncts to management. Intravenous amiodarone and procainamide are effective in the treatment of postoperative JET. Congenital JET may be seen in the absence of surgery. It is often incessant, can be difficult to treat, and can lead to a dilated cardiomyopathy. Patients who require chronic therapy may respond to amiodarone or sotalol. Congenital JET can be cured by catheter ablation, but long-term AV block requiring a pacemaker is an occasional important complication.

Atrial flutter, also known as *intraatrial reentrant tachycardia,* is an atrial tachycardia characterized by atrial activity at a rate of 250-300 beats/min in children and adolescents and 400-600 beats/min in neonates. The mechanism of common atrial flutter consists of a reentrant rhythm originating in the right atrium circling the tricuspid valve annulus. Because the AV node cannot transmit such rapid impulses, some degree of **AV block** is virtually always present, and the ventricles respond to every second to fourth atrial beat (Fig. 484.8). Occasionally, the response is variable, and the rhythm appears irregular.

In older children, atrial flutter usually occurs in the setting of CHD; neonates with atrial flutter frequently have normal hearts. Atrial flutter may occur during acute infectious illnesses but is most often seen in patients with large stretched atria, such as those associated with long-standing mitral or tricuspid insufficiency, tricuspid atresia, Ebstein anomaly, or rheumatic mitral stenosis. Atrial flutter can also occur after any palliative or corrective cardiac surgery involving an atriotomy. Uncontrolled atrial flutter may precipitate heart failure. Vagal maneuvers or adenosine may produce a temporary slowing of the heart rate as a result of increased AV block, allowing a diagnosis to be made. The diagnosis is confirmed by ECG, which demonstrates the rapid and regular atrial saw-toothed flutter waves. *Atrial flutter usually converts immediately to sinus rhythm by synchronized DC cardioversion, which is most often the treatment of choice.* If pacing wires or atrial pacemaker leads are present, pace termination with atrial overdriving pacing may be a treatment option. In infants, an esophageal pacing lead can also be used, but care must be taken to avoid inadvertent ventricular pacing. Patients with chronic atrial flutter in the setting of CHD may be at increased risk for thromboembolism and stroke and should thus undergo anticoagulation before elective cardioversion. β Blockers or calcium channel blockers may be used to slow the ventricular response in atrial flutter by prolonging the AV node refractory period. Other agents may be used to maintain sinus rhythm, including **class I agents** such as procainamide or propafenone or **class III** agents such as amiodarone and sotalol. **Catheter ablation** has been used in patients with normal hearts and those with CHD with moderate success. After cardioversion, neonates with normal hearts may be followed off antiarrhythmic therapy or may be treated with digoxin, propranolol, or sotalol for 6-12 months, after which the medication can usually be discontinued, because neonatal atrial flutter generally does not recur.

Atrial fibrillation is uncommon in children and is rare in infants. The atrial excitation is chaotic and more rapid (400-700 beats/min) and produces an *irregularly irregular* ventricular response and pulse (Fig. 484.9). This rhythm disorder is often associated with atrial

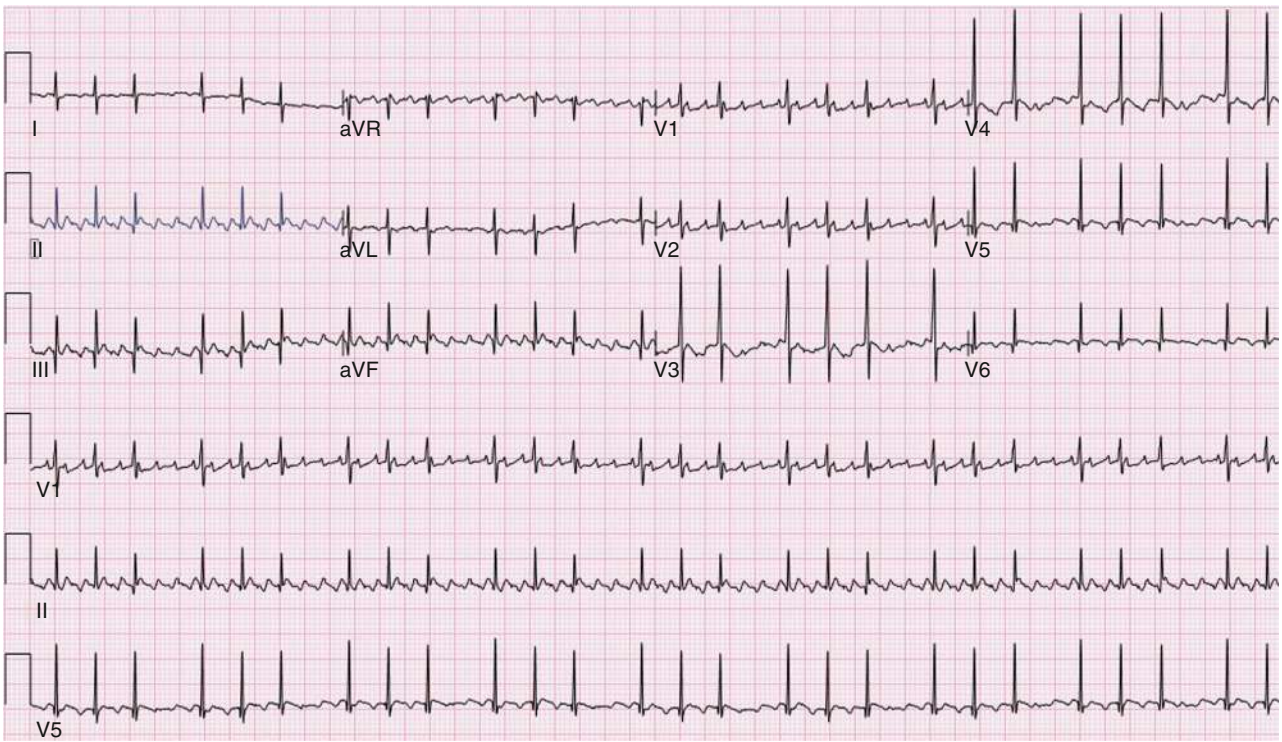

Fig. 484.8 Neonatal atrial flutter. Note that there is variable AV conduction and the flutter waves have a cycle length of 160 msec, corresponding to an atrial rate of 375 bpm.

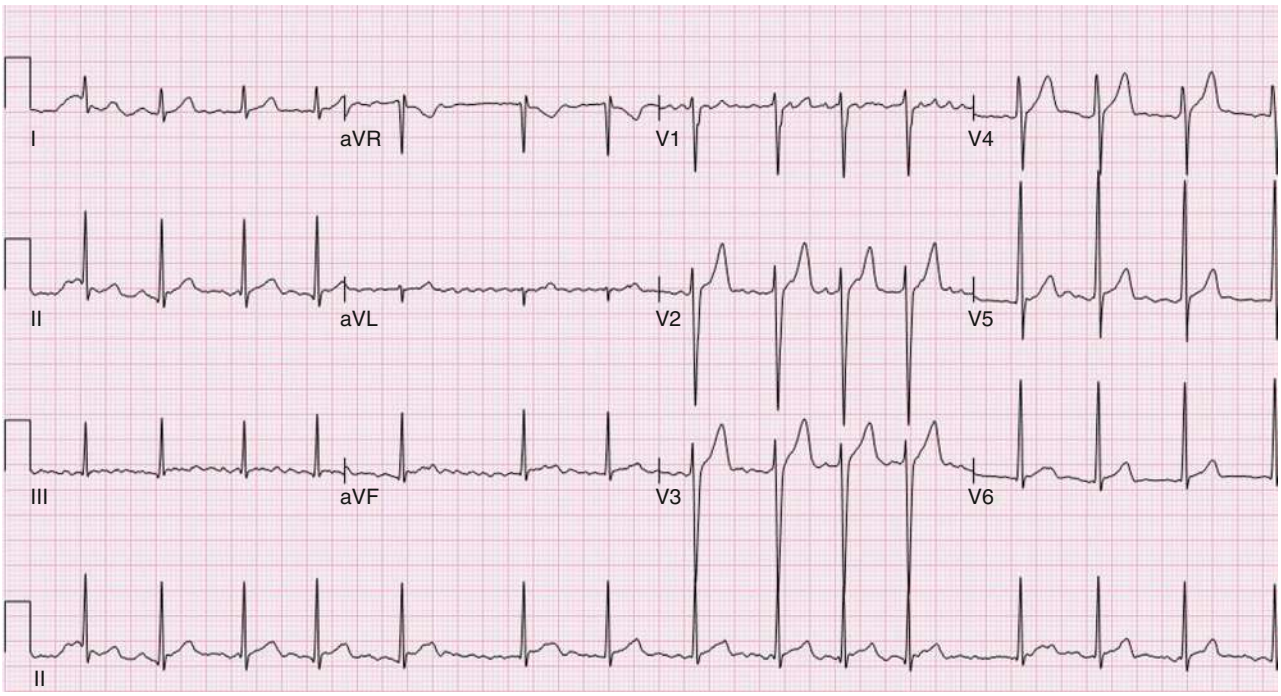

Fig. 484.9 Atrial fibrillation, characterized by the absence of clear P waves and an irregularly irregular ventricular response. One can appreciate the irregular, rapid undulations (F waves). Fibrillatory waves may not be visible in all leads and should be carefully sought in every tracing with irregular R-R intervals. Note that no two R-R intervals are the same.

enlargement or disease. Atrial fibrillation may be seen in older children with rheumatic mitral valve stenosis. It is also seen rarely as a complication of atrial surgery, in patients with left atrial enlargement secondary to left AV valve insufficiency, and in patients with WPW syndrome. Thyrotoxicosis, pulmonary embolism, pericarditis, or cardiomyopathy may be suspected in a previously normal older child or adolescent who presents with atrial fibrillation. Very rarely, atrial fibrillation may be familial and is usually an autosomal dominant disorder often affecting the potassium or sodium channel genes. The best initial treatment is **rate control**, most effectively with calcium channel blockers, to limit the ventricular rate during atrial fibrillation. Digoxin is not given if WPW syndrome is present. Normal sinus rhythm may be restored with intravenous procainamide, ibutilide, or amiodarone; DC cardioversion is the first choice in hemodynamically unstable patients. Patients with chronic atrial fibrillation are at risk for thromboembolism and stroke and should undergo anticoagulation with warfarin. Patients being treated by elective cardioversion should also undergo anticoagulation.

484.4 Ventricular Tachyarrhythmias

Aarti S. Dalal and George F. Van Hare

Ventricular tachycardia (VT) is much less common than SVT in pediatric patients. VT is defined as at least three PVCs at >120 beats/min (Fig. 484.10). It may be paroxysmal or incessant. VT can be seen in congenital or acquired heart disease, including inherited arrhythmia syndromes secondary to channelopathies, myopathies, or laminopathies. VT may be associated with structural disease such as myocarditis, anomalous origin of a coronary artery, mitral valve prolapse, primary cardiac tumors, arrhythmogenic cardiomyopathy (previously known as *arrhythmogenic right ventricular cardiomyopathy*), dilated or hypertrophic cardiomyopathy, and cardiac laminopathies (associated with lamin A/C gene pathogenic variants). Patients with laminopathies associated with a variant in the lamin A/C gene *(LMNA)*, as seen in Emery Dreifuss muscular dystrophy or 1B limb girdle muscular dystrophy are at risk of primary ventricular arrhythmias in addition to development of cardiomyopathies. VT can also be seen in patients with channelopathies such as catecholaminergic polymorphic ventricular tachycardia, Brugada syndrome, *TANGO2*-related encephalopathy and arrhythmias, and long QT syndrome. A prolonged QT interval of either congenital or acquired (proarrhythmic medication or hypokalemia, hypocalcemia, hypomagnesemia) causation can increase a patient's risk of arrhythmias. Other causes include WPW syndrome and drug use (cocaine, amphetamines). VT may develop years after intraventricular surgery (especially tetralogy of Fallot and related defects) or occur without obvious organic heart disease. VT must be distinguished from SVT with aberrancy or rapid conduction over an accessory pathway (Table 484.2). The presence of clear capture and fusion beats confirms the diagnosis of VT. Although some children tolerate rapid ventricular rates for many hours, this arrhythmia should be promptly treated because hypotension and degeneration into ventricular fibrillation may result. For patients who are hemodynamically stable, intravenous amiodarone, lidocaine, and procainamide are the initial drugs of choice. If treatment is to be successful, it is critical to search for and correct any underlying abnormalities, such as electrolyte imbalance, hypoxia, or drug toxicity. **Amiodarone** is the treatment of choice during cardiac arrest (see Chapter 79). Hemodynamically unstable patients with VT should be immediately treated with DC cardioversion. Overdrive ventricular pacing, through temporary pacing wires or a permanent pacemaker, may also be effective, although it may cause the arrhythmia to deteriorate into ventricular fibrillation. In the neonatal period, VT may be associated with an anomalous left coronary artery (see Chapter 481.2) or a myocardial tumor.

Unless a clearly reversible cause is identified, an electrophysiology study is usually indicated for patients in whom VT has developed, and depending on the findings, catheter ablation and/or implantable cardioverter-defibrillator (ICD) implantation may be indicated.

A related arrhythmia, **ventricular accelerated rhythm**, is occasionally seen in infants. It is defined the same way as VT, but the rate is only slightly faster than the coexisting sinus rate (within 10%). It is generally benign and resolves spontaneously.

Ventricular fibrillation (VF) is a chaotic rhythm that results in death unless an effective ventricular beat is rapidly reestablished. Usually, cardiopulmonary resuscitation and DC defibrillation are necessary. If defibrillation is ineffective or VF recurs, amiodarone or lidocaine may be given intravenously and defibrillation repeated (see Chapter 79). After recovery from VF, a search should be made for the

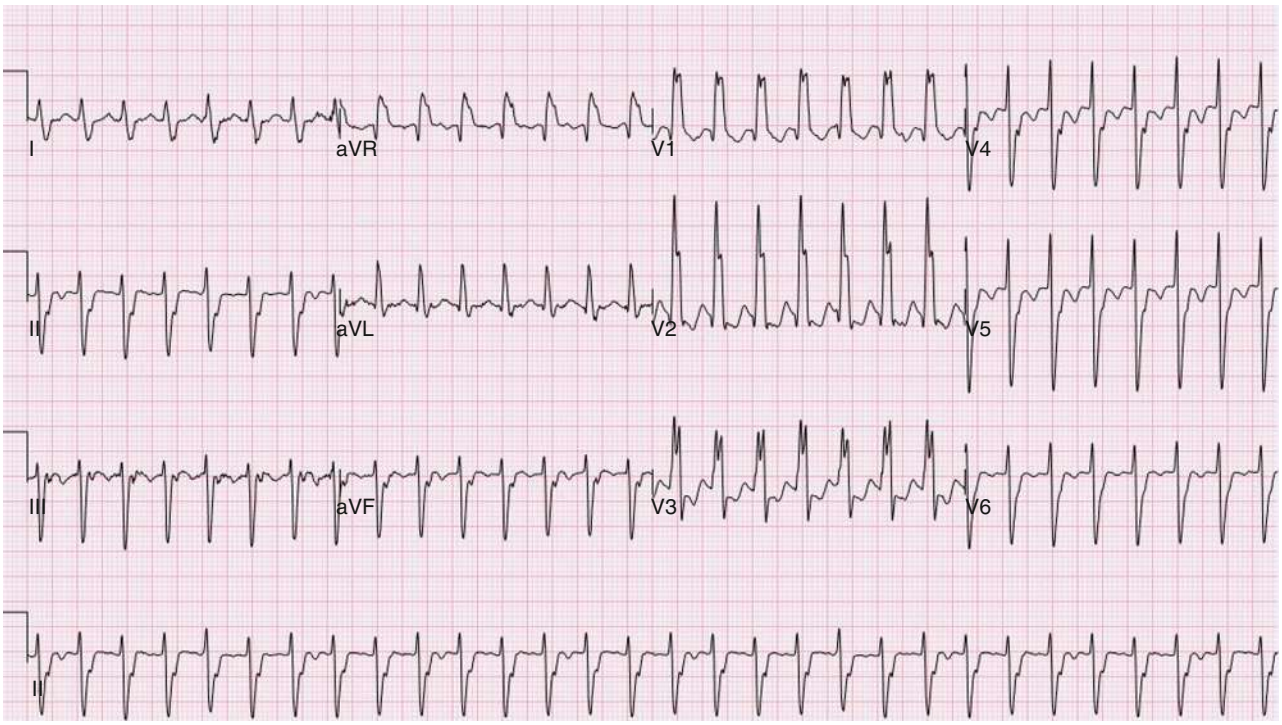

Fig. 484.10 Ventricular tachycardia. The QRS complexes are wide and abnormal. Atrioventricular dissociation can be best appreciated in the lead II rhythm strip at the bottom.

Table 484.2 Diagnosis of Tachyarrhythmias: Electrocardiographic Findings

	HEART RATE (BEATS/MIN)	P WAVE	QRS DURATION	REGULARITY
Sinus tachycardia	<230	Always present, normal axis	Normal	Rate varies with respiration
Atrial tachycardia	180-320	Present Abnormal P-wave morphology and axis	Normal or prolonged (with aberration)	Usually regular, but ventricular response may be variable because of Wenckebach conduction
Atrial fibrillation	120-180	Fibrillatory waves	Normal or prolonged (with aberration)	Irregularly irregular (no two R-R intervals alike)
Atrial flutter	Atrial: 250-400 Ventricular response variable: 100-320	Saw-tooth flutter waves	Normal or prolonged (with aberration)	Regular ventricular response (e.g., 2:1, 3:1, 3:2)
Junctional tachycardia	120-280	Atrioventricular dissociation with no fusion, and normal QRS capture beats	Normal or prolonged (with aberration)	Regular (except with capture beats)
Ventricular tachycardia	120-300	Atrioventricular dissociation with capture beats and fusion beats	Prolonged for age	Regular (except with capture beats)

underlying cause. EPS is indicated for patients who have survived VF unless a clearly reversible cause is identified. If WPW syndrome is noted, catheter ablation should be performed. For patients in whom no correctable abnormality can be found, an ICD is almost always indicated because of the high risk of sudden death.

484.5 Long QT Syndromes

Aarti S. Dalal and George F. Van Hare

Long QT syndrome is a genetic abnormality of ventricular repolarization, with an estimated incidence of about 1 per 10,000 births (Table 484.3; also includes other genetic arrhythmia syndromes). It presents as a long QT interval on the surface ECG and is associated with malignant ventricular arrhythmias (**torsades de pointes** and VF). Long QT syndrome can cause syncope and sudden death and may be the cause of some cases of sudden infant death syndrome, drowning, and intrauterine fetal demise (Fig. 484.11). In perhaps 80% of cases, there is an identifiable pathogenic variant. The distinction between dominant and recessive forms of the disease (Romano-Ward syndrome vs Jervell-Lange-Nielsen syndrome) is no longer made because the latter recessive condition is known to result from the homozygous state. **Jervell-Lange-Nielsen syndrome** is associated with congenital sensorineural deafness. Asymptomatic but at-risk patients carrying the gene variant may not all have a prolonged QT duration. QT interval prolongation may become apparent with exercise, position change or during catecholamine infusions.

Genetic studies have identified pathogenic variants in cardiac potassium and sodium channels (see Table 484.3). Additional forms (up to 13 variants) of long QT syndrome (LQTS) have been described, but these are much less common. Genotype may predict clinical manifestations;

LQTS type 1 (**LQT1**) events are usually induced by stress or exertion, whereas events in **LQT3** often occur at rest, especially during sleep (see Fig. 484.11). **LQT2** events have an intermediate pattern, often occurring in the postpartum period or with auditory triggers. LQT3 has the highest probability for sudden death, followed by LQT2 and then LQT1. Drugs may prolong the QT interval directly but more often do so when drugs such as erythromycin or ketoconazole inhibit their metabolism (Table 484.4).

The **clinical manifestation** of LQTS in children is most often a syncopal episode brought on by exercise, fright, or a sudden startle; some events occur during sleep (LQT3). Patients can initially be seen with seizures, presyncope, or palpitations; approximately 10% are initially in cardiac arrest. The diagnosis is based on electrocardiographic and clinical criteria. Not all patients with long QT intervals have LQTS, and patients with normal QT intervals on a resting ECG may have LQTS. A heart rate–corrected QT interval (QTc) of >0.47 second is highly indicative, whereas a QTc interval of >0.44 second is suggestive. Other features include notched T waves in three leads, T-wave alternans, a low heart rate for age, a history of syncope (especially with stress), and a familial history of either LQTS or unexplained sudden death. Exercise testing, provocative drug testing, and 24-hour Holter monitoring are adjuncts to the diagnosis. Genotyping is available and can identify the pathogenic variant in approximately 80% of patients known to have LQTS by clinical criteria. Genotyping is not useful in ruling out the diagnosis in individuals with suspected disease, but when positive is very useful in identifying asymptomatic affected relatives of the index case.

Short QT syndromes manifest with atrial or ventricular fibrillation and are associated with syncope and sudden death (see Table 484.3). They are often caused by a gain-of-function mutation in cardiac potassium channels.

Treatment of LQTS includes the use of β-blocking agents at doses that blunt sympathetic tone. Nonselective β blockers such as propranolol and nadolol seem to be more effective than atenolol and metoprolol for some genotypes. Some patients require a **pacemaker** because of drug-induced bradycardia. An **implantable cardiac defibrillator** (ICD) is indicated in patients with continued syncope despite treatment with β blockers and those who have experienced cardiac arrest. Genotype-phenotype correlative studies suggest that β blockers are not as effective in patients with LQT3, but these patients may respond to mexiletine with shortening of the QT interval.

484.6 Sinus Node Dysfunction

Aarti S. Dalal and George F. Van Hare

Sinus arrest and sinoatrial block may cause a sudden pause in the heartbeat. **Sinus arrest** is presumably caused by failure of impulse formation within the sinus node. **Sinoatrial block** results from a block between the sinus pacemaker complex and the surrounding atrium. These arrhythmias are rare in childhood except in patients who have had extensive atrial surgery.

Sick sinus syndrome is the result of abnormalities in the sinus node or atrial conduction pathways, or both. This syndrome may occur in the absence of CHD and has been reported in siblings, but it is most commonly seen after surgical correction of congenital heart defects,

From Tester DJ, Ackerman MJ. Genetics of cardiac arrhythmias. In Zipes DP, Libby P, Bonow RO, et al., eds. *Braunwald's Heart Disease*, 11th ed. Philadelphia: Elsevier; 2019, Table 33.1, p. 605.

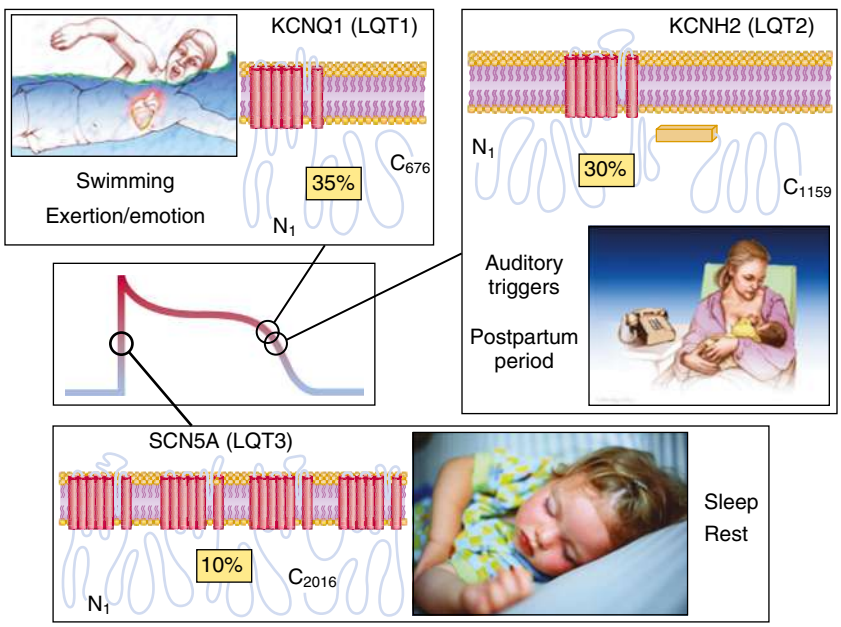

Fig. 484.11 Genotype-phenotype correlations in long QT syndrome (LQTS). About 75% of clinically strong LQTS is caused by mutations in three genes (35% *KCNQ1*, 30% *KCNH2*, and 10% *SCN5A*) encoding for ion channels that are critically responsible for the orchestration of the cardiac action potential. Observed genotype-phenotype correlations include swimming/exertion/emotion and LQT1, auditory triggers/postpartum period and LQT2, and sleep/rest and LQT3. *(From Tester DJ, Ackerman MJ. Genetics of cardiac arrhythmias. In: Zipes DP, Libby P, Bonow RO, et al., eds. Braunwald's Heart Disease, 11th ed. Philadelphia: Elsevier; 2019: Fig 33-3, p. 607.)*

Table 484.4 Acquired Causes of QT Prolongation*

DRUGS
Antibiotics—erythromycin, clarithromycin, azithromycin, telithromycin, trimethoprim/sulfamethoxazole, fluoroquinolones†
Antifungal agents†—fluconazole, itraconazole, ketoconazole
Antiprotozoal agents—pentamidine isethionate
Antihistamines—astemizole, terfenadine (Seldane; Seldane has been removed from the market for this reason)
Antidepressants—tricyclics such as imipramine (Tofranil), amitriptyline (Elavil), desipramine (Norpramin), and doxepin (Sinequan)
Antipsychotics—haloperidol, risperidone, phenothiazines such as thioridazine (Mellaril) and chlorpromazine (Thorazine), selective serotonin uptake inhibitors
Antiarrhythmic agents
Class 1A (sodium channel blockers)—quinidine, procainamide, disopyramide
Class III (prolong depolarization)—amiodarone (rare), bretylium, dofetilide, *N*-acetyl-procainamide, sotalol
Lipid-lowering agents—probucol
Antianginals—bepridil
Diuretics (through K^+ loss)—furosemide (Lasix), ethacrynic acid (bumetanide [Bumex])
Opiates—methadone, oxycodone
Oral hypoglycemic agents—glibenclamide, glyburide
Organophosphate insecticides
Motility agents—cisapride, domperidone
Vasodilators—prenylamine
Other drugs—ondansetron, HIV protease inhibitors, Chinese herbs
ELECTROLYTE DISTURBANCES
Hypokalemia—diuretics, hyperventilation
Hypocalcemia
Hypomagnesemia
UNDERLYING MEDICAL CONDITIONS
Bradycardia—complete atrioventricular block, severe bradycardia, sick sinus syndrome
Myocardial dysfunction—anthracycline cardiotoxicity, congestive heart failure, myocarditis, cardiac tumors
Endocrinopathy—hyperparathyroidism, hypothyroidism, pheochromocytoma
Neurologic—encephalitis, head trauma, stroke, subarachnoid hemorrhage
Nutritional—alcoholism, anorexia nervosa, starvation

*A more exhaustive updated list of medications that can prolong the QTc interval is available at the University of Arizona Center for Education and Research of Therapeutics website (www.crediblemeds.org).
†Combinations of quinolones plus azoles increase the risk of prolonged QT intervals.
From Park MY. *Pediatric Cardiology for Practitioners,* 5th ed. Philadelphia: Mosby; 2008: Box 24-1, p. 433.

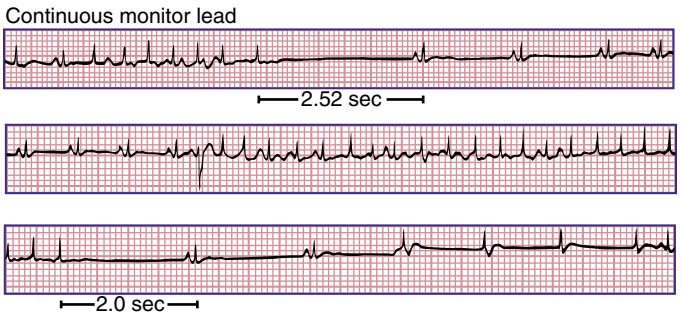

Fig. 484.12 The "tachy-brady" syndrome with sinus node dysfunction. Note the bursts of supraventricular tachycardia, probably multifocal atrial in origin, followed by long periods of sinus arrest and by sinus bradycardia. Often, symptoms are caused by the long sinus pauses after termination of tachycardia, rather than by the tachycardia itself.

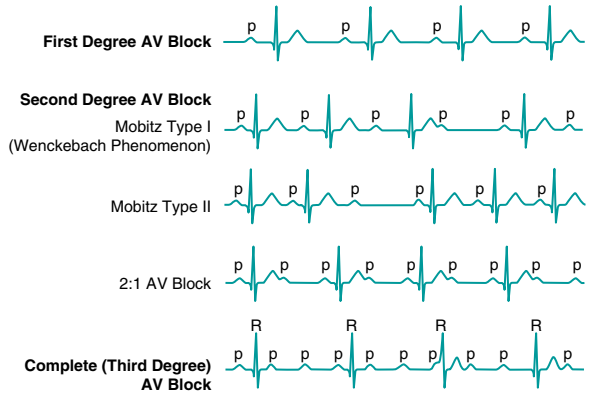

Fig. 484.13 Atrioventricular (AV) block. *(From Park MY. Pediatric Cardiology for Practitioners, 5th ed. Philadelphia: Mosby; 2008: Fig 25-1, p. 446.)*

especially the **Fontan procedure** and the **atrial switch** (Mustard or Senning) operation for transposition of the great arteries. Clinical manifestations depend on the heart rate. Most patients remain asymptomatic without treatment, but dizziness and syncope can occur during periods of marked sinus slowing with failure of junctional escape. Pacemaker therapy is indicated in patients who experience symptoms such as exercise intolerance or syncope.

Patients with sinus node dysfunction may also have episodes of SVT **("tachy-brady" syndrome)** with symptoms of palpitations, exercise intolerance, or dizziness (Fig. 484.12). Treatment must be individualized. Drug therapy to control tachyarrhythmias (propranolol, sotalol, amiodarone) may suppress sinus and AV node function to such a degree that further symptomatic bradycardia may be produced. Therefore insertion of a pacemaker in conjunction with drug therapy is usually necessary for such patients, even in the absence of symptoms ascribable to low heart rate.

484.7 Atrioventricular Block

Aarti S. Dalal and George F. Van Hare

Atrioventricular block may be divided into three forms (Fig. 484.13). In **first-degree AV block**, the PR interval is prolonged but all the atrial impulses are conducted to the ventricle. In **second-degree AV block**, not every atrial impulse is conducted to the ventricle. In the variant of second-degree block known as the **Wenckebach type** (also called **Mobitz type I**), the PR interval increases progressively until a P wave is not conducted. In the cycle following the dropped beat, the PR interval normalizes. In **Mobitz type II** there is no progressive conduction delay or subsequent shortening of the PR interval after a blocked beat. This conduction defect is less common but has more potential to cause syncope and may be progressive. A related condition is **high-grade second-degree AV block**, in which two or more P waves in a row fail to conduct. This is even more dangerous. In **third-degree AV block (complete heart block)**, no impulses from the atria reach the ventricles. An independent escape rhythm is usually present but may not be reliable, leading to syncope or even sudden death.

Congenital complete AV block in children is presumed to be caused by autoimmune injury of the fetal conduction system by maternally derived immunoglobulin G antibodies (anti-SSA/Ro, anti-SSB/La) in a mother with overt or, more often, asymptomatic systemic lupus erythematosus (SLE) or Sjögren syndrome. Autoimmune disease accounts for 60–70% of all cases of congenital complete AV block and 80% of cases in which the heart is structurally normal (Fig. 484.14). A pathogenic variant in *NKX2-5* is associated with congenital AV block and an atrial septal defect.

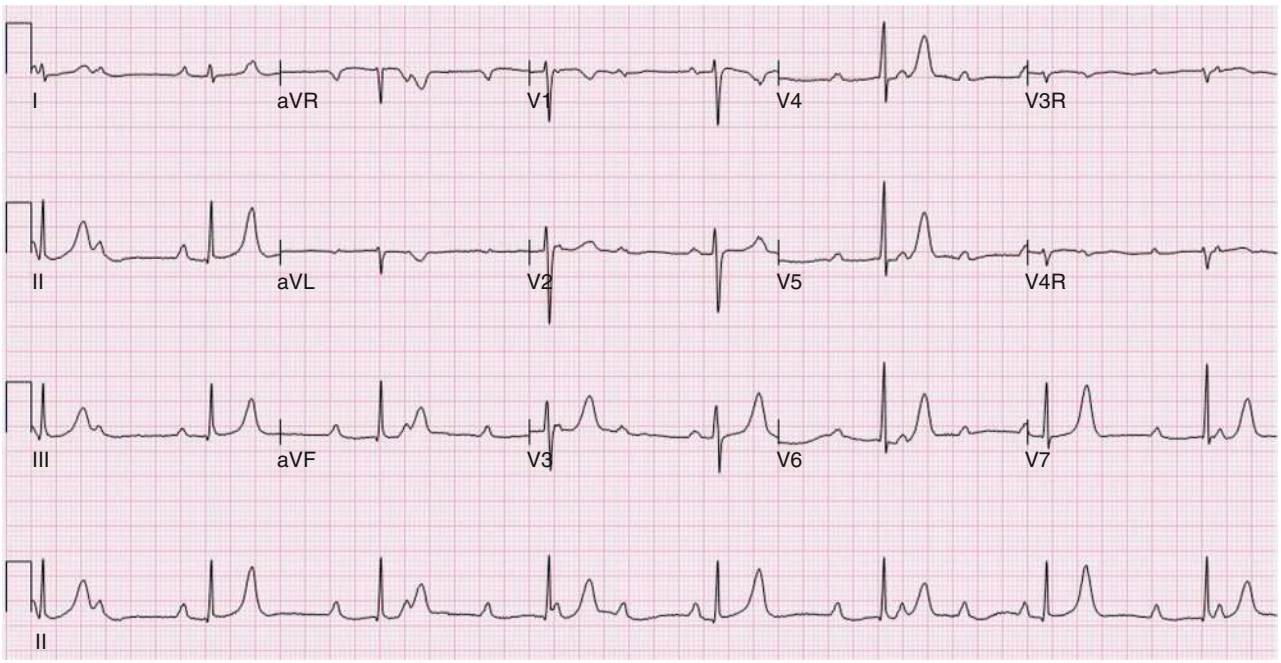

Fig. 484.14 Congenital complete atrioventricular (AV) block. The ventricular rate is regular at 44 beats/min. The atrial rate is approximately 100 beats/min and completely dissociated from the ventricle. The QRS morphology is normal, which is common in congenital complete AV block.

Complete AV block is also seen in patients with complex CHD and abnormal embryonic development of the conduction system. It has been associated with myocardial tumors and myocarditis. Acquired heart block (first, second, or third degree) is seen in Lyme disease and COVID-19–associated multisystem inflammatory syndrome. In these syndromes, first-degree heart block may progress to second- or third-degree heart block. Complete AV block is a known complication of myocardial abscess secondary to endocarditis. It is also seen in genetic conditions, including LQTS, Emery Dreifuss muscular dystrophy, and Kearns-Sayre syndrome. Postoperative AV block can be a complication of CHD repair—in particular, those repairs involving closure of a ventricular septal defect.

The incidence of congenital complete AV block is 1 per 20,000-25,000 live births; a high fetal loss rate may cause an underestimation of its true incidence. In some infants of mothers with SLE, complete AV block is not present at birth but develops within the first 3-6 months after birth. The arrhythmia is often diagnosed in the fetus (secondary to the dissociation between atrial and ventricular contractions seen on fetal echocardiography) and may produce hydrops fetalis. Maternal treatment with corticosteroids to halt progression or reverse AV block is controversial. Infants with associated CHD and heart failure have a high mortality rate.

In older children with otherwise normal hearts, complete AV block is often asymptomatic, although syncope and sudden death may occur. Infants and toddlers may have night terrors, tiredness with frequent naps, and irritability. The peripheral pulse is prominent because of the compensatory large ventricular stroke volume and peripheral vasodilation; systolic blood pressure is elevated. Jugular venous pulsations occur irregularly and may be large when the atrium contracts against a closed tricuspid valve (cannon wave). Exercise and atropine may produce an acceleration of 10-20 beats/min. Systolic murmurs are frequently audible along the left sternal border, and apical mid-diastolic murmurs are not unusual. The first heart sound is variable because of variable ventricular filing with AV dissociation. AV block may result in enlargement of the heart because of slow rates and increased diastolic ventricular filling.

The **diagnosis** is confirmed by electrocardiography; the P waves and QRS complexes have no constant relationship (see Fig. 484.14). The QRS duration may be prolonged, or it may be normal if the heartbeat is initiated high in the AV node or bundle of His.

The **prognosis** for congenital complete AV block is usually favorable; patients who have been observed to age 30-40 have lived normal, active lives. Some patients have episodes of exercise intolerance, dizziness, and syncope (Stokes-Adams attacks); syncope requires the implantation of a permanent cardiac pacemaker. Pacemaker implantation should be considered for patients who develop symptoms such as progressive cardiac dilation, prolonged pauses, or daytime average heart rates of ≤50 beats/min. In addition, prophylactic pacemaker implantation in adolescents is reasonable considering the low risk of the implant procedure and the difficulty in predicting who will develop sudden severe symptoms.

Cardiac pacing is recommended in neonates with low ventricular rates (≤55 beats/min), evidence of heart failure, wide complex rhythms, or CHD (with ventricular rates <70 beats/min). Isoproterenol, atropine, or epinephrine may be tried to increase the heart rate temporarily until pacemaker placement can be arranged. Transthoracic epicardial pacemaker implants have traditionally been used in infants; transvenous placement of pacemaker leads is available for young children. Postsurgical complete AV block can occur after any open heart procedure requiring suturing near the AV valves or crest of the ventricular septum. Postoperative heart block is initially managed with temporary pacing wires. The likelihood of a return of normal conduction after 10-14 days is low; a permanent pacemaker is recommended after that time.

Chapter 485

Sudden Death

Aarti S. Dalal and George F. Van Hare

Sudden death other than sudden infant death syndrome is rare in children. The causes of sudden death can be divided into traumatic versus nontraumatic in origin. *Traumatic* causes of sudden death are the most common in children; these include motor vehicle crashes, violent deaths, recreational deaths, and occupational deaths. *Nontraumatic* sudden deaths are often the result of specific cardiac causes. The incidence of sudden death varies from 0.8 to 6.2 per 100,000 per year in children and adolescents, in contrast to the higher incidence of **sudden cardiac death (SCD)** in adults of 1 per 1,000. Approximately 65% of sudden deaths are a result of heart-related problems in patients with either normal or congenitally (repaired, palliated, or unoperated) abnormal hearts. Competitive high school **sports** (basketball, soccer, football) are high-risk environmental factors. Common identifiable causes of death in competitive athletes include hypertrophic cardiomyopathy, with or without obstruction to left ventricular outflow, other cardiomyopathies, channelopathies, and anomalous coronary arteries; most are sudden *unexplained* deaths (Fig. 485.1). Table 485.1 lists other potential causes. These can be classified as *structural* abnormalities, including aortic stenosis and coronary artery abnormalities; myocardial disease, such as myocarditis; conduction system disease, including long QT syndrome; and miscellaneous causes, including seizures, pulmonary hypertension, and commotio cordis. Symptoms may be absent before the event but, if present, include syncope, chest pain, dyspnea, exercise intolerance, and palpitations. Patients may have a family history of heart disease (dilated or hypertrophic cardiomyopathy, long QT interval, arrhythmogenic [right ventricular] cardiomyopathy, Brugada or Marfan syndromes) or sudden unexplained death. Death often follows exertion or exercise. Some patients with sudden death during sports have anatomically normal hearts at autopsy; these patients should undergo genetic testing for hereditary arrhythmia syndromes.

MECHANISM OF SUDDEN DEATH

There are three recognized mechanisms of sudden death: *arrhythmic, nonarrhythmic cardiac* (circulatory and vascular causes), and *noncardiac*. **Ventricular fibrillation (VF)**, although the most common final cause of sudden death in adults, is only the final cause in 10–20% of children with SCD. More often, **bradycardia** leads either to VF or asystole (see Chapter 484).

CONGENITAL HEART DISEASE

Valvar aortic stenosis is the congenital defect most often associated with sudden death in children. Historically, approximately 5% of children with this disease die, although this has become quite rare in the modern era. A history of syncope, chest pain, and evidence of severe obstruction and left ventricular hypertrophy are risk factors (see Chapter 476.5).

Coronary artery anomalies are also frequently associated with sudden death in children and adolescents. The most common abnormality associated with sudden death is the origin of the left main coronary artery from the right sinus of Valsalva. The coronary artery takes an interarterial course between the aorta and pulmonary artery and may also have an intramural course, traveling within the ventricular myocardium. Exercise results in a rise in pulmonary and aortic pressure, and this is thought to compress the left main coronary artery and results in ischemia caused by compression or kinking. Anomalous origin of the right coronary artery from the left sinus of Valsalva is much more common, but only rarely is a cause of sudden death.

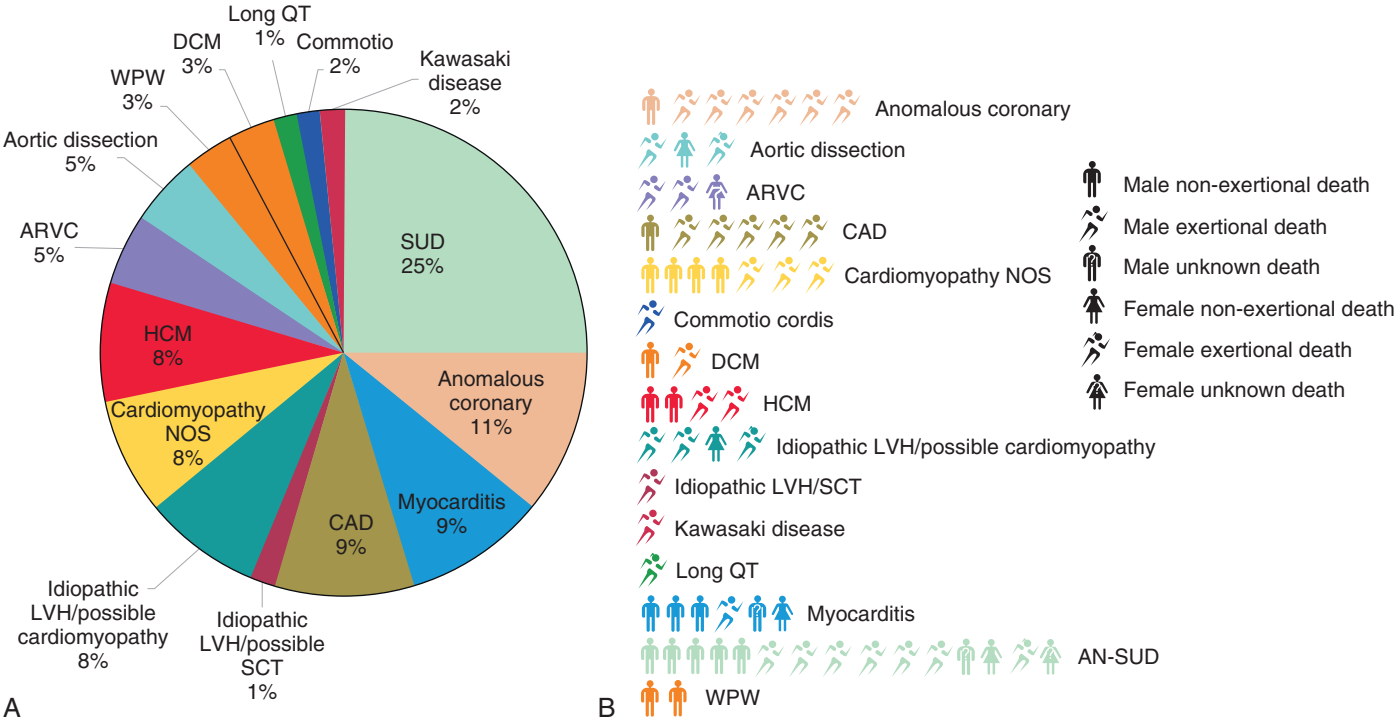

Fig. 485.1 A, Causes of sudden cardiac death in adolescent and young adult athletes. B, Cause and activity at time of death. One person figure equals one death; female figures follow male figures unless no male deaths were present. AN-SUD, Autopsy-negative sudden unexplained death; ARVC, arrhythmogenic right ventricular cardiomyopathy; CAD, coronary artery disease; DCM, dilated cardiomyopathy; HCM, hypertrophic cardiomyopathy; LVH, left ventricular hypertrophy; NOS, not otherwise specified; SCT, sickle cell trait; SUD, sudden unexplained death; WPW, Wolff-Parkinson-White syndrome. *(From Harmon KG, Asif I, Maleszewski JJ, et al. Incidence, cause, and comparative frequency of sudden cardiac death in National Collegiate Athletic Association athletes. Circulation. 2015;132:10–19, Fig. 2.)*

CARDIOMYOPATHY

All three major types of cardiomyopathy (hypertrophic, dilated, and restrictive) are associated with sudden death in the pediatric population; cardiac arrest or sudden death may be the initial manifestation of the cardiomyopathy (see Chapter 488.1).

Hypertrophic cardiomyopathy (HCM) is the most common cause of sudden death in the athletic adolescent in the United States. The annual risk of sudden death in young patients with HCM is 2% per year. Risk factors for sudden death include a history of syncope, symptoms, myocardial size, ventricular arrhythmias, and presentation at an early age. Many patients with HCM have left ventricular outflow tract obstruction (LVOTO). The mechanism of sudden death is arrhythmic and may be secondary to the development of dynamic obstruction with exercise and resultant loss of cardiac output, or may be related to cardiac ischemia. Thus patients without LVOTO are also at risk of sudden death. The **dilated cardiomyopathies** are also associated with SCD in children, although the risk is clearly lower than in adults.

Arrhythmogenic cardiomyopathy (also referred to as *arrhythmogenic right ventricular cardiomyopathy*) is a specific form of cardiomyopathy associated with exercise-induced ventricular arrhythmias and sudden death. It mainly affects the right ventricle, but the left can be involved as well. The diagnosis can be difficult; MRI, electrophysiology study, or endomyocardial biopsy is used with limited reliability. Pathologically, the disease is characterized by transmural fatty replacement of right ventricular myocardium, with patchy areas of fibrosis. Pathogenic variants are noted in ~60% of this autosomal dominant (with incomplete penetrance) disorder; associated genes include *PKP2, DSP, DSC2, DSG2, JUP, CTNNA3, PLN, TMEN43, SCN5A, CDH2,* and *DES*.

Myocarditis has often been found on pathology of patients with sudden death of unknown etiology. Symptoms before sudden death may be absent or may include overt heart failure or subtle findings such as a high heart rate. Pediatric patients with this disease may have complete atrioventricular block or ventricular arrhythmias.

*Common.
CHD, Congenital heart disease; SIDS, sudden infant death syndrome.

CARDIAC ARRHYTHMIA

A primary conduction system abnormality may result in sudden death. Causes include Wolff-Parkinson-White (WPW) syndrome, long QT syndrome, short QT syndrome, and Brugada syndrome. Besides causing supraventricular tachycardia, **WPW syndrome** can result in atrial fibrillation with rapid conduction across the accessory pathway, leading to VF and sudden death (Fig. 485.2). This is unusual in pediatric patients but has an increasing incidence in adolescence. In adults, there is an incidence of sudden death in asymptomatic patients of 1 per 1,000 patient-years, but this rate may well be higher in children, who have not yet survived to adulthood. As digoxin and verapamil can augment conduction down accessory pathways, these drugs are contraindicated in WPW syndrome.

Long QT syndrome (LQTS; see Chapter 484), a group of channelopathies that affect ventricular repolarization, is also associated with sudden death (Fig. 485.3). The mechanism of sudden death is polymorphic ventricular tachycardia **(torsades de pointes)** (Fig. 485.4). An initial presentation of SCD is found in 9% of patients. Thus treatment of asymptomatic patients with a long QT interval on electrocardiogram (ECG) and positive family history is advised.

Acquired long QT interval may be seen in patients with marked electrolyte abnormalities, central nervous system injury, or starvation (including bulimia and anorexia nervosa). Medications can also result in prolongation of the QT interval (see Table 484.4). These patients are also at risk of malignant ventricular arrhythmias, and correction of the underlying problem or withdrawal of the inciting medication may be necessary to reduce the risk of sudden death.

Brugada syndrome, an autosomal dominant disorder associated with SCD, often occurs with fever, drugs, nighttime electrolyte disorders, or after a large meal (Fig. 485.5). The most common pathogenic variant is a loss of function in *SCN5A,* seen in up to 30% of patients. Typical ECG findings include *coved* ST segment elevations in leads V_1-V_3; death results from either VF or ventricular tachycardia.

MISCELLANEOUS CAUSES

Commotio cordis is an often fatal condition that follows blunt nonpenetrating trauma to the chest (e.g., from a baseball or hockey puck). Occasionally, innocent-appearing chest blows incurred at home or at a playground may be fatal. Patients experience immediate VF in the absence of identifiable cardiac trauma (contusion, hematoma, lacerated coronary artery). This risk is highest in children before adolescence. Historically, death results from VF that is unresponsive to resuscitative efforts in 85–90% of children. Immediate direct current (DC) defibrillation may be effective, if available, particularly if employed

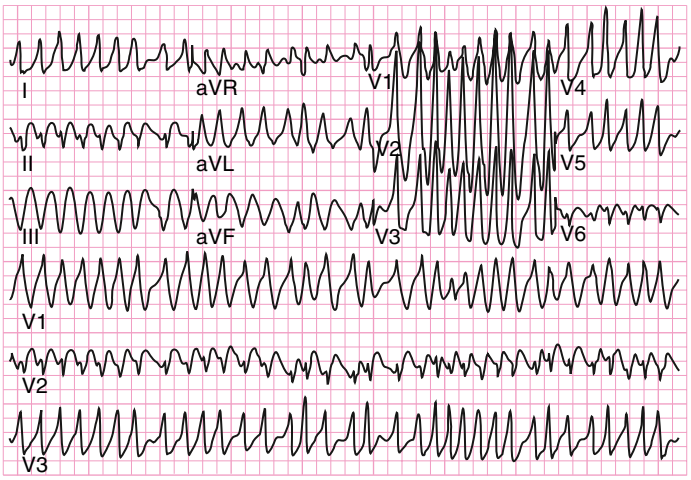

Fig. 485.2 Atrial fibrillation in a patient with Wolff-Parkinson-White syndrome and rapid conduction to the ventricle. Note the wide QRS complexes, a result of full preexcitation, and the irregularly irregular ventricular response, caused by the atrial fibrillation.

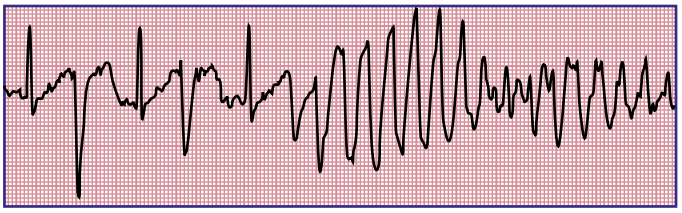

Fig. 485.4 Episode of torsades de pointes in a patient with long QT syndrome.

immediately; however, it is reported to be successful in only approximately 25% of cases.

EVALUATION AND THERAPY FOR RESUSCITATED PATIENTS

It is important to focus therapy on potentially reversible causes of sudden death. These include correction of major hemodynamic defects, pacing therapy for a patient with bradycardia, or supportive therapy for myocarditis. Unfortunately, reversible causes are not always found in young cardiac arrest survivors. Adding to this dilemma is the limited ability to predict antiarrhythmic drug response or risk of recurrence. The **implantable-cardioverter defibrillator** (ICD) is the therapy of choice for survivors of most forms of arrhythmic sudden death, with the exception of correctable causes such as WPW (see Chapter 484).

MEDICATION FOR ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Concern has been raised that stimulant medications prescribed for children with attention-deficit/hyperactivity disorder might increase the risk of sudden death (see Chapter 50). The concern arises from a limited number of reports to the U.S. Food and Drug Administration (FDA) of sudden death of unknown etiology in individuals taking stimulant medications, mostly adults. In a few cases, left ventricular hypertrophy caused by hypertension, coarctation of the aorta, or HCM has been identified at postmortem examination. No prospective studies support the notion that these medications increase the risk, and there is no evidence that ECG screening will reliably identify a subgroup at risk. Some have suggested ECG screening of children before starting these medications, but there is no consensus that such an approach is effective. The current recommendations do not support ECG screening before the initiation of stimulant medication in the absence of a positive cardiac history.

PREVENTION OF SUDDEN DEATH

The probability of survival to hospital discharge for a young patient who experiences an out-of-hospital cardiac arrest is <20%. The

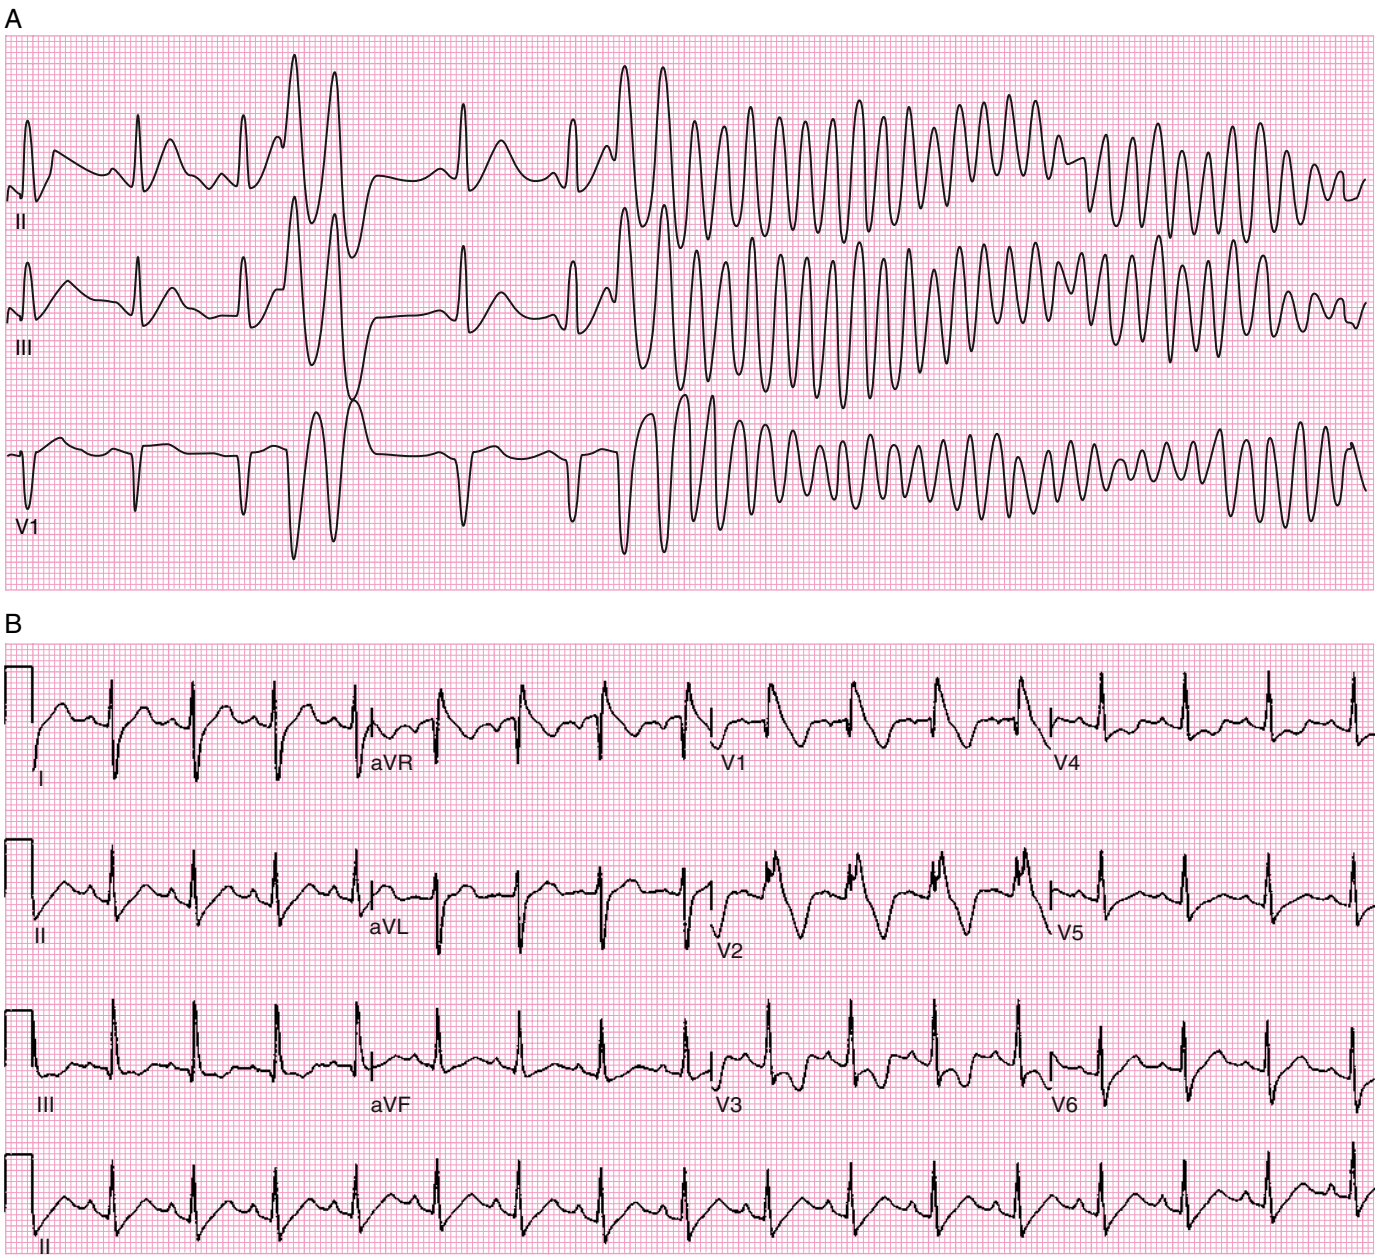

Fig. 485.5 Brugada syndrome. **A**, Frequent ventricular ectopy and sustained polymorphic ventricular tachycardia. **B**, Persistent coved-type ST segment elevation in lead V_1 and V_2 characteristic of Brugada type I. *(A from Talib S, van de Poll SE. Brugada syndrome diagnosed after Ramadan. Lancet. 2013;382:100.)*

presence of immediate **automatic external defibrillators** (AEDs), when combined with standard cardiopulmonary resuscitation (CPR) at the site of exercise (gym, track, basketball, or football arena), improves survival substantially. Thus identifying patients at risk is extremely important. The American Academy of Pediatrics Policy Statement on Sudden Death in the Young provides primary care providers with guidelines screening for life-threatening conditions, regardless of athletic status.

Some of the more common causes of sudden death in children and adolescents can be identified from the patient's history (prodromal symptoms), the family history, and physical examination. The American Heart Association (AHA) has a recommended 14-point preparticipation evaluation (PPE) that includes questions about personal and family history in addition to physical exam findings (Table 485.2). The screening for sudden cardiac arrest and SCD should be performed at the time of PPE or upon entry into middle school and high school. The AAP's Preparticipation Physical Evaluation form is available at https://www.aap.org/. Of paramount importance is the careful evaluation of any child who experiences **syncope** in association with **exercise** because this may be the last opportunity to diagnose a life-threatening condition in such a patient.

Patient avoidance of high-risk behavior (cocaine use, anorexia nervosa) and knowledge of drug side effects or drug interactions and contraindications are critical. Chest-protecting equipment has not been shown to prevent commotio cordis. Prompt bystander CPR and rapid defibrillation with an AED has the highest chance of leading to survival. Family survivors of victims of sudden death should also be evaluated for genetic etiologies of SCD (e.g., LQTS, HCM).

The 14-element screening checklist underperforms and may miss high-risk cardiac lesion. Depending on the population (elite vs recreational athletes) and the screening protocol (checklist, with ECG, with echocardiogram, with cardiac MRI), the incidence of

Table 485.2 Fourteen-Element Cardiovascular Screening Checklist for Congenital and Genetic Heart Disease

PERSONAL HISTORY
1. Chest pain/discomfort/tightness/pressure related to exertion
2. Unexplained syncope/near-syncope: Judged not to be of neurocardiogenic (vasovagal) origin; of particular concern when occurring during or after physical exertion
3. Excessive exertional and unexplained dyspnea/fatigue or palpitations, associated with exercise
4. Prior recognition of a heart murmur
5. Elevated systemic blood pressure
6. Prior restriction from participation in sports
7. Prior testing for the heart, ordered by a physician
FAMILY HISTORY
8. Premature death (sudden and unexpected, or otherwise) before age 50 attributable to heart disease in at least one relative
9. Disability from heart disease in close relative <50 yr of age
10. Hypertrophic or dilated cardiomyopathy, long QT syndrome, or other ion channelopathies, Marfan syndrome, or clinically significant arrhythmias; specific knowledge of certain cardiac conditions in family members
PHYSICAL EXAMINATION
11. Heart murmur: Refers to heart murmurs judged likely to be organic and unlikely to be innocent; auscultation should be performed with the patient in both the supine and standing positions (or with Valsalva maneuver), specifically to identify murmurs of dynamic left ventricular outflow tract obstruction
12. Femoral pulses to exclude aortic coarctation
13. Physical stigmata of Marfan syndrome
14. Brachial artery blood pressure (sitting position): Preferably taken in both arms

From American College of Cardiology: ACC/AHA release recommendations for congenital and genetic heart disease screenings in youth. https://www.acc.org/latest-in-cardiology/articles/2014/09/15/14/24/acc-aha-release-recommendations-for-congenital-and-genetic-heart-disease-screenings-in-youth

at-risk cardiac lesions varies from 0.3–0.4% to 1.4%. The use of a preparticipation ECG for the detection of those athletes at risk for sudden death has long been controversial. Because many athletes either have no pre-event symptoms or are unwilling to admit to symptoms for concern of not being able to play, some have proposed that the ECG may identify a small but at-risk group with HCM or prolonged QT, Brugada, or WPW syndromes. These ECGs would fail to identify patients with phenotype-negative LQTS or catecholaminergic polymorphic ventricular tachycardia, as well as coronary artery anomalies. In addition, many false positives may be identified, requiring further evaluation to exclude worrisome diagnoses. Preparticipation ECG testing is mandatory in several European countries but not in the United States, although many athletic groups with varsity-level or professional membership (e.g., collegiate or professional sports organizations) require such testing as part of the medical evaluation. If the ECG is abnormal, **echocardiography** is performed. Cost-effectiveness studies suggest that the cost for implementation of a national program in the United States would be prohibitive because of the low incidence of sudden death in the pediatric population, the high rate of false-positive ECGs, and the difficulty in definitively excluding cardiac disease in patients with borderline ECG findings. Although studies of regional or national screening programs have suggested some benefit (e.g., the Veneto region of Italy), others have failed to demonstrate any effect of screening on the background incidence of sudden death in young individuals.

Section 5

Acquired Heart Disease

Chapter 486

Infective Endocarditis*

Erin Faherty and Thomas S. Murray

Infective endocarditis includes acute and subacute *bacterial* endocarditis, as well as *nonbacterial* endocarditis, caused by viruses, fungi, and other microbiologic agents. It is a significant cause of morbidity and mortality in children and adolescents despite advances in the management and prophylaxis of the disease with antimicrobial agents. The inability to eradicate infective endocarditis by prevention or early treatment stems from several factors. The disease represents a complex interplay between a pathogen and host factors such as endothelial disruption and immune function that is still not completely understood; the nature of the infecting organism changes over time; and diagnosis may be difficult during early stages and thus is often delayed until a more serious manifestation has developed. Special risk groups include intravenous drug users; survivors of cardiac surgery, especially those with mechanical prosthesis; patients taking immunosuppressant medications; and patients who require chronic intravascular catheters. Some patients have endocarditis on a native valve previously thought to be healthy but found to have mild structural abnormalities on surgical inspection.

ETIOLOGY

Viridans-type streptococci (α-hemolytic streptococci groups such as *Streptococcus mitis, S. anginosus, S. mutans, S. salivarius, S. bovis, S. sanguinis,* and *S. mitis*) and *Staphylococcus aureus* remain the leading causative agents for endocarditis in pediatric patients. Other organisms cause endocarditis less frequently, and in approximately 6% of cases, blood cultures are negative for any organisms (Table 486.1). No relationship exists between the infecting organism and the type of congenital defect, duration of illness, or age of the child. Staphylococcal endocarditis is more common in patients with no underlying heart disease. Viridans group streptococcal infection is more common after dental procedures; enterococci are seen more often after lower bowel or genitourinary manipulation.

Pseudomonas aeruginosa or *Serratia marcescens* is seen more frequently in intravenous drug users, and fungal organisms are encountered after open heart surgery. Coagulase-negative staphylococci are common in the presence of an indwelling central venous catheter.

EPIDEMIOLOGY

Infective endocarditis is often a complication of congenital or rheumatic heart disease but can also occur in children without any abnormal valves or cardiac malformations. In developed countries, congenital heart disease (CHD) is the overwhelming predisposing factor. Endocarditis is rare in infancy; in this age-group it usually follows open heart surgery or is associated with a central venous line.

Patients with congenital heart lesions where there is turbulent blood flow because of a hole or stenotic orifice, especially if there is a high-pressure gradient across the defect, are most susceptible to

* The authors would like to thank Dr Robert S. Baltimore for his work on previous editions of this chapter.

Diphtheroids
*Legionella spp.**
HACEK group†
Fungi‡

*These fastidious bacteria plus some fungi may produce culture-negative endocarditis. Detection may require special media, incubation for >7 days, polymerase chain reaction on blood or valve for 16SrRNA (bacteria) or 18SrRNA (fungi), or serologic tests.
†The HACEK group includes Haemophilus spp. (H. paraphrophilus, H. parainfluenzae, H. aphrophilus), Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, and Kingella spp.
‡Candida spp., Aspergillus spp., Pseudallescheria boydii, Histoplasma capsulatum.

endocarditis. This turbulent flow traumatizes the vascular endothelium, creating a substrate for deposition of fibrin and platelets, leading to the formation of a *nonbacterial thrombotic embolus (NBTE)* that is thought to be the initiating lesion for infective endocarditis. Biofilm forms on the surface of implanted mechanical devices such as valves, catheters, or pacemaker wires, which also serves as the adhesive substrate for infection. The development of transient bacteremia then colonizes this NBTE or biofilm, leading to proliferation of bacteria within the lesion. Bacterial surface proteins, such as the FimA antigen in viridans streptococci, act as adhesion factors to the NBTE or biofilm, after which bacteria can rapidly proliferate within the vegetation. Given the heavy colonization of mucosal surfaces (the oropharynx or gastrointestinal, vaginal, or urinary tracts) by potentially pathogenic bacteria, these surfaces are thought to be the origin of this transient bacteremia. There is controversy over the extent to which daily activities (e.g., brushing or flossing the teeth) vs invasive procedures (e.g., dental cleaning or surgery) contribute to this bacteremia. Transient bacteremia is reported to occur in 20–68% of patients after tooth brushing and flossing, and even in 7–51% of patients after chewing food. The magnitude of this bacteremia is also similar to that resulting from dental procedures. Maintenance of good oral hygiene may be a more important factor in decreasing the frequency and magnitude of bacteremia. Case reports suggest that body piercing and tattoos may be additional risk factors.

Children at **highest risk** of adverse outcome after infective endocarditis include those with prosthetic cardiac valves or other prosthetic material used for cardiac valve repair, unrepaired cyanotic CHD (including those palliated with shunts and conduits), completely repaired defects with prosthetic material or device during the first 6 months after repair, repaired CHD with residual defects at or adjacent to the site of a prosthetic patch or device, valve stenosis or insufficiency occurring after heart transplantation, permanent valve disease from **rheumatic fever** (mitral stenosis, aortic regurgitation), and previous infective endocarditis. Patients with high-velocity blood flow lesions such as ventricular septal defects (VSDs) and aortic stenosis are also at high risk. In older patients, congenital bicuspid aortic valves and mitral valve prolapse with regurgitation pose additional risks for endocarditis. Surgical correction of CHD may reduce but does not eliminate the risk of endocarditis, except for the repair of a simple atrial septal defect or patent ductus arteriosus without prosthetic material.

In ~30% of patients with infective endocarditis, a predisposing factor is presumably recognized. Although a preceding dental procedure may be identified in 10–20% of patients, the time of the procedure may range from 1 to 6 months before the onset of symptoms—thus the continued controversy over the absolute risk of infective endocarditis after dental procedures. Primary bacteremia with *S. aureus* is thought to be another risk for endocarditis. The occurrence of endocarditis directly after most routine heart surgery is relatively low, but it can be an antecedent event, especially if prosthetic material is used. In the small group of patients with culture-negative endocarditis, epidemiologic or exposure factors may contribute to the diagnosis (Table 486.2).

CLINICAL MANIFESTATIONS

Table 486.3 outlines the manifestations of infective endocarditis. Early manifestations are usually mild, especially when viridans group streptococci are the infecting organisms. Prolonged fever without other manifestations (except occasionally weight loss) that persists for as long as several months may be the only symptom. Alternatively, with pathogenic organisms such as *S. aureus,* the onset may be acute and severe, with high intermittent fever and prostration. Usually, the onset and course vary between these two extremes. Fever in the absence of signs of URI in a patient with congenital heart disease must be considered as endocarditis. The symptoms are often nonspecific and consist of low-grade fever with afternoon elevations, fatigue, myalgia, arthralgia, headache, and at times chills, nausea, and vomiting. The cardiac examination often depends on the underlying heart disease and the location of infection. A new pathologic murmur or changing heart murmur may be appreciated and can be associated with heart failure. Of note, children with palliated congenital heart disease, such as those palliated with a shunt, may not present with a change in murmur. Splenomegaly and petechiae are seen in <50% of patients. Serious neurologic complications such as embolic strokes, cerebral abscesses, mycotic aneurysms, and hemorrhage are most often associated with staphylococcal disease and may be late manifestations. Meningismus, increased intracranial pressure, altered sensorium, and focal neurologic signs are manifestations of these complications. Meningitis may be seen together with pneumococcal endocarditis. Myocardial abscesses may occur with staphylococcal disease and may damage the cardiac conducting system, causing heart block, or may rupture into the pericardium and produce purulent pericarditis. Pulmonary (with right-sided endocarditis) and systemic emboli (with left-sided lesions) are infrequent, except with fungal disease.

Many of the classic **skin findings** develop late in the disease; they are seldom seen in appropriately treated patients. Such manifestations include **Osler nodes** (tender, pea-size intradermal nodules in the pads of the fingers and toes), **Janeway lesions** (painless, small,

erythematous, or hemorrhagic lesions on the palms and soles), and **splinter hemorrhages** (linear lesions beneath the nails). These lesions may represent vasculitis produced by circulating antigen-antibody complexes. Retinal lesions are seen in 10–20%.

In the newborn infant the major risk factor for infective endocarditis is the presence of a central intravenous line. Thus prematurity is a risk, as are other severe congenital abnormalities. CHD is less likely to be the underlying condition than it is for older children. The clinical conditions are variable and may be indistinguishable from sepsis or congestive heart failure. Identification of infective endocarditis is most often based on a high index of suspicion during evaluation of an infection in a child with an underlying risk factor.

DIAGNOSIS

The critical information for appropriate treatment of infective endocarditis is obtained from blood cultures. All other laboratory data are secondary in importance (see Table 486.3). Blood specimens for culture should be obtained as promptly as possible, even if the child feels well and has no other physical findings. Although increased blood volume can increase the sensitivity of the blood culture, smaller volumes are reasonable in neonates and small children. When small volumes of blood are present, a single aerobic blood culture bottle should be inoculated. Ideally, for patients weighing 2-12.7 kg, the volume of the first blood culture is 4 mL (repeat culture is 2 mL); for patients 12.8-36.3 kg it is 10 mL for initial and repeat, and for patients >36.3 kg, 20-30 mL for both. Three to five separate blood collections should be obtained after careful preparation of the phlebotomy site. Contamination presents a special problem because bacteria found on the skin may cause infective endocarditis. The timing of collections is not important because bacteremia can be expected to be relatively constant. In 90% of cases of endocarditis, the causative agent is recovered from the first two blood cultures. Bacteremia is low grade in 80% (<100 colony-forming units/mL of blood). The laboratory should be notified that endocarditis is suspected so that, if necessary, the blood can be cultured on enriched media for longer than usual (>5 days) to detect nutritionally deficient and fastidious bacteria or fungi.

Table 486.3 Manifestations of Infectious Endocarditis

HISTORY
Prior congenital or rheumatic heart disease
Preceding dental, urinary tract, or intestinal procedure
Intravenous drug use
Central venous catheter
Prosthetic heart valve
SYMPTOMS
Fever
Chills
Chest and abdominal pain
Arthralgia, myalgia
Dyspnea
Malaise, weakness
Night sweats
Weight loss
CNS manifestations (stroke, seizures, headache)
SIGNS
Elevated temperature
Tachycardia
Embolic phenomena (Roth spots, petechiae, splinter nail bed hemorrhages, Osler nodes, CNS or ocular lesions)
Janeway lesions
New or changing murmur
Splenomegaly
Arthritis
Heart failure
Arrhythmias
Metastatic infection (arthritis, meningitis, mycotic arterial aneurysm, pericarditis, abscesses, septic pulmonary emboli)
Clubbing
LABORATORY STUDIES
Positive blood culture
Elevated erythrocyte sedimentation rate; may be low with heart or renal failure
Elevated C-reactive protein
Anemia
Leukocytosis
Immune complexes
Hypergammaglobulinemia
Hypocomplementemia
Cryoglobulinemia
Rheumatoid factor
Hematuria
Renal failure: azotemia, high creatinine (glomerulonephritis)
Chest radiograph: bilateral infiltrates, nodules, pleural effusions
Echocardiographic evidence of valve vegetations, prosthetic valve dysfunction or leak, myocardial abscess, or new-onset valve insufficiency

CNS, Central nervous system.

Table 486.4 Diagnostic Approach to Uncommon Pathogens Causing Endocarditis

PATHOGEN	DIAGNOSTIC PROCEDURE
Brucella spp.	Blood cultures; serology; culture, immunohistology, and mNGS of surgical material or blood/plasma
Coxiella burnetii	Serology (IgG phase I >1 in 800); tissue culture, immunohistology, and mNGS of surgical material or blood/plasma
Bartonella spp.	Blood cultures; serology; culture, immunohistology, and mNGS of surgical material or blood/plasma
Chlamydia spp.	Serology; culture, immunohistology, and mNGS of surgical material or blood/plasma
Mycoplasma spp.	Serology; culture, immunohistology, and mNGS of surgical material or blood/plasma
Legionella spp.	Blood cultures; serology; culture, immunohistology, and mNGS of surgical material or blood/plasma
Tropheryma whipplei	Histology and mNGS of surgical material or blood/plasma

IgG, Immunoglobulin G; mNGS, metagenomic next-generation sequencing; PCR, polymerase chain reaction
From Moreillon P, Que YA. Infective endocarditis *Lancet*. 2004;363:139–148.

Although bacteremia may occur in the absence of endocarditis, bacteremia secondary to *S. mutans, S. bovis I*, *S. mitis, S. sanguinis,* and *S. aureus* (in the absence of focal musculoskeletal infection) is highly concerning for endocarditis. Antimicrobial pretreatment of the patient reduces the yield of blood cultures by 50–60%. Other specimens that may be cultured include scrapings from cutaneous lesions, urine, synovial fluid, abscesses, and in the presence of manifestations of meningitis, cerebrospinal fluid. Serologic diagnosis or metagenomic next-generation sequencing or polymerase chain reaction for 16S and 28S ribosomal RNA (rRNA) for bacteria and fungi, respectively, of resected valve tissues is necessary in patients with unusual or fastidious microorganisms when there is suspicion of culture-negative endocarditis or if the patient has received prior antibiotics (Table 486.4 and Fig. 486.1). Metagenomic next-generation sequencing on blood and plasma may help identify pathogens in patients with culture-negative endocarditis. Suspicion should be high when evaluating infection in a child with an underlying contributing factor.

Echocardiography remains the mainstay of diagnosis. Two-dimensional echocardiography can identify the size, shape, location, and mobility of the lesion; when combined with Doppler interrogation, the presence of valve dysfunction (regurgitation, obstruction) can be determined. (Fig. 486.2). In pediatric patients, transthoracic echocardiogram is usually adequate for detection of lesions, especially for children <60 kg. Transesophageal echocardiogram should be considered in pediatric patients with limited transthoracic views; it is superior to transthoracic echocardiogram in evaluating prosthetic valves or complications of infective endocarditis, such as aortic root abscess. Intracardiac echocardiography can be useful for patients with suspicion for an infected pacemaker lead or implanted percutaneous pulmonary valve. Cardiac MRI may be useful in suspected perivalvular complications, and PET-CT may aid in the diagnosis of endocarditis for those patients with prosthetic valves.

Echocardiography may also be helpful in predicting embolic complications, given that lesions >1 cm and fungating masses are at greatest risk for embolization. The absence of vegetations does not exclude endocarditis, and vegetations are often not visualized in the early phases of the disease or in patients with complex congenital heart lesions. Electrocardiography should be part of the evaluation and can demonstrate new rhythm disorders such as **ventricular**

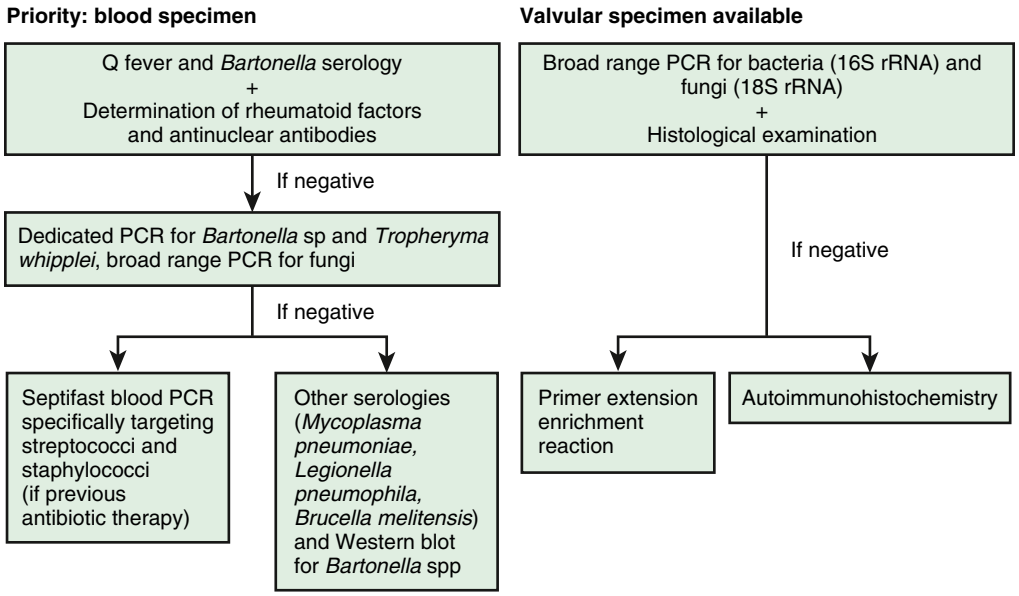

Fig. 486.1 Algorithm of diagnostic tests applied to clinical specimens for the identification of the causative agents of **blood culture–negative endocarditis**. Septifast, LightCycler SeptiFast (Roche). Serum should be considered a priority specimen, with Q fever and *Bartonella* serologic analysis routinely done. We also suggest that detection of antinuclear antibodies and rheumatoid factor be routinely done for the diagnosis of noninfective endocarditis. *(From Thuny F, Grisoli D, Collart F, et al. Management of infective endocarditis: challenges and perspectives. Lancet. 2012;379:965–975, Fig. 2.)*

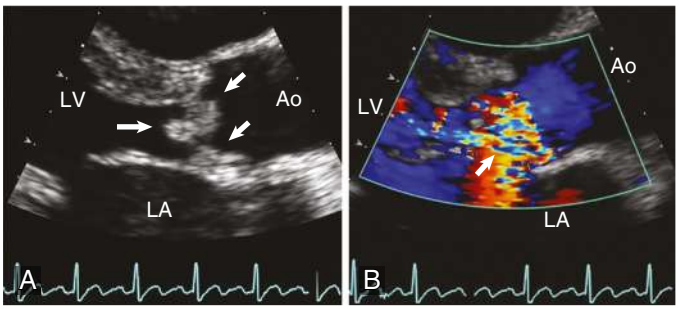

Fig. 486.2 Infective endocarditis of the native aortic valve. **A,** Transthoracic echocardiography shows vegetations *(small arrows)* attached to the left ventricular aspects of the valve cusps and prolapsing into the left ventricular outflow tract *(large arrow)* during diastole. **B,** Severe aortic regurgitation *(arrow)* is shown by color Doppler. Ao, Ascending aorta; LA, left atrium; LV, left ventricle. *(From Baddour LM, Freeman WK, Suri RM, Wilson WR. Cardiovascular infections. In: Zipes DP, Libby P, Bonow RO, et al., eds. Braunwald's Heart Disease, 11th ed. Philadelphia: Elsevier; 2019: Fig. 73-1, p. 1490.)*

ectopy and conduction disorders such as **complete heart block**. The presence of either of these findings, particularly heart block, may signal a serious or even life-threatening complication of endocarditis.

The **Duke criteria** help in the diagnosis of endocarditis (Table 486.5). Two major criteria, one major and three minor, or five minor criteria suggest definite endocarditis. Additional minor criteria to those listed include newly diagnosed clubbing, splenomegaly, splinter hemorrhages, or petechiae; high erythrocyte sedimentation rate or C-reactive protein level; presence of central nonfeeding or peripheral lines; and microscopic hematuria.

PROGNOSIS AND COMPLICATIONS

Despite the use of antibiotic agents, mortality remains high, up to 25%. Serious morbidity occurs in 50–60% of children with documented infective endocarditis; the most common is heart failure caused by worsening valvular regurgitation due to aortic or mitral valve vegetations, accompanied by ventricular dysfunction. Myocardial abscesses and toxic myocarditis may also lead to heart failure without characteristic changes in auscultatory findings and, occasionally, to life-threatening arrhythmias. Systemic emboli, often with central nervous system manifestations, are a major threat. Pulmonary emboli may occur in children with VSD or tetralogy of Fallot, although massive life-threatening pulmonary embolization is rare. Other complications include mycotic aneurysms, rupture of a sinus of Valsalva, obstruction of a valve secondary to large vegetations, acquired VSD, and heart block as a result of involvement (abscess) of the conduction system. Additional complications include meningitis, osteomyelitis, arthritis, renal abscess, purulent pericarditis, and immune complex–mediated glomerulonephritis.

TREATMENT

Antibiotic therapy should be instituted immediately once a definitive diagnosis of infectious endocarditis is made. When virulent organisms are responsible, small delays may result in progressive endocardial damage and are associated with a greater likelihood of severe complications. The choice of antibiotics, method of administration, and length of treatment should be coordinated with consultants from both cardiology and infectious diseases (Tables 486.6 and 486.7). Empirical therapy after appropriate blood cultures are drawn but before the identifiable agent is recovered may be initiated with vancomycin plus gentamicin in patients without a prosthetic valve and when there is a high risk of *S. aureus,* enterococcus, or viridans streptococci (the three most common organisms). High serum bactericidal levels must be maintained long enough to eradicate organisms that are growing in relatively inaccessible avascular vegetations. Between 5 and 20 times the in vitro minimal inhibitory concentration must be produced at the site of infection to destroy bacteria growing at the core of these lesions. Several weeks are required for a vegetation to organize completely; therapy must be continued through this period so that recrudescence can be avoided. A total of 4-6 weeks of treatment is usually recommended. Depending on the clinical and laboratory responses, antibiotic therapy may require modification, and some patients require more

Table 486.5 Definition of Infective Endocarditis (IE): Modified Duke Criteria

DEFINITE INFECTIVE ENDOCARDITIS

Pathologic Criteria

- Microorganisms demonstrated by results of cultures or histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen; *or*
- Pathologic lesions; vegetation, or intracardiac abscess confirmed by results of histologic examination showing active endocarditis

Clinical Criteria

- Two major criteria, *or*
- One major criterion and three minor criteria, *or*
- Five minor criteria

Possible Infective Endocarditis

- One major criterion and one minor criterion, *or*
- Three minor criteria

Rejected Diagnosis of Infective Endocarditis

- Firm alternative diagnosis explaining evidence of suspected IE, *or*
- Resolution of IE syndrome with antibiotic therapy for ≤4 days, *or*
- No evidence of IE at surgery or autopsy, on antibiotic therapy for ≤4 days, *or*
- Does not meet criteria for possible IE

DEFINITION OF TERMS USED IN MODIFIED DUKE CRITERIA

Major Criteria

- Blood culture findings positive for IE
  Typical microorganisms consistent with IE from two separate blood cultures:
  - Viridans streptococci, *Streptococcus gallolyticus* (formerly known as *S. bovis*), *Staphylococcus aureus,* HACEK group, *or*
  - Community-acquired enterococci, in the absence of a primary focus, *or*

  Microorganisms consistent with IE from persistently positive blood culture findings, defined as:
  - At least two positive culture findings of blood samples drawn >12 hr apart, *or*
  - Three or most of at least four separate culture findings of blood (with first and last sample drawn ≥1 hr apart)
  - Single positive blood culture for *Coxiella burnetii* or anti–phase I IgG titer ≥1:800
- Evidence of endocardial involvement
  Echocardiographic findings positive for IE (TEE recommended in patients with prosthetic valves, rated at least *possible* IE by clinical criteria or *complicated* IE [paravalvular abscess]; TTE as first test in other patients), defined as follows:
  - Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation, *or*
  - Abscess, *or*
  - New partial dehiscence of prosthetic valve

  New valvular regurgitation; worsening or changing of preexisting murmur not sufficient

Minor Criteria

- Predisposition, predisposing heart condition, or intravenous drug use
- Fever—temperature >38°C
- Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions
- Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor
- Microbiologic evidence: positive blood culture finding but does not meet a major criterion as noted earlier (excludes single positive culture findings for coagulase-negative staphylococci and organisms that do not cause endocarditis) or serologic evidence of active infection with organism consistent with IE

TEE, Transesophageal echocardiography; TTE, transthoracic echocardiography.
Modified from Li JS, Sexton DJ, Mick N, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis.* 2000;30:633.

prolonged treatment. With highly sensitive viridans group streptococcal infections, shortened regimens that include oral penicillin for some portion have been recommended for certain adults, but effectiveness studies in children are lacking. In *nonstaphylococcal* disease, bacteremia usually resolves in 24-48 hours, whereas fever resolves in 5-6 days with appropriate antibiotic therapy. Resolution with *staphylococcal* disease takes longer.

If the infection occurs on a valve and induces or increases symptoms and signs of heart failure, appropriate therapy should be instituted, including diuretics, inotropic medications, and afterload reducing agents. Surgical intervention for infective endocarditis is indicated for severe aortic, mitral, or prosthetic valve involvement with intractable heart failure (Table 486.8). Severe heart failure may be associated with acute valve regurgitation, obstruction of conduits or shunts, or periannular extension of infection, including fistula formation. Rarely, a mycotic aneurysm, rupture of an aortic sinus, intraseptal abscess causing complete heart block, or dehiscence of an intracardiac patch requires emergency surgery. Other surgical indications include failure to sterilize the blood despite adequate antibiotic levels in 7-10 days in the absence of extracardiac infection, myocardial abscess, recurrent emboli, and increasing size of vegetations while receiving therapy. Vegetations (aortic, mitral, prosthetic valve) >10-15 mm are at high risk of embolism. Although antibiotic therapy should be administered for as long as possible before surgical intervention, active infection is not a contraindication if the patient is critically ill as a result of severe hemodynamic deterioration from infective endocarditis. Emergent surgical intervention in patients with severe heart failure may improve the likelihood of survival. Removal of vegetations and, in some instances, valve replacement may be lifesaving, and sustained antibiotic administration will most often prevent reinfection. Replacement of infected prosthetic valves carries a higher risk.

Fungal endocarditis is difficult to manage and has a poorer prognosis. It has been encountered after cardiac surgery, in severely debilitated or immunosuppressed patients, and in patients on a prolonged course of antibiotics. The drugs of choice are amphotericin B (liposomal or standard preparation) and 5-fluorocytosine. Surgery to excise infected tissue is occasionally attempted, but often with limited success. Recombinant tissue plasminogen activation may help lyse intracardiac vegetations and avoid surgery in some high-risk patients.

PREVENTION

The American Heart Association (AHA) recommendations for antimicrobial prophylaxis before dental and other surgical procedures has resulted in a substantial reduction in the number of patients who require prophylactic treatment, and the procedures requiring coverage were recommended. The primary reasons for these revised recommendations were that (1) infective endocarditis is much more likely to result from exposure to the more frequent random bacteremias associated with daily activities than from a dental or surgical procedure, (2) routine prophylaxis may prevent "an exceedingly small" number of cases, and (3) the risk of antibiotic-related adverse events exceeds the benefits of prophylactic therapy. Improving general dental hygiene was thought to be a more important factor in reducing the risk of infective endocarditis resulting from routine daily bacteremias. The current recommendations limit the use of prophylaxis to those patients with cardiac conditions associated with the greatest risk of an adverse outcome from infective endocarditis (Table 486.9). Patients with permanently damaged valves from rheumatic heart disease should also be considered for prophylaxis. Prophylaxis for these patients is recommended for "all dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa." Furthermore, "placement of removable prosthodontic or endodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth and bleeding from trauma to the lips or oral mucosa" are not indications for

Table 486.6 Therapy of Pediatric Native Valve Endocarditis Caused by Highly Penicillin-Susceptible[^] Viridans Group Streptococci and *Streptococcus bovis*

REGIMEN	DOSAGE*† AND ROUTE	DURATION	COMMENTS
Penicillin G	200,000-300,000 U/kg/24 hr IV given every 4 hr up to 12-24 million U/day	4 wk	Avoids nephrotoxicity of gentamicin
Or			
Ceftriaxone sodium	100 mg/kg/24 hr IV given every 12 hr **or** 80 mg/kg/24 hr given every 24 hr up to 4 g/day (If total amount is over 2 g/day then dosing should be every 12 hr)	4 wk	Avoids nephrotoxicity of gentamicin
Or			
Vancomycin hydrochloride¶	40 mg/kg/24 hr IV given every 8-12 hr up to 2g/day	4 wk	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone; vancomycin dosage should be adjusted to obtain a trough concentration range of 10-15 μg/mL

[^]Defined as minimum inhibitory concentration (MIC) ≤0.10 μg/mL.
*Dosages recommended are for patients with normal renal function.
†Pediatric dose should not exceed that of a normal adult.
¶Vancomycin dosages should be infused during course of at least 1 hr to reduce risk of histamine release and facial flushing. Peak vancomycin levels should only be obtained to calculate the area under the curve to mean MIC ratio.
Data from Baltimore RS, Gewitz M, Baddour LM, et al. Infective endocarditis in childhood: 2015 update. A scientific statement from the American Heart Association. *Circulation.* 2015;132:1487–1515.

Table 486.7 Therapy for Pediatric Endocarditis Caused by Staphylococci in the Absence of Prosthetic Materials

REGIMEN	DOSAGE*§ AND ROUTE	DURATION	COMMENTS
OXACILLIN-SUSCEPTIBLE STRAINS			
Nafcillin or oxacillin† ± gentamicin‡ for first 3-5 days	200 mg/kg/24 hr IV given every 4-6 hr up to 12 g/day AND consider gentamicin 3-6 mg/kg/24 hr IV every 8 hr	4-6 wk	Clinical benefit of aminoglycosides has not been established. Gentamicin trough levels of <1-2 μg/mL should be targeted to avoid risk of toxicity. Gentamicin peak levels should be obtained 30 min after the completion of an infusion with a peak goal of 3-5 μg/mL (for synergy).
For penicillin-allergic (non-anaphylactoid-type) patients:			Consider skin testing for oxacillin-susceptible staphylococci and questionable history of immediate-type hypersensitivity to penicillin.
Cefazolin ± gentamicin‡ for first 3-5 days	100 mg/kg/24 hr IV given every 8 hr up to 12 g/day AND consider gentamicin 3-6 mg/kg/24 hr IV given every 8 hr	4-6 wk	Cephalosporins should be avoided in patients with anaphylactoid-type hypersensitivity to β-lactams; vancomycin should be used in these cases.§ Gentamicin trough levels of <1-2 μg/mL should be targeted to avoid risk of toxicity. Gentamicin peak levels should be obtained 30 min after the completion of an infusion with a peak goal of 3-5 μg/mL (for synergy).
OXACILLIN-RESISTANT STRAINS			
Vancomycin¶ ± gentamicin‡ for first 3-5 days	40 mg/kg/24 hr IV given every 8-12 hr up to 2 g/day AND consider gentamicin 3-6 mg/kg/24 hr IV given every 8 hr	6 wk	Adjust vancomycin dosage to achieve trough concentration of 10-15 μg/mL. Gentamicin trough levels of <1-2 μg/mL should be targeted to avoid risk of toxicity. Gentamicin peak levels should be obtained 30 min after the completion of an infusion with a peak goal of 3-5 μg/mL (for synergy).
Daptomycin ± gentamicin‡ for first 3-5 days	6 mg/kg/24 hr given every 24 hr <6 yr of age; 10 mg/kg/24 hr given every 24 hr AND consider gentamicin 3-6 mg/kg/24 hr IV given every 8 hr	4-6 wk	Gentamicin trough levels of <1-2 μg/mL should be targeted to avoid risk of toxicity. Gentamicin peak levels should be obtained 30 min after the completion of an infusion with a peak goal of 3-5 μg/mL (for synergy).

*Dosages recommended are for patients with normal renal function.
§Pediatric dose should not exceed that of a normal adult.
†Penicillin G 200,000-300,000 U/kg/24 hr IV given every 4 hr up to 12-24 million U/day may be used in place of nafcillin or oxacillin if strain is penicillin susceptible (minimum inhibitory concentration ≤0.1 μg/mL) and does not produce β-lactamase.
‡Gentamicin should be administered in close temporal proximity to nafcillin, or oxacillin dosing and blood levels monitored to reduce the risk of nephrotoxicity and ototoxicity.
¶For specific dosing adjustment and issues concerning vancomycin, see Table 464.6 footnotes.
IE, Infective endocarditis; IV, intravenously.

Table 486.8 Echocardiographic Features that Suggest Potential Need for Surgical Intervention

VEGETATION
Persistent vegetation after systemic embolization
Anterior mitral valve leaflet vegetation, particularly if it is highly mobile with size >10 mm*
One or more embolic events during the first 2 wk of antimicrobial therapy*
Increase in vegetation size despite appropriate antimicrobial therapy*†
VALVULAR DYSFUNCTION
Acute aortic or mitral insufficiency with signs of ventricular failure†
Heart failure unresponsive to medical therapy†
Valve perforation or rupture†
PERIVALVULAR EXTENSION
Valvular dehiscence, rupture, or fistula†
New heart block†‡
Large abscess or extension of abscess despite appropriate antimicrobial therapy†

*Surgery may be required because of risk of embolization.
†Surgery may be required because of heart failure or failure of medical therapy.
‡Echocardiography should not be the primary modality used to detect or monitor heart block.
From Baddour LM, Freeman WK, Suri RM, et al. Cardiovascular infections. In: Zipes DP, Libby P, Bonow RO, et al., eds. *Braunwald's Heart Disease*, 11th ed. Philadelphia: Elsevier, 2019: Table 73-5, p. 1492.

Table 486.9 Cardiac Conditions Associated with Highest Risk of Adverse Outcome from Infective Endocarditis for Which Prophylaxis with Dental Procedures Is Reasonable (2007 AHA Statement)

Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
Previous infective endocarditis
Congenital heart disease (CHD)*
• Unrepaired cyanotic CHD, including palliative shunts and conduits
• Completely repaired CHD with prosthetic material or device, whether placed by surgery or catheter intervention, during the first 6 mo after the procedure†
• Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibits endothelialization)
• Cardiac transplantation recipients who develop cardiac valvulopathy

*Except for the conditions listed here, antibiotic prophylaxis is no longer recommended by the AHA for any other form of CHD.
†Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 mo after the procedure.
From Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis: guidelines from the American Heart Association. *Circulation*. 2007;116:1736–1754.

prophylaxis. The 2023 recommendations of the European Society of Cardiology are noted in Table 486.10. Given that many invasive respiratory tract procedures do cause bacteremia, prophylaxis for many of these procedures is considered reasonable. In contrast to prior recommendations, prophylaxis for gastrointestinal or genitourinary procedures is no longer recommended in the majority of cases. Prophylaxis for patients undergoing cardiac surgery with placement of prosthetic material is still recommended. Given the highly individual nature of these recommendations, direct consultation with the child's cardiologist is still the best method for determining a specific patient's ongoing need for prophylaxis (Table 486.11).

Continuing education regarding both oral hygiene and, in appropriate cases, the need for prophylaxis is important, especially in teenagers and young adults. Vigorous treatment of sepsis and local infections and careful asepsis during heart surgery and catheterization reduce the incidence of infective endocarditis.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

Table 486-10 2023 European Recommendations for Antibiotic Prophylaxis in Patients with Cardiovascular Diseases Undergoing Oro-Dental Procedures at Increased Risk of Infective Endocarditis

• Antibiotic prophylaxis is recommended in patients with previous IE.
• Antibiotic prophylaxis is recommended in patients with surgically implanted prosthetic valves and with any material used for surgical cardiac valve repair.
• Antibiotic prophylaxis is recommended in patients with transcatheter implanted aortic and pulmonary valvular prostheses.
• Antibiotic prophylaxis should be considered in patients with transcatheter mitral and tricuspid valve repair.
• Antibiotic prophylaxis is recommended in patients with untreated cyanotic CHD, and patients treated with surgery or transcatheter procedures with post-operative palliative shunts, conduits, or other prostheses. After surgical repair, in the absence of residual defects or valve prostheses, antibiotic prophylaxis is recommended only for the first 6 months after the procedure.

Chapter 487

Rheumatic Heart Disease

Michael R. Carr and Stanford T. Shulman

Rheumatic involvement of the cardiac valves is the most important sequela of **acute rheumatic fever (ARF)**, and the second most common major manifestation after arthritis (see Chapter 229.1). The definitions of three subgroups of rheumatic heart disease (RHD) are noted in Table 487.1. The valvular lesions begin as small verrucae composed of fibrin and blood cells along the borders of one or more of the heart valves. The mitral valve is affected most often, followed in frequency by the aortic valve. Isolated aortic valve disease is rare and generally seen with concomitant mitral valve involvement. Right-sided heart manifestations are rarer and are virtually only associated with left-sided valve disease. As the inflammation subsides, the verrucae tend to disappear and leave scar tissue. With repeated attacks of rheumatic fever, new verrucae form near the previous ones and the mural endocardium and chordae tendineae become involved. A single episode of **acute rheumatic carditis** often results in complete healing of the valvular lesions, whereas *repeated* episodes, especially involving previously affected valves, result in chronic **RHD**, which is the rationale for secondary prophylaxis. The prevalence of RHD ranges from 3 to 4 cases per 100,000 population in nonendemic countries to >1,000 cases per 100,000 in endemic countries (Fig. 487.1). On a global scale, the sequelae of RHD is significant, with up to 300,000 deaths per year related to the disease process, as well as an exponential degree of related comorbidity.

The diagnosis of ARF requires the fulfillment of the **Jones criteria** (see Chapter 229.1), with carditis being a major criterion. The diagnosis of RHD was once only based on cardiac auscultatory findings of mitral or aortic valve involvement, which was insensitive for early valve involvement/injury. This was based on valvulitis being seen more frequently in ARF compared with pericarditis or myocarditis, both of which lack more readily apparent physical examination findings. Screening large, high-risk populations with echocardiography demonstrated a substantially greater number of patients with RHD than those detected by auscultation alone. Because access to echocardiography is often available, the current version of the Jones criteria focused on the concept of **subclinical carditis (SCC)** detected by echocardiography (see Table 487.1). SCC is defined as echocardiographic evidence of mitral or aortic valvulitis in the absence of auscultatory findings and not consistent with physiologic mitral or aortic insufficiency (Table 487.2). Echocardiography with Doppler should be performed for all cases of confirmed or suspected ARF (Table 487.3). Additional recommendations are that echocardiography should be performed in moderate- to high-risk patient populations if ARF is considered likely and that echocardiography can be used to exclude cardiac findings consistent with ARF in patients with cardiac murmurs thought to be suggestive of rheumatic carditis. Additionally, serial echocardiography should be considered in patients with diagnosed or suspected ARF even if there is no evidence of valvulitis by echocardiography at diagnosis. The echocardiographic finding of SCC fulfills the major criterion for carditis. The category of latent RHD is another approach to include patients with mild asymptomatic valve changes not typically detected on physical exam but identified by screening high-risk populations with echocardiography (see Table 487.1).

PATTERNS OF VALVULAR DISEASE

Mitral Insufficiency

Mitral insufficiency is the result of structural changes that may include some loss of valvular substance and/or changes to the subvalvular apparatus, including elongation of the chordae, both of which can lead to valve dysfunction. During ARF with severe cardiac involvement, heart failure is caused by a combination of mitral insufficiency coupled with a pancarditis involving the pericardium and myocardium in addition to the endocardium/valve. Because of the increased volume load from the mitral insufficiency and the inflammatory process, the left ventricle dilates. The left atrium also enlarges to accommodate the regurgitant volume. Increased left atrial pressure results in pulmonary congestion and symptoms of left-sided heart failure. Spontaneous improvement often occurs with time, even in patients in whom mitral insufficiency is severe at the onset. The resultant chronic lesion is most often mild or moderate in severity, and the patient is often asymptomatic. More than half of patients with acute mitral insufficiency no longer have an audible mitral insufficiency murmur 1 year later, although they still may demonstrate insufficiency on echocardiography. In patients with severe chronic mitral insufficiency, pulmonary artery pressure (PAP) becomes elevated, the right ventricle and atrium become enlarged, and right-sided heart failure subsequently develops.

Clinical Manifestations

Physical signs of mitral insufficiency depend on its severity. With mild disease, signs of heart failure are not present, the precordium is quiet, and auscultation reveals a high-pitched **holosystolic murmur** at the apex that radiates to the axilla. With severe mitral insufficiency, signs of acute or chronic heart failure may be noted. The heart is enlarged, with a heaving apical left ventricular (LV) impulse and often an apical systolic **thrill**. The second heart sound (S_2) may be accentuated if pulmonary hypertension is present. A third heart sound or **gallop** is generally prominent. A holosystolic murmur is heard at the apex with radiation to the axilla. A short mid-diastolic rumbling murmur is caused by increased blood flow across the mitral valve as a result of the significant insufficiency. Therefore auscultation of a diastolic murmur, often referred to as **relative mitral stenosis (Carey-Coombs murmur)**, does not necessarily mean that true mitral stenosis is present. The latter lesion takes many years to develop and is characterized by a diastolic murmur of greater length, usually with presystolic accentuation.

The electrocardiogram and chest radiographs are normal if the mitral insufficiency is mild. With more severe insufficiency, the ECG shows a prominent, longer duration and often bifid P waves, signs of LV hypertrophy, and associated right ventricular (RV) hypertrophy if pulmonary hypertension is present. On chest radiograph, prominence of the left atrium and ventricle can be seen, the former of which is better seen on lateral projections. Congestion of the perihilar vessels, a sign of pulmonary venous hypertension, may also be evident. Calcification of the mitral valve is rare in children. Echocardiography in the acute phase may demonstrate enlargement of the left atrium and ventricle. LV systolic function can be impaired if there is also a component of myocardial inflammation. Mitral annular dilation, chordal elongation, and at times, evidence of chordal rupture resulting in a flail leaflet may be noted. The leaflet tips demonstrate a nodular appearance, and prolapse of the anterior mitral valve leaflet tip (much more often than the posterior leaflet) is seen. Doppler evaluation demonstrates the severity of the mitral regurgitation. Chronic mitral insufficiency from RHD is characterized on echocardiography by leaflet and chordal thickening, chordal fusion, and restricted leaflet motion. These changes often lead to stenosis, but poor coaptation of the abnormal leaflets can also lead to variable degrees of regurgitation. Cardiac catheterization and left ventriculography are considered only if diagnostic questions are not completely resolved by noninvasive assessment or in rare cases with a concern for significantly elevated PAP.

Complications

Severe mitral insufficiency may result in cardiac failure that may be precipitated by progression of the rheumatic process, recurrent episodes of ARF, the onset of **atrial fibrillation (AF)** or other arrhythmias, or infective endocarditis. The effects of chronic mitral insufficiency may become manifest after many years and include LV and RV failure and atrial and ventricular arrhythmias.

Treatment

In patients with mild mitral insufficiency, **prophylaxis** against recurrences of rheumatic fever is all that is required in addition to the typical treatment for ARF (Table 487.4). For more significant insufficiency, corticosteroids are added in the acute phase. Treatment of complicating heart failure (see Chapter 491), arrhythmias (see Chapter 484), and infective endocarditis (see Chapter 486) is described elsewhere. Afterload-reducing

agents—angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs)—may reduce the regurgitant volume, attenuate pathologic compensatory mechanisms, and preserve LV function, but these have not been proven to alter the natural history of the disease process. Diuretics may also provide some symptomatic and clinical benefit in select cases. In rare cases, phosphodiesterase inhibitors such as milrinone may be used in the acute stage because of their inotropic, lusitropic, and systemic vascular dilating effects. Surgical treatment is indicated for patients who, despite adequate medical therapy, have persistent heart failure, dyspnea with moderate activity, and progressive cardiomegaly, often with pulmonary hypertension. Although annuloplasty and other forms of mitral valve repair provide good results in some children and adolescents, mitral valve replacement may be required, which can be more complicated in younger children. In patients with a prosthetic mitral valve replacement, prophylaxis against bacterial endocarditis is warranted for dental procedures, as the routine antibiotics taken by these patients for rheumatic fever prophylaxis are insufficient to prevent endocarditis. Additionally, current recommendations suggest selecting a different class of antibiotic for such procedures, rather than increasing the dose of the antibiotic taken for rheumatic fever prophylaxis. Lastly, it is important to remember that all attempts should be made at maximizing medical management of severe mitral insufficiency during the acute phase of the disease process, before considering surgical intervention, because surgery carries a poorer prognosis and an increased risk for reoperation when performed during the acute phase.

Table 487.1 Proposed RHD Definitions

Latent RDH	All cases of RHD diagnosed through echocardiographic screening, to include previously unrecognized clinical RHD and subclinical RHD.
Clinical RDH	All cases of RHD that have clinical signs or symptoms, including pathologic heart murmur* diagnosed either through echocardiographic screening or clinical evaluation. Clinical RHD is typically more advanced than subclinical RHD.
Subclinical RDH	All cases of RHD that do not have clinical signs or symptoms, including heart murmur.* Subclinical RHD is only diagnosed by echocardiography and is typically less advanced than clinical RHD.

*Detection of a pathologic heart murmur without echocardiography has been shown to be poorly sensitive and specific in echocardiographic screening studies for RHD.
RHD, Rheumatic heart disease.
Modified from Beaton A, Engelman D, Mirabel M. Echocardiographic screening for rheumatic heart disease. In: Dougherty S, Carapetis J, Zühlke, Wilson N, eds. *Acute Rheumatic Fever and Rheumatic Heart Disease.* Philadelphia: Elsevier; 2021: Table 13.1.

Mitral Stenosis

Mitral stenosis of rheumatic origin results from fibrosis of the mitral ring, commissural adhesions, and contracture of the valve leaflets, chordae, and papillary muscles over time. This is a chronic process and often takes ≥10 years for the lesion to become fully established, although the process may occasionally be accelerated. In the developed world, rheumatic mitral stenosis is seldom encountered before adolescence and is not usually recognized until adult life. Significant mitral stenosis results in increased left atrial pressure and subsequent enlargement and hypertrophy of the left atrium, pulmonary venous hypertension, increased pulmonary vascular resistance, and eventually overt pulmonary hypertension (Fig. 487.2). RV hypertrophy and right atrial dilation ensue and are followed by RV dilation, tricuspid regurgitation, and clinical signs of right-sided heart failure.

Clinical Manifestations

Generally, the correlation between symptoms and the severity of obstruction is good. Patients with mild stenosis are asymptomatic. More severe degrees of obstruction are associated with exercise intolerance and dyspnea. Critical lesions can result in orthopnea, paroxysmal nocturnal dyspnea, and overt pulmonary edema, as well as atrial arrhythmias. When pulmonary hypertension has developed, RV dilation may result in functional tricuspid insufficiency, hepatomegaly, ascites, and edema. Hemoptysis caused by rupture of bronchial or pleurohilar veins and, occasionally, pulmonary infarction may occur.

Jugular venous pressure is increased in severe disease with heart failure, tricuspid valve disease/regurgitation, or severe pulmonary hypertension. In mild disease, the heart size is normal; however, moderate cardiomegaly is typical with severe mitral stenosis. Cardiac enlargement can be massive when AF and heart failure supervene. A parasternal RV lift is palpable when PAP is high. The principal auscultatory findings are a loud first heart sound, an opening snap of the mitral valve, and a long, low-pitched, rumbling mitral diastolic murmur with presystolic accentuation at the apex. The mitral diastolic murmur may be virtually absent in patients who are in significant heart failure from the elevated LV filling pressures. A holosystolic murmur secondary to tricuspid insufficiency may be audible at the left lower sternal border. In the presence of pulmonary hypertension, the pulmonic component of S_2 is accentuated. An early diastolic murmur may

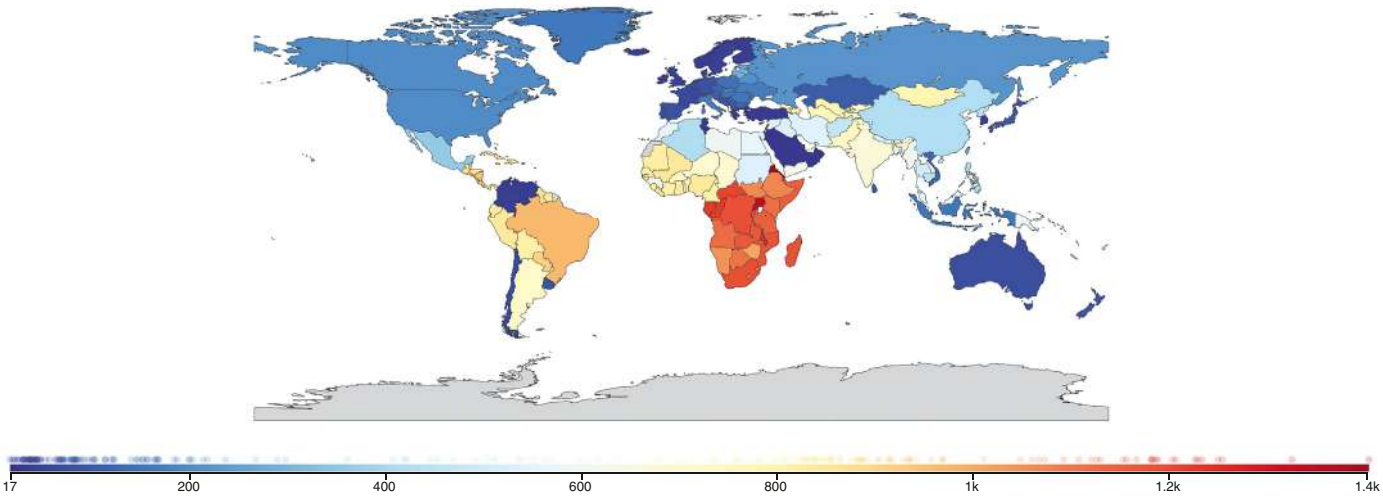

Fig. 487.1 Prevalence of rheumatic heart disease global map showing prevalence/100,000 population in 2017 by country. *(From the Institute for Health Metrics and Evaluation Global Burden of Disease 2019, Non-communicable disease data. Seattle: University of Washington IHME. https://www.healthdata.org/research-analysis/gbd.)*

be caused by associated rheumatic aortic insufficiency or pulmonary valvular insufficiency secondary to pulmonary hypertension.

ECGs and chest radiographs are normal if the stenosis is mild; as the severity increases, prominent and notched P waves and varying degrees of RV hypertrophy become evident. AF or other atrial arrhythmias are common late manifestations. Moderate to severe lesions are associated with radiographic signs of left atrial enlargement and prominence of the pulmonary artery and right-sided heart chambers; calcifications may be noted in the region of the mitral valve (see Fig. 487.2). Severe stenosis is associated with a redistribution of pulmonary blood flow so that the apices of the lung have greater perfusion (the reverse of normal). Lastly, horizontal lines in the lower lung periphery, called *Kerley B lines,* may be evident.

Echocardiography demonstrates thickening of the mitral valve and chordal apparatus, as well as restricted motion of the valve (Fig. 487.3). The typical "elbow" or "dog leg" appearance of the anterior leaflet of the mitral valve can aid in the distinction of a rheumatic valve from the various forms of congenital mitral stenosis. Left atrial dilation is common; color Doppler flow across the mitral valve shows a narrow jet with flow acceleration, and variable degrees of tricuspid insufficiency can be seen from left atrial hypertension. Doppler can estimate the transmitral pressure gradient but can underestimate the gradient if there is LV dysfunction. Estimates of the RV/PAP can be made by echocardiographic assessment of the tricuspid and pulmonary insufficiency, as well as changes in the RV size and function and the systolic septal position. Cardiac catheterization quantitates the diastolic gradient across the mitral valve well, allows for the calculation of cross-sectional valve area in older children, and assesses the degree of left atrial hypertension and PAP elevation.

Table 487.2 Echocardiographic Findings in Rheumatic Valvulitis

PATHOLOGIC MITRAL REGURGITATION*	PATHOLOGIC AORTIC REGURGITATION*
1. Seen in at least two views	1. Seen in at least two views

can be attempted but is generally used only for symptom control and much less often in children. However, it should not be considered adequate treatment in severe, symptomatic disease. Surgical valvotomy or balloon catheter mitral valvuloplasty generally yields good results (see Fig. 487.3); mitral valve replacement is avoided unless absolutely necessary. Balloon valvuloplasty is indicated for symptomatic, stenotic, pliable, noncalcified valves in patients without significant atrial arrhythmias or thrombi. Unfortunately, neither surgical nor interventional options may exist in areas of the world with high disease burden.

Aortic Insufficiency

In *acute* rheumatic aortic insufficiency, poor coaptation of the leaflets or leaflet prolapse is seen. *Chronic* rheumatic aortic insufficiency leads to sclerosis of the valve and results in distortion and retraction of the cusps. In both settings, regurgitation of blood leads to LV volume overload with dilation and hypertrophy of the left ventricle as it attempts to compensate for the excessive volume load. Concomitant mitral annular dilation accompanying LV dilation can further exacerbate mitral valve disease, specifically regurgitation. Combined mitral and aortic insufficiency in the acute phase of ARF is much more common than aortic involvement alone. However, in cases of isolated significant aortic insufficiency, RHD should not be discounted, even given the rare nature of this finding.

Clinical Manifestations

Symptoms are unusual except in severe aortic insufficiency or in the presence of significant concomitant mitral valve involvement or myocardial dysfunction. The large stroke volume and forceful LV contractions may result in palpitations. Sweating and heat intolerance are related to excessive vasodilation. Dyspnea on exertion can progress to orthopnea and pulmonary edema; angina may be precipitated by heavy exercise. Nocturnal attacks with sweating, tachycardia, chest pain, and hypertension may occur.

The pulse pressure is wide with bounding peripheral pulses (**water hammer** or **Corrigan pulse**). Systolic blood pressure is elevated, and diastolic pressure is lowered. In severe aortic insufficiency, the heart is enlarged, with an LV apical heave. A diastolic thrill may be present. The typical murmur begins immediately with S_2 and continues until late in diastole. The murmur is heard over the upper left and mid-left sternal border with radiation to the apex and upper right sternal border. Characteristically, it has a high-pitched blowing quality and is easily audible in full expiration with the diaphragm of the stethoscope placed firmly on the chest and the patient leaning forward. An aortic systolic ejection murmur is frequently heard because of the increased stroke volume. An apical presystolic murmur **(Austin Flint murmur)** resembling that of mitral stenosis is sometimes heard and is caused by the large regurgitant aortic flow in diastole preventing the mitral valve from opening fully.

Chest radiographs demonstrate enlargement of the left ventricle and aorta. The ECG may be normal, but in advanced cases it reveals signs of LV hypertrophy with a strain pattern and prominent P waves. Echocardiography shows a dilated left ventricle and diastolic mitral valve flutter or oscillations caused by aortic regurgitant flow hitting the valve leaflets. The aortic valve may demonstrate irregular or focal thickening, decreased systolic excursion, a coaptation defect, and leaflet prolapse. Doppler evaluation demonstrates the degree of aortic insufficiency. Cardiac magnetic resonance imaging/angiography (cMRI/MRA) can be useful in quantitating regurgitant volume and in assessing LV size and systolic function. Cardiac catheterization is generally only necessary when echocardiographic or axial imaging data are equivocal.

Prognosis and Treatment

Mild and moderate degrees of aortic insufficiency are well tolerated. Unlike mitral insufficiency, aortic insufficiency does not generally regress. Patients with combined lesions during the episode of ARF may have only aortic involvement 1-2 years later. Treatment consists of ACE inhibitors or ARBs and prophylaxis against ARF recurrence. Surgical intervention, which is typically aortic valve repair but occasionally can involve aortic valve prosthetic (biologic or mechanical) replacement, should be done well in advance of the onset of heart failure, pulmonary edema, and angina or when signs of decreasing myocardial performance become evident, as manifested by increasing LV dimensions and decreasing systolic function on echocardiography. Surgery is considered when early symptoms are present, significant ST-T wave changes are seen on the ECG, or evidence of decreasing LV ejection fraction is noted.

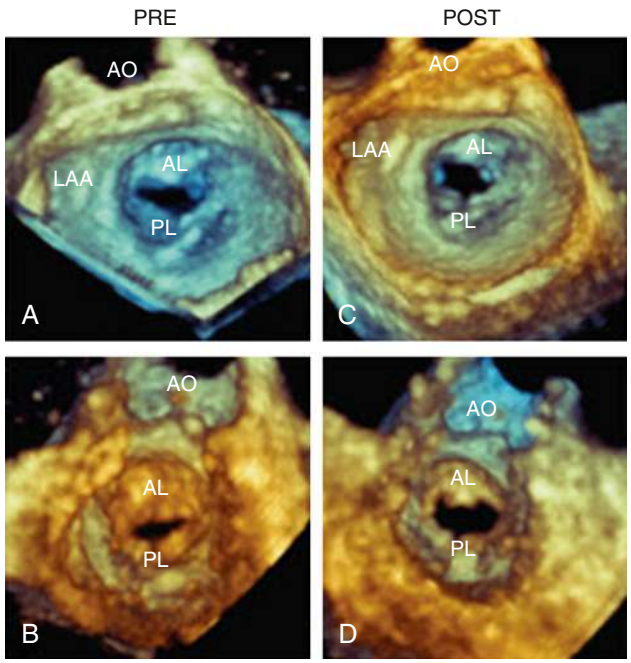

Fig. 487.3 Balloon mitral valvotomy. Real-time three-dimensional transesophageal echocardiographic images obtained before, during, and after balloon mitral valvotomy in a patient with mitral stenosis. A and B illustrate the stenotic mitral orifice as seen from the left atrium (A) and from the left ventricle (B) immediately prior to the procedure. C and D, obtained immediately after the procedure, show the commissure splitting and the larger mitral valve orifice. AL, anterior leaflet; AO, aorta; LAA, left atrial appendix; PL, posterior leaflet. *(From Salcedo EE, Carroll JD. Imaging guidance of transcatheter valve procedures. In Otto CM, Bonow RO (eds). Valvular Heart Disease: A Companion to Braunwald's Heart Disease. Philadelphia: Elsevier, 2013. Fig 16.11.)*

Tricuspid Valve Disease

Primary tricuspid valve involvement is rare during both the acute and chronic stages of rheumatic fever. Tricuspid insufficiency is more common secondary to RV dilation, resulting from significant left-sided cardiac lesions. The clinical signs of tricuspid insufficiency include prominent pulsations of the jugular veins, systolic pulsations of the liver, and a blowing holosystolic murmur at the lower left sternal border that increases in intensity during inspiration. Concomitant signs of mitral or aortic valve disease, with or without AF, are common. In these cases, signs of tricuspid insufficiency often decrease or even disappear when heart failure produced by the left-sided valvular lesions is successfully treated. Tricuspid valvuloplasty may be required in very rare cases.

Pulmonary Valve Disease

Pulmonary insufficiency secondary to ARF is rare and usually occurs on a functional basis secondary to pulmonary hypertension and is a late finding with severe mitral stenosis. The murmur **(Graham Steell murmur)** is similar to that of aortic insufficiency, but peripheral arterial signs (bounding pulses) are absent. The correct diagnosis is confirmed by two-dimensional echocardiography and Doppler studies demonstrating nonphysiologic pulmonary insufficiency, evidence of pulmonary hypertension, and the presence of mitral valve disease. Surgical intervention on the pulmonary valve is highly unusual.

Section 6

Diseases of the Myocardium and Pericardium

Chapter 488

Diseases of the Myocardium

John J. Parent and Stephanie M. Ware

The heterogeneous heart muscle diseases associated with structural remodeling and abnormalities of cardiac function **(cardiomyopathy)** are important causes of morbidity and mortality in the pediatric population. Several classification schemes have been formulated in an effort to provide logical, useful, and scientifically based etiologies for the cardiomyopathies. Insight into the molecular genetic basis of cardiomyopathies has increased exponentially, and etiologic classification schemes continue to evolve (Table 488.1).

Table 488.2 classifies the cardiomyopathies based on their anatomic (ventricular morphology) and functional pathophysiology. **Dilated cardiomyopathy**, the most common form of cardiomyopathy, is characterized predominantly by left ventricular (LV) dilation and decreased LV systolic function (Fig. 488.1). **Hypertrophic cardiomyopathy** demonstrates increased ventricular myocardial wall thickness, normal or increased systolic function, and often, diastolic (relaxation) abnormalities with fibrosis of varying degrees (Table 488.3 and Figs. 488.2 and 488.3). **Restrictive cardiomyopathy** is characterized by near-normal ventricular chamber size and wall thickness with preserved systolic function but dramatically impaired diastolic function leading to elevated filling pressures and atrial enlargement (Fig. 488.4). **Arrhythmogenic right ventricular (RV) cardiomyopathy** is characterized by fibrofatty infiltration and replacement of the normal RV myocardium and occasionally the left ventricle, leading to RV (and LV) systolic and diastolic dysfunction and arrhythmias. **Left ventricular noncompaction** is characterized by a hypertrabeculated LV apex and lateral wall, with a heterogeneous group of associated phenotypes (most often a dilated phenotype with LV dilation and dysfunction). Cardiomyopathies may be primary or associated with other organ involvement (Tables 488.4-488.6).

488.1 Dilated Cardiomyopathy

John J. Parent and Stephanie M. Ware

Dilated cardiomyopathy **(DCM)**, the most common form of cardiomyopathy in children, is the cause of significant morbidity and mortality and a common indication for cardiac transplantation. The etiologies are diverse. Unlike adult patients with DCM, ischemic etiologies are rare in children, although these include anomalous origin of the left coronary artery from the pulmonary artery, premature coronary atherosclerosis (homozygous familial hypercholesterolemia, rare genetic syndromic diseases such as progeria), and coronary inflammatory diseases such as Kawasaki disease. It is estimated that up to 50% of cases are **genetic** (usually autosomal dominant; some are autosomal recessive or X-linked), including some with metabolic causes (see Tables 488.1 and 488.2). Although the most common etiology of DCM remains **idiopathic**, it is likely that undiagnosed familial/genetic conditions and myocarditis predominate. The annual incidence of DCM in children younger than 18 years is 0.57 cases per 100,000 per year. The incidence is higher in males, Blacks, and infants <1 year old.

PATHOGENESIS

The pathogenesis of the ventricular dilation and altered contractility seen in DCM varies depending on the underlying etiology; systolic dysfunction and myocyte injury are common. Genetic abnormalities of several components of the cardiac muscle, including sarcomere proteins, the cytoskeleton, and the proteins that bridge the contractile apparatus to the cytoskeleton, have been identified in autosomal dominant and X-linked inherited disorders. DCM can occur after viral myocarditis. Although the primary pathogenesis varies from direct myocardial injury to viral-induced inflammatory injury, the resulting myocardial damage, ventricular enlargement, and poor function likely occur by a final common pathway similar to that in genetic disorders.

In 20–50% of cases, the DCM is familial, with autosomal dominant inheritance most common (see Table 488.3). **Duchenne and Becker muscular dystrophies** are X-linked cardiomyopathies that account for 5–10% of DCM cases (see Chapter 649.1). These dystrophinopathies result in an abnormal sarcomere-cytoskeleton connection, causing impaired myocardial force generation, myocyte damage/scarring, chamber enlargement, and altered function (see Table 488.6). Female carriers of dystrophinopathies may also manifest DCM.

Mitochondrial myopathies, as with the muscular dystrophies, may present clinically with a predominance of extracardiac findings, although in some children cardiomyopathy may be the first symptom. These are inherited in a recessive or mitochondrial pattern (see Tables 488.4 and 488.5). Disorders of **fatty acid oxidation** present with systemic derangements of metabolism (hypoketotic hypoglycemia, acidosis, and hepatic dysfunction), some with peripheral myopathy and neuropathy, and others with sudden death or life-threatening cardiac arrhythmias.

Anthracycline cardiotoxicity (doxorubicin [Adriamycin]) on rare occasion causes acute inflammatory myocardial injury, but more classically results in DCM and occurs in up to 30% of patients given a cumulative dose of doxorubicin exceeding 550 mg/m^2. The risk of toxicity appears to be exacerbated by concomitant radiation therapy.

CLINICAL MANIFESTATIONS

Although more prevalent in patients <1 year of age, all age-groups may be affected. Clinical manifestations of DCM are typically those of heart failure but can also include palpitations, syncope, and sudden death. Irritability or lethargy can be accompanied by additional nonspecific complaints of failure to thrive, nausea, vomiting, or abdominal pain. Respiratory symptoms (tachypnea, wheezing, cough, orthopnea, or dyspnea on exertion) are often present. Infrequently, patients may present acutely with pallor, altered mentation, hypotension, and shock. Patients can be tachycardic with narrow pulse pressure and may have hepatic enlargement and rales or wheezing. The precordial cardiac impulse is increased, and the heart may be enlarged to palpation or percussion. Auscultation may reveal a gallop rhythm in addition to tachycardia, and occasionally murmurs of mitral or, less often, tricuspid insufficiency may be present. The presence of hypoglycemia, acidosis, hypotonia, or signs of liver dysfunction suggests an inborn error of metabolism. Neurologic or skeletal muscle deficits are associated with mitochondrial disorders or muscular dystrophies (see Tables 488.4-488.6).

LABORATORY FINDINGS

Electrocardiographic screening reveals atrial or ventricular hypertrophy, nonspecific T-wave abnormalities, and occasionally, atrial or ventricular arrhythmias. The chest radiograph may demonstrate cardiomegaly and pulmonary vascular prominence or pleural effusions. The echocardiogram is often diagnostic, demonstrating the characteristic findings of LV enlargement, decreased ventricular contractility, and occasionally a globular (remodeled) LV contour (see Fig. 488.1).

Table 488.1 Classification of the Cardiomyopathies by Phenome and Genome

	PHENOTYPE				GENOME	
TYPE	**MORPHOLOGY**	**PHYSIOLOGY**	**PATHOLOGY**	**SYSTEMIC CONDITIONS, CLINICAL FEATURES, RISK FACTORS**	**NONSYNDROMIC, USUALLY SINGLE GENE**	**SYNDROMIC**
Dilated (DCM)	Dilation of LV and RV with minimal or no wall thickening	Reduced contractility is the primary defect; variable degree of diastolic dysfunction	Myocyte hypertrophy; scattered fibrosis	Hypertension, alcohol, thyrotoxicosis, myxedema, persistent tachycardia, toxins (e.g., chemotherapy, especially anthracyclines), radiation	Diverse gene ontology with >50 genes implicated	Diverse array of associated conditions, especially muscular dystrophies: Emery-Dreifuss, limb-girdle, Duchenne/Becker; Laing distal myopathy; Barth syndrome; Kearns-Sayre syndrome; other mitochondrial disorders; fatty acid oxidation disorders; Alstrom syndrome, others
Restrictive (RCM)	Usually normal chamber sizes; minimal wall thickening	Contractility normal or near-normal with a marked increase in end-diastolic filling pressure	Specific to type, diagnosis: amyloid, iron, glycogen storage disease, others	Endomyocardial fibrosis, amyloid, sarcoid, scleroderma, Churg-Strauss syndrome, cystinosis, lymphoma, pseudoxanthoma elasticum, hypereosinophilic syndrome, carcinoid	If not associated with systemic genetic disease, genetic cause usually from sarcomeric pathogenic gene variants	Gaucher disease, hemochromatosis, Fabry disease, familial amyloidosis, mucopolysaccharidoses, Noonan syndrome
Hypertrophic (HCM)	Usually normal or reduced internal chamber dimension; wall thickening pronounced, especially septal hypertrophy	Systolic function increased or normal	Myocyte hypertrophy, classically with disarray	Severe hypertension can confound clinical, morphologic diagnosis	Pathogenic variants of genes encoding sarcomeric proteins	Noonan syndrome, Noonan syndrome with multiple lentigines, Danon syndrome, Fabry disease, Wolff-Parkinson-White syndrome, Friedreich ataxia, MERRF, MELAS, other mitochondrial disorders, fatty acid oxidation disorders
Arrhythmogenic right ventricular cardiomyopathy (ARVC)	Scattered fibrofatty infiltration, classically of RV but also of LV; dilation of RV or LV, or both, is common but not universal	Ventricular arrhythmias (VT, VF) early or late, reduced contractility with progressive disease; can mimic DCM	Islands of fatty replacement; fibrosis	Palmoplantar keratoderma, wooly hair in Naxos syndrome	Pathogenic variants of genes encoding proteins of desmosome	Naxos syndrome
Left ventricular noncompaction (LVNC)	Ratio of noncompacted to compacted myocardium increased with normal LV or RV or any other phenotype	Normal to reduced systolic function	Myocardium normal and ranging to findings consistent with other coexisting cardiomyopathies	Phenotype observed in setting of other types of cardiomyopathy	Various cardiomyopathy genes associated, but uncertain whether genetic cause or developmental defect during organogenesis

Table 488.2 Etiology of Pediatric Myocardial Disease

CARDIOMYOPATHY	
Dilated Cardiomyopathy (DCM)	
Neuromuscular diseases	Muscular dystrophies (e.g., Duchenne, Becker, limb-girdle, Emery-Dreifuss, congenital muscular dystrophy), myotonic dystrophy, myofibrillar myopathy
Inborn errors of metabolism	Fatty acid oxidation disorders (trifunctional protein, VLCAD, LCHAD), carnitine abnormalities (carnitine transport, CPTI, CPTII), mitochondrial disorders (including Kearns-Sayre syndrome), organic acidemias (propionic acidemia), Danon disease (DCM more common in females)
Genetic variants in cardiomyocyte structural apparatus	Familial or sporadic DCM
Genetic syndromes	Alström syndrome, Barth syndrome (phospholipid disorders)
Ischemic	Most common in adults
Chronic tachyarrhythmias	Atrial tachycardias (intractable reentrant supraventricular tachycardia [AVRT, AVNRT], multifocal atrial tachycardia, permanent junctional reciprocating tachycardia), ventricular tachycardia
Hypertrophic Cardiomyopathy (HCM)	
Inborn errors of metabolism	Mitochondrial disorders (including Friedreich ataxia, variants in nuclear or mitochondrial genome), storage disorders (glycogen storage disorders, especially Pompe; mucopolysaccharidoses; Fabry disease; sphingolipidoses; hemochromatosis; Danon disease); fatty acid oxidation disorders
Genetic variants in cardiomyocyte structural apparatus	Familial or sporadic HCM
Genetic syndromes	Noonan, Costello, cardiofaciocutaneous, and Beckwith-Wiedemann syndromes
Infant of a diabetic mother	Transient hypertrophy
Restrictive Cardiomyopathy (RCM)	
Neuromuscular disease	Myofibrillar myopathies
Metabolic	Storage disorders
Genetic variants in cardiomyocyte structural apparatus	Familial or sporadic RCM
Secondary	Rare in children; radiation therapy of thorax, amyloidosis, sarcoidosis, hemochromatosis, β-thalassemia
Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC)	
Genetic variants in cardiomyocyte structural apparatus	Familial or sporadic ARVC
Left Ventricular Noncompaction	
Genetic variants in cardiomyocyte structural apparatus	LVNC phenotype associated with HCM or DCM
Other	X-linked (Barth syndrome), autosomal recessive, mitochondrial inheritance, 1p36 deletion syndrome, and other chromosome abnormalities or genomic disorders; associated with congenital heart defects
SECONDARY OR ACQUIRED MYOCARDIAL DISEASE	
Myocarditis (see also Table 488.7)	**Viral:** parvovirus B19, adenovirus, coxsackievirus A and B, echovirus, rubella, varicella, influenza, mumps, Epstein-Barr virus, cytomegalovirus, measles, poliomyelitis, smallpox vaccine, hepatitis C virus, human herpesvirus 6, HIV, SARS-CoV-2 (COVID-19), opportunistic infections **Rickettsial:** psittacosis, *Coxiella,* Rocky Mountain spotted fever, typhus **Bacterial:** diphtheria, mycoplasma, meningococcus, leptospirosis, Lyme disease, typhoid fever, tuberculosis, streptococcus, listeriosis **Parasitic:** Chagas disease, toxoplasmosis, *Loa loa, Toxocara canis,* schistosomiasis, cysticercosis, echinococcus, trichinosis **Fungal:** histoplasmosis, coccidioidomycosis, actinomycosis
Systemic inflammatory disease	SLE, infant of mother with SLE, scleroderma, Churg-Strauss vasculitis, rheumatoid arthritis, rheumatic fever, sarcoidosis, dermatomyositis, periarteritis nodosa, hypereosinophilic syndrome (Löffler syndrome), acute eosinophilic necrotizing myocarditis, giant cell myocarditis, Kawasaki disease, multisystem inflammatory syndrome in children (COVID-19)
Nutritional deficiency	Beriberi (thiamine deficiency), kwashiorkor, Keshan disease (selenium deficiency)
Drugs, toxins	Doxorubicin (Adriamycin), cyclophosphamide, chloroquine, ipecac (emetine), sulfonamides, mesalazine, chloramphenicol, alcohol, hypersensitivity reaction, envenomations, irradiation, herbal remedy (blue cohosh), immune checkpoint inhibitors
Coronary artery disease	Kawasaki disease, medial necrosis, anomalous left coronary artery from pulmonary artery, other congenital coronary anomalies (anomalous right coronary artery, coronary ostial stenosis), familial hypercholesterolemia
Hematology-oncology	Anemia, sickle cell disease, leukemia
Endocrine-neuroendocrine	Hyperthyroidism, carcinoid tumor, pheochromocytoma, adrenal crisis
Stress (takotsubo) cardiomyopathy	Endocrine (see earlier) Neurologic (stroke, bleed) Induction of anesthesia Fright Medications/drugs (sympathomimetic agents, venlafaxine)

CPTI/CPTII, Carnitine palmitoyltransferase 1/2; LCHAD, long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency; LVNC, left ventricular noncompaction; SLE, systemic lupus erythematosus; VLCAD, very-long-chain acyl-coenzyme A dehydrogenase.

RV enlargement and depressed function are occasionally noted. Echo Doppler studies can reveal evidence of pulmonary hypertension, mitral regurgitation, or other structural cardiac or coronary abnormalities. Cardiac MRI is useful for patients with suboptimal imaging echocardiographic windows or in patients with concern of acute myocarditis where, in contrast to echocardiography, recognition of inflammation of the myocardium is possible.

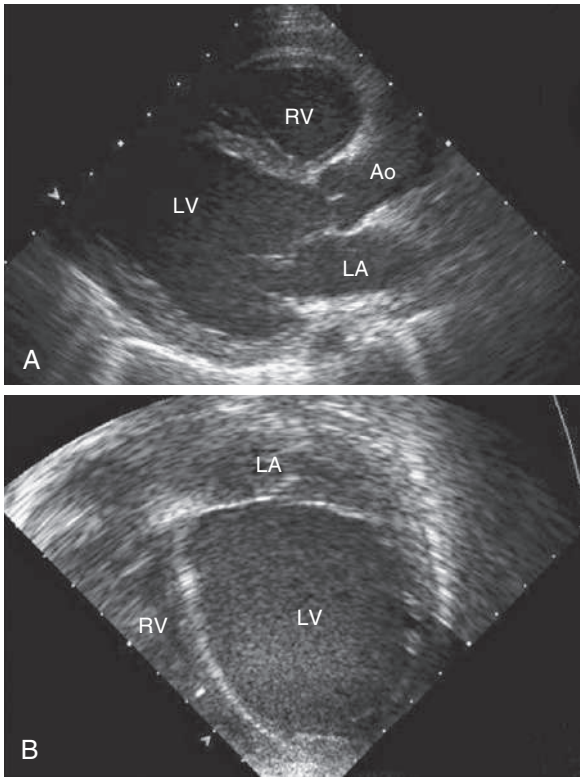

Fig. 488.1 Echocardiogram of a patient with dilated cardiomyopathy. **A,** Parasternal long-axis view showing the enlarged left ventricle. **B,** Apical four-chamber view showing the large left ventricle compressing the right ventricle. Ao, Ascending aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

Additional testing may include complete blood count, renal and liver function tests, creatine phosphokinase (CPK), cardiac troponin I, lactate, brain natriuretic peptide (BNP) and pro-BNP, plasma amino acids, urine organic acids, and an acylcarnitine profile. Additional genetic testing is typically indicated, and enzymatic testing may be useful (see Table 488.3). Cardiac catheterization and endomyocardial biopsy are not routine but may be useful in patients with acute DCM. Biopsy samples can be examined histologically for the presence of mononuclear cell infiltrates, myocardial damage, storage abnormalities, and evidence of infection. It is considered standard of care to screen first-degree family members using echocardiography and electrocardiogram (ECG) in idiopathic and familial cases of DCM.

PROGNOSIS AND MANAGEMENT

The 1- and 5-year freedom from death or transplantation in patients diagnosed with DCM is 60–70% and 50–60%, respectively. Independent risk factors at DCM diagnosis for subsequent death or transplantation include older age, heart failure, lower LV fractional shortening *z* score, and underlying etiology. DCM is the most common cause for cardiac transplantation in pediatric and adult studies.

The therapeutic approach to patients with DCM includes a careful assessment to uncover possible treatable etiologies, screening of family members, and rigorous pharmacologic therapy. **Medications** aimed at reverse remodeling (improving ventricular size and function) include angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) plus β-adrenergic blockade with carvedilol or metoprolol. The combination medication valsartan/sacubitril, which is an ARB/neprilysin inhibitor, respectively, that is FDA approved for patients 1 year of age and older, has been readily used in this setting in pediatrics in lieu of either an ACE or ARBs alone (see Chapter 491). Each of these medications have proved independently and in combination to improve survival and symptoms and reduce hospital admissions in adults with DCM. Additionally, furosemide may be used to reduce symptoms of pulmonary or systemic venous congestion. Digoxin therapy can also be considered in some patients. Implantable cardiac defibrillators may be considered for certain select patients with a high risk of sudden cardiac arrest. **Pacemakers**, including dual-chamber and biventricular pacing therapy, can improve patients with

Table 488.3 Cardiomyopathies

	DCM	HCM	RCM	LVNC	ARVC
Prevalence	50/100,000	1/500	Unknown	Unknown	1/2,000
Causes	Sarcomeric/ cytoskeletal/ desmosomal gene variant, neuromuscular disease, inborn error of metabolism, mitochondrial disease, genetic syndrome, infection	Sarcomeric/ cytoskeletal/ desmosomal gene variant, genetic syndrome, inborn error of metabolism/ mitochondrial disease	Sarcomeric gene variant, neuromuscular disease, genetic syndrome, storage or infiltrative disease	Sarcomeric-cytoskeletal-desmosomal gene mutation, neuromuscular disease, inborn error of metabolism, mitochondrial disease, genetic syndrome	Desmosomal gene variants
Inheritance	30–50% AD, AR, X-L, Mt	50% AD, Mt	AD, up to 50%	AD, X-L, Mt, % unknown	30–50% AD, rare AR (Naxos disease; Carvajal syndrome)
Sudden death	Yes	Yes	Yes	Yes	Yes
Arrhythmias	Atrial, ventricular, and conduction disturbances	Atrial and ventricular	Atrial fibrillation	Atrial, ventricular, and conduction disturbances	Ventricular and conduction disturbances
Ventricular function	Systolic and diastolic dysfunction	Diastolic dysfunction Dynamic systolic outflow obstruction	Diastolic dysfunction Normal systolic function	Systolic or diastolic dysfunction	Normal-reduced systolic and diastolic function

ACE, Angiotensin-converting enzyme; AD, autosomal dominant inheritance; AR, autosomal recessive inheritance; ARVC, arrhythmogenic right ventricular cardiomyopathy; DCM, dilated cardiomyopathy; HCM, hypertrophic cardiomyopathy; ICD, implantable cardioverter-defibrillator; LVNC, left ventricular noncompaction; Mt, mitochondrial inheritance; RCM, restrictive cardiomyopathy; X-L, X-linked inheritance.

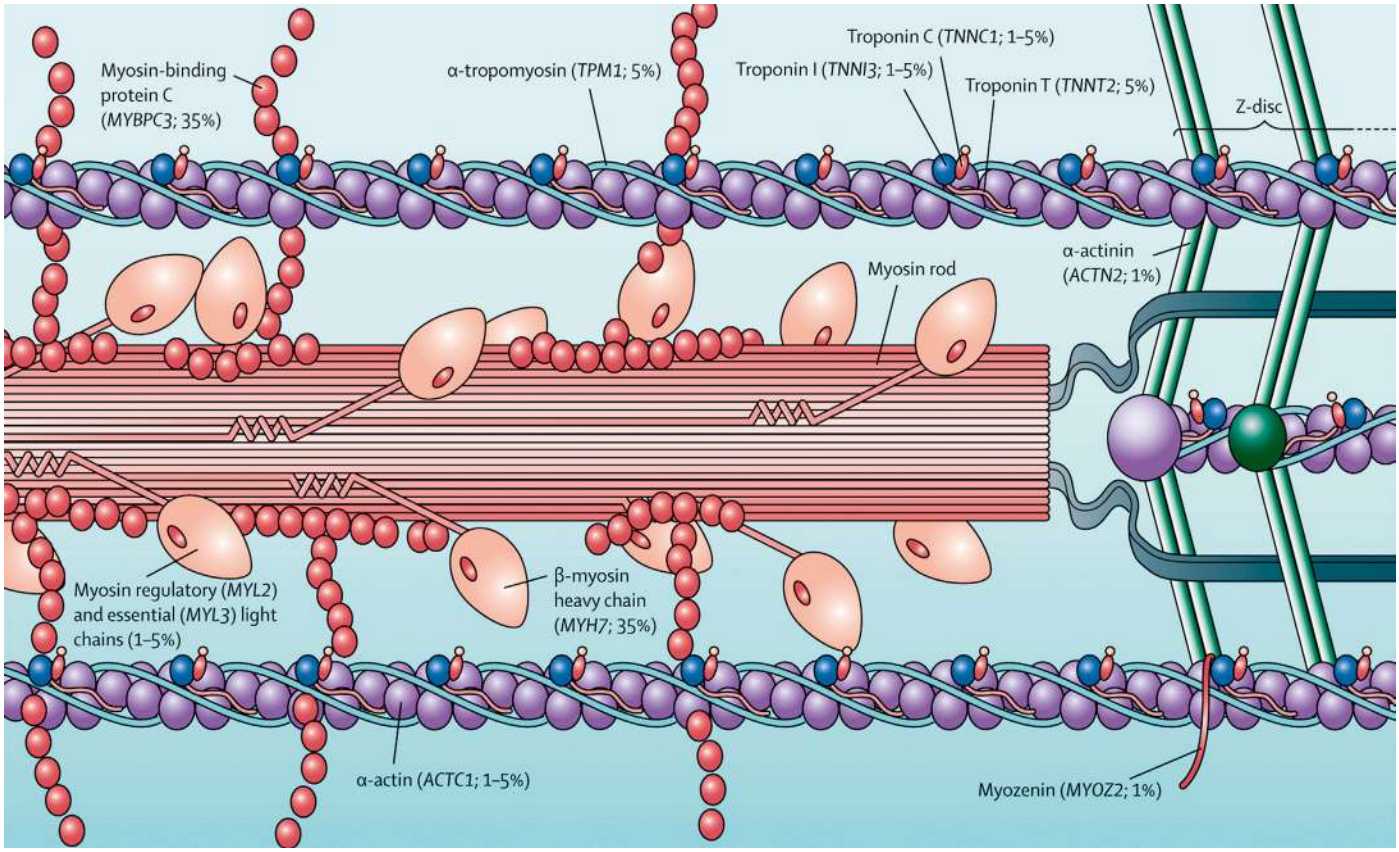

Fig. 488.2 Locations of genes within the cardiac sarcomere known to cause hypertrophic cardiomyopathy. Prevalence of every gene (derived from data of unrelated hypertrophic cardiomyopathy probands with positive genotyping) is shown in parentheses. *(From Maron BJ, Maron MS. Hypertrophic cardiomyopathy. Lancet 2013;381:242–252, Fig 1.)*

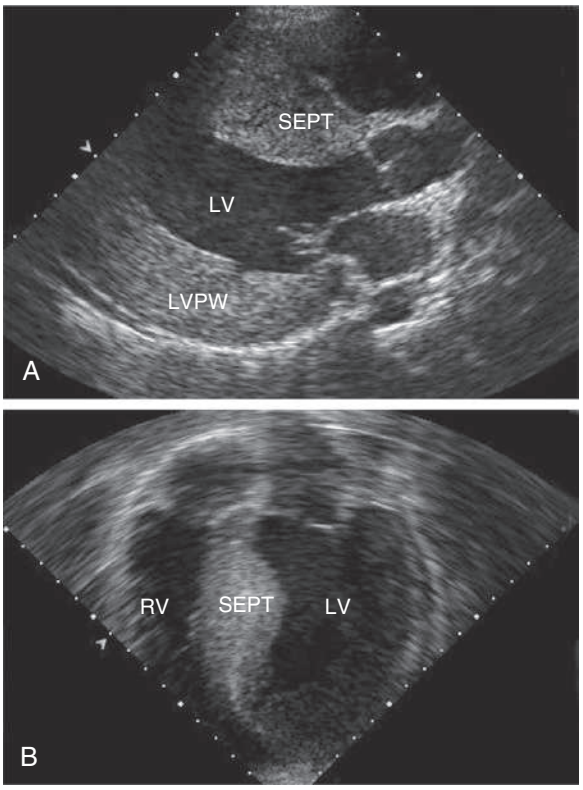

Fig. 488.3 Echocardiograms demonstrating hypertrophic cardiomyopathy. A, Parasternal long-axis view of a patient with severe concentric left ventricular hypertrophy. B, Four-chamber view of a patient with asymmetric septal hypertrophy. LV, Left ventricle; LVPW, left ventricular posterior wall; RV, right ventricle; SEPT, septum.

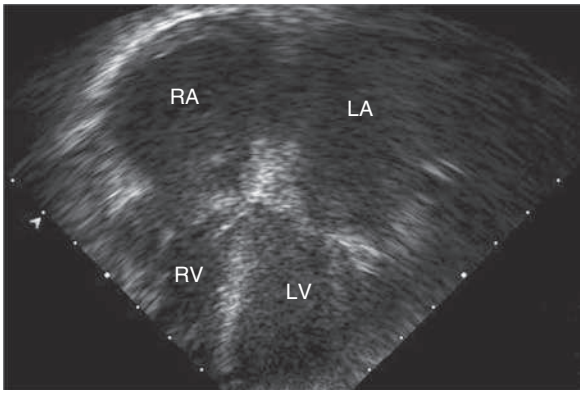

Fig. 488.4 Echocardiogram of a patient with restrictive cardiomyopathy. Apical four-chamber view shows the greatly enlarged right and left atria compared to the normal-size left and right ventricular chambers. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Table 488.4 Nuclear DNA Abnormalities Associated with Cardiomyopathy and Arrhythmias or Conduction Defects*

CONDITION	GENETIC DEFECT	HEART FINDINGS	OTHER CLINICAL FEATURES
ISOLATED COMPLEX DEFICIENCIES			
Complex I deficiency	Multiple complex I subunit genes, *ACAD9, FOXRED1*	HCM, DCM, LVNC, WPW	Leigh syndrome, FILA, MELAS, leukoencephalopathy, seizures, hypotonia, pigmentary retinopathy, optic atrophy, hearing loss, liver dysfunction
Complex II deficiency	*SDHA, SDHD*	HCM, DCM, LVNC, AF, heart block	Leukoencephalopathy, cerebellar atrophy, seizures, spasticity, myopathy, liver dysfunction, kidney dysfunction
Complex III deficiency	*BCS1L*	HCM	Developmental delay, psychosis, hearing loss
Complex IV deficiency	*SCO2, SURF1, C2orf64, Cl2orf62, COX6B1*	HCM, DCM	Leigh syndrome, encephalopathy, ataxia, liver dysfunction, kidney dysfunction
MITOCHONDRIAL TRANSLATION DEFECTS			
GTP-binding protein-3 deficiency	*GTPBP3*	HCM, DCM, heart block, WPW	Leigh syndrome, encephalopathy
Mitochondrial translational activator protein deficiency	*MTOI*	HCM, heart block	Encephalopathy, hypotonia
Alanyl-tRNA synthetase deficiency	*AARS2*	HCM	Leukoencephalopathy, myopathy
Tyrosyl-tRNA synthetase deficiency	*YARS2*	HCM	MLASA syndrome
tRNA methyltransferase-*5* deficiency	*TRMTS*	HCM	Developmental delay, hypotonia, peripheral neuropathy, renal tubulopathy
RNA processing defect	*ELAC2*	HCM, PSVE	Microcephaly, growth deficiency, hearing loss
Mitochondrial ribosomal subunit deficiencies	*MRPS22, MRPl3, MRPL44*	HCM, WPW	Leukoencephalopathy, seizures, liver dysfunction, renal tubulopathy
mtDNA DEPLETION SYNDROMES			
MNGIE	*TYMP*	Mild or asymptomatic HCM	Leukoencephalopathy, severe gastrointestinal dysmotility, ophthalmoplegia, hearing loss, peripheral neuropathy
F-box protein deficiency	*FBXL4*	Cardiomyopathy, unspecified	Encephalopathy, brain atrophy
Coenzyme Q_{10} biosynthesis defects	*COQ2, COQ4, COQ9*	HCM	Leigh syndrome, encephalomyopathy, retinitis pigmentosa, hearing loss, liver dysfunction, renal tubulopathy
3-METHYLGLUTACONIC ACIDURIAS			
Barth syndrome	*TAZ*	HCM, DCM, LVNC, EFE, VT, LQTS	Myopathy, short stature, neutropenia
Dilated cardiomyopathy and ataxia syndrome	*DNAJC19*	DCM, LVNC	Ataxia, optic ataxia, short stature, testicular abnormalities, liver disease
Complex V deficiency	*TMEM70*	HCM	Cataracts, leukodystrophy, ataxia, myopathy, short stature
Sengers syndrome	*AGK*	HCM	Cataracts, myopathy, exercise intolerance, short stature

*Examples of conditions that are associated with heart disease and feature abnormal nDNA are shown, along with the causative molecular defects and clinical findings. The genetic defects noted here are provided as major contributors to the various mitochondrial conditions but are not a comprehensive compilation.

AF, Atrial fibrillation; DCM, dilated cardiomyopathy; EFE, endocardial fibroelastosis; FILA, fatal infantile lactic acidosis; GTP, guanosine triphosphate; HCM, hypertrophic cardiomyopathy; LQTS, long QT syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes; MLASA, myopathy, lactic acidosis, sideroblastic anemia; MNGIE, mitochondrial neurogastrointestinal encephalopathy; nDNA, nuclear DNA; PSVE, paroxysmal supraventricular extrasystoles; LVNC, left ventricular noncompaction; VT, ventricular tachycardia; WPW, Wolff-Parkinson-White syndrome.
