Hip fractures in children account for <1% of all pediatric fractures. These injuries result from high-energy trauma and can be associated with injury to the chest, head, or abdomen. Treatment of hip fractures in children is associated with a complication rate of up to 60%, including an overall avascular necrosis rate of 50% and a malunion rate of up to 30%. The unique blood supply to the femoral head accounts for the high rate of avascular necrosis. Fractures are classified by the Delbet classification as transphyseal separations, transcervical fractures, cervicotrochanteric fractures, and intertrochanteric fractures. The management principles include urgent anatomic reduction (either open or closed), stable internal fixation (avoiding the physis if possible), and

spica casting if the child is younger. Urgent management has been associated with a lower rate of avascular necrosis and superior overall outcomes. Capsular decompression also has been advocated as decreasing overall pressure on the epiphyseal vessels and has been demonstrated experimentally; the clinical results, however, remain mixed.

FEMORAL SHAFT FRACTURES

Fractures of the femur in children are common. All age groups, from early childhood to adolescence, can be affected. The mechanism of injury varies from low-energy twisting type injuries to high-velocity injuries in vehicular accidents. *Femur fractures in children younger than age 2 years should raise concern for child abuse.* A thorough physical examination is necessary to rule out other injuries and assess the neurovascular status. In the case of high-energy trauma, any signs of hemodynamic instability should prompt the examiner to look for other sources of bleeding. AP and lateral radiographs of the femur demonstrate the fracture. An AP radiograph of the pelvis is obtained to rule out any associated pelvic fracture. Treatment of shaft fractures varies with the age group, as described in Table 724.3.

PROXIMAL TIBIA FRACTURES

Proximal tibia fractures can be physeal injuries, metaphyseal injuries, or avulsion injuries of the tibial spine or tubercle. Physeal injuries can be either isolated or as part of tibial tubercle fracture. If the distal segment is displaced posteriorly the trifurcation of the popliteal vessels may be involved. Careful neurovascular examination is warranted both pre- and postreduction. Anatomic reduction and pin fixation is preferred with unstable fractures or displaced SH III or IV fractures.

Proximal tibial metaphyseal fractures, or the Cozen fracture, are most common in the 3- to 6-year-old age group. They may result in a late valgus deformity even if anatomically reduced. This deformity tends to remodel within 1-2 years but can cause great distress to parents and treating clinicians.

Tibial eminence fractures are fractures of the bony prominence that is the attachment of the anterior cruciate ligament. The mechanism of injury is similar to an anterior cruciate ligament tear in an adult. Displaced fractures require surgical reduction and fixation. This may be done either open or arthroscopically.

Tibial tubercle fractures are common in patients with Osgood-Schlatter syndrome. Care must be taken to observe for compartment syndrome as the injury is associated with injury of the recurrent anterior tibial artery. The injury may be treated nonoperatively if the fracture is displaced <2 mm and the patient has no extensor lag (rare). Open reduction and internal fixation is preferred otherwise.

TIBIA AND FIBULA SHAFT FRACTURES

The tibia is the most commonly fractured bone of the lower limb in children. This fracture generally results from a direct injury. Most tibial fractures are associated with a fibular fracture, and the mean age of presentation is 8 years. The child presents with pain, swelling, and deformity of the affected leg and is unable to bear weight. Distal neurovascular examination is important in assessment. The AP and lateral radiographs should include the knee and ankle. Closed reduction and immobilization are the standard method of treatment. Most fractures heal well, and children usually have excellent results. Open fractures need to undergo irrigation and debridement as well as antibiotic treatment. The tibia is a subcutaneous bone, so if severe soft tissue loss occurs with an open fracture, the patient may need plastic surgery consultation. Definitive external fixation versus internal fixation and simultaneous soft tissue coverage are alternative treatment strategies to minimize infection. Tibia fractures are associated with compartment syndrome. Vigilance is necessary to avoid disastrous outcomes associated with missed compartment syndrome. *Emergent fasciotomy is indicated as soon as compartment syndrome is diagnosed.* Several return trips to the operating room are often necessary to close, versus cover, the fasciotomy wounds.

TODDLER FRACTURES

Toddler fractures occur in young ambulatory children. The age range for this fracture is typically around 1-4 years (Fig. 724.13). The injury often occurs after a seemingly harmless twist or fall and is often unwitnessed. It is a result of a torsional injury. The children in this age group are usually unable to articulate the mechanism of injury clearly or to describe the area of injury well. The radiographs may show no fracture; in these cases, the diagnosis is made by physical examination. The classic symptom is refusal to bear weight, which can manifest as pulling up the affected extremity or florid display of protest. The other common sign is point tenderness at the fracture site. The AP and lateral views of the tibia-fibula might show a nondisplaced spiral fracture of the distal tibial metaphysis. An oblique view is often helpful because the fracture line may be visible in only one of the three views. Often the fracture

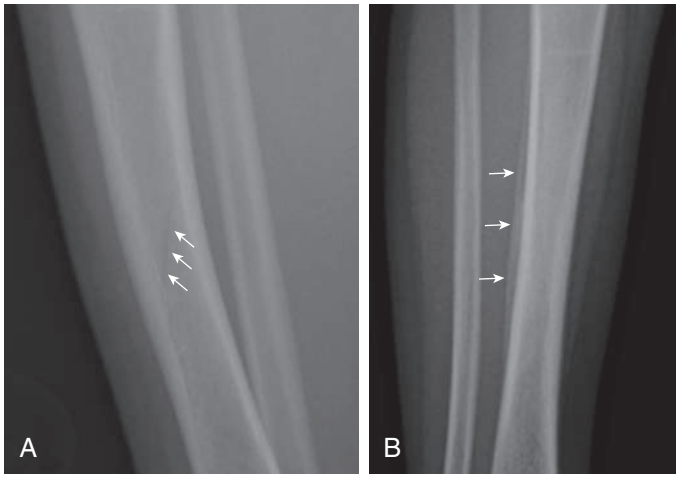

Fig. 724.13 Toddler's fracture of the tibia in a 2-yr-old child presenting with a limp and no history of trauma. **A,** Lateral radiograph of the lower leg shows a subtle, nondisplaced, oblique fracture through the tibial shaft *(arrows).* **B,** Anteroposterior radiograph obtained 10 days later shows healing, with subperiosteal new bone formation along the tibial shaft *(arrows). line is not visualized until 2-3 weeks later, when periosteal reaction and resorption at the fracture site allow better visualization. Inflammatory markers may be ordered to rule out infectious processes if the diagnosis is in doubt. Bone scans were employed in the past but impart a large amount of radiation to the child. The fracture can be safely treated with a below-knee cast or a controlled ankle motion (CAM) walking boot for approximately 3 weeks.

TRIPLANE AND TILLAUX FRACTURES

Triplane and Tillaux fracture patterns occur at the end of the growth period and are based on relative strength of the bone-physis junction and asymmetric closure of the tibial physis. The triplane fractures are so named because the injury has coronal, sagittal, and transverse components (Fig. 724.14). The Tillaux fracture is an avulsion fracture of the anterolateral aspect of the distal tibial epiphysis. Radiographs and further imaging with CT and three-dimensional reconstructions are necessary to analyze the fracture geometry. The triplane fracture involves the articular surface and hence anatomic reduction is necessary. The reduction is further stabilized with internal fixation. The Tillaux fracture is treated by closed reduction. Open reduction is recommended if a residual intraarticular step-off persists.

METATARSAL FRACTURES

Metatarsal fractures are common in children. They usually result from direct trauma to the dorsum of the foot. High-energy trauma or multiple fractures of the metatarsal base are associated with significant swelling. A high index for compartment syndrome of the foot must be maintained and compartment pressures must be measured if indicated. Diagnosis is obtained by AP, lateral, and oblique radiographs of the foot. Most metatarsal fractures can be treated by closed methods in a below-knee cast or walking boot. Weight-bearing is allowed as tolerated. The Jones fracture of the proximal fifth metatarsal is an exception as it lies at a watershed area of vascular supply and thus has an increased risk of nonunion. Patients with Jones fractures should initially be nonweightbearing and should be referred to an orthopedics specialist. Displaced fractures can require closed or open reduction with internal fixation. Percutaneous, smooth Kirschner wires (K-wires) generally provide sufficient internal fixation for these injuries.

TOE PHALANGEAL FRACTURES

Fractures of the lesser toes are common and are usually secondary to direct blows. They commonly occur when the child is barefoot. The toes are swollen, ecchymotic, and tender. There may be a mild deformity. Diagnosis is made radiographically. Bleeding suggests the possibility of an open fracture. The lesser toes usually do not require closed reduction unless significantly displaced. If necessary, reduction can usually be accomplished with longitudinal traction on the toe. Casting is not usually necessary. Buddy taping of the fractured toe to an adjacent stable toe usually provides satisfactory alignment and relief of symptoms. Crutches and heel walking may be beneficial for several days until the soft tissue swelling and the discomfort decrease.

724.5 Operative Treatment of Fractures

Jason B. Anari, Alexandre Arkader, and Lawrence Wells

Surgery is required for 4–5% of pediatric fractures. The common indications for operative treatment in children and adolescents include displaced physeal fractures, displaced intraarticular fractures, unstable fractures, multiple injuries, open fractures, failure to achieve adequate reduction in older children, failure to maintain an adequate reduction, and certain pathologic fractures.

The aim of operative intervention is to obtain anatomic alignment and relative stability. Rigid fixation is not necessary as it is in adults for early mobilization. The relatively stable construct can be supplemented with external immobilization such as a cast, splint, or CAM walking boot. SH types III and IV injuries require anatomic alignment, and if they are unstable, internal fixation is used (smooth K-wires, preferably avoiding the course across the growth plate). Multiple closed reductions of an epiphyseal fracture are contraindicated because they can cause permanent damage to the physis.

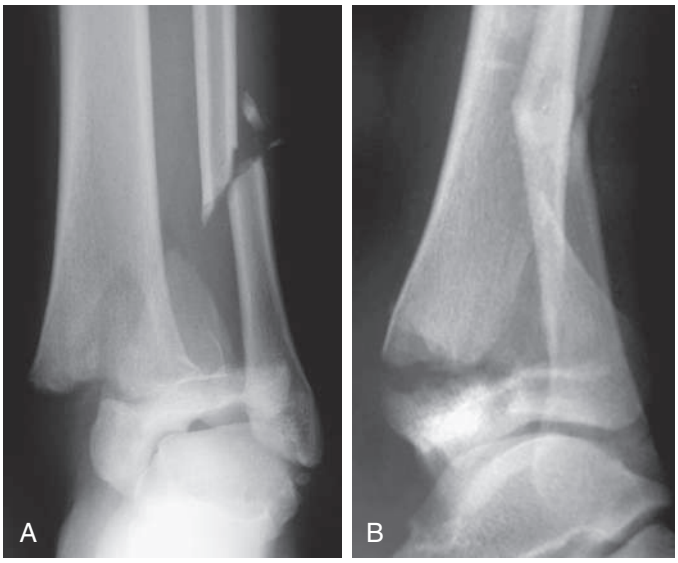

Fig. 724.14 The triplane fracture is a transitional fracture: anteroposterior (A) and lateral (B) radiographs. *(From Dormans JP. Pediatric Orthopedics: Introduction to Trauma. Philadelphia: Mosby; 2005:38.)*

Table 724.4 Common Indications for External Fixation in Pediatric Fractures

Grades II and III open fractures
Fractures associated with severe burns
Fractures with soft tissue loss requiring free flaps or skin grafts
Fractures requiring distractions such as those with significant bone loss
Unstable pelvic fractures
Fractures in children with associated head injuries and spasticity
Fractures associated with vascular or nerve repairs or reconstruction

SURGICAL TECHNIQUES

It is important to take great care with soft tissues and skin. The other indications for open reduction and internal fixation are unstable fractures of the spine, ipsilateral fractures of the femur and tibia, neurovascular injuries requiring repair, and open fractures. Closed reduction and minimally invasive fixation are specifically used for supracondylar fractures of the distal humerus and most phalangeal fractures. Failure to obtain anatomic alignment by closed means is an indication for an open reduction. Percutaneous techniques such as intramedullary fixation and minimally invasive plate osteosynthesis are increasingly popular as well.

As children become older, surgical techniques become more similar to adult techniques. The classic example of this is the femoral shaft fracture. Newborns may be treated with a soft dressing or Pavlik harness; young children may have a spica cast; older children will often be treated with flexible nails. Adolescents will frequently be treated with rigid intramedullary fixation similar to their adult counterparts.

Table 724.4 summarizes the main indications for external fixation. The advantages of external fixation include rigid immobilization of the fractures, access to open wounds for continued management, and easier patient mobilization for treatment of other injuries and transportation for diagnostic and therapeutic procedures. The majority of

complications with external fixation are pin tract infections, chronic osteomyelitis, and refractures after pin removal.

724.6 Complications of Fractures in Children

Jason B. Anari, Alexandre Arkader, and Lawrence Wells

Complications of fractures in children can be categorized as (1) complications of the injury itself, (2) complications of treatment, and (3) late complications resulting from growth disturbance or deformity.

COMPLICATIONS RESULTING FROM INJURY

Growth arrest is possible in physeal fractures, particularly widely displaced physeal fractures about the distal femur, proximal tibia, or distal ulna. Fractures about the hip may cause **avascular necrosis** or premature physeal closure, particularly when the fracture involves the proximal femoral physis. Unacceptable alignment may cause loss of motion or limb malalignment. Fracture malunion may cause cosmetically unappealing bumps or curves in the limb, and at times functional impairment. **Compartment syndrome** can occur, particularly in diaphyseal tibia fractures or high energy or open both bone forearm fractures. Supracondylar humerus fractures, distal femur fractures, and proximal tibia fractures may result in neurovascular compromise. Nonunions are rare in children but can be seen with intraarticular fractures, such as distal humerus lateral condyle fractures. Malunions or missed Monteggia fracture dislocations about the elbow can cause permanent stiffness and loss of function if the deformity is not corrected. Displaced intraarticular fractures can result in posttraumatic arthritis and early joint degeneration. Open fractures can result in infection and osteomyelitis if inadequately treated. Older children with severe injuries of the lower extremity can be vulnerable to **deep vein thrombosis**.

COMPLICATIONS OF TREATMENT

Treatment may complicate fractures. Cast immobilization can result in **cast ulcers**, either from inadequate padding of bony prominences or from patients placing objects in the cast. Casts that are too tight can cause neurovascular compromise and compartment syndrome. Patients can get cast saw burns from using cast saws that are too dull to remove the cast. Safe operation of a cast saw requires monitoring of blade temperature. The saw blade should be intermittently cooled by taking a break to avoid overheating and thermal injury to the skin. Improperly placed casts can promote fracture displacement and malunion. Surgical treatment can be complicated by blood loss, neurovascular compromise, iatrogenic physeal damage, and hardware complications such as infection or hardware failure. Symptomatic hardware may require later removal.

LATE COMPLICATIONS OF TRAUMA

Late effects of trauma can be from partial or complete closure of the physis or malunion of the fracture. This can lead to limb angular deformity, shortening, or incongruency. Angular deformities can be treated by hemiepiphysiodesis or osteotomy. Joint incongruency may be a very difficult problem to deal with and may ultimately lead to early degenerative joint disease. Reflex sympathetic dystrophy is another poorly understood late effect of trauma but can be debilitating. Distal radius fractures have an above average rate of reflex sympathetic dystrophy relative to other injuries. Physical and occupational therapists are very helpful in managing this condition. Limited evidence exists that vitamin C may be useful in the acute setting of high-risk injuries to prevent this complication.

Chapter 725 Osteomyelitis

Samir S. Shah

Osteomyelitis, or infection of the bone, may be classified as acute or chronic. These clinical definitions correspond with treatment recommendations. **Acute osteomyelitis** is defined as the diagnosis of bone infection within 4 weeks after onset of clinical signs or symptoms in a previously uninfected bone. **Chronic osteomyelitis** is defined as a protracted and indolent disease process with presence of a sequestrum or relapse of infection at the same site following apparently successful treatment; sequestra may arise as a complication of treated or untreated acute hematogenous osteomyelitis.

ETIOLOGY

Bacteria are the most common pathogens in acute skeletal infections. *Staphylococcus aureus* (see Chapter 227.1) is the most common infecting organism in osteomyelitis among all age groups, including newborns. The prevalence of community-acquired methicillin-resistant *S. aureus* (CA-MRSA) as a cause of osteomyelitis varies substantially by region.

Group B streptococcus (see Chapter 230) and gram-negative enteric bacilli (*Escherichia coli,* see Chapter 246) are prominent pathogens in neonates; group A streptococcus (see Chapter 229) constitutes <10% of all cases in this group. After 6 years of age, most cases of osteomyelitis are caused by *S. aureus,* group A streptococci, or *Pseudomonas aeruginosa* (see Chapter 251.1). Cases of *Pseudomonas* infection are related almost exclusively to puncture wounds of the foot, with direct inoculation of *P. aeruginosa* from the foam padding of the shoe into bone or cartilage, which develops as osteochondritis. *Salmonella* spp. (see Chapter 244) and *S. aureus* are the two most common causes of osteomyelitis in children with sickle cell disease (see Chapter 511.1). *Streptococcus pneumoniae* (see Chapter 228) most commonly causes osteomyelitis in children younger than 24 months of age and in children with sickle cell disease, but its frequency has declined because of pneumococcal conjugate vaccines. *Bartonella henselae* (see Chapter 255) can cause osteomyelitis of any bone but is most often seen in pelvic and vertebral bones.

Kingella kingae (see Chapter 239) is the second most common cause of osteomyelitis in children younger than 4 years of age. The organism causes osteomyelitis, spondylodiscitis, and septic arthritis (see Chapter 726) in this age group, especially when there is a subacute presentation. *K. kingae* can be difficult to detect unless polymerase chain reaction (PCR) testing is used.

Infection with atypical mycobacteria (see Chapter 263), *S. aureus,* or *Pseudomonas* can occur after penetrating injuries. These organisms, as well as coagulase-negative staphylococci or gram-negative enteric bacteria, may cause bone infection related to implanted materials such as orthopedic hardware. Fungal infections usually occur as part of multisystem disseminated disease; *Candida* (see Chapter 280) osteomyelitis sometimes complicates fungemia in neonates with or without indwelling vascular catheters. Blastomycosis causes multiple bone lesions in endemic areas.

EPIDEMIOLOGY

The median age of children with musculoskeletal infections is approximately 6 years. Bone infections are more common in males than females.

Minor closed trauma is a common preceding event in cases of osteomyelitis, occurring in approximately 30% of patients. Impaired host defenses (e.g., hemoglobinopathies, human immunodeficiency virus, or chronic granulomatous disease) also increase the risk of skeletal infection. Table 725.1 lists other risk factors.

Table 725.1 Microorganisms Isolated from Patients with Osteomyelitis and Their Clinical Associations

MOST COMMON CLINICAL ASSOCIATION	MICROORGANISM
Frequent microorganism in any type of osteomyelitis	*Staphylococcus aureus* (susceptible or resistant to methicillin)
Associated with septic arthritis, spondylodiscitis, long or unusual bones, age <4 yr, mild symptoms	*Kingella kingae*
Foreign body–associated infection	Coagulase-negative staphylococci, other skin flora, atypical mycobacteria, fungi
Common in nosocomial infections	*Enterobacteriaceae, Pseudomonas aeruginosa, Candida* spp.
Decubitus ulcer or ulceration associated with sensory autonomic neuropathies	*S. aureus*, streptococci, gram-negative enterics, and/or anaerobic bacteria; polymicrobial infections are common
Sickle cell disease	*Salmonella* spp., *S. aureus*, or *Streptococcus pneumoniae*
Exposure to kittens	*Bartonella henselae*
Human or animal bites	*Pasteurella multocida* or *Eikenella corrodens*
Immunocompromised patients	*Aspergillus* spp., *Candida albicans*, or *Mycobacteria* spp.
Populations in which tuberculosis is prevalent	*Mycobacterium tuberculosis*
Populations in which these pathogens are endemic	*Brucella* spp., *Coxiella burnetii*, fungi found in specific geographic areas (coccidioidomycosis, blastomycosis, histoplasmosis)

Modified from Lew DP, Waldvogel FA. Osteomyelitis. *Lancet.* 2004;364:369–379.

PATHOGENESIS

Bacteria reach bone matrices most commonly via hematogenous spread (primary bacteremia). Less common mechanisms include direct inoculation (i.e., trauma or procedures) or contiguous spread from infection of adjacent sites such as synovial fluid or soft tissues.

The unique anatomy and circulation of the ends of long bones result in the predilection for localization of bloodborne bacteria. In the metaphysis, nutrient arteries branch into non-anastomosing capillaries under the physis, which make a sharp loop before entering venous sinusoids draining into the marrow. Low-velocity blood flow in this area predisposes to bacterial invasion. Once a bacterial focus is established, phagocytes migrate to the site and produce an inflammatory exudate (metaphyseal abscess). The generation of proteolytic enzymes, toxic oxygen radicals, and cytokines results in decreased oxygen tension, decreased pH, osteolysis, and tissue destruction. As the inflammatory exudate progresses, pressure increases spread through the porous metaphyseal space via the Haversian system and Volkmann canals into the subperiosteal space. Purulence beneath the periosteum may lift the periosteal membrane of the bony surface, further impairing blood supply to the cortex and metaphysis.

In newborns and young infants, transphyseal blood vessels connect the metaphysis and epiphysis, so it is common for pus from the metaphysis to enter the joint space. This extension through the physis has the potential to result in abnormal growth and bone or joint deformity. During the latter part of the first year of life, the physis forms, obliterating the transphyseal blood vessels. Joint involvement can occur where the metaphysis is intraarticular (hip, ankle, shoulder, and elbow), and subperiosteal pus ruptures into the joint space.

In later childhood, the periosteum becomes more adherent, favoring pus to decompress through the periosteum. Once the growth plate closes in late adolescence, hematogenous osteomyelitis more often begins in the diaphysis and can spread to the entire intramedullary canal. Septic arthritis contiguous with a site of osteomyelitis is also seen in older children with *S. aureus* osteomyelitis, which may be related to simultaneous hematogenous inoculation of bone and joint space. Septic arthritis may also result from infected material entering the synovial space from an adjacent osteomyelitis.

CLINICAL MANIFESTATIONS

The earliest signs and symptoms of acute osteomyelitis, often subtle and nonspecific, generally depend on patient age. Neonates might exhibit *pseudoparalysis* or pain with movement of the affected extremity (e.g., diaper changes). Half of neonates do not have fever and might not appear ill. Older infants and children are more likely to have pain, fever, and localizing signs such as edema, erythema, and warmth. With involvement of the lower extremities, limp or refusal to walk is seen in approximately half of patients.

Focal tenderness over a long bone can be an important finding. Local swelling and redness with osteomyelitis suggests spread of infection beyond the metaphysis and into the subperiosteal space, representing a secondary soft tissue inflammatory response. Pelvic osteomyelitis can manifest with subtle findings such as hip, thigh, groin, or abdominal pain. Vertebral osteomyelitis typically presents as back pain with or without tenderness to palpation over the vertebral processes (Chapter 720.7).

Long bones are principally involved in osteomyelitis (Table 725.2); the femur and tibia are equally affected and together constitute almost half of all cases. The bones of the upper extremities account for 25% of all cases. Flat bones are less commonly affected.

Usually, a single site of bone or joint is involved, although multifocal osteomyelitis may be noted in up to 20% of children with *S. aureus* infections. In neonates, two or more bones are involved in almost half of the cases. Multifocal disease may also be seen with tuberculosis, cat-scratch disease, and brucellosis. Clinical manifestations of chronic infection are more indolent, and fever is unusual. Children with *subacute* symptoms and focal findings in the metaphyseal area (usually of the tibia) might have a **Brodie abscess**, with a well-defined radiographic lucency and surrounding reactive bone. The contents of Brodie abscesses are often sterile, but *S. aureus* is often the most common pathogen (Fig. 725.1).

Some patients with osteomyelitis due to *S. aureus* infection develop a deep venous thrombosis adjacent to the affected bone that can produce septic pulmonary emboli; these patients are often critically ill. Uncomplicated disease should be distinguished from more complicated osteomyelitis (Table 725.3).

DIAGNOSIS

The diagnosis of osteomyelitis begins with clinical suspicion and requires appropriate cultures and imaging studies. *Blood cultures should be performed in all suspected cases before administration of antibiotic therapy.* Blood cultures are positive in ~30% of patients. Blood culture contamination rates are low, generally <5%; microbes such as coagulase-negative staphylococci, α-streptococci (except *S. pneumoniae* and *S. anginosus* group), *Bacillus* species, *Corynebacterium*, and *Cutibacterium* are usually considered contaminants when identified in blood culture from a patient with acute or subacute hematogenous osteomyelitis.

Depending on the results of imaging studies, aspiration or biopsy of bone or subperiosteal abscess for Gram stain, standard bacterial culture, PCR for *K. kingae,* and possibly bone histology provides the optimal specimen for culture to confirm the diagnosis and significantly increases the yield compared with blood culture alone. These specimens, which identify a causative bacteria in ~60% of cases, are often obtained by the interventional radiologist or at the time of surgical

drainage by the orthopedic surgeon. Direct inoculation of clinical specimens into aerobic blood culture bottles can improve the recovery of *K. kingae,* particularly if held for 1 week. PCR is the most sensitive technique to detect *K. kingae*, even up to 6 days after antibiotics are initiated. Anaerobic, fungal, and mycobacterial cultures may be performed if risk factors are identified by history or physical examination.

There are no specific laboratory tests for osteomyelitis. Laboratory evaluation of children with suspected osteomyelitis may include a complete blood count and C-reactive protein (CRP). A complete blood count may contribute to assessment of infection severity (e.g., anemia, thrombocytopenia) and suggest an alternative diagnosis (e.g., hematologic malignancy). The initial CRP is elevated in most children with acute osteomyelitis. CRP is nonspecific and does not establish the diagnosis of osteomyelitis, but serial monitoring of an elevated CRP may be of value in assessing response to therapy or identifying complications. Erythrocyte sedimentation rate (ESR) is no longer routinely recommended in cases of acute hematogenous osteomyelitis. Data on procalcitonin are insufficient.

RADIOGRAPHIC EVALUATION

Radiographic studies play a crucial role in the evaluation of osteomyelitis. Conventional radiographs and MRI are the primary modalities. Ultrasonography, CT, and radionuclide studies can also contribute to establishing the diagnosis in selected cases.

Plain Radiographs

Within 72 hours of onset of symptoms of osteomyelitis, plain radiographs of the involved site using soft tissue technique and compared with the opposite extremity, if necessary, can show displacement of the deep muscle planes from the adjacent metaphysis caused by deep-tissue edema. Lytic bone changes are not visible on radiographs until 30–50% of the bony matrix is destroyed. Tubular long bones do not show lytic changes for 7-14 days after onset of infection. Infection in flat and irregular bones can take longer to appear. Radiographs in children with possible osteomyelitis are important to exclude other possible causes (e.g., fracture) of the presenting symptoms and signs.

Magnetic Resonance Imaging and Computed Tomography

MRI is more sensitive than CT or radionuclide imaging in acute osteomyelitis and is the best radiographic imaging technique for identifying abscesses and for differentiating between bone and soft tissue infection. MRI provides precise anatomic detail of subperiosteal pus and accumulation of purulent debris in the bone marrow and metaphyses for possible surgical intervention. In acute osteomyelitis, purulent debris and edema appear dark, with decreased signal intensity on T1-weighted images, with fat appearing bright (Figs. 725.2 and 725.3). The opposite is seen in T2-weighted images. The signal from fat can be diminished with fat-suppression techniques to enhance visualization. Gadolinium administration can also enhance MRI. Cellulitis and sinus tracts appear as areas of high signal intensity on T2-weighted images. Short tau inversion recovery (STIR) MRI is a rapid imaging modality for osteomyelitis (Fig. 725.4). MRI can also demonstrate contiguous or isolated septic arthritis, pyomyositis, or venous thrombosis. *Whole body rapid STIR MRI is an effective alternative to radionuclide imaging where multiple sites of infection are suspected or the site of infection cannot be clearly localized on exam.* CT can demonstrate osseous and soft tissue abnormalities and is ideal for detecting gas in soft tissues but has poor sensitivity for detecting the presence of osteomyelitis.

Radionuclide Studies

Radionuclide imaging, an alternative to MRI, may be useful if multiple foci are suspected. Technetium-99 (^{99m}Tc) methylene diphosphonate, which accumulates in areas of increased bone turnover, is the preferred agent for radionuclide bone imaging (three-phase bone scan). Any areas of increased blood flow or inflammation can cause increased uptake of ^{99m}Tc in the first and second phases, but osteomyelitis causes increased uptake of ^{99m}Tc in the third phase (4-6 hours). Three-phase imaging with ^{99m}Tc has excellent sensitivity (84–100%) and specificity (70–96%) in hematogenous osteomyelitis and can detect osteomyelitis within 24-48 hours after onset of symptoms. The sensitivity in neonates is much lower because of poor bone mineralization. Advantages include infrequent need for sedation and the ability to image the entire skeleton for detection of multiple foci. Disadvantages include exposure to radiation, inability to image surrounding soft tissues, and overall lack of detail, which limits the tests' utility for preoperative planning.

DIFFERENTIAL DIAGNOSIS

Distinguishing osteomyelitis from cellulitis or trauma (unintentional or abuse) may be difficult, particularly when the history is limited. Myositis or pyomyositis can also appear similar to osteomyelitis with fever, warm and swollen extremities, and limping; tenderness to palpation of the affected soft tissue area is generally more diffuse than noted in acute osteomyelitis. Myositis and pyomyositis may be isolated but are often found adjacent to an osteomyelitis on MRI. **Pyomyositis** is most often caused by *S. aureus,* followed by group A streptococcus. The pelvic muscles are a common site of pyomyositis and can mimic a pelvic osteomyelitis. MRI is the definitive

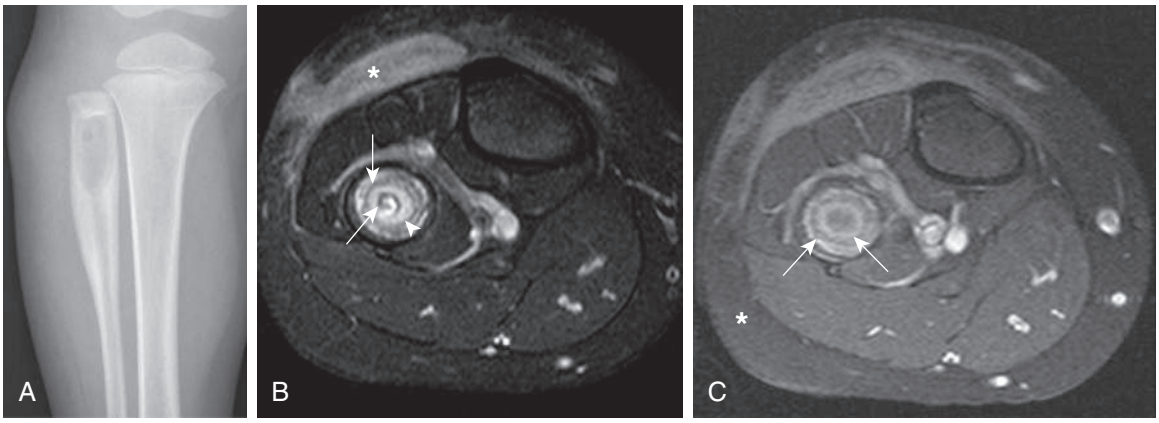

Fig. 725.1 A, Radiograph demonstrates a lytic lesion in the proximal fibula with laminated thick periostitis. Axial T2-weighted fat-saturated MR image (B) shows a layered appearance with intermediate signal *(arrowhead)* between inner and outer rims of lower signal intensity *(arrows)* and a more central hyperintense region. Also note the soft tissue phlegmon/early abscess formation *(asterisk)*. On an axial T1-weighted, fat-saturated, postgadolinium MR image (C), a rim of low signal sclerosis *(outer arrow)* surrounds an inner rim of enhancing granulation tissue *(inner arrow)*, which surrounds the nonenhancing abscess. *(From Kan JH, Meyers AB, Azouz EM. Musculoskeletal infections. In: Coley BD, ed. Caffey's Pediatric Diagnostic Imaging, 13th ed. Philadelphia: Elsevier; 2019: Fig. 137.17.)*

Table 725.3 Characteristics of Uncomplicated vs Complicated Osteomyelitis*

CHARACTERISTIC	UNCOMPLICATED	COMPLICATED
Sites of infection	Single bone	Two or more bones involved Additional soft tissue sites of infection beyond the bone (e.g., muscle [myositis or pyomyositis], pneumonia, and liver abscess)
Clinical response to medical and surgical treatment	Rapid (within 3-5 days), including signs of sepsis or septic shock	Slow, prolonged response, or lack of clinical response Need for more than one surgery for source control
Course of bacteremia when present	Rapid resolution of bacteremia (serial blood cultures become negative when obtained within 1-2 days after the initiation of therapy and source control)	Prolonged bacteremia (3 or more days), suggestive of uncontrolled infection/distant site(s) of infection
Acute sequelae of infection	None	Venous thrombosis or septic thrombophlebitis Endocarditis
Late sequelae of infection	No findings that suggest risk of physis injury or other short- or long-term osteoarticular sequelae of infection	Findings concerning for physeal injury with potential impacts on bone growth with long-term sequelae Presence of or concern for pathologic fracture

*This set of criteria is consensus based with primary focus on clinical findings and course. It may be reasonable to include additional laboratory tests such as the serum C-reactive protein (CRP) in making a determination of an uncomplicated vs complicated course. Concepts such as (1) rapid fall of the CRP concentration within 48 hr of initiation of treatment or (2) a 50% or more decline from peak CRP concentration within 3-5 days of admission or first surgical debridement may be considered. Further research into the various components and functionality of this definition, and any added utility of the CRP or other laboratory markers, will have value and is encouraged.

From Woods CR, Bradley JS, Chatterjee A, et al. Clinical practice guideline by the Pediatric Infectious Diseases Society of America: 2021 guideline on diagnosis and management of acute hematogenous osteomyelitis in pediatrics. *J Pediatric Infect Dis Soc.* 2021;10(8):801–844. Table 1.

study to identify and localize pelvic pyomyositis (Fig. 725.5). An **iliopsoas abscess** can manifest with thigh pain, limp, and fever and must be considered in the differential diagnosis of osteomyelitis. The iliopsoas abscess may be primary (hematogenous: *S. aureus*) or secondary to infection in adjacent bone *(S. aureus)*, kidney *(E. coli)* or intestine (*E. coli*, *Bacteroides* spp.). *Mycobacterium tuberculosis* has been reported in patients with HIV infection. Any child with negative x-ray imaging and a negative hip aspiration who presents with fever, limp, and elevated inflammatory markers should be evaluated for pyomyositis.

Appendicitis, urinary tract infection, and gynecologic disease are among the conditions in the differential diagnosis of pelvic osteomyelitis. Children with leukemia commonly have bone pain or joint pain as an early symptom. Neuroblastoma with bone involvement may be mistaken for osteomyelitis. Primary bone tumors need to be considered, but fever and other signs of illness are generally absent except in Ewing sarcoma. In patients with sickle cell disease, distinguishing bone infection from infarction may be challenging.

Chronic recurrent multifocal osteomyelitis (CRMO) (also called chronic nonbacterial osteomyelitis, CNO) is a nonpyrogenic, sterile inflammatory bone disease that is considered an autoinflammatory disorder (see Chapter 204). It may also be associated with a family history of autoimmune disease; the affected patient may have other inflammatory diseases such as Crohn disease, Sweet syndrome, psoriasis, and palmar plantar pustulosis. CRMO in children has many similarities with synovitis, acne, pustulosis, hyperostosis, and osteitis syndrome (SAPHO), seen in adults. CRMO also has similarities to Majeed syndrome, an autosomal recessive disorder with a microcytic dyserythropoietic anemia, and with a deficiency of interleukin-1 receptor antagonist (DIRA), an autosomal recessive autoinflammatory disease.

In contrast to infectious osteomyelitis, CRMO is multifocal, recurrent, and may involve bones not typical of osteomyelitis (spine, pelvis, clavicle, mandible, and calcaneus). Plain radiographs reveal osteolytic lesions or sclerosis; whole body STIR MRI imaging is the diagnostic study of choice (Fig. 725.6).

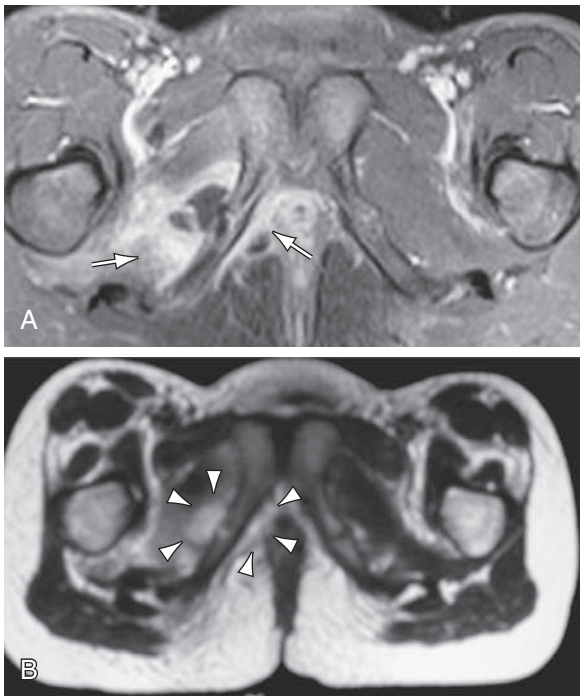

Fig. 725.2 MRI of an 8-year-old female with acute pelvic hematogenous osteomyelitis. **A,** Axial T1-weighted contrast-enhanced MRI with fat saturation reveals a nonenhancing fluid collection adjacent to the inflamed pubic synchondrosis. **B,** The fluid collection appears hyperintense on the corresponding T2-weighted image *(arrowheads)*. In addition, a contrast enhancement within the adjacent internal obturator muscle is seen *(arrow)*, indicating acute pelvic hematogenous osteomyelitis with complicating adjacent abscess formation and soft tissue inflammation. *(From Weber-Chrysochoou C, Corti N, Goetschel P, et al. Pelvic osteomyelitis: a diagnostic challenge in children. J Pediatr Surg. 2007;42:553–557.)*

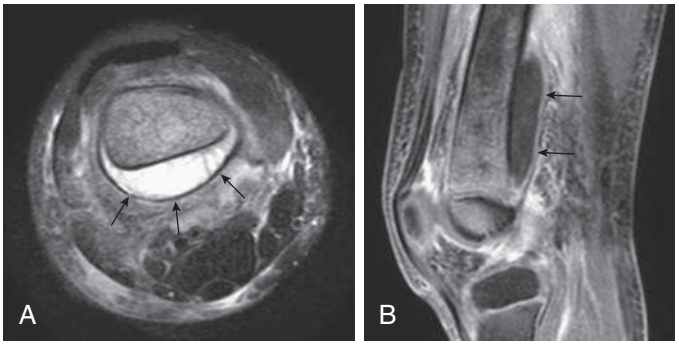

Fig. 725.3 Acute osteomyelitis of the distal femur in a 5-yr-old male. **A,** T2-weighted fat-saturated axial MRI shows a large subperiosteal abscess *(arrows)* at the posterior aspect of the femur. Increased signal is seen within the bone, and there is adjacent soft tissue edema. **B,** T1-weighted fat-saturated postgadolinium sagittal MRI shows the longitudinal extent of the subperiosteal abscess with enhancing wall *(arrows)*. *(From Kan JH, Azouz EM. Musculoskeletal infections. In: Coley BD, ed. Caffey's Pediatric Diagnostic Imaging, 13th ed. Philadelphia: Elsevier; 2019: Fig. 137.13.)*

Pain in CRMO is usually insidious and noted at night; fever is not always present. The mean age of onset is 10 years. The CRP may be elevated but is not as high as in bacterial osteomyelitis. Pain usually responds to nonsteroidal antiinflammatory drugs. Second-line treatments include systemic corticosteroids or tumor necrosis factor-α inhibitors.

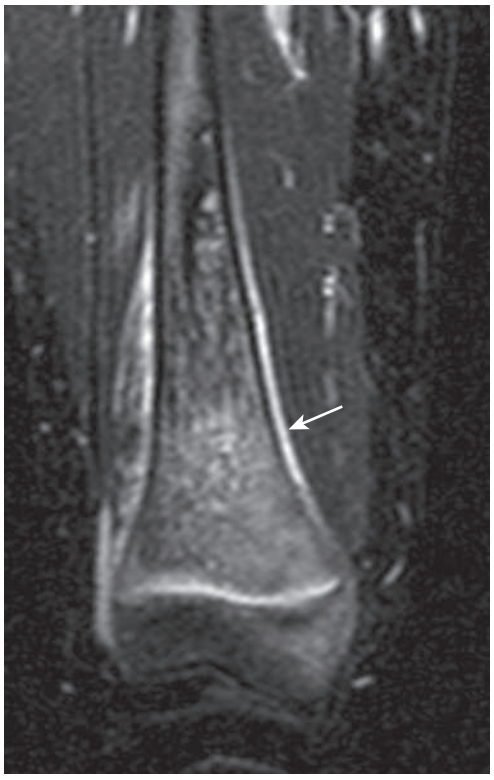

Fig. 725.4 Coronal STIR MR image demonstrates a salt-and-pepper appearance of marrow edema and periosteal reaction *(arrow)*. *(From Kan JH, Azouz EM. Musculoskeletal infections. In: Coley BD, ed. Caffey's Pediatric Diagnostic Imaging, 13th ed. Philadelphia: Elsevier; 2019: Fig. 137.14.)*

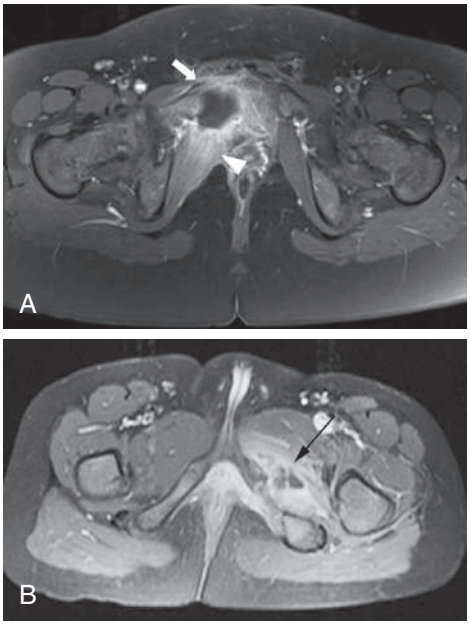

Fig. 725.5 **A,** Pelvic pyomyositis in a 10-yr-old male presenting with limping. Pelvis MRI demonstrates an avid contrast enhancement of the internal obturator muscle *(arrowhead)* with an abscess on T1-weighted fat-saturated postcontrast axial image *(arrow)*. **B,** Pyomyositis in a 7-yr-old male with left pelvic pain and fever. Axial T1 fat-saturated postcontrast image through the inferior ramus of the obturator ring demonstrates multiloculated, rim-enhancing fluid collections in the adductor muscles *(arrow)*, which is characteristic of pyomyositis. *(**A** from Bartoloni A, Gómez A, Pilar M, et al. Imaging of the limping child. Eur J Radiol. 2018;109:155–170. Fig 13; **B** from Pruthi S, Thapa MM. Infectious and inflammatory disorders. Magn Reson Imaging Clin North Am. 2009;17:423. Fig 7.)*

Chronic recurrent multifocal osteomyelitis. Joint Bone Spine. 2011;78:555–560. Fig. 3, p. 557.)*

TREATMENT

Optimal treatment of skeletal infections requires collaborative efforts of pediatricians, orthopedic surgeons, and interventional radiologists. Obtaining a blood culture *before* antibiotics are given is essential. Most patients with osteomyelitis have an indolent, non–life-threatening condition, and in these circumstances antibiotics may be deferred until a decision about whether to obtain additional diagnostic cultures (periosteal abscess, bone) has been made. A short duration of antibiotic pretreatment (<48 hours) for osteomyelitis caused by *S. aureus* has minimal impact on culture yield from abscess or bone specimens. In critically ill patients, empirical antimicrobial therapy should be initiated without delay.

Antimicrobial Therapy

The initial empirical antimicrobial therapy is based on knowledge of likely bacterial pathogens at various ages, the results of the Gram stain of aspirated material, and additional considerations (Table 725.4). In neonates, an antistaphylococcal penicillin, such as nafcillin or oxacillin (100-200 mg/kg/24 hr divided q6hr IV), and a broad-spectrum cephalosporin, such as cefepime (100-150 mg/kg/24 hr divided q12hr IV), provide coverage for the methicillin-susceptible *S. aureus* (MSSA), group B streptococcus, and gram-negative bacilli. If methicillin-resistant *Staphylococcus* (MRSA) is suspected, clindamycin or vancomycin is substituted for nafcillin. If the neonate is a premature infant or has a central vascular catheter, the possibility of nosocomial bacteria (gram-negative enteric, *Pseudomonas,* or *S. aureus*) or fungi (*Candida* spp.) should be considered. In older infants and children, the principal pathogens are *S. aureus, K. kingae,* and group A streptococcus.

Cefazolin (100-150 mg/kg/24 hr divided q6hr IV) or nafcillin (100-200 mg/kg/24 hr divided q6hr) is the agent of choice for parenteral treatment of osteomyelitis caused by MSSA and is the backbone of empirical treatment for acute hematogenous osteomyelitis. A major factor influencing the selection of empirical therapy is the rate of methicillin resistance among community *S. aureus* isolates. In areas where the prevalence of CA-MRSA is >10–20%, clindamycin (30-40 mg/kg/24 hr divided q6-8hr) or vancomycin (40-60 mg/kg/24 hr divided q6-8hr IV) should be used as empirical treatment. Clindamycin is often preferred over vancomycin when the rate of clindamycin resistance is low among community *S. aureus* isolates given the renal toxicity associated with vancomycin. Because β-lactams are superior to clindamycin and vancomycin for the treatment of MSSA, dual drug therapy in critically ill children should be continued until the causative organism is identified and susceptibilities are known. Rapid molecular diagnostic tests that can accurately differentiate MRSA from MSSA within hours of blood culture positivity can help to avoid prolonged exposure to multiple agents. Clindamycin is the best studied alternative therapy for susceptible isolates of MRSA and for MSSA when a β-lactam cannot otherwise be used.

Penicillin is first-line therapy for treating osteomyelitis caused by susceptible strains of *S. pneumoniae* and all group A streptococci. Cefotaxime or ceftriaxone is recommended for pneumococcal isolates with resistance to penicillin and for most *Salmonella* spp.

Special situations dictate deviations from the usual empirical antibiotic selection. In patients with sickle cell disease with osteomyelitis, gram-negative enteric bacteria *(Salmonella)* are common pathogens, as well as *S. aureus,* so a broad-spectrum cephalosporin such as cefepime (150 mg/kg/24 hr q8hr IV) is used in addition to clindamycin or vancomycin. Clindamycin is a useful alternative drug for patients allergic to β-lactam drugs. In addition to good antistaphylococcal activity, clindamycin has broad activity against anaerobes and is useful for treating infections secondary to penetrating injuries or compound fractures. For immunocompromised patients, combination therapy is usually initiated, such as with vancomycin and ceftazidime, cefepime, or piperacillin-tazobactam, with or without an aminoglycoside. *K. kingae* responds to β-lactam antibiotics, including penicillin and cephalosporins, but some isolates produce a β-lactamase. Thus a first-generation cephalosporin (cefazolin) is a reasonable component of empirical therapy in children younger than 4 years of age. Although

Table 725.4 Antibiotic Choice and Duration of Therapy for Uncomplicated Pediatric Acute Hematogenous Osteomyelitis Caused by *Staphylococcus aureus*[*,†]

PATHOGEN	PARENTERAL THERAPY	ORAL CONVALESCENT THERAPY	DURATION[‡]
Staphylococcus aureus, methicillin susceptible	*Preferred:*[§] Cefazolin Semisynthetic penicillin,[#] e.g., oxacillin and nafcillin	*Preferred:* Cephalexin	3-4 weeks if uncomplicated
	Alternatives:[#] Clindamycin Vancomycin Ceftaroline	*Alternative:* Clindamycin	3-4 weeks if uncomplicated
S. aureus, methicillin resistant, susceptible to clindamycin	*Preferred:* Clindamycin	*Preferred:* Clindamycin	3-4 weeks if uncomplicated
	Alternatives: Vancomycin Daptomycin Ceftaroline Linezolid	*Alternatives:*[¶] Linezolid	No data
S. aureus, methicillin resistant, resistant to clindamycin	*Preferred:* Vancomycin	*Preferred:* Linezolid	No data
	Alternatives: Daptomycin Ceftaroline Linezolid	*Alternatives:* Insufficient clinical data for the treatment of AHO to recommend other oral antibiotics with in vitro activity against *S. aureus*	No data

*Uncomplicated AHO is defined as the presence of infection in a single site with rapid clinical response to antimicrobial therapy (i.e., resolution of fever and marked improvement in clinical signs within 3-5 days), with no more than a single early surgical procedure required as source control for the infection. Complicated infections may require a longer duration of treatment than uncomplicated infections, particularly if multiple surgeries are needed to establish source control.

†Not all antibiotics listed have been prospectively evaluated in clinical trials of acute bacterial osteomyelitis. Prospective studies to evaluate the effectiveness of a range of antibiotic doses in various degrees of severity of uncomplicated and complicated osteomyelitis, with or without surgery, have not been performed, although retrospective data have been reported for many antibiotics in the treatment of pediatric osteomyelitis.

‡The suggested duration of therapy should be based on clinical course (pace of resolution of fever and clinical signs and symptoms, noting the need for surgical intervention[s] required, if any), supported by decline of inflammatory markers.

§Preferred and alternative agents are selected based on published data regarding in vitro activity, clinical efficacy, and safety. Agents are generally listed in order of preference.

#Many of the β-lactamase-stable penicillins cause significant phlebitis in peripheral veins with infusion; administration through a central venous catheter is preferred.

¶Alternative antibiotics that may display in vitro activity against *S. aureus* have not been evaluated prospectively in AHO. However, linezolid has been evaluated in prospective controlled clinical trials for invasive methicillin-resistant *S. aureus* nosocomial pneumonia in adults and is more likely to provide adequate therapy of invasive *S. aureus* AHO, compared with trimethoprim-sulfamethoxazole, which is not recommended for children with AHO by the Infectious Diseases Society of America (IDSA) Clinical Practice Guidelines for Treatment of Methicillin-Resistant *Staphylococcus aureus* Infections in Adults and Children.

AHO, Acute hematogenous osteomyelitis.

From Woods CR, Bradley JS, Chatterjee A, et al. Clinical practice guideline by the Pediatric Infectious Diseases Society of America: 2021 guideline on diagnosis and management of acute hematogenous osteomyelitis in pediatrics. *J Pediatric Infect Dis Soc.* 2021;10(8):801–844. Table 4.

the efficacy of treating osteomyelitis caused by *B. henselae* is uncertain, azithromycin plus rifampin may be considered.

When the pathogen is identified and antibiotic susceptibilities are determined, appropriate adjustments should be made to use the antibiotic with the narrowest spectrum, lowest adverse effect profile, and most favorable host tolerance. If a pathogen is not identified and a patient's condition is improving, therapy is continued with the initially selected antibiotic or an agent with a comparable spectrum of coverage. This selection is more complicated owing to the presence of MRSA isolates in the community. If a pathogen is not identified and a patient's condition is not improving, repeat aspiration or biopsy and the possibility of a noninfectious condition should be considered.

Duration of antibiotic therapy is individualized depending on the organism isolated and clinical course. Most acute cases of osteomyelitis, including those caused by *S. aureus,* can be treated with antibiotics for 21-28 days provided that the patient shows prompt resolution of signs and symptoms (within 5-7 days) and the CRP has normalized; a total of 4-6 weeks of therapy may be required for those with substantially slower resolution of symptoms or normalization of CRP. For group A streptococcus, *S. pneumoniae,* or *Haemophilus influenzae* type b, treatment duration may be shorter. A total of 7-10 postoperative days of treatment is adequate for *Pseudomonas* osteochondritis from a foot puncture wound, when curettage of infected tissue has been performed. Immunocompromised patients generally require prolonged courses of therapy, as do patients with mycobacterial or fungal infection.

For typical cases, antimicrobial agents may be changed from intravenous to oral administration when a patient's condition clearly has improved, the child is afebrile, and bacteremia has resolved. Oral cephalexin (75-100 mg/kg/24 hr divided q8hr) may be used for susceptible staphylococcal or streptococcal infections. Oral clindamycin (30-40 mg/kg/24 hr divided q6-8hr) can be used to complete therapy for children with clindamycin-susceptible CA-MRSA or for patients who are seriously allergic or cannot tolerate β-lactam antibiotics. The oral regimen decreases the risk of complications related to prolonged intravenous therapy, is more comfortable for patients, and permits treatment outside the hospital if adherence to treatment can be ensured. Outpatient intravenous antibiotic therapy via a central venous catheter can be used for completing therapy at home for (1) patients unable or unwilling to take oral medication; (2) patients with underlying medical conditions that make enteral

drug absorption unreliable; (3) patients without comparable oral antibiotic options (e.g., resistant bacteria, drug allergy); and (4) patients with disseminated infection (e.g., endocarditis, pulmonary septic emboli). Catheter-related complications, including infection or mechanical problems, can lead to readmission or emergency department visits.

In children with venous thrombosis complicating osteomyelitis, administration of anticoagulants under the supervision of a hematologist until the thrombus has resolved is a generally accepted practice, although high-quality evidence to support this practice is lacking; antibacterial therapy alone may be sufficient.

Surgical Therapy

When frank pus is obtained from subperiosteal or metaphyseal aspiration or is suspected based on MRI findings, a surgical drainage procedure is usually indicated. Surgical intervention is also often indicated after a penetrating injury and when a retained foreign body is possible. In selected cases, catheter drainage performed by an interventional radiologist is adequate.

Treatment of chronic osteomyelitis consists of surgical removal of sinus tracts and sequestrum, if present. Surgical implantation of antibiotics is not generally recommended. Antimicrobial therapy, typically administered orally, is continued for several months or longer until clinical and radiographic findings suggest that healing has occurred. Normalization of CRP and ESR is expected in successful treatment of chronic osteomyelitis but does not by itself indicate clearance of the underlying infection. Many patients with chronic osteomyelitis have a normal CRP and ESR even at the onset of illness.

Physical Therapy

The major role of physical therapy is a preventive one. If a child is allowed to lie in bed with an extremity in flexion, limitation of extension can develop within a few days. The affected extremity should be kept in extension with sandbags, splints, or, if necessary, a temporary cast. Casts are also indicated when there is a potential for pathologic fracture. After 2-3 days, when pain is easing, passive range-of-motion exercises are started and continued until the child resumes normal activity. In neglected cases with flexion contractures, prolonged physical therapy is required.

Prognosis

When pus is drained and appropriate antibiotic therapy is given, the improvement in signs and symptoms is rapid. Failure to improve or worsening by 48-72 hours requires review of the appropriateness of the antibiotic therapy, the need for surgical intervention, or the accuracy of the diagnosis. Acute phase reactants may be useful as monitors. In acute osteomyelitis, the serum CRP typically decreases below 2 mg/dL within 7-10 days after starting treatment, whereas the ESR typically rises for 5-7 days and then falls slowly, dropping sharply after 10-14 days. Failure of CRP to follow the usual course should raise concerns about the adequacy of therapy. Recurrence of disease and development of chronic infection after treatment occur in <10% of patients.

Because children are in a dynamic state of growth, sequelae of skeletal infections might not become apparent for months or years; therefore long-term follow-up is necessary, with close attention to range of motion of joints and bone length. Although firm data about the impact of delayed treatment on outcome are not available, it appears that initiation of medical and surgical therapy within 1 week of onset of symptoms provides a better prognosis than delayed treatment.

Chapter 726

Septic Arthritis

Samir S. Shah

Without early recognition and prompt institution of appropriate medical and surgical therapy, septic arthritis in infants and children has the potential to damage the synovium, adjacent cartilage, and bone and may cause permanent disability.

ETIOLOGY

Staphylococcus aureus (see Chapter 227.1) is the most common cause of bacterial arthritis in all age groups. Methicillin-resistant *S. aureus* (MRSA) accounts for a high proportion (>25%) of community *S. aureus* isolates in many areas of the United States and throughout the world. Group A streptococcus (see Chapter 229) and ***Streptococcus pneumoniae*** (pneumococcus; see Chapter 228) historically cause 10–20%; *S. pneumoniae* is most likely in the first 2 years of life, but its frequency has declined since the introduction of the pneumococcal conjugate vaccines. ***Kingella kingae*** is recognized as a relatively common etiology with improved culture and polymerase chain reaction (PCR) methods in children younger than 4 years (see Chapters 239 and 725). In sexually active adolescents, **gonococcus** (see Chapter 238) is a common cause of septic arthritis and tenosynovitis, usually of small joints or as a monoarticular infection of a large joint (knee). ***Neisseria meningitidis*** (see Chapter 237) can cause either a septic arthritis that occurs in the first few days of illness or a reactive arthritis that is typically seen several days after antibiotics have been initiated. **Group B streptococcus** (see Chapter 230) is an important cause of septic arthritis in neonates. Q fever and brucellosis should be considered in endemic areas and with an exposure risk.

Fungal infections usually occur as part of multisystem disseminated disease; *Candida* arthritis can complicate systemic infection in neonates with or without indwelling vascular catheters. Primary viral infections of joints are rare, but arthritis accompanies many viral (parvovirus, mumps, rubella live vaccines) syndromes, suggesting an immune-mediated pathogenesis.

A microbial etiology is confirmed in approximately 65% of cases of septic arthritis. In addition, some cases treated as bacterial arthritis are actually postinfectious (gastrointestinal or genitourinary) **reactive arthritis** (see Chapter 198) rather than primary infection. **Lyme disease** produces an arthritis more like a rheumatologic disorder and not typically suppurative.

EPIDEMIOLOGY

Septic arthritis is more common in young children. Half of all cases occur by 2 years of age, and 75% of all cases occur by 5 years of age. Adolescents and neonates are at risk of gonococcal septic arthritis.

Most infections in otherwise healthy children arise hematogenously. Less commonly, infection of joints can follow penetrating injuries or procedures such as trauma, arthroscopy, prosthetic joint surgery, intraarticular steroid injection, and orthopedic surgery. Immunocompromised patients and those with rheumatologic joint disease are also at increased risk of joint infection.

PATHOGENESIS

Septic arthritis primarily occurs as a result of hematogenous seeding of the synovial space. Less often, organisms enter the joint space by direct inoculation or extension from a contiguous focus. The synovial membrane has a rich vascular supply and lacks a basement membrane, providing an ideal environment for hematogenous seeding. The presence of bacterial products (endotoxin or other toxins) within the

joint space stimulates cytokine production (tumor necrosis factor-α, interleukin-1) within the joint, triggering an inflammatory cascade. The cytokines stimulate chemotaxis of neutrophils into the joint space, where proteolytic enzymes and elastases are released by neutrophils, damaging the cartilage. Proteolytic enzymes released from the synovial cells and chondrocytes also contribute to destruction of cartilage and synovium. Bacterial hyaluronidase breaks down the hyaluronic acid in the synovial fluid, making the fluid less viscous and diminishing its ability to lubricate and protect the joint cartilage. Damage to the cartilage can occur through increased friction, especially for weight-bearing joints. The increased pressure within the joint space from accumulation of purulent material can compromise the vascular supply and induce pressure necrosis of the cartilage. Synovial and cartilage destruction results from a combination of proteolytic enzymes and mechanical factors.

CLINICAL MANIFESTATIONS

Most septic arthritides are monoarticular. The signs and symptoms of septic arthritis depend on the age of the patient. Early signs and symptoms may be subtle, particularly in neonates. As with osteomyelitis, neonates might exhibit **pseudoparalysis** or pain that limits voluntary movement of the affected extremity (e.g., diaper changes). Septic arthritis in neonates and young infants is often associated with adjacent osteomyelitis caused by transphyseal spread of infection, although osteomyelitis contiguous with an infected joint can be seen at any age (see Chapter 725).

Older infants and children might have fever and pain, with localizing signs such as swelling, erythema, and warmth of the affected joint. With involvement of joints of the pelvis and lower extremities, limp or refusal to walk often occurs.

Erythema and edema of the skin and soft tissue overlying the site of infection are seen earlier in septic arthritis than in osteomyelitis because the bulging infected synovium is usually more superficial, whereas the metaphysis is located more deeply. Septic arthritis of the hip is an exception because of the deep location of the hip joint. With Lyme arthritis, joint swelling is typically quite prominent and may be disproportionate to the relatively lesser degree of pain and limited range of motion when compared with suppurative arthritis. Lyme arthritis has a predilection for large joints, particularly the knees and hips, and may be either monoarticular or pauciarticular at presentation.

Joints of the lower extremity constitute 75% of all cases of septic arthritis (Table 726.1). The elbow, wrist, and shoulder joints are involved in approximately 25% of cases, and small joints are uncommonly infected, except in gonococcal arthritis. Suppurative infections of the hip, shoulder, elbow, and ankle in infants and children may be associated with an adjacent osteomyelitis of the proximal femur, proximal humerus, proximal radius, and distal tibia because the metaphysis extends intraarticularly. Concomitant osteomyelitis is less common in older children and adolescents as their anatomy and physiology become more adult-like.

Table 726.1 Distribution of Hematogenous Bacterial Arthritis*

BONE	PERCENT (%)
Knee	~35
Hip	~25
Ankle	~10
Elbow	~10
Wrist	~4
Shoulder	~5
Small joints	~1–2

*Excludes Lyme disease and immune-complex postinfectious arthritis. Viral (rubella, mumps, chikungunya) infectious arthritis is often small and multiple joints. Septic bursitis (shoulder, prepatellar) may be confused with bacterial joint infections.

DIAGNOSIS

The white blood cell count (WBC) and differential, ESR, and CRP are generally elevated in children with joint infections, but elevations are nonspecific and might not be helpful in distinguishing between infection and other inflammatory processes. Most children with septic arthritis will have normal leukocyte counts and ESR at presentation, and normal test results do not preclude the diagnosis of septic arthritis. A CBC, however, may assist with assessment of illness severity (e.g., anemia, thrombocytopenia) or with identification of other causes of the patient's symptoms (e.g., leukemia).

Blood cultures should be performed in all cases of suspected septic arthritis but are positive in ~20% of proven or probable septic arthritis. Cervical, anal, and throat cultures should be obtained when gonococcus is suspected. Aspiration of the joint fluid provides the optimal specimen to confirm the diagnosis. Most large joint spaces are easy to aspirate, but the hip can pose technical problems; ultrasound guidance facilitates aspiration. Although yield for joint aspirate cultures is higher than from blood cultures, the overall culture yield when combining both methods remains less than 50%. Multiplex bacterial PCR panels have a yield around 50% from joint fluid specimens, but this increase over culture is almost entirely because of their enhanced ability to detect *K. kingae*. Other strategies to increase detection of *K. kingae* include prompt inoculation onto solid media and inoculation of the joint fluid in blood culture bottles. A diagnosis of Lyme arthritis is made via a two-step test of an ELISA or IFA followed by a reflex Western blot for samples that are positive or equivocal by the first methodology. Patients with Lyme arthritis are seropositive because arthritis is a late manifestation of infection. PCR is rarely necessary but can detect *Borrelia burgdorferi* in joint aspirate specimens in cases of Lyme arthritis.

Synovial fluid analysis for cell count, differential, protein, and glucose has limited utility in diagnosing infectious arthritis. Joint fluid WBC counts >50,000 cells/mm^3 (often >100,000 cells/mm^3) suggest bacterial infection as the most likely etiology, but this finding is neither sensitive nor specific enough to exclude or confirm a bacterial infection in isolation. When the results of joint aspirate cell counts and culture are not strongly suggestive of a joint infection, but the clinical presentation is worrisome for a bacterial etiology, infectious causes of sympathetic joint effusions such as adjacent pyomyositis and osteomyelitis should be investigated by MRI (see Chapter 725).

Monitoring elevated CRP may be of value in assessing response to therapy or identifying complications. In addition, patients with adjacent infections complicating septic arthritis more frequently have a CRP >10-13 mg/dL compared with patients with septic arthritis alone. Other findings such as older age, prolonged symptoms, bacteremia, alterations in other lab values (such as elevated absolute neutrophil count or thrombocytopenia), and failure to rapidly improve with therapy have been less consistently associated with adjacent infection. Nonetheless, adjacent infection should be considered in patients demonstrating multiple risk factors.

Radiographic Evaluation

Radiographic studies play a crucial role in evaluating septic arthritis. Conventional radiographs and ultrasonography are performed as part of the routine workup. CT, MRI, and radionuclide studies can all contribute to establishing the diagnosis in selected cases (Fig. 726.1).

Plain Radiographs

Plain films can suggest the diagnosis of septic arthritis by showing widening of the joint capsule, soft tissue edema, and obliteration of normal fat lines. Plain films can also help to exclude other causes of joint pain such as fractures. Plain films of the hip can show medial displacement of the obturator muscle into the pelvis (the obturator sign), lateral displacement or obliteration of the gluteal fat lines, and elevation of Shenton's line with a widened arc.

Fig. 726.1 MRI of staphylococcal septic arthritis of left hip, with fluid collections between planes of gluteal muscles. *Arrows* indicate fluid collection. *(From Matthews CJ, Weston VC, Jones A, et al. Bacterial septic arthritis in adults. Lancet. 2010;375:846–854.)*

Ultrasonography

Ultrasonography is included with plain films in routine evaluations because it is particularly helpful in detecting joint effusion and fluid collection in the soft tissue and subperiosteal regions. Ultrasonography is highly sensitive in detecting joint effusion, particularly for the hip joint, where plain radiographs are normal in more than 50% of cases of septic arthritis of the hip. Ultrasonography can serve as an aid in performing hip aspiration.

Magnetic Resonance Imaging and Computed Tomography

MRI and CT can confirm the presence of joint fluid in patients with suspected osteoarthritis infections but are not routinely indicated. MRI is useful in evaluating for adjacent osteomyelitis or pyomyositis but is typically reserved for cases when the index of suspicion for these conditions is high. Considerations include patient factors such as younger age, the clinical presentation (e.g., protracted pain preceding joint swelling), the results of laboratory investigations such as joint aspiration and CRP, and response to therapy.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of septic arthritis depends on the joint or joints involved and the age of the patient. For the hip, transient synovitis, pyomyositis, Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, psoas abscess, and proximal femoral, pelvic, or vertebral osteomyelitis, as well as diskitis, should be considered. Transient synovitis (toxic synovitis) is a postinfectious arthritis of the hip that is often seen in young children after a viral infection (see Chapter 719.2). For the knee, distal femoral or proximal tibial osteomyelitis, pauciarticular rheumatoid arthritis, and referred pain from the hip should be considered. Knee or thigh pain may be referred from the hip. Other conditions such as trauma, cellulitis, pyomyositis, sickle cell disease, hemophilia, Lyme arthritis, leukemia, serum sickness, and IgA vasculitis (Henoch-Schönlein purpura) can mimic purulent arthritis. When several joints are involved, serum sickness, collagen vascular disease, rheumatic fever, and IgA vasculitis should be considered. Arthritis is one of the extraintestinal manifestations of inflammatory bowel disease. Reactive arthritis after a variety of bacterial (gastrointestinal or genital) and parasitic infections, streptococcal pharyngitis, or viral hepatitis can resemble acute septic arthritis (see Chapter 198).

TREATMENT

Optimal treatment of septic arthritis requires coordination between primary care physicians, orthopedic surgeons, and radiologists.

Surgical Therapy

Drainage and irrigation of the infected joint via arthroscopy or arthrotomy is typically performed to decompress the joint and remove inflammatory debris. The decision to proceed to one of these procedures after arthrocentesis is based on the gross appearance of the joint fluid, or joint fluid WBC and differential, in the context of the clinical presentation and the specific joint that is infected. Infection of the hip is generally considered a surgical emergency because of the vulnerability of the blood supply to the head of the femur. For joints other than the hip, daily aspirations of synovial fluid may be required. In general, one or two subsequent aspirations suffice. If fluid continues to accumulate after 4-5 days, arthrotomy or video-assisted arthroscopy is needed. At the time of surgery, the joint is flushed with sterile saline solution. Antibiotics are not instilled because they are irritating to synovial tissue, and adequate amounts of antibiotic are achieved in joint fluid with systemic administration.

Antimicrobial Therapy

Empiric antimicrobial therapy should be started immediately in a child with presumed septic arthritis who is ill-appearing or has a rapidly progressive infection. Antibiotic therapy may be deferred until initial joint aspirate has been collected for diagnostic purposes in a child with presumed septic arthritis who does not appear clinically ill.

The initial empirical antimicrobial therapy is based on likely bacterial pathogens at various ages, the results of the Gram stain of aspirated material, and additional considerations. In neonates, an antistaphylococcal penicillin, such as nafcillin or oxacillin (100-200 mg/kg/24 hr divided q6hr IV), and a broad-spectrum cephalosporin, such as cefepime (100-150 mg/kg/24 hr divided q12hr IV), provide coverage for the *S. aureus,* group B streptococcus, and gram-negative bacilli. If MRSA is a concern, clindamycin or vancomycin is selected instead of nafcillin or oxacillin. If the neonate is a small premature infant or has a central vascular catheter, the possibility of nosocomial bacteria (*S. aureus*, gram-negative enterics, or *Pseudomonas aeruginosa*) or fungi *(Candida)* should be considered.

In children with septic arthritis, empirical therapy to cover for *S. aureus* and streptococci includes at minimum nafcillin (100-200 mg/kg/24 hr divided q6hr). In preschool-age children (i.e., 6 months to 4 years), empiric therapy should include an antibiotic with activity against *Kingella kingae* as well as *S. aureus*, such as cefazolin (100-150 mg/kg/24 hr divided q8hr).

In areas where methicillin resistance is noted in ≥10–15% of community-acquired methicillin-resistant *S. aureus* (CA-MRSA) strains, adding an antimicrobial that is effective against local CA-MRSA isolates is suggested. Vancomycin (15 mg/kg q6hr IV) is preferred in patients who are ill-appearing, suspected to be bacteremic, or if local clindamycin resistance is more than 10–15%. Clindamycin (30-40 mg/kg/24 hr divided q6-8hr) is a good alternative when treating CA-MRSA infections. For immunocompromised patients, combination therapy is usually initiated, such as with vancomycin and ceftazidime, cefepime, or piperacillin/tazobactam, with or without an aminoglycoside. Adjunct therapy with dexamethasone has been shown in some studies to decrease the duration of fever and promote a more rapid decline in inflammatory markers, but this is not yet part of routine care. **Lyme arthritis** is treated with oral doxycycline (4.4 mg/kg/24 hr divided q12hr) for 28 days in children >8 years old. For children <8 years old, oral amoxicillin (50 mg/kg/24 hr divided q8hr) or cefuroxime (30 mg/kg/24 hr divided q12hr) is recommended. A second 28-day course may be considered for patients with persistent or recurrent symptoms after completing the initial course of treatment. Intravenous ceftriaxone (50 mg/kg q24hr IV) for 14-28 days may be considered as an initial or second course of therapy for severe or refractory cases.

Empirical antimicrobials are narrowed to targeted therapy when the pathogen is identified. If a pathogen is not identified and a patient's condition is improving, therapy is continued with the antibiotic selected

initially. If a pathogen is not identified and a patient's condition is not improving, consideration should be given to the need for repeat aspiration, the presence of an extraarticular infection requiring surgical debridement, or the possibility of a noninfectious etiology. In such cases, MRI may be performed to assist with subsequent management decisions.

Duration of antibiotic therapy is individualized depending on the organism isolated and the clinical course. A total of 10-14 days is usually adequate for streptococci, *S. pneumoniae*, and *K. kingae;* longer therapy may be needed for *S. aureus* and gram-negative infections (3 weeks), concomitant osteomyelitis (4 weeks), extensive disease, or slow response to treatment. Normalization of CRP in addition to a normal examination supports discontinuing antibiotic therapy. The prognostic significance of an improved but still minimally elevated ESR in the third or fourth week of therapy is not clear if all other clinical and laboratory parameters are favorable. In selected patients, obtaining a plain radiograph of the joint before completing therapy can provide evidence (typically periosteal new bone) of a previously unappreciated contiguous site of osteomyelitis that would likely prolong antibiotic treatment. Oral antibiotics can be used to complete therapy once the patient is afebrile for 48-72 hours and is clearly improving.

Surgically administered intraarticular antibiotics are not recommended.

PROGNOSIS

Improvement in signs and symptoms occurs rapidly after joint drainage and antibiotic administration. Failure to improve or worsening by 48-72 hours requires review of the appropriateness of the antibiotic therapy, the need for surgical intervention, and the correctness of the diagnosis. CRP may be useful to monitor response to therapy. Failure of CRP to decline should raise concerns about the adequacy of therapy. Recurrence of disease and development of chronic infection after treatment occur in <10% of patients.

Septic arthritis can lead to numerous long-term sequelae in children, including leg-length discrepancy or angular deformity from growth arrest, limitations in range of motion due to chondral damage, and avascular necrosis of the femoral head from septic arthritis of the hip. The overall rate of these sequelae with current therapies is <5%. However, children are in a dynamic state of growth, so these abnormalities might not become apparent for months or years; therefore long-term follow-up is necessary, with close attention to range of motion of joints and bone length. Involvement of the hip is associated with a higher rate of sequelae. Initiation of medical and surgical therapy within 1 week of onset of symptoms provides a better prognosis than delayed treatment.

Section 2
Sports Medicine

Chapter 727
Prevention of Injuries

Gregory L. Landry and Andrew M. Watson

The Centers for Disease Control and Prevention, the American College of Sports Medicine, and the American Academy of Pediatrics all recommend daily moderate to vigorous physical activity for all adolescents. Physical activity has favorable effects on blood pressure, body composition, and serum lipid levels in youths and is associated with lower rates of cardiovascular disease, type 2 diabetes mellitus, osteoporosis, and colon and breast cancer among adults.

Pediatricians should promote physical activity to their patients, especially those with lower rates of physical activity and sports participation, including children with special healthcare needs (see Chapter 756) and those from lower socioeconomic groups. Physicians also have the responsibility of providing medical clearance for participation in physical activity and sports as well as for the diagnosis and rehabilitation of injuries.

Approximately 30 million children and adolescents participate in organized sports in the United States. Around 3 million sport-related injuries occur annually in young athletes, if injury is defined as time lost from the sport. Deaths in sports are rare, with the majority of nontraumatic deaths caused by cardiac diseases (see Chapter 485). Nonetheless, approximately 30% of life-threatening injuries in children presenting to an emergency room are sports related. Overall, injury rates and injury severity in sports increase with age and pubertal development, related to the greater speed, strength, and intensity of competition.

Identifying mechanisms of injury and establishing and enforcing rules that reduce the likelihood of that mechanism of injury, including penalizing dangerous play, have reduced catastrophic injury rates. Injury rates also have been reduced by removing environmental hazards, such as trampolines in gymnastics and stationary (versus breakaway) bases in softball, and by modifying heat injury rates in soccer tournaments by adding water breaks and reducing the playing time. Certain types of equipment can mitigate the risk of some injuries, such as the use of mouth guards to reduce dental injuries. The most consistently identified risk factor for injury is prior injury. In other words, although reinjury may often be due to insufficient recovery and rehabilitation of a prior injury, appropriate rehabilitation reduces injury risk. Preseason training for adolescent athletes, with an emphasis on speed, agility, core strength, landing mechanics, and flexibility, is associated with lower injury rates in soccer and fewer serious knee injuries in female athletes. Traditional stretching maneuvers or massage have not been demonstrated to reduce the risk of injury or muscle soreness, but ankle taping and use of lace-up ankle braces are helpful in preventing ankle injuries. One setting for implementing some of these prevention strategies and for detecting unrehabilitated injuries and medical problems that could affect participation in sports is the preparticipation sports examination (PSE).

PREPARTICIPATION SPORTS EXAMINATION

The PSE is performed with a directed history and physical examination, including a screening musculoskeletal examination (see Table 485.2 in Chapter 485). It identifies possible problems in 1–8% of athletes and excludes fewer than 1% from participation. The PSE is not a substitute for the recommended comprehensive annual evaluation, which looks at behaviors that are potentially harmful to teens, such as sexual activity, drug use, and violence, and assesses for depression and suicidal ideation and addresses broader issues of prevention. Table 727.1 identifies the purposes of the PSE. If possible, the PSE should be combined with the comprehensive annual health visit with an emphasis on preventive healthcare (see Chapters 13 and 28).

State requirements for how often a young athlete needs a PSE differ, ranging from annually to entry to a new school level (middle school, high school, college). At a minimum, a focused, annual interim evaluation should be done on an otherwise healthy young athlete. The PSE is optimally performed 3-6 weeks before the start of practice.

History and Physical Examination

The essential components of the PSE are the history and focused medical and musculoskeletal screening examinations. Identified problems require more investigation (Table 727.2). While many medical conditions should not limit sports participation, many specialty organizations have released recommendations regarding sports participation (Table 727.3). In the absence of symptoms, no screening laboratory tests are required. Return to sports after COVID-19 infection is based on the severity of infection (mild, moderate, or ICU admission and/or MIS-C), and the intensity of follow-up, especially for those with active cardiac involvement during the acute phase of the illness (Fig. 727.1).

Seventy-five percent of significant findings are identified by the history; a standardized questionnaire given to the parent and athlete is important

Table 727.1 Objectives of the Preparticipation Sports Examination

- Determination of the general health of the athlete
- Disclosure of defects that may limit participation
- Detection of conditions that may predispose the athlete to injury
- Determination of optimal level of performance
- Classification of the athlete according to individual qualifications
- Fulfillment of legal and insurance requirements for organized athletic programs
- Evaluation of size and level of maturation of younger athletes
- Improvement of fitness and performance
- Provision of opportunities for students to compete who have either physiologic or pathologic health conditions that may preclude blanket approval
- Provision of the opportunity to counsel youths and answer health and personal questions
- Entry of the athlete into the local sports medicine system, establishing a doctor-patient relationship that continues

From Sanders B, Blackburn TA, Boucher B. Preparticipation screening-the sports physical therapy perspective. *Int J Sports Phys Ther*. 2013;8(2):180–193. Table 1.

Table 727.2 Preparticipation Sports Examination

COMPONENT OF THE PHYSICAL EXAMINATION	CONDITION TO BE DETECTED
Vital signs	Hypertension, cardiac disease, bradycardia or tachycardia
Height and weight	Obesity, eating disorders, malabsorption
Vision and pupil size	Legal blindness, absent eye, anisocoria, amblyopia
Lymph node	Infectious diseases, malignancy
Cardiac (performed standing and supine)	Heart murmur, prior surgery, dysrhythmia, femoral pulses
Pulmonary	Recurrent and exercise-induced bronchospasm, chronic lung disease
Abdomen	Organomegaly, abdominal mass
Skin	Contagious diseases (impetigo, herpes, staphylococcal, streptococcal)
Genitourinary	Varicocele, undescended testes, tumor, hernia
Musculoskeletal	Acute and chronic injuries, physical anomalies (scoliosis)

Table 727.3 Sports Participation Recommendations by Condition

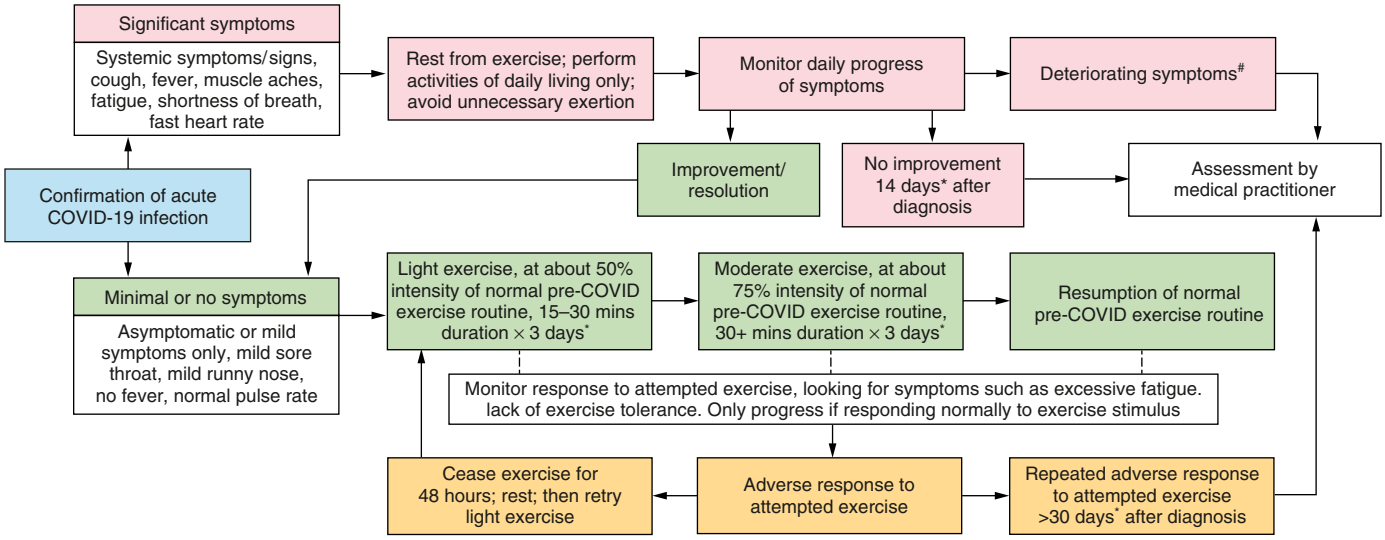
CONDITION	RECOMMENDATION
Hemophilia	Restrict contact or collision sports until evaluation by a hematologist who can assess degree of hemostatic abnormality and the sport-specific risk
Sickle cell disease	Individual decision-making given variation in phenotypic expression
Diabetes mellitus	No restrictions
Skin infections (herpes gladiatorum, tinea gladiatorum, impetigo, molluscum contagiosum, warts, and MRSA)	Prevent transmission by: • Covering infected site • Using prophylactic medications as prescribed • No sharing of personal items • Thorough cleaning of equipment
Mononucleosis infection	Light, noncontact activity may be introduced as tolerated 3 weeks after illness onset with avoidance of contact/collision sports until 4 weeks after illness onset
Blood-borne infections (hepatitis B, hepatitis C, HIV)	No restrictions
COVID-19 infection	See Fig. 727.1
Heat illness, history of	Gradual acclimatization to heat over 7-14 days, avoid participation while ill (fever, skin rash, viral symptoms), ensure free access to fluids at all times, consume sodium-containing food/fluids to replace insensible losses, rest periods of at least 3 hours before practice or games
Down syndrome	Individual decision-making based on the presence of congenital heart disease or atlantoaxial instability

Data from Herman D, Gadi N, Peck E. Team medical coverage. In Miller MD, Thompson SR, eds. *DeLee, Drez, & Miller's Sports Medicine*, 5th ed. Philadelphia: Elsevier, 2020.

because the young athlete might not know or might forget important aspects of the history. The questionnaire should include questions about the family history and the patient's previous medical, surgical, cardiac, pulmonary, neurologic, dermatologic, visual, psychologic, musculoskeletal, and endocrinologic problems, as well as about prior heat illness, medications, allergies, immunizations, and diet. The most commonly identified problems are *unrehabilitated injuries*. An investigation of previous injuries, including diagnostic tests, treatment, and present functional status, is indicated.

Sudden death during sports can result from undetected cardiac disease, such as hypertrophic or other **cardiomyopathies** (see Chapter 488), **anomalous coronary vessels** (see Chapter 481.2), or a ruptured aorta in **Marfan syndrome** (see Chapter 743). In many cases, the underlying heart disease is not suspected, and death is the first sign of underlying heart disease (see Chapter 485). However, in approximately 25–50% of cases, preceding symptoms of dizziness, chest pain, syncope, palpitations, shortness of breath, and/or a family history of early, unexpected death are identified retrospectively. Chest radiographs, electrocardiograms, and echocardiograms are not recommended as routine screening tests in the United States, but screening electrocardiograms are recommended in a number of other countries and are becoming more commonly used among higher risk groups in the United States, such as collegiate and professional athletes. If there is a suspicion of heart disease, such as a history of syncope, presyncope, palpitations, or excessive dyspnea with exercise, or a family history of a condition such as hypertrophic cardiomyopathy or prolonged QT or Marfan syndrome, the evaluation should be complete and include a 12-lead electrocardiogram, an echocardiogram, Holter or event-capture monitoring, and a stress test with electrocardiographic monitoring. Recommendations for participation with identified cardiac disease should be made in consultation with a cardiologist.

Sports may also be classified by intensity (Fig. 727.2) and contact (Table 727.4). Athletes may seek to participate in sports against medical advice and have done so successfully for professional sports. Section 504(a) of the Rehabilitation Act of 1973 prohibits discrimination against disabled athletes if they have the capabilities or skills required to play a competitive sport. This was reinforced through the Americans with Disabilities Act of



- Dry, post-viral cough may persist beyond the acute COVID-19 infection
- Individuals should be 10 days post diagnosis or onset of symptoms (or have negative RAT on days 6 & 7), before rejoining group / team activities
- *Number of days at each step may be modified in high performance sport, where athletes have the benefit of close medical supervision
- Those with medical comorbidities should adopt a more cautious approach to return to exercise
- # **Cardiac symptoms should be treated as a medical emergency: Pressure, tightness, squeezing pain in chest, arms, neck, jaw, or back, cold sweat, difficulty breathing, collapse, sudden dizziness**

Fig. 727.1 Graduated return to exercise after COVID-19 infection. RAT, rapid home antigen test. *(From Hughes DC, Orchard JW, Partridge EM, et al. Return to exercise post-COVID-19 infection: a pragmatic approach in mid-2022. J Sci Med Sport. 2022;25:544–547. Fig. 1.)*

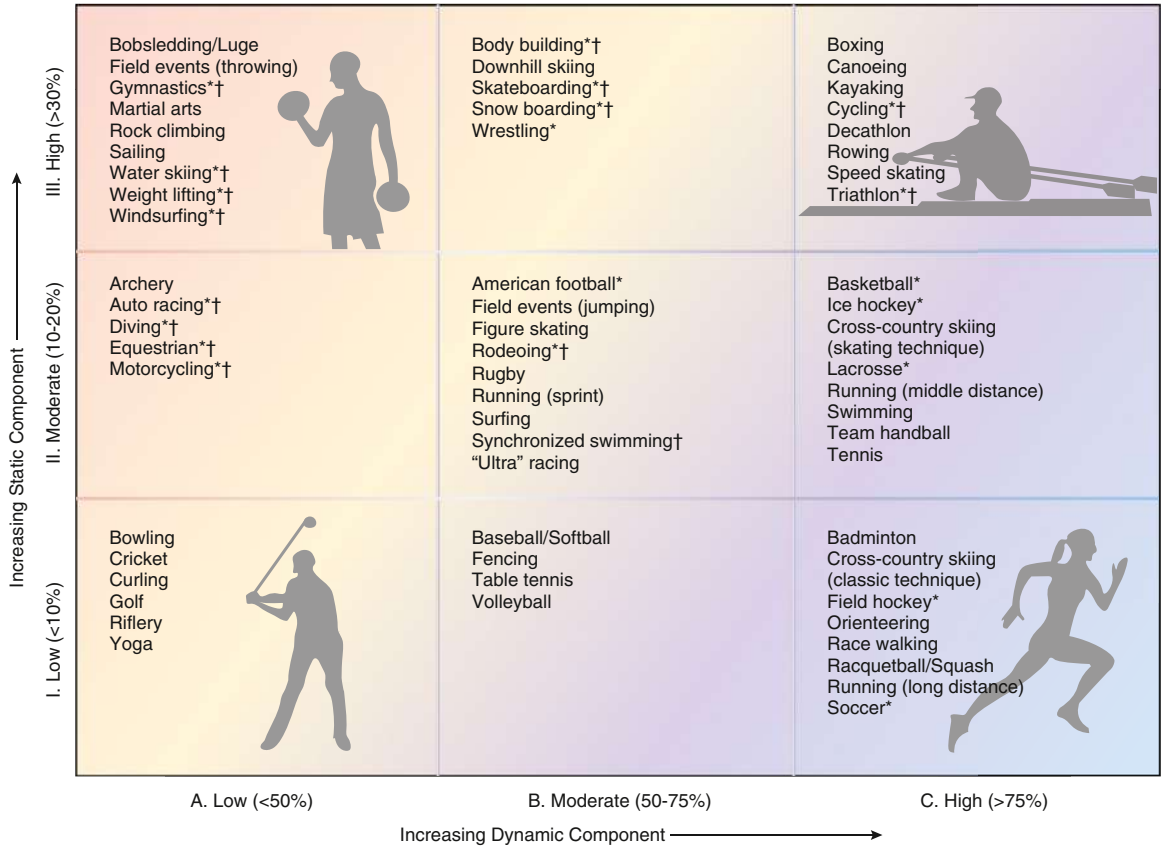


Fig. 727.2 Classification of sports. This classification is based on peak static and dynamic components achieved during competition; however, higher values may be reached during training. The increasing dynamic component is defined in terms of the estimated percentage of maximal oxygen uptake ($\dot{V}o_{2max}$) achieved and results in an increasing cardiac output. The increasing static component is related to the estimated percentage of maximal voluntary contraction reached and results in an increasing blood pressure load. The lowest total cardiovascular demands (cardiac output and blood pressure) are shown in the palest color, with increasing dynamic load depicted by increasing blue intensity and increasing static load by increasing red intensity. Note the graded transition between categories, which should be individualized on the basis of player position and style of play. *Danger of bodily collision (see Table 727.4 for more detail on collision risk). †Increased risk if syncope occurs. *(Modified from Mitchell JH, Haskell W, Snell P, et al. 36th Bethesda conference. Task force 8: classification of sports. J Am Coll Cardiol. 2005;45:1364–1367.)*

Chapter 728

Management of Musculoskeletal Injury

Gregory L. Landry and Andrew M. Watson

MECHANISM OF INJURY

Acute Injuries

Sprains, strains, and contusions account for the majority of musculoskeletal injuries. A **sprain** is an injury to a ligament or joint capsule. Most sprains are graded I-III. A *grade I* sprain is defined as mild damage to a ligament or ligaments without instability of the affected joint. A *grade II* sprain is considered a partial tear to the ligament, such that it exhibits excessive laxity but has a firm endpoint on examination. A *grade III* sprain is a complete tear of the ligament with instability to the affected joint and without a firm endpoint on examination. A **strain** is an injury to a muscle or tendon, and these are also graded I-III. *Grade I* muscle strains involve disruption of only a few muscle fibers, pain is mild to moderate, and range of motion and strength are at or near normal. *Grade II* strains represent a more significant, partial tear of the muscle and frequently involve loss of range of motion and strength. *Grade III* strains are defined as complete rupture of the musculotendinous unit. On examination, *grade III* strains, and often *grade II* strains, present with ecchymosis and a palpable step-off at the site of injury. A **contusion** is a crush injury to any soft tissue. The history of the injury is especially helpful in assessing musculoskeletal trauma. More severe injuries, including fractures or internal derangement of a joint, may have acute signs and symptoms such as immediate swelling, deformity, numbness or "give-way" weakness, a loud painful pop, mechanical locking of the joint, or instability.

Overuse Injuries

Overuse injuries are caused by repetitive microtrauma that exceeds the body's rate of repair. This can occur in muscles, tendons, bone, bursae, cartilage, and nerves. Overuse injuries can occur in all sports but are more commonly seen in sports emphasizing repetitive motion such as swimming, running, tennis, baseball pitching, and gymnastics. Factors leading to overuse injuries can be categorized as extrinsic (i.e., training errors, poor equipment, or workout surface) and intrinsic (i.e., athlete's anatomy or medical conditions). Training error is the most commonly identified factor. For example, at the beginning of the training program, athletes might violate the "10% rule" by increasing the duration or intensity of workouts by more than 10% per week. This may exceed the body's capacity to recover between bouts of activity, leading to accumulated microtrauma that manifests as an overuse injury. Intrinsic factors include abnormal biomechanics that may be due to underlying anatomic causes (e.g., leg-length discrepancy, pes planus, pes cavus, tarsal coalition, valgus heel, external tibial torsion, and femoral anteversion), muscle imbalance, inflexibility, and medical conditions (deconditioning, nutritional deficits, amenorrhea, and obesity). To identify the cause of an overuse injury, the athlete should be questioned about the specifics of their training. Specifically, runners, for example, should be asked about their shoes, orthotics, running surface, weekly mileage or time spent running per week, speed or hill workouts, and previous injuries and rehabilitation. When causative factors are identified, they can be modified or eliminated so that after rehabilitation the athlete does not suffer a recurrent overuse injury.

For athletes engaged in excessive training that causes an overuse injury, curtailing all exercise may not be necessary. Treatment incorporates a reduction of training load (relative rest) combined with a rehabilitation program designed to return athletes to their sport as soon as possible while minimizing risk of re-injury. Early identification of an overuse injury requires less alteration of the workout regimen. In addition, proper sleep, nutrition, and stress management can optimize recovery between bouts of activity, promoting physiologic adaptation and reducing the risk of accumulated damage that leads to injury.

It has become more commonplace for young athletes to *specialize* in a single sport and engage in year-round training. Families should be advised about the risks of specialization in young athletes because this is associated with burnout, decreased motivation and enjoyment, and increased risk of overuse injuries. This is especially evident among baseball pitchers, in whom repeated exposure to the highly repetitive and forceful throwing motion can damage the tissues in the elbow and shoulder in a growing athlete. These athletes and their parents should be counseled to diversify their sport participation at younger ages, which may increase their enjoyment and performance in sport, as well as reduce the risk of overuse injury.

The goals of treatment in overuse injuries are to control pain and spasm to rehabilitate flexibility, strength, endurance, and proprioceptive deficits (Table 728.1). In many overuse injuries, the role of inflammation in the process is minimal. For most injuries to tendons, the term

Table 728.1 Staging of Overuse Injuries

GRADE	GRADING SYMPTOMS	TREATMENT
I	Pain only after activity Does not interfere with performance or intensity Generalized tenderness Disappears before next session	Modification of activity, consider cross-training, home rehabilitation program
II	Minimal pain with activity Does not interfere with performance More localized tenderness Disappears before next session	Modification of activity, cross-training, home rehabilitation program
III	Pain interferes with activity and performance Definite area of tenderness Usually disappears between sessions	Significant modification of activity, strongly encourage cross-training, home rehabilitation program, and outpatient physical therapy
IV	Pain with activities of daily living Pain does not disappear between sessions Marked interference with performance and training intensity	Discontinue activity temporarily, cross-training only, oral analgesic, home rehabilitation program, and intensive outpatient physical therapy
V	Pain interferes with activities of daily living Signs of tissue injury (e.g., edema) Chronic or recurrent symptoms	Prolonged discontinuation of activity, cross-training only, oral analgesic, home rehabilitation program, and intensive outpatient physical therapy

tendinitis is no longer used because there is little or no inflammation on histopathology of the affected tendons. Rather, there is evidence of microscopic trauma to the tissue and a disorientation of the tendon fibers. Most of these entities are more appropriately called **tendinosis**; when the tendon tissue is scarred and when markedly abnormal, **tendinopathy**. With tendinosis, there is less of a role for antiinflammatory medication in the treatment, except as an analgesic.

Novel treatments are emerging for the effective treatment of chronic tendinopathies. Under ultrasound guidance, pathologic areas of tendon tissue can be targeted with injections of autologous blood or platelet-rich plasma to stimulate a proinflammatory and more robust healing response. Platelet-rich plasma is a controversial therapy with a mixed body of evidence related to its effectiveness for certain acute and chronic tendinopathies; there is a lack of consensus regarding its role in the standard of care. Pathologic tissue can also be targeted with percutaneous needle fenestration or tenotomy, and tendon-fat pad adhesions can also be addressed through mechanical needle scraping or hydrodissection techniques using ultrasound.

INITIAL EVALUATION OF THE INJURED EXTREMITY

Initially, the examiner should determine the quality of the peripheral pulses and capillary refill rate, as well as the gross motor and sensory function to assess for neurovascular injury. The first priorities are to maintain vascular integrity and skeletal stability.

Criteria for immediate attention and rapid orthopedic consultation include vascular compromise, nerve compromise, and open fracture. With the latter, the exposed wound should be covered with sterile saline-soaked gauze, the injured limb should be padded and splinted, and systemic antibiotics should be administered. Pressure should be applied to any site of excessive bleeding. Additional criteria include deep laceration over a joint, unreducible dislocation, grade III (complete) tear of a muscle-tendon unit, and displaced, significantly angulated fractures.

TRANSITION FROM IMMEDIATE MANAGEMENT TO RETURN TO PLAY

Rehabilitation of a musculoskeletal injury should be initiated on the day of the injury.

Phase 1

Limit further injury, control swelling and pain, and minimize strength and flexibility losses. **PRICE** principles (**P**rotection, **R**est, **I**ce, **C**ompression, and **E**levation) need to be applied. Crutches, air stirrups for ankle sprains, slings for arm injuries, and elastic wraps (4-8 inches) for compression are a helpful inventory of medical supplies. Ice can be placed directly over the injury as tolerated for 20 minutes continuously 3 or 4 times per day until the swelling resolves. Compression limits further bleeding and swelling but should not be so tight that it limits perfusion. Elevation of the extremity promotes venous return and limits swelling. A nonsteroidal antiinflammatory drug (NSAID) or acetaminophen are indicated for analgesia.

Pain-free isometric strengthening and range of motion exercises should be initiated as soon as tolerable. Pain inhibits full muscle contraction; deconditioning results if the pain and resultant disuse persist for days to weeks, thus delaying recovery. Education about the nature of the injury and the specifics of rehabilitation exercises, including handouts with written instructions and drawings demonstrating the exercises, are helpful.

Phase 2

Improve strength and range of motion (e.g., flexibility) while allowing the injured structures to heal. Protective devices are removed when the patient's strength and flexibility improve and activities of daily living are pain-free. Flexibility can then be addressed by a program of specific stretches, held for 15-30 seconds for three to five repetitions, once or twice daily. A physical therapist or athletic trainer is invaluable in guiding the athlete through this process. Protective devices might need to be used upon return to sports participation. Swimming, water jogging, and stationary cycling are good, low-impact aerobic exercises that can allow the injured lower extremity to be used pain-free while maintaining cardiovascular fitness.

Phase 3

Achieve near-normal strength and flexibility of the injured structures and further improve or maintain cardiovascular fitness. Strength and endurance are improved under controlled conditions using elastic bands and closed kinetic chain exercises (movement of multiple joints and limb segments with foot fixed to a static surface, such as the floor or wall) at this point and then progressing next to using exercise equipment followed by free weights. Additional sensory proprioceptive training allows the athlete to redevelop the kinesthetic sense critical to joint function and stability during activity.

Phase 4

Return to exercise or competition without restriction. When the athlete has reached normal range of motion, strength, proprioception, and endurance, the athlete can initiate sports-specific exercises. The athlete will transition from the rehabilitation program to functional rehabilitation appropriate for the sport. Substituting sports participation for rehabilitation is inappropriate; rather, there should be progressive stepwise

functional return to a full activity or play program. For instance, a basketball player recovering from an ankle injury might begin a walk-run-sprint-cut program before returning to competition. At any point in this progression, if pain is experienced, the athlete needs to stop, apply ice, avoid running for 1-2 days, continue to perform ankle stabilizing exercises, and then resume running at a lower intensity and progress accordingly.

Relative Rest and Return-to-Play Guidelines

Relative rest refers to the concept that the athlete participates in rehabilitation and return to sport activities provided the injured structures do not hurt during or within 24 hours of the activity. Exercising beyond the pain threshold delays recovery.

IMAGING

Traditional imaging modalities such as x-ray, ultrasound, MRI, and CT are well-established in the routine diagnostic workup of musculoskeletal injury. An obvious advantage of ultrasound is a lack of radiation. It is also better tolerated by younger children who may have difficulty complying with MRI or CT protocols. Dynamic movement or stressing of a limb, joint, or structure can provide valuable diagnostic information and can easily be compared to the contralateral side for comparison. Snapping or popping sensations, suspected intramuscular hematomas, stress fractures, and prognostic scrutiny of strains, sprains, and tendinopathies are all high-yield applications of diagnostic musculoskeletal sonography. Ultrasound imaging can also increase the accuracy of therapeutic injections, improving injection efficacy while simultaneously reducing adverse outcomes by erroneous needle placement.

DIFFERENTIAL DIAGNOSES OF MUSCULOSKELETAL PAIN

Traumatic, rheumatologic, infectious, hematologic, psychologic, congenital, and oncologic processes—especially under the age of 12 years old —can result in a presenting complaint of musculoskeletal pain. Symptoms such as fatigue, weight loss, rash, multiple joint complaints, fever, chronic or recent illness, pain out of proportion to the nature of the injury, and persistent pain despite conservative care suggest a diagnosis other than sports-related trauma. The possibility of child abuse, including sexual abuse, should not be overlooked. Incongruity between the patient's history and physical examination findings should lead to further evaluation. A negative review of systems with an injury history consistent with the physical findings suggests a sports-related etiology.

728.1 Growth Plate Injuries

Gregory L. Landry and Andrew M. Watson

Approximately 20% of pediatric sports injuries seen in the emergency department are fractures, and 25% of those fractures involve an epiphyseal growth plate or physis (see Chapter 724). Growth in long bones occurs in three areas and is susceptible to injury. Immature bone can be acutely injured at the physis (e.g., Salter-Harris fractures, see Chapter 724.2), the articular surface (e.g., osteochondritis dissecans [OCD]), or the apophysis (e.g., avulsion fractures). Males suffer nearly twice as many physeal fractures as females, with the highest incidence of fracture occurring during peak height velocity (females: age 12 ± 2.5 years; males: age 14 ± 2 years). The physis is a pressure growth plate and is responsible for longitudinal growth in bone. The apophysis is a bony outgrowth at the attachment of a tendon and is a traction physis. The epiphysis is the end of a long bone, distal or proximal to the long bone, and contains articular cartilage at the joint.

Physeal injuries of the upper extremity are most commonly seen at the distal radius in the growing child or adolescent and are typically due to excessive force applied to the upper extremity. Injuries of this nature can be seen in athletes, including those participating in gymnastics, cheerleading, ice skating, hockey, and weightlifting. Mechanisms of injury include falls onto an outstretched hand or repetitive dorsiflexion and axial loading through the distal radius (see Chapter 734). Chronic wrist pain can be seen in up to 79% of young gymnasts—particularly female gymnasts between the ages of 12-14 years—and is commonly termed **gymnasts' wrist** (see Chapter 722). With repetitive axial loading, temporary metaphyseal ischemia may be induced, preventing cartilage calcification and causing the physis to widen. With widening of the distal radial physis, microfractures can develop. Clinical features include radial wrist pain (particularly dorsal) that is aggravated with passive and active hyperextension activities and relieved with suspension of the offending activity. Tenderness or focal pain around the circumference of the distal radius is often noted. Differential diagnosis includes metacarpal fractures, scaphoid fracture and, in the older child or adolescent, de Quervain tenosynovitis. Juvenile idiopathic arthritis, malignancy, and infection need to be considered in a child with a painful, swollen wrist without a history of trauma. X-rays of the wrist can be helpful, particularly when compared to the contralateral extremity. Radiographs can show physeal widening with cystic changes involving the metaphyseal segment, breaking of the distal epiphysis, and, in later stages, positive ulnar variance (longer ulna compared to the radius). MRI is often helpful for stress fractures when radiographs are inconclusive and will show signs of stress reaction (bone marrow edema, periosteal reaction, etc.), even if a fracture line is not evident. PRICE principles are followed with nonnarcotic pain management. Salter-Harris fractures types I and II can be treated with closed reduction and immobilization. Ulnar-shortening osteotomy may be necessary in the athlete with significant ulnar positive variance. Physeal injuries at the knee (distal femur, proximal tibia) are rare, whereas those at the ankle (distal fibula most commonly) are more frequent—typically occurring as a result of an inversion injury—and predominantly consist of Salter-Harris I fractures.

Growth disturbance following a growth plate injury is a function of location of the physeal fracture. This influences the probability that a physeal bar will form, resulting in growth arrest. In the upper extremity, the areas making the largest contribution to longitudinal growth are the proximal humerus and distal radius and ulna; in the lower extremities, the distal femur and the proximal tibia and fibula are the greatest contributors to longitudinal growth. Injuries to these areas are more likely to cause growth disturbance compared with physeal injuries at the other end of these long bones. The type of physis fracture relative to the risk of growth disturbance is described by the Salter-Harris classification system (see Table 724.1). A grade I injury is least likely to result in growth disturbance, and grade V is the most likely fracture to result in growth disturbance.

Osteochondritis dissecans (OCD) affects the subchondral bone and overlying articular surface (see Chapter 718.3). With avascular necrosis of subchondral bone, the articular surface can flatten, soften, or break off in fragments. The etiology may be related to repetitive stress injury in some patients. OCD most commonly presents in the lower extremities at the knee, affecting the lateral aspect of the medial femoral condyle in 70% of patients, the lateral femoral condyle in 20%, and the patella in 10%. In the upper extremities, it is most frequently seen at the elbow (Fig. 728.1)—affecting the capitellum—and is often associated with repetitive overhead throwing or swinging activities (e.g., baseball). Other sites where OCD lesions are seen are the ankle (talus) and radial head. OCD classically affects athletes in their second decade. The most common presentation is poorly localized, vague joint pain. There is rarely a history of recent acute trauma. Some OCD lesions are asymptomatic and incidental—diagnosed on "routine" radiographs—whereas others manifest as joint effusion, pain, decreased range of motion, and mechanical symptoms (e.g., locking, popping, or catching). Activity usually worsens the pain.

Physical examination might show no specific findings. Sometimes tenderness over the involved condyle can be elicited by deep palpation. Diagnosis is usually made with plain radiographs. Treatment of OCD includes both nonoperative and surgical management (Chapter 718.3). Long-term sequelae can be seen in up to 25% with atypical lesions, older age, effusion, and lesions of large size.

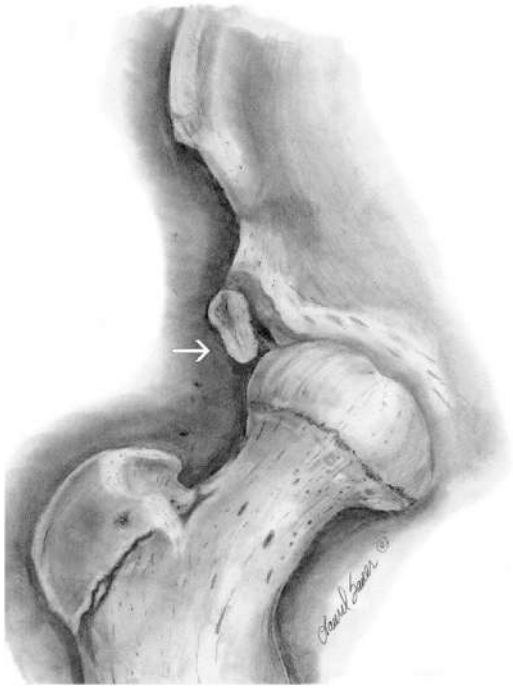

Fig. 728.2 Anterior inferior iliac spine avulsion. *(Copyright Laurel Sauer, 2017.)*

Fig. 728.3 Calcaneal apophysitis (Sever disease). *(Copyright Laurel Sauer, 2017.)*

Avulsion fractures occur when a forceful muscle contraction dislodges the apophysis from the bone. They occur most commonly around the hip (Fig. 728.2) and are typically treated nonsurgically if no significant displacement of the avulsed fragment is present. Acute fractures to other apophyses (i.e., knee and elbow) require urgent orthopedic consultation. Chronically increased traction at the muscle-apophysis attachment can lead to repetitive microtrauma and pain at the apophysis. The most common areas affected are the knee (**Osgood-Schlatter** and **Sinding-Larsen-Johansson disease**), the ankle **(Sever disease)** (Fig. 728.3), the proximal fifth metatarsal **(Iselin disease)**, and the medial epicondyle **(Little Leaguer's elbow)**. Traction apophysitis of the knee and ankle can often be treated in a primary care setting. The main goal of treatment is to minimize the intensity and incidence of pain and disability. Exercises that increase the strength, flexibility, and endurance of the muscles attached at the apophysis, using the relative rest principle, are appropriate. The use of a patellar strap can provide benefit in reducing the traction force placed upon the tibial apophysis during activity. Symptoms can last for 12-24 months if untreated. As growth slows, symptoms abate.

728.2 Shoulder Injuries

Gregory L. Landry and Andrew M. Watson

Shoulder pain associated with radiating symptoms down the arm should raise the possibility of a neck injury (see Chapter 730). Neck pain and tenderness or limitation of cervical range of motion requires cervical spine immobilization and transfer of the athlete for further evaluation. If there is no neck pain, tenderness, or limitation of motion of the cervical spine, the shoulder is likely the site of the primary injury.

CLAVICLE FRACTURES

Clavicle fracture is one of the most common shoulder injuries (see Chapter 724.3). Injury is usually sustained by a fall on the lateral side of an adducted shoulder, on an outstretched hand, or by direct blow. Approximately 80% of fractures occur in the middle third of the clavicle. With younger children, plastic bowing of the clavicle may be present instead of an overt fracture but should be treated in the same fashion. Treatment is conservative and includes the use of an arm sling or figure-of-8 brace for comfort and protection. An arm sling is preferred because it is generally more comfortable and easier to apply with similar clinical outcomes. Healing time is shorter in comparison to that in adults—generally 3-6 weeks. An additional 2- to 3-week period of protection from contact/collision activities is recommended after clinical and radiographic healing is achieved to prevent re-injury. If nondisplaced, most medial and lateral clavicular fractures can be managed similar to middle-third clavicular fractures. Displaced lateral and medial third fractures require orthopedic consultation because of a higher incidence of acromioclavicular (AC) osteoarthritis (lateral), and physeal involvement (medial). **Distal clavicular osteolysis** is likely an overuse injury associated with slow dissolution and resorption of

bone. The cause of injury is unclear, appearing most consistent with a stress reaction or fracture at the site of considerable force. This lesion is commonly seen in weightlifting athletes and can be seen in older children. Nonoperative treatment, including activity limitations, ice, NSAIDs, and cortisone injections, can be helpful. For weightlifters, narrowing their hand spacing on the barbell and slowing descent phase of the bench press to end 4-6 cm above the chest are recommended activity modifications. For those not willing to modify weightlifting activity or those with persistent symptoms despite conservative care, surgery can be very successful and involves removal of the distal clavicle (approximately 1 cm) with no loss of strength and full return to activity anticipated.

ACROMIOCLAVICULAR JOINT SEPARATION

An AC joint separation most commonly occurs when an athlete sustains a direct blow to the acromion with the humerus in an adducted position, forcing the acromion inferiorly and medially. Force is directed toward the AC joint and coracoclavicular ligaments because of the inherent stability of the sternoclavicular joint. Patients have point tenderness at the AC joint, pain with lifting their arms above the level of their shoulder, and possibly an apparent step-off between the distal clavicle and the acromion (Fig. 728.4).

Type I AC joint injuries involve isolated sprain of the AC ligament with the periosteal sleeve intact (Fig. 728.5). There is no visible deformity, and the radiographs are normal. Pain is elicited with adduction of the humerus across the chest and palpation of the AC joint. **Type II** injuries involve disruption of the AC and coracoclavicular ligaments, as well as partial disruption of the periosteal sleeve. Radiographs may show slight widening of the AC joint, though the distance between the clavicle and the coracoid process is unchanged in comparison to the uninjured shoulder. Treatment of type I and type II AC injuries is conservative and consists of ice, NSAIDs, and a sling for immobilization. Shoulder range of motion exercises and strengthening of the rotator cuff, deltoid, and trapezius musculature are incorporated early in the rehabilitative course once pain-free range of motion is achieved in order to prevent residual joint stiffness. A short course of physical therapy may be helpful if range of motion limitations are present 2-4 weeks out from injury. Consideration for return to play is made when the patient no longer has focal AC joint tenderness, exhibits full, painless range of motion, has strength sufficient to be functionally protected from a collision or fall, and can perform maneuvers required within their sport. Typically, return to play from a type I AC injury is 1-2 weeks, and 2-4 weeks for type II.

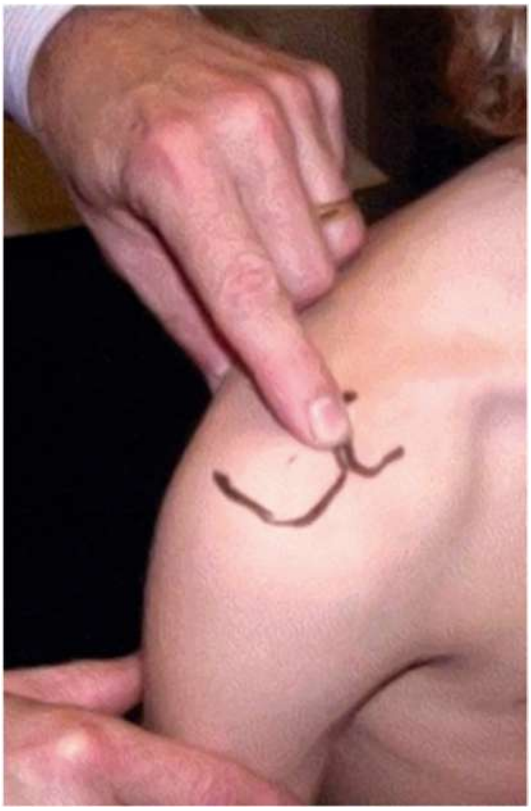

Fig. 728.4 Palpitation of acromioclavicular joint. *(From Anderson SJ. Sports injuries. Curr Probl Pediatr Adolesc Health. 2005;35:105–176.)*

Type III AC joint injury is more severe, involving further tearing of the AC and coracoclavicular ligaments and disruption of the periosteal sleeve with instability of the distal clavicle because of deltotrapezial fascial detachment. Radiographs will commonly show superior displacement of the distal clavicle from the coracoid of 25–100%. The treatment of type III AC injuries is controversial. Many can be treated nonoperatively—similar to that described for types I and II AC injuries—if there is no damage to the overlying skin or neurovascular compromise to the injured limb. The patient should be counseled that this injury is likely to result in a noticeable defect to ascertain whether this is acceptable. Surgery for type III AC injuries is uncommon and primarily for athletes involved with throwing sports or for cosmesis. **Types IV**, **V**, **and VI** AC joint injuries have progressive worsening of ligamentous and fascial disruption with varied locations of the clavicular displacement. These injuries should be referred to an orthopedist for consultation and operative repair.

ANTERIOR GLENOHUMERAL DISLOCATION

The most common mechanism of injury causing an anterior glenohumeral dislocation is contact with the shoulder abducted to 90 degrees and forcefully externally rotated. Patients complain of severe pain and that their shoulder "popped out of place" or "shifted." Patients with an unreduced anterior dislocation have a hollow region inferior to the acromion and a bulge in the anterior portion of the shoulder caused by anterior displacement of the humeral head. Abnormal sensation of the lateral deltoid region and the extensor surface of the proximal forearm should be assessed to evaluate for concomitant injury to the radial or musculocutaneous nerves, respectively.

Reduction of a dislocated shoulder should be made expediently, assuming that there is no crepitus to suggest a fracture. Numerous safe methods for closed reduction have been described, including the traction–counter traction technique, the **Stimson maneuver**, and the abduction maneuver. Postreduction radiographs are helpful and may show evidence of a posterior lateral humeral head impaction fracture **(Hill-Sachs lesion)**. Injuries to the surrounding soft tissues, including the anterior capsule and labrum, are best evaluated by MRI—often with an accompanying arthrogram of the glenohumeral joint. Once reduced, initial treatment of a dislocation includes placing the patient into an arm sling for comfort and protection. The duration of immobilization is controversial and may last from a few days to 6 weeks. The most significant risk after an acute traumatic dislocation is recurrence. Most sports medicine practitioners encourage early range of motion and strengthening exercises as tolerated. Rehabilitation focuses on progressive strengthening of the rotator cuff, deltoid, and periscapular muscles at increasing degrees of abduction and external rotation. Strengthening of the rotator cuff muscles is extremely important because they are the dynamic stabilizers of the glenohumeral joint and are integral to the prevention of future dislocation. Plyometric exercises also may be incorporated near the end of rehabilitation to improve proprioceptive function in preparation for return to athletics. Patients can return to play when strength, range of motion, and proprioception are equal to the uninjured shoulder to the extent that they are able to protect the shoulder and perform sports-specific activities without pain. Surgery is to be considered in cases of recurrent dislocations or in those individuals that fail to heal adequately after prolonged rehabilitation. Additionally, early operative repair should be considered for athletes participating in contact or collision sports that inherently have higher recurrence rates.

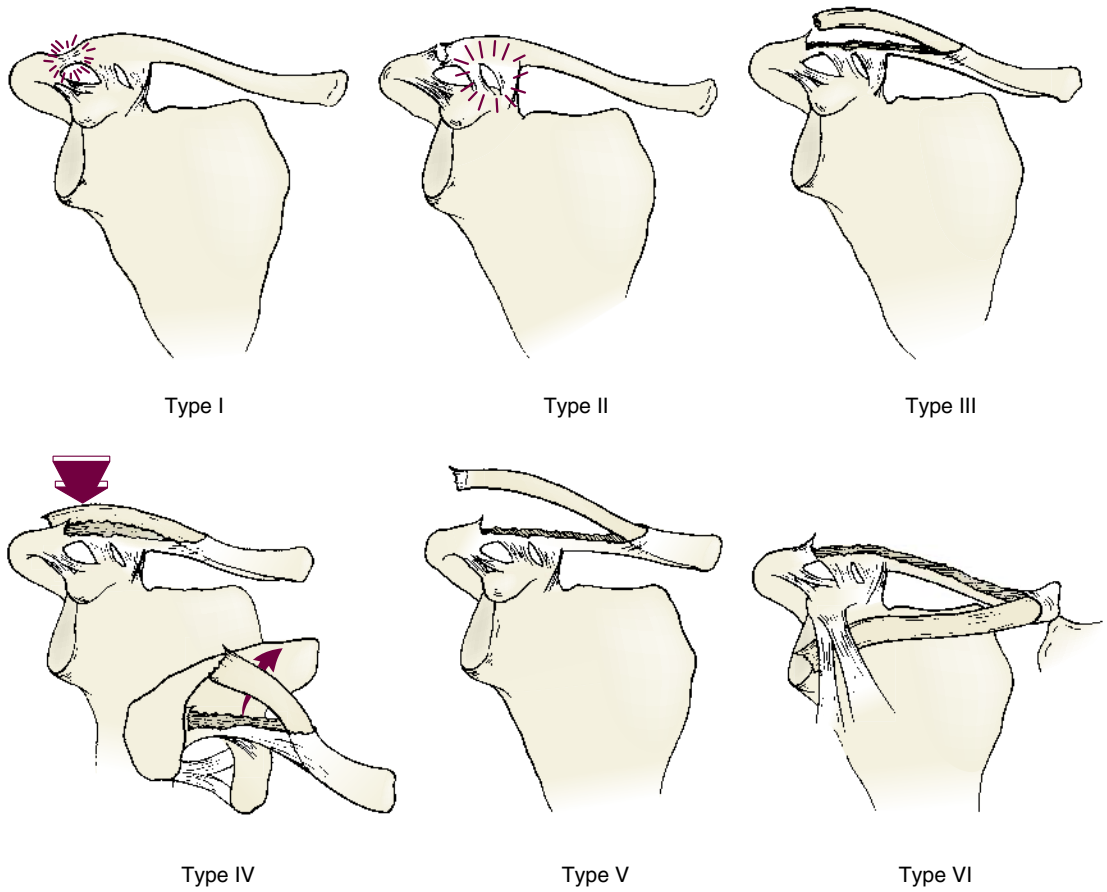

Fig 728.5 Rockwood's classification of acromioclavicular (AC) joint injuries in children. *Type 1*, sprain of the AC ligaments without disruption of the periosteal tube. *Type II*, partial disruption of the periosteal tube. This may produce some AC instability. *Type III*, large split in the periosteal tube allowing superior displacement of the lateral clavicle. *Type IV*, large split in the periosteal tube *(large arrow)* with posterior displacement of the lateral clavicle through the trapezius muscle *(curved arrow)*. *Type V*, complete disruption of the periosteal tube with displacement of the clavicle through the deltoid and trapezius muscles into the subcutaneous tissues. *Type VI*, inferior dislocation of the distal clavicle below the coracoid process. *(Redrawn from Sanders JO, Rockwood CA, Curtis RJ. Fractures and dislocations of the humeral shaft and shoulder. In Rockwood CA, Wilkins KE, Beaty JH, eds. Fractures in Children. Vol 3. Philadelphia, PA: Lippincott-Raven; 1996:974.)*

ROTATOR CUFF INJURY

The muscles of the rotator cuff consist of the supraspinatus, infraspinatus, teres minor, and subscapularis. The function of these muscles is to rotate the humerus and stabilize the humeral head against the glenoid. The supraspinatus is most commonly injured, either by an acute traumatic injury or chronic tendinosis from overuse. Specifically, rotator cuff tendinosis commonly presents with the complaint of pain with overhead arc of motion, such as with throwing, lifting, or reaching for objects above one's head. Pain is often poorly localized about the shoulder, although it may be referred to the deltoid. The onset of pain is often insidious and is commonly associated with increased frequency or duration of overhead throwing or lifting activities. Pain is exacerbated with overhead activities but is often present at rest as well; nighttime pain occurs in more severe cases. On exam, manual muscle testing of the rotator cuff muscles often produces pain and in some cases weakness in comparison to the uninjured shoulder. Supraspinatus tendinosis produces pain with active abduction against resistance in which the patient abducts the arm to 90 degrees, forward flexes to 30 degrees anterior to the parasagittal plane, and internally rotates the humerus.

The treatment of rotator cuff tendinosis includes relative rest from athletics or activities causing pain as well as the use of ice, analgesia, and/or NSAIDs. Strengthening of the rotator cuff and scapular stabilizer musculature, modifications of technique, and core strengthening are important components of rehabilitation often supervised by a physical therapist. In the young athlete, rotator cuff pain is most commonly a result of glenohumeral instability and not rotator cuff impingement syndrome. The latter is more commonly seen in adults and is caused by impingement of the rotator cuff by the bony structures superior to it. As a result, treatment focusing on stretching alone can make symptoms worse. Return to play often includes gradual increases in load placed upon the rotator cuff as the patient resumes prior activities, such as an interval throwing program in baseball.

Glenoid labrum tears may present in similar insidious fashion to rotator cuff tendinosis or may be associated with an acute traumatic dislocation. This frequently manifests with pain in the glenohumeral joint and may be associated with mechanical sensations of clicking or catching in the shoulder. This can frequently be reproduced on exam. One of the most common lesions is a superior labrum anterior and posterior (SLAP) lesion. Throwing athletes are at particular risk. The mechanism of injury is thought to be related to a traction injury along the long head of the biceps at its attachment at the superior glenoid labrum, occurring during the throwing cycle. Radiographs are usually normal. MRI with arthrogram is the best study to identify glenoid labrum pathology (Fig. 728.6).

Proximal humeral stress fracture (epiphysiolysis) is an uncommon cause of proximal shoulder pain and is suspected when shoulder pain does not respond to routine measures. Gradual onset of deep shoulder pain occurs in a young athlete involved in repetitive overhead motion, such as in baseball, tennis, or swimming, but with no history of trauma. Tenderness is noted over the proximal humerus; the diagnosis is confirmed by detecting a widened epiphyseal plate on plain

Fig. 728.6 Coronal intermediate-weighted MRI showing superior labral tear *(arrow)* and tendinosis of the supraspinatus tendon *(arrowhead)*. There is no adjacent perilabral edema, suggesting chronic injury. *(From Chang, I-Yuan J, Polster JM. Pathomechanics and magnetic resonance imaging of the thrower's shoulder. Radiol Clin N Am. 2016;54[5]:801-805. Fig. 13.)*

radiographs, increased uptake on nuclear scan, or edema of the physis on MRI. Treatment is total rest from throwing for at least 6-8 weeks.

Non–sports-related conditions that need to be considered in any child with a painful shoulder include an undiagnosed Sprengel deformity. This deformity involves the scapula, which fails to descend from its cervical region overlying the first through fifth ribs. Children often present with a shortened neckline and a lack of normal scapular thoracic motion. Malpositioning of a glenoid can cause limited forward flexion and abduction of the shoulder. An omovertebral bar is present in up to 50% of cases. This bar connects the superior medial angle of the scapula and the cervical spine and consists of fibrous cartilaginous tissue or bone. Other regional abnormalities can include scoliosis with a prominent scapula on the convex side, congenital rib anomalies, and undiagnosed Klippel-Feil syndrome. Winging of the scapula raises the question of facioscapulohumeral muscular dystrophy. Family histories can be most helpful. Primary bone tumors (see Chapter 550) common to the upper extremities include Ewing sarcoma of the scapula and osteogenic sarcoma of the proximal humerus, in addition to osteoblastomas and chondroblastomas common to the diaphysis and epiphysis of long bones. The most common presenting manifestations of osteosarcoma are pain, upper limb dysfunction, and swelling. Similar presentations can be seen in Ewing sarcoma, along with weight loss and fever. Symptoms not responding to conservative treatment require further investigation and specialty consultation.

728.3 Elbow Injuries

Gregory L. Landry and Andrew M. Watson

ACUTE INJURIES

The most commonly dislocated joint in childhood is the elbow. Radial head subluxation, or "nursemaid's elbow," comprises the majority of these (see Chapter 722). Posterior dislocation is the next most common type of **elbow dislocation**, typically resulting from falling backward onto an outstretched arm with the elbow in extension. The dislocation may be complete or incomplete—termed "perched"—with the trochlea subluxed upon the top of the coronoid process. The ulnar collateral ligament (UCL) is commonly disrupted along with other components of the soft tissue capsule about the elbow. Fractures of the olecranon (>80% occurrence) or medial epicondyle may be present as well. An obvious deformity is visualized with the olecranon process displaced prominently behind the distal humerus. Careful examination of the distal radius and ulnar pulses to assess vascular integrity of the distal upper arm is important because of the potential for injury to the brachial artery. Sensation to the distal extremity should also be assessed because of possible injury to the radial, median, and ulnar nerves. Reduction should be performed as soon as possible before significant swelling and muscle spasm potentially complicate the procedure. Longitudinal traction is applied to the forearm with gentle upward pressure on the distal humerus so that the coronoid process clears the trochlea. If reduction is unable to be performed, the arm should be placed in a padded splint and sling and the patient transported to an emergency facility.

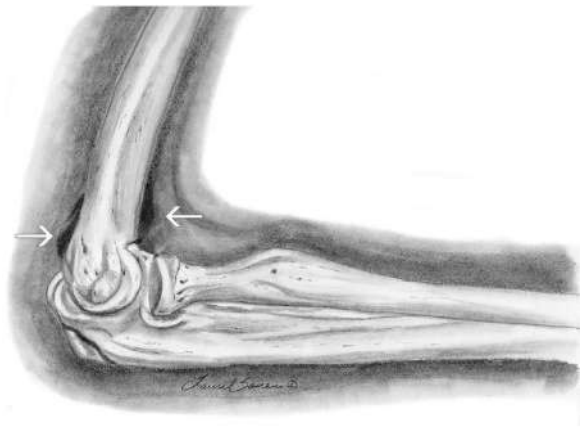

Fig. 728.7 Deflection of the supracondylar fat pad with a joint effusion (fat pad sign) *(arrows)* showing evidence of a fracture. *(Copyright Laurel Sauer, 2017.)*

Supracondylar humeral fractures can result from the same mechanism of injury as elbow dislocations and can be difficult to distinguish on exam from a posterior dislocation because of significant swelling about the elbow joint. These, too, can be complicated by concomitant injury to the brachial artery and to a lesser extent the median, radial, and ulnar nerves. The injury typically occurs in the first decade of life, which is associated with peak hyperlaxity of the elbow joint in children between the ages of 5-8 years. An acute compartment syndrome can develop after these fractures, which is associated with a fat pad sign on radiographs (Fig. 728.7). These fractures should be referred for orthopedic consultation and are discussed in more depth in Chapter 724.

Direct trauma to the elbow can cause bleeding and inflammation in the olecranon bursa resulting in **olecranon bursitis**. Aspiration is rarely required, and this injury can be managed with ice, compressive dressing, and analgesia (PRICE principles). An overlying elbow pad provides comfort during activity and prevents re-injury.

Chronic Injuries

Overuse injuries in the upper extremities occur primarily in throwing sports, sports that require repetitive wrist flexion or extension, or sports that demand weight-bearing on hands (gymnastics).

Little Leaguer's elbow is a broad term for several different elbow problems. Throwing overhand creates valgus stress to the elbow with medial opening of the joint and lateral compressive forces. **Medial elbow pain** is a common complaint of young throwers, resulting from repetitive valgus overload of the wrist flexor-pronator muscle groups and their attachment on the medial apophysis. In preadolescents who still have maturing secondary ossification centers, traction apophysitis of the medial epicondyle is likely. Patients have tenderness along the medial epicondyle; pain is exacerbated by valgus stress or resisted wrist flexion and pronation. Wrist pain may be present in more severe cases. Radiographs may show widening of the growth plate at the medial

apophysis in comparison to the uninjured elbow. Treatment includes no throwing for 4-6 weeks and pain-free strengthening and stretching of the flexor-pronator group followed by a 1-2 week progressive functional throwing program with careful rehabilitation. Incorporation of core strengthening and scapular stabilizing exercises, as well as addressing proper throwing mechanics (to reduce the load upon the medial elbow), are important components of the rehabilitation program. Little Leaguer's elbow has to be treated with a period of rest from throwing because of the risk of nonunion of the apophysis and chronic pain. If pain occurs acutely, an avulsion fracture of the medial epicondyle must be considered. Radiographs should be taken in any thrower with acute elbow pain. If the medial epicondyle is avulsed (Fig. 728.8), orthopedic consultation is indicated.

In older adolescents and young adults with a fused apophysis, the structure at the elbow vulnerable to injury is the UCL. UCL sprains/tears are common in sports requiring high-velocity throwing or overhead activities. Medial elbow pain that is worst during the acceleration phase of throwing is common. A loss of throwing velocity and control, as well as a sensation of elbow joint "opening" during throwing is also frequently described. On exam, focal tenderness to palpation over the UCL is present. Additionally, laxity may be appreciated with valgus stress of the elbow when flexed to 30 and/or 90 degrees. Radiographs are generally unremarkable. Diagnostic ultrasonography or MRI with arthrography is often necessary to assess the integrity of the UCL. Partial tears can be treated with a period of time off from throwing (2-4 weeks) followed by careful progressive rehabilitation as discussed earlier for medial elbow pain. If there is a complete tear, surgical repair is indicated if the athlete desires to continue a pitching career.

Fig. 728.8 The many faces of little Leaguer's elbow in a 14-yr-old pitcher. A, AP radiograph and coronal oblique fat-saturated T2-weighted MRI demonstrate features of chronic medial epicondyle stress injury *(yellow arrow)* as well as findings of capitellar osteochondritis dissecans *(white arrowhead)*. Proximal medial ulnar collateral ligament edema/grade 1 sprain also noted at the humeral attachment *(red arrow)*. B, Sagittal short tau inversion recovery and fat-saturated T1-weighted MR arthrogram images emphasize the classic features of injury to the "metaphyseal equivalent" bone deep to the disorganized and obliterated secondary physis of the ossifying capitellum. *(From Braithwaite KA, Marshall KW. The skeletally immature and newly mature throwing athlete. Radiol Clin N Am. 2016;54[5]:841–855. Fig. 11.)*

Medial epicondylitis, or golfer's elbow**,** is another common cause of medial elbow pain in the individual with fused apophyses. It is commonly caused by overuse of the flexor pronator muscle groups at their origin at the medial humeral epicondyle. This occurs frequently in athletics or activities with repetitive wrist flexion. Tenderness is noted over the medial epicondyle and exacerbated by passive wrist extension or resisted wrist flexion. Treatment includes rest from the inciting activity, ice, stretching and strengthening of the wrist flexors, forearm straps, counterforce bracing, and analgesia. Local injection of corticosteroids can be considered as an adjunctive treatment if initial conservative measures fail. Ulnar nerve dysfunction can be a complication of valgus overload and can occur with any of the diagnoses previously discussed. Persisting paresthesia or motor weakness in the ulnar nerve distribution should be evaluated with electromyography and nerve conduction studies. Diagnostic ultrasonography can also be of use to assess for focal thickening of the nerve, as a sign of irritation, as well as dynamically visualizing the nerve through the arc of elbow flexion to assess for subluxation over the medial epicondyle (Fig. 728.9).

Lateral elbow pain can be caused by compression during the throwing motion at the radiocapitellar joint. **Panner disease** is osteochondrosis of the capitellum that occurs between ages 7 and 12 years (Fig. 728.10). **OCD** of the capitellum occurs at age 13-16 years (see Fig. 728.1). Although patients with both conditions present with insidious onset of lateral elbow pain exacerbated by throwing, patients with OCD have mechanical symptoms (popping, locking) and, more commonly, decreased range of motion. Patients with Panner disease have no mechanical symptoms and often have normal range of motion. The prognosis of Panner disease is excellent, and treatment consists of relative rest (no throwing), brief immobilization, and repeat radiographs in 6-12 weeks to assess bone remodeling. In OCD, radiographs show a more focal lesion in the capitellum with eventual flattening and potentially fragmentation. MRI can be very helpful in early diagnosis and with subsequent staging. A diagnosis of OCD requires orthopedic consultation, with treatment depending on the severity of the lesion and fragmentation.

Lateral epicondylitis, or "tennis elbow," is the most common overuse elbow injury in adults but is relatively uncommon in children and adolescents (Fig. 728.11). It is a tendinosis of the extensor muscle origin at the lateral humeral epicondyle, which is commonly found in individuals performing activities requiring repetitive or prolonged grip. Tenderness is localized over the upper lateral epicondyle and is worsened with passive wrist flexion or resisted wrist extension. Treatment includes relative rest, analgesia, and specific stretching and strengthening exercises for the elbow and forearm. As with medial epicondylitis, corticosteroid injection can be considered as an adjunctive treatment if initial conservative measures fail. Improper equipment (i.e., wrong grip size or overstrung racket) and poor technique can contribute to the onset of symptoms. Return to play should be gradual and progressive to prevent re-injury.

Elbow injuries can be minimized but not necessarily prevented by preseason stretching and strengthening exercises. The importance of core strengthening and scapular stabilization with respect to preventing elbow and shoulder injuries in the throwing athlete cannot be overstated. The most important consideration for preventing elbow injuries in throwers is limitation of the number of pitches and advising players, coaches, and athletes that they should stop immediately when they experience elbow pain. If it persists, they need medical evaluation. It has been recommended that a young pitcher have age-specific limits

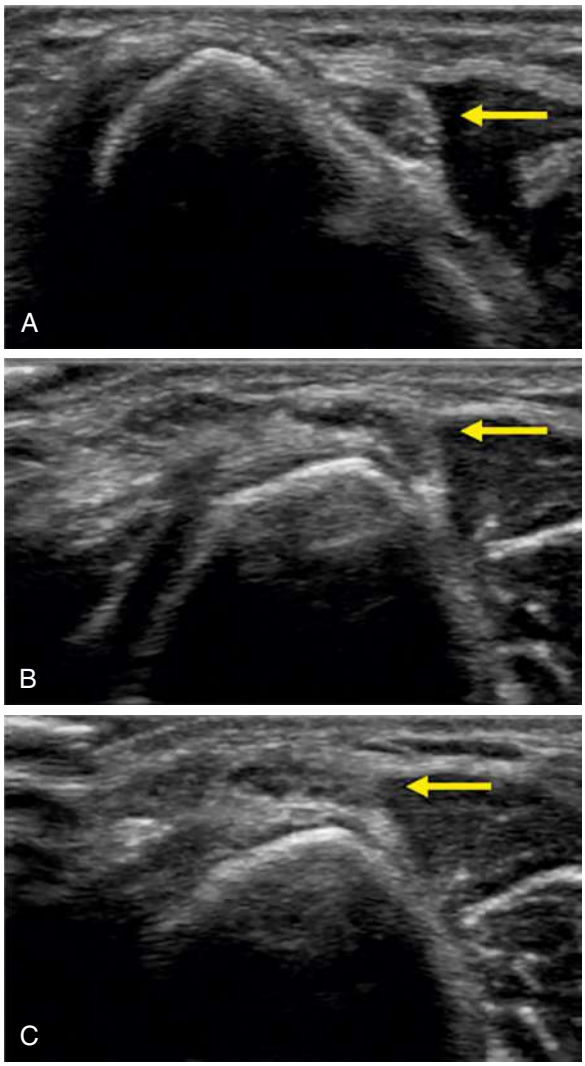

Fig. 728.9 Ulnar nerve subluxation. Dynamic ultrasound imaging of the ulnar nerve (arrow) in the ulnar groove at the elbow. A, The ulnar nerve positioned appropriately in the ulnar groove with the elbow extended. With elbow flexion, (B) the nerve becomes perched upon the medial epicondyle. As the elbow moves into terminal flexion, (C) the nerve is completely dislocated anteriorly over the medial epicondyle. *(Courtesy Nicholas Goyeneche, MD, ultrasound clinic files, Ochsner Clinic Medical Center.)*

on pitch counts, including the number of pitches thrown per game and per week, as well as maintaining appropriate days off between games pitched. A good rule of thumb is that the maximal number of pitches per game should be approximately 6 times the pitcher's age in years.

Other less-common problems that cause elbow pain are ulnar neuropathy/subluxation, tricipital or bicipital tendonitis (distal), olecranon apophysitis, and loose bodies. Non–sports-related injuries that need to be considered in the child with a painful elbow include undiagnosed congenital conditions such as radial dysplasia, including radial ulnar synostosis and mild persistent brachial plexus palsy. The elbow is not an uncommon site for inflammatory arthritides, including juvenile idiopathic arthritis, sepsis, hemophilia, and sickle cell disease. Neoplasia to consider includes osteoblastomas and chondroblastomas, which are common in the diaphysis and epiphysis of longer bones, in addition to osteosarcoma. As always, in the child with persistent symptoms who is not responding to conservative care, further diagnostic workup is indicated.

728.4 Low Back Injuries

Gregory L. Landry and Andrew M. Watson

SPONDYLOLYSIS, SPONDYLOLISTHESIS, AND FACET SYNDROME

Spondylolysis

Spondylolysis, a common cause of back pain in athletes, is a stress fracture of the pars interarticularis (see Chapter 720.6). It can occur at any vertebral level but is most likely at L5. Complete spondylolysis has never been found in the newborn. Its occurrence increases between the ages of 5.5 and 6.5 years to a rate of 5%. Prevalence in adolescent athletes evaluated for low back pain is 13–47%. Besides hyperextension that causes an acute fracture, the mechanism of injury is either a congenital defect or hypoplastic pars. This is exacerbated by repetitive lumbar extension loading. Ballet, weightlifting, gymnastics, and football are examples of sports in which repetitive extension loading of the lumbar spine frequently occurs.

Patients often present with pain of insidious onset. However, there may be a precipitating injury, such as a fall, or a single episode of hyperextension. The pain is worse with extension, may radiate to the buttocks, and can eventually affect activities of daily living. Rest or supine positioning usually alleviates the pain.

On examination, the pain is reproduced with lumbar extension while standing, especially when standing on one leg (single-leg hyperextension test). Limited forward spinal flexion and tight hamstrings may be seen. Neurologic examination is generally normal. There is often well-localized tenderness to deep palpation just lateral to the involved spinous process.

The diagnosis can be confirmed by finding a pars defect on an oblique lumbar spine radiograph. The defect is rarely seen on anteroposterior

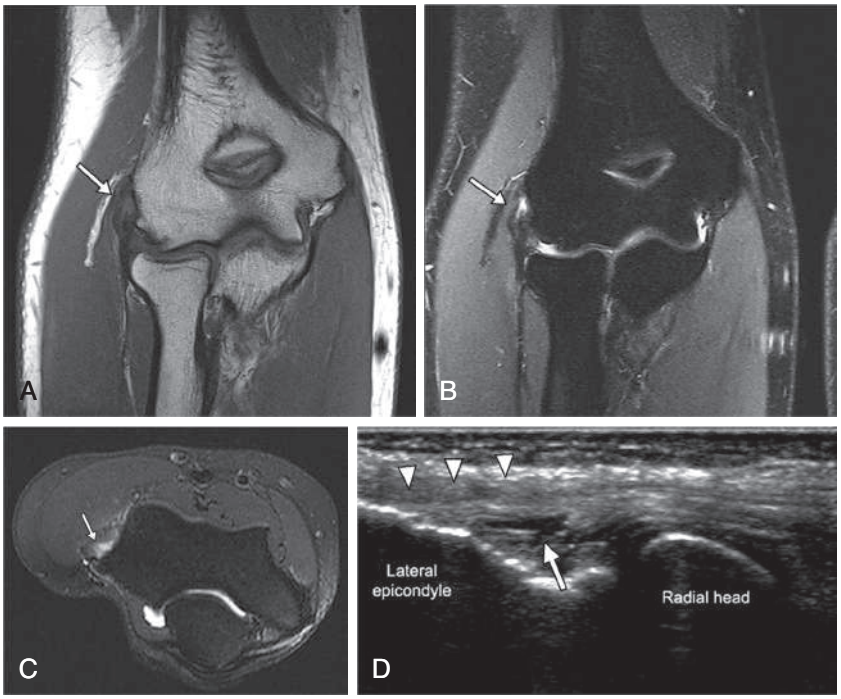

Fig. 728.11 A 22-yr-old tennis player with persistent lateral elbow pain despite 3 months of physical therapy. **A,** Coronal T1 sequence shows thickening and intermediate signal in the common extensor tendon (CET; *arrow*). **B,** Coronal T2 fat suppression (FS) (CET; *arrow*) and **(C)** axial proton density FS sequences reveal fluid signal within the CET and discontinuity of tendon fibers, consistent with a partial-thickness tear (CET; *arrow*). **D,** Corresponding long axis ultrasound image shows an anechoic fluid cleft *(arrow)* in the undersurface of the CET *(arrowheads). (From Gustas CN, Lee KS. Current imaging concepts and image-guided treatments for the injured thrower's elbow. Radiol Clin N Am. 2016;54[5]:817–839. Fig. 2.)*

(AP) and lateral views. MRI or bone single-photon emission CT (SPECT) is needed to confirm diagnosis if radiographs are normal and spondylolysis is suspected. A plain CT scan can help identify the degree of bony involvement and is sometimes used to assess healing.

Treatment includes pain relief and activity restriction. Rehabilitation consisting of trunk strengthening, hip flexor stretching, and hamstring stretching is important in most cases. A thoracic lumbar sacral orthotic may be considered for symptom management in cases in which conservative measures fail, but the overall benefit of bracing on healing is unclear.

Spondylolisthesis and Facet Syndrome

Spondylolysis, spondylolisthesis, and facet syndrome are injuries to the posterior elements of the vertebrae. Spondylolisthesis occurs when bilateral pars defects exist and forward displacement or slippage of a vertebra occurs upon the vertebra inferior to it (see Chapter 720.6). Facet syndrome has history and physical examination findings similar to those of spondylolysis. It is caused by instability or injury to the facet joint, posterior to the pars interarticularis and at the interface of the inferior and superior articulating processes. Facet syndrome can be established by identifying facet abnormalities on CT or by exclusion, if a radiograph and MRI rule out spondylolysis.

Treatment of posterior element injuries is conservative and directed at reducing the extension-loading activity, often for 2-3 months. Body mechanics, posture principals, core strengthening, and lumbar pelvic stabilization routines can be very helpful in the functional recovery of the motivated athlete. Walking, swimming, and cycling can be appropriate exercises during the rehabilitation phase. Rarely, spinal segmental fusion can be indicated in the athlete with spondylolisthesis and persistent symptomatic segmental instability despite conservative care.

LUMBAR DISK HERNIATION, STRAIN, AND CONTUSION

Intervertebral disk injury in children and adolescents is uncommon. Symptoms include pain with prolonged standing and prolonged periods of lumbar flexion, such as sitting in a car. Presentation is variable, and patients may report an acute pain onset with an obvious inciting event or an insidious onset with a history of heavy lifting or repetitive axial load activities. In contrast to the selective motor and sensory deficits often observed in adults with disk herniation, athletes younger than 20 years of age less commonly have pain or tenderness over the course of the sciatic nerve. Physical examination findings may be minimal but usually include pain with forward flexion and lateral bending. It is unusual to have a positive straight leg test or any neurologic deficit in the young athlete with an injured disk. There may be tenderness of the vertebral spinous process at the level of the disk injury. A general aching sensation in the lower back or upper buttocks may be present. MRI usually confirms a clinical diagnosis. Assuming the herniation is not large and the pain is not intractable, treatment is conservative with analgesia and physical therapy. Surgery is rarely necessary.

Acute lumbar strain or contusion can be seen in the younger athlete and is usually associated with precipitating activity often outside of the normal routine. Physical examination reveals tenderness in the paraspinal and lateral soft tissues often associated with recreating the mechanism of injury. Thoracic and lumbar strain in the school-age child is frequently associated with obesity, deconditioning, positive family history, and poorly supervised and equipped recreational activity. Up to 20% of youths have experienced back pain at some point in their life before the age of 15 years. The backpack is the most common cause of back pain of a benign nature in children, with up to 74% of school backpack–wearers experiencing pain. Back pain is more common with the heavy backpack (>10–20% of body weight), female sex, large body mass index, and single shoulder strap.

Treatment is conservative and includes analgesia, myofascial release, massage, and physical therapy, as tolerated. The natural history of acute back strain in adults is that 50% are better in 1 week, 80% in 1 month, and 90% in 2 months, regardless of therapy. The course of back pain in young athletes is likely similar given the elimination of obvious precipitating influence and/or activities, as discussed previously.

Sacroiliitis manifests as pain over the sacroiliac joints; it is usually chronic but is occasionally associated with a history of trauma. Patients

have a positive result with the **Patrick test**, performed in the supine position by resting the foot of the affected side across the opposite knee ("figure-4" position), stabilizing the contralateral iliac crest, and externally rotating the hip on the affected side (pushing the knee down and lateral). Symptomatic improvement with knee-to-chest maneuvers and subsequent posterior pelvic tilt may be present. A radiograph of the sacroiliac joints is indicated, and if results are positive, exploration for a rheumatologic disease (ankylosing spondylitis [see Chapter 197], juvenile idiopathic arthritis [see Chapter 196], or inflammatory bowel disease [see Chapter 382]) is warranted.

Treatment is with relative rest, NSAIDs, and physical therapy. Ankylosing spondylitis is more likely if the onset of lower back pain is before 40 years of age, if there is morning stiffness demonstrating improvement with activity, a family history is present, there is clear benefit from antiinflammatory medication, and if the pain has a gradual onset having lasted longer than 3 months.

OTHER CAUSES

Non–sports-related causes of low back pain in the young athlete are numerous and include infection (osteomyelitis, diskitis) and neoplasia (see Chapter 720.5). These should be considered in patients with fever, weight loss, other constitutional signs, or lack of response to initial therapy. Osteomyelitis of the lower back or pelvis is often, but not always, associated with fever. Undiagnosed Scheuermann disease needs to be considered with a history of chronic back pain; it is more common in males and younger adolescents and should be distinguished from symptomatic postural roundback and congenital decompensating kyphosis. Atypical Scheuermann disease or thoracolumbar apophysitis can progress and become the pediatric equivalent of an adult compression fracture. Benign tumors of the spine include osteoid osteoma, which presents with intense focal nighttime pain that is not activity related and is almost always relieved by aspirin or NSAIDs. Undiagnosed osteoblastoma, eosinophilic granuloma, aneurysmal bone cyst, and fibrous dysplasia are additional benign tumors not to be excluded. Malignant spinal tumors include Ewing sarcoma (onion skin appearance) and osteogenic sarcoma (sunburst pattern); both are associated with the *Codman triangle*, which is the triangular area of new subperiosteal bone seen on radiographs when a tumor raises the periosteum away from the bone. Metastatic tumors of the spine include neuroblastoma, spinal cord tumors, leukemia, and lymphoma. Wilms tumor can also metastasize to the spine and be associated with hemihypertrophy. Referred pain to the spine always needs to be considered. Conditions that can refer pain include pyelonephritis, renal osteodystrophy, pneumonia, endocarditis, cholecystitis, nephrolithiasis, pancreatitis, megacolon, constipation/ileus, hiatal hernia/reflux, pelvic inflammatory disease, and sickle cell crisis. Undiagnosed pregnancy is a consideration in the age-appropriate female. Psychogenic pain and fibromyalgia can be seen in children. Child abuse can present in the spine, with soft tissue injuries more common than fractures. Posterior rib and spinous process fractures can be seen in up to 30% of abused children.

728.5 Hip and Pelvis Injuries

Gregory L. Landry and Andrew M. Watson

Injuries to the hip and pelvis represent a small percentage of sports injuries, but they are potentially severe and require prompt diagnosis. Hip pathology can manifest as knee pain with normal findings on knee examination.

In children, **transient synovitis** (see Chapter 719.2) is the most common nontraumatic cause of hip pain. It usually manifests with acute onset of a limp, with the child refusing to use the affected leg and painful range of motion on examination. There may be a history of minor trauma or a recent viral infection. This is a self-limiting condition that usually resolves in 48-72 hours.

Legg-Calvé-Perthes disease (avascular necrosis of the femoral head) also presents in childhood with insidious onset of limp and hip pain (see Chapter 719.3).

Until skeletal maturity (Table 728.2), younger athletes are susceptible to apophyseal injuries (e.g., the anterior superior iliac spine). **Apophysitis** develops from overuse or from direct trauma. **Avulsion fractures** occur in adolescents playing sports requiring sudden, explosive bursts of speed (see Fig. 728.2). Large muscles contract and create force greater than the strength of the attachment of the muscle to the apophysis. Biomechanical susceptibility of the pelvis allows separation to occur in the cartilaginous region between the apophysis and the adjoining bone. The most common sites of pelvic avulsion fractures are the anterior superior iliac spine (sartorius and tensor fasciae lata), anterior inferior iliac spine (rectus femoris), lesser femoral trochanter (iliopsoas), ischial tuberosity (hamstrings), and the iliac crest (abdominal muscles). Symptoms include localized pain and swelling with decreased strength and range of motion. Bilateral radiographs are important for comparison to assess for displacement, if any, of the fracture fragment. Significant displacement or the presence of a large fragment may require orthopedic consultation. Initial treatment includes ice, analgesics, rest, and pain-free range of motion exercises. Crutches are usually needed initially for ambulation. Surgery is not typically indicated because most of these fractures—even large or displaced ones—heal well. Direct contact to the bone around the hip and pelvis causes exquisitely tender subperiosteal hematomas called "**hip pointers**." These injuries are more commonly seen around the anterior superior iliac spine and the iliac crest. Limited active range of motion can be identified about the hip, brought on by contracture of locally attached musculature such as hip flexors and hip abductors. Symptomatic care includes rest, ice, analgesia, and protection from re-injury.

Slipped capital femoral epiphysis usually occurs among 11- to 15-year-olds during the time of rapid linear bone growth (see Chapter 719.4) and often presents with complaints of pain in the groin area or, on occasion, referred pain felt at the knee. Bilateral hip radiographs confirm the diagnosis.

A **femoral neck stress fracture** can manifest as vague progressive hip pain in an endurance athlete. Females are at higher risk. This diagnosis should be suspected in the running athlete with vague anterior

Table 728.2 Age of Appearance and Fusion of Apophyses in Hip and Pelvis

APOPHYSIS	APPEARANCE (YR)	FUSION (YR)	RELATED MUSCLE GROUP(S)
Anterior inferior iliac spine	13-15	16-18	Quadriceps
Anterior superior iliac spine	13-15	21-25	Sartorius
Lesser trochanter	11-12	16-17	Iliopsoas
Greater trochanter	2-3	16-17	Gluteal
Ischial tuberosity	13-15	20-25	Hamstrings
Iliac crest	13-15	21-25	Abdominal obliques Latissimus dorsi

From Waite BL, Krabak BJ. Examination and treatment of pediatric injuries of the hip and pelvis. *Phys Med Rehabil Clin N Am.* 2008;19:305–318.

thigh pain without a history of trauma or acute injury. On examination, there may be pain with passive stretch of the hip flexors and pain with hip rotation. If radiographs do not demonstrate a periosteal reaction consistent with a stress fracture, MRI may be indicated to confirm the suspected diagnosis and determine the location of the fracture. Orthopedic consultation is necessary in femoral neck stress fractures because of their predisposition to nonunion and displacement with minor trauma or continued weight-bearing. These fractures carry increased risk of avascular necrosis of the femoral head. Whereas compression (inferomedial) side femoral neck stress fractures can typically be treated conservatively with non–weight-bearing, tension side (superolateral femoral neck) fractures may be at particular risk of progression and often require surgical fixation.

Osteitis pubis is an inflammation at the pubic symphysis that may be caused by excessive side-to-side rocking of the pelvis. It can be seen in an athlete in any running sport and is more common in sports requiring additional use of the adductor muscles such as ice hockey, soccer, and inline skating. Athletes typically present with vague groin pain that may be unilateral or bilateral. On physical examination, there is tenderness over the symphysis and sometimes over the proximal adductors. Adduction strength testing causes discomfort. Radiographic evidence (irregularity, sclerosis, widening of the pubic symphysis with osteolysis) may not be present until symptoms are present for 6-8 weeks; MRI is more sensitive to early changes. Relative rest for 6-12 weeks may be required. Some patients require corticosteroid injection as adjunctive therapy. Ultrasound needle guidance may be used to improve the accuracy of the injection while simultaneously avoiding injury to surrounding structures, such as the bladder, and vascular structures of the genitalia.

Acetabular labrum tears can occur in the hip, similar to glenoid labrum tears in the shoulder. Athletes may have a history of trauma and complain of sharp anterior hip pain associated with a clicking or catching sensation. Clinical diagnosis is often difficult; magnetic resonance arthrography is the gold standard for diagnosis, but MRI may be useful as well.

Snapping hip syndrome is caused by the iliopsoas musculotendinous unit riding over the pectineal eminence of the pelvis, anterior hip capsule, or the iliotibial band (ITB) over the greater trochanter. Lack of flexibility in these muscles results in snapping, as the musculotendinous unit slides over the associated bony prominence. It is most commonly seen in ballet dancers and runners, and it can occur as an acute or, more commonly, overuse injury. Athletes present with either a painful or painless click or snap in the hip, usually located lateral or anterior and deep within the joint. Examination often reproduces the symptoms. Radiographs are not usually needed in the workup. Ultrasound examination can be useful to visualize the anatomic structures in question causing the snapping sensation. Core weakness may be present, leading to excessive movement about the hip girdle contributing to increased sliding of the tight muscle over the boney prominence. Treatment involves analgesia, relative rest, biomechanical assessment, core flexibility, and stretching/strengthening of the involved soft tissue. Patients with concomitant greater trochanteric bursitis may benefit from a corticosteroid injection into the inflamed bursa to improve pain control and facilitate rehabilitation. The athlete may return to activity as tolerated. Common soft tissue injuries around the hip and pelvis include strain and tendinosis of the hip flexors (groin) and hamstrings in addition to quadriceps contusions and greater trochanteric bursitis.

The term **athletic pubalgia** is commonly used to describe a number of different pathologies that may cause lower abdominal or groin pain. Often called a sports hernia, this is a source of confusion as no true hernia exists through the inguinal canal or abdominal wall. The pathophysiology stems from tissue injury to the structures that comprise the pubic aponeurosis, most commonly the tendinous attachment of the abdominal and hip adductor musculature. Like a true hernia, pain may radiate into the anterior thigh, inguinal region, perineum, and/or scrotum. Physical exam may exhibit tenderness over, or adjacent to, the pubic ramus and/or reproduction of pain with resisted abdominal flexion or hip adduction. MRI, CT scan, and bone scan can be helpful in ruling out other diagnoses but usually are negative. Some radiology departments may have MRI protocols specific for athletic pubalgia that provide more detailed imaging of the pathologic area. Patients who continue with symptoms despite conservative care, such as physical therapy, may be candidates for surgical intervention.

Femoroacetabular impingement (FAI) may coexist with athletic pubalgia to produce groin pain. FAI is defined as an abnormal contact between the femoral neck and the acetabulum as a result of excessive bone on the acetabular rim, the femoral neck, or both. X-rays and MRI can be diagnostic. As in athletic pubalgia, a period of rest and rehabilitation should be attempted, and those who fail conservative treatment should be referred to a sports medicine specialist.

Undiagnosed **non–sports-related conditions** need to be considered. Differential diagnoses may include the epiphyseal dysplasias, congenital or developmental hip dysplasia, additional causes of avascular necrosis, including sickle cell disease, Gaucher disease, rheumatoid arthritis, and other collagen disorders and steroid therapy. Inguinal hernia should be recognized in those patients with groin pain exacerbated with coughing/Valsalva maneuver and a palpable mass in the groin. Traumatic hip dislocations are relatively rare in children but should not be overlooked. Leg-length discrepancies (usually >1 cm) can be symptomatic at the hip in an otherwise healthy child. Common tumors in the lower extremities include osteosarcoma along with osteoblastoma, aneurysmal bone cysts, and fibrous dysplasia (more common in the pelvis). Metastatic tumors to the lower extremities include neuroblastoma, lymphoma, and leukemic infiltration with joint arthralgia. Child abuse always needs to be considered in a young patient with musculoskeletal pain.

728.6 Knee Injuries

Gregory L. Landry and Andrew M. Watson

Knee pain is common among adolescents. Acute knee injuries that cause immediate disability and/or effusion are likely to be due to fracture, patellar dislocation, anterior or posterior cruciate ligament injury, or meniscal tear. The mechanism of injury is usually a weight-bearing event. Physeal injuries tend to predominate in younger patients, whereas more skeletally mature adolescents tend to sustain ligamentous injuries. If the knee swells more immediately (within several hours of injury), the swelling is likely caused by a hemarthrosis and more severe injury. The injury most likely to occur with a hemarthrosis is an **anterior cruciate ligament (ACL)** injury. This injury (rare in children younger than 12 years) is usually caused by direct contact, landing off-balance from a jump, quickly changing direction while running, or hyperextension. Instability is often present but may be hard to detect in the presence of significant swelling. Females are more than twice as likely as males to disrupt their ACL, often during sports such as basketball or soccer. Occasionally, these injuries are associated with an avulsion injury of the anterior tibial spine. Most athletes with significant ACL injury need orthopedic consultation with consideration of ACL reconstruction. Chronic ACL insufficiency may increase the risk of meniscal injury, early osteoarthritis, and further joint dysfunction. Physeal-sparing reconstructions with minimal risk of growth arrest or angular deformity have been reported with success in children younger than 12 years and adolescents.

Posterior cruciate ligament (PCL) injury occurs from a direct blow to the region of the proximal tibia when the knee is flexed, such as might occur with a dashboard injury or a fall to the knees in volleyball. PCL injuries are rare and are usually treated nonsurgically.

Medial collateral ligament injuries typically result from a valgus blow to the outside of the knee. Isolated **lateral collateral ligament** injuries are uncommon and result from significant varus knee stress. Because they are extra-articular, lateral collateral and medial collateral ligament injuries should not produce a significant knee effusion and

are generally less disabling. Isolated medial and lateral collateral injuries are generally managed nonsurgically with conservative care and appropriate rehabilitation.

Meniscal tears generally occur by the same mechanisms as ACL injuries. They are often associated with less hemarthrosis, significant joint line pain, and increased pain with full knee flexion. MRI will usually yield the diagnosis; conservative care, including PRICE principles, is therapeutic for smaller injuries. Orthopedic consultation is indicated for meniscus tears in children and adolescents, and surgery may be indicated for larger tears, displaced tears, or those not healing with conservative care over 6-8 weeks. An isolated meniscal tear in a child younger than 10 years of age is unusual. The surgical choice is often repair of the meniscus rather than resection because of the increased potential in children for cartilaginous healing. Discoid meniscus (an anatomic variant covering lateral tibial plateau) should be considered in children younger than 12 years of age and those with a suspected meniscus injury without a history of notable trauma.

Patellar dislocation occurs most often as a noncontact injury when the quadriceps muscles forcefully contract to extend the knee while the tibia is externally rotated in relation to the femur. Patellar dislocation is the second most common cause of hemarthrosis. The patella is almost always dislocated laterally, and this motion tears the medial patellar retinaculum, causing bleeding in the joint. Recurrent episodes of patellar instability are associated with less swelling. Patellar dislocations are often associated with genu valgum, external tibial torsion, and general ligamentous hyperlaxity. Exercises to strengthen the quadriceps, particularly the vastus medialis, and the use of patella-tracking braces may be helpful. Recurrent instability can require surgical intervention. Surgical stabilization of the medial patellar tissues and lateral retinacular release can be helpful in more difficult cases.

INITIAL TREATMENT OF ACUTE KNEE INJURIES

The physician should inspect for an effusion and obvious deformities; if any deformity is present, the physician should assess neurovascular status and transfer the patient for emergency care as indicated. If no gross deformities are present and neurovascular integrity is intact, initial maneuvers include full passive extension and gentle valgus and varus stress to the knee while in extension. *Any laxity to varus or valgus stress in full extension implies a multiligamentous injury*. Comparison to the noninjured knee is always helpful for assessing degrees of laxity and range of motion. The patient's ability to contract the quadriceps should be noted. Pain occurring with quadriceps contraction, or the inability to contract the quadriceps muscle, implies an injury to the extensor mechanism. Tenderness over the medial patella, medial retinaculum, or above the adductor tubercle is associated with a patellar dislocation (usually lateral). Point tenderness is consistent with fracture or injury to the underlying structure. Meniscal tears usually manifest as tenderness along the joint line, accentuated with flexion of the knee beyond 90 degrees. Pain or limitation in either flexion or extension while rotating the tibia implies a meniscal injury. Ligament injury is manifested as pain or laxity with the appropriate maneuver (Fig. 728.12).

If a patient cannot weight-bear without pain, or has clinical signs of instability, significant swelling, or any other major concern, the knee should be immobilized and crutches provided. The Ottawa knee rule, which has been validated for children over 5 years of age, helps determine which patients with mild knee injuries require radiographs. X-rays should be obtained if *any* of the following apply: 55 years or older, point tenderness of fibular head, tenderness of the patella, inability to flex knee to 90 degrees, or inability to bear weight (inability to take four steps) both immediately after the injury and in the emergency department.

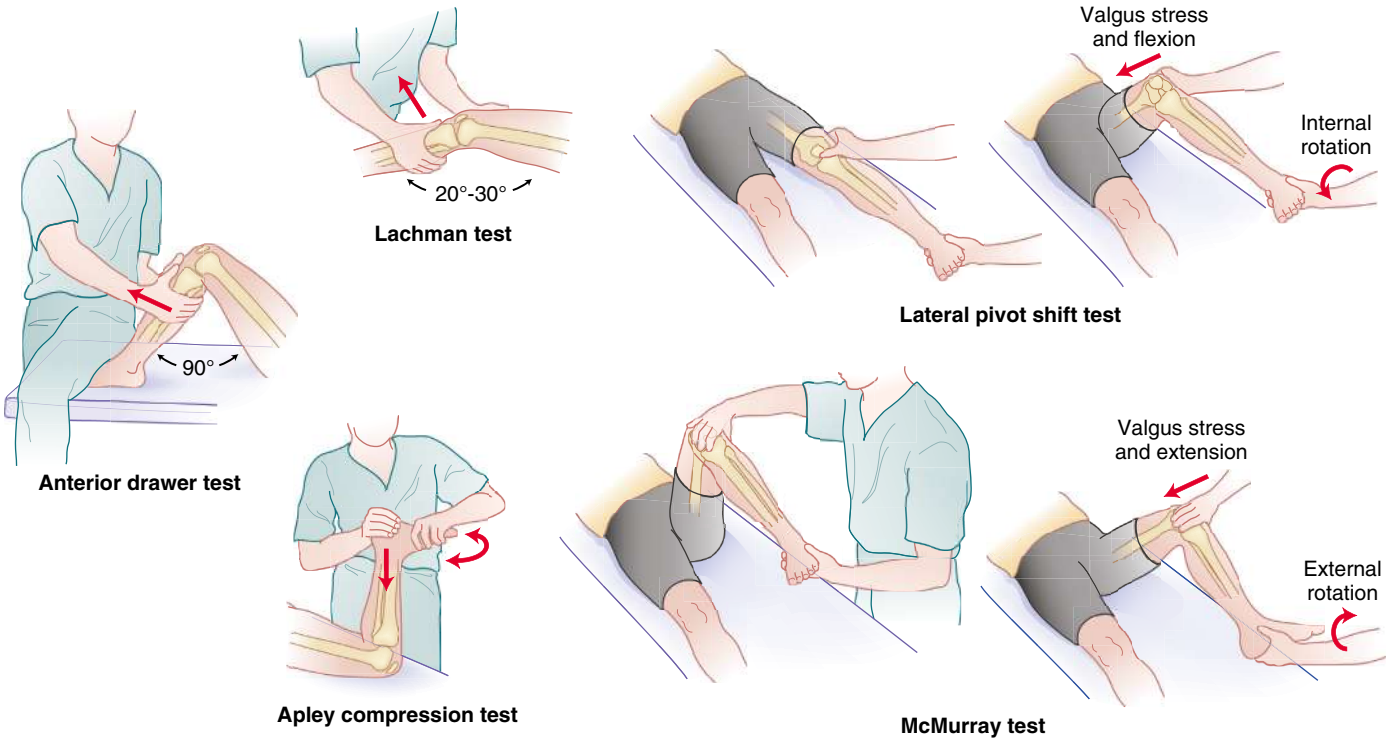

Fig. 728.12 Examination maneuvers include the Lachman, anterior drawer, lateral pivot shift, Apley compression, and McMurray tests. The Lachman test, performed to detect anterior cruciate ligament (ACL) injuries, is conducted with the patient supine and the knee flexed 20-30 degrees. The anterior drawer test detects ACL injuries and is performed with the patient supine and the knee in 90 degrees of flexion. The lateral pivot shift test is performed with the patient supine, the hip flexed 45 degrees, and the knee in full extension. Internal rotation is applied to the tibia while the knee is flexed to 40 degrees under a valgus stress (pushing the outside of the knee medially). The Apley compression test, used to assess meniscal integrity, is performed with the patient prone and the examiner's knee over the patient's posterior thigh. The tibia is externally rotated while a downward compressive force is applied over the tibia. The McMurray test, used to assess meniscal integrity, is performed with the patient supine and the examiner standing on the side of the affected knee.

If the patella is dislocated, reduction may be achieved with gentle active assistive knee extension. Straight-leg immobilizers offer no structural support and are only used for comfort and reminding the patient to be careful with any weight-bearing. A derotational hinge brace may be indicated for stabilization, such as after an injury involving both the ACL and medial collateral ligament. The leg should be elevated, and an elastic wrap can be applied for compression (PRICE principles).

CHRONIC INJURIES

Patellofemoral Stress Syndrome

Patellofemoral stress syndrome (PFSS), or runner's knee, is the most common cause of anterior knee pain. PFSS is also known as **patellofemoral pain syndrome** or **patellofemoral dysfunction** (see Chapter 718.5). It is a diagnosis of exclusion used to describe anterior knee pain that has no other identifiable pathology. Chondromalacia may be seen in association with softening of the articular cartilage underneath the patellar surface. Pain is usually difficult to localize. Patients indicate a diffuse area over the anterior knee as the source, or they might feel as if the pain is originating from underneath the patella. Bilateral pain is common, and pain is often worse going up stairs, after sitting for prolonged periods, or after squatting or running. There should be a negative history for significant swelling or true mechanical symptoms, which would indicate a more serious injury. History of change in activity is common, such as altered training surface or terrain, increased training regimen, or performance of new tasks.

Examination should include evaluation of stance and gait for lower limb alignment, musculature, and midfoot hyperpronation. Flexibility of the hamstrings, iliotibial band, and gastrocnemius should be assessed, because stress is increased across the patellofemoral joint when these structures are excessively tight. Hip range of motion should be assessed to rule out hip pathology. Medial patellar tenderness or pain with compression of the patellofemoral joint confirms the diagnosis in the absence of a significant effusion and other positive findings. PFSS is a clinical diagnosis usually managed without imaging.

Treatment focuses on assessing and improving flexibility, strength, and gait abnormalities. In the presence of midfoot hyperpronation (ankle valgus), new shoes or the use of arch supports can improve patellofemoral mechanics and alleviate pain. Ice and analgesics can be used to help control pain. Reduced overall activity or training is important initially in rehabilitation. Short arc quadriceps strengthening exercises can be helpful: active knee extension with or without resistance between 0 and 30 degrees of knee flexion. Hip and core strengthening exercises are also beneficial. Therapeutic taping techniques to improve patella tracking within the trochlear groove can be helpful with the assistance of a sports physical therapist. The use of a patellar stabilizing brace with a lateral buttress to maintain patellar alignment may be of benefit in more chronic cases as well.

Osgood-Schlatter Disease

Osgood-Schlatter disease is a traction apophysitis occurring at the insertion of the patellar tendon on the tibial tuberosity (see Chapter 718.4). Because it is also related to overuse of the extensor mechanism, Osgood-Schlatter disease is treated like PFSS. A protective pad to protect the tibial tubercle from direct trauma can be used. Therapeutic taping of the tibial tubercle may provide comfort, along with well-fitted knee sleeves and/or straps. NSAIDs are often prescribed for comfort. Stretching focused on the quadriceps and hamstrings is recommended, and PRICE principles apply. Patients and parents should be made aware that resolution is usually slow, often requiring 12-18 months. Complications are rare and can include growth arrest with recurvatum deformity and rupture or avulsion of the patellar tendon/tibial tubercle.

Other Chronic Injuries

Sinding-Larsen-Johansson disease is a traction apophysitis occurring at the inferior pole of the patella. It occurs most often in volleyball and basketball athletes. Treatment is similar to PFSS and Osgood-Schlatter disease.

Patellar tendinosis, or jumper's knee, is caused by repetitive microtrauma of the patellar tendon, usually at the inferior pole of the patella. In approximately 10% of cases, the quadriceps tendon above the patella is affected. It is associated with jumping sports but may occur in runners as well. Treatment is similar to that for PFSS, with an emphasis on eccentric strengthening in physical therapy. Relative rest is more important in patellar tendinosis because chronic pain can be associated with irreversible changes in the tendon. In these cases, recalcitrant to rest, activity modifications, and physical therapy, there may be a role of biologic injections such as platelet-rich plasma to the pathologic area. Surgical techniques also have a good success rate if needed.

Iliotibial band (ITB) friction syndrome is the most common cause of chronic lateral knee pain. Generally, it is not associated with swelling or instability. It is from friction of the ITB along the lateral knee, resulting in bursitis. Tenderness is elicited along the ITB as it courses over the lateral femoral condyle or at its insertion at Gerdy's tubercle along the lateral tibial plateau. Tightness of the ITB is also noted using the Ober test. To perform an Ober test, the athlete lies on one side, the inferior hip is flexed, and the superior hip is extended with the knee flexed. The examiner holds the superior foot in midair, and if the superior knee drops inferiorly toward the exam table, it implies a flexible ITB and a negative Ober test. If the knee and leg stay in midair, the Ober test is positive, suggesting a tight ITB. Treatment principles follow those for PFSS, except the emphasis is on improving flexibility of the ITB.

Other soft tissue injuries to be considered include prepatellar and pes anserine **bursitis**, plical syndromes, and Hoffa syndrome. The pes anserine bursa lies just under the conjoined tendon of the sartorius, gracilis, and semitendinosus muscles as it attaches medially to the proximal tibia. In **Hoffa syndrome**, the fat pad beneath the patella and posterior to the patella ligament becomes pinched with anterior pain on knee extension. These conditions are generally more common in adolescents, those with genu recurvatum, and long-distance runners. Undiagnosed non–sports-related conditions always need to be considered in the context of any child with a painful knee, particularly those younger than 12 years old. These include conditions such as OCD (see Chapter 718.3), which is most common on the lateral aspect of the medial femoral condyle. Inflammatory and infectious arthritis, Baker cyst (see Chapter 718.2), and hip pain referred to the knee are additional considerations. Tumors more common to the knee joint include osteogenic sarcoma (distal femoral and proximal tibial), Langerhans cell histiocytosis in the diaphysis, and eosinophilic granuloma in the epiphysis of long bones. Metastatic tumors to the lower extremities include neuroblastoma and lymphoma. As with any musculoskeletal injury in a child not responding to conservative care, more in-depth diagnostic pursuit for alternative pathology is mandatory.

728.7 Lower Leg Exertional Pain: Shin Splints, Stress Fractures, and Chronic Compartment Syndrome

Gregory L. Landry and Andrew M. Watson

Stress injury to the bones of the lower leg occurs on a continuum from mild injury (shin splints) to stress fracture. All occur by an overuse mechanism.

Medial tibial stress syndrome, or shin splints, manifests with pain along the medial tibia and is the most common overuse injury of the lower leg. The pain initially appears toward the end of exercise, and if exercise continues without rehabilitation, the pain worsens and occurs earlier in the exercise period. There is diffuse tenderness over the lower third to half of the distal medial tibia. Any focal tenderness of the tibia is suspicious for a **tibial stress fracture**. A stress fracture tends to be associated with more severe pain and is painful during the entire workout. Shin splints and stress fractures represent a continuum of stress injury to the tibia and are thought to be related to traction of the soleus

on the tibia. Eccentric contraction of the medial aspect of the soleus is required to control pronation from initial contact to mid-stance with running. This contraction increases the stress of the fascial origin of the soleus, possibly through Sharpey fibers, causing disruption to the tibial periosteum and fibrocartilaginous attachments.

The diagnosis can be made by history and physical examination. Findings on plain radiographs of the tibia are typically unremarkable with shin splints, as well as with tibial stress fractures within the first 2 weeks of injury. Beyond this time frame, radiographs may demonstrate periosteal reaction if a stress fracture is present but may still be unremarkable. Sensitivity of plain radiographs can be increased by obtaining four views of the tibia: AP, lateral, and both oblique views. MRI is the most sensitive test to diagnose stress injuries as it can reveal both a stress fracture and stress reaction in the affected bone. Stress reactions may include bone marrow edema or periosteal reaction without a fracture line but represent an impending progression to a fracture if the offending stress is not reduced or eliminated.

The treatment of shin splints involves relative rest, correcting training errors, and addressing muscle imbalances and abnormal mechanical alignment. Orthotics and/or new shoes may be useful in patients who hyperpronate. Fitness can be maintained with non–weight-bearing activities, such as swimming, cycling, and water jogging. With shin splints, after 7-10 days, patients can usually start on the walk-jog program. If pain worsens, 2-3 pain-free days are required before resuming the walk-jog program. Ice should be used daily, and an analgesic should be used for pain control. Stretching the plantar flexors and hamstrings and strengthening the ankle dorsiflexors may be useful. Therapeutic taping and wrapping techniques to support the soft tissue attachments have been useful in some when directed by a skilled sports therapist. Being pain free for 7-10 days is recommended before exercises are commenced. Individuals with pain at rest and who are not responsive to treatment require continued evaluation for stress fracture. Treatment of tibial stress fractures is similar but requires more prolonged avoidance of running and jumping, usually 6-8 weeks.

Chronic compartment syndrome occurs in an athlete in a running sport, usually during a period of heavy training. It is caused by muscle hypertrophy and increased intracompartmental pressure with exercise. There is typically a pain-free period of about 10 minutes at the beginning of a workout before onset of constant throbbing pain that is difficult to localize. It lasts for minutes to hours after exercise and is relieved by ice and elevation. Classically, there is numbness of the foot associated with high pressure within the corresponding muscle compartment. The most common compartment affected is the anterolateral compartment with compression of the fibular nerve followed by the deep posterior compartment. The physical examination in the office is often normal, but weakness of the extensor hallucis longus (anterolateral compartment) and decreased sensation between the first and second toe may be present. Symptoms may be elicited through exercise in or near the examination room (jogging in place, stair climbing, etc.), and prompt evaluation after symptom onset may aid in diagnosis. Radiologic evaluation is typically negative and used primarily to rule out other conditions. Compartment pressure measurements are the test of choice. Treatment involves reduction of activity, antiinflammatory medication, orthotics (hyperpronation), heel cord stretching, light strengthening of distal musculature, optimal footwear, and cross-training (swimming, cycling, and water jogging). Cryotherapy and superficial heat can also be of help. Persistent systems, despite conservative care, may require fasciotomy.

Popliteal artery entrapment syndrome occurs when the popliteal artery is compressed by the medial head of the gastrocnemius muscle and the fascial band of the soleus with activity; the entrapment may be anatomic or functional (from hypertrophy). Patients may have claudication and paresthesia (involvement of the tibial nerve), and calf swelling (primary venous obstruction). Most patients have exertional leg pain with no symptoms at rest; pain may be unilateral or bilateral depending on the type of entrapment syndrome. The tibial or dorsalis pedis pulse may be reduced or absent with passive ankle dorsiflexion with the knee extended. Doppler exam in the neutral and flexion position confirms the diagnosis in most patients; magnetic resonance angiography or CT angiography may be needed if the Doppler exam is inconclusive. Surgical correction is the treatment of choice and involves medical gastrocnemius fasciotomy, take down of the soleus tibial attachments, and resection of the fibula soleus band. If the artery is injured, it requires bypass surgery.

728.8 Ankle Injuries

Gregory L. Landry and Andrew M. Watson

Ankle injuries are the most common acute athletic injury. Approximately 85% of ankle injuries are ankle sprains, and 85% of these are inversion injuries (foot planted with the lateral fibula moving toward the ground), 5% are eversion injuries (foot planted with the medial malleolus moving toward the ground), and 10% are combined.

EXAMINATION AND INJURY GRADING SCALE

In obvious cases of fracture or dislocation, evaluating neurovascular status with as little movement as possible is the initial priority. If no deformity is obvious, the next step is inspection for edema, ecchymosis, and anatomic variants. Key sites to palpate for tenderness are the entire length of the fibula; the medial malleolus; the base of the fifth metatarsal; the anterior, medial, and lateral joint lines; the navicular; and the Achilles tendon complex. Assessment of active range of motion (patient alone) in dorsiflexion, plantar flexion, inversion, and eversion along with gentle resisted range of motion can be helpful.

Provocative testing attempts to evaluate the integrity of the ligaments. In a patient with a markedly swollen, painful ankle, provocative testing is difficult because of muscle spasm and involuntary guarding. It is more useful on the field before much bleeding and edema have occurred. The anterior drawer test assesses for anterior translation of the talus and competence of the anterior talofibular ligament. The inversion stress test examines the competence of the anterior talofibular and calcaneofibular ligaments (Fig. 728.13). In the acute setting, the integrity of the tibiofibular ligaments and syndesmosis can be examined by the syndesmosis squeeze test. Pain at the ankle joint with squeezing the superior aspect of the lower leg implies injury to the interosseous membrane and syndesmosis between the tibia and fibula—suspicious for a high ankle sprain or more severe injury. Athletes with this injury cannot bear any weight and have severe pain with dorsiflexion and external rotation of the foot. Occasionally, the peroneal tendon dislocates from the fibular groove simultaneously with an ankle sprain. To assess for peroneal tendon instability, the examiner applies pressure from behind the peroneal tendon with resisted eversion and plantar

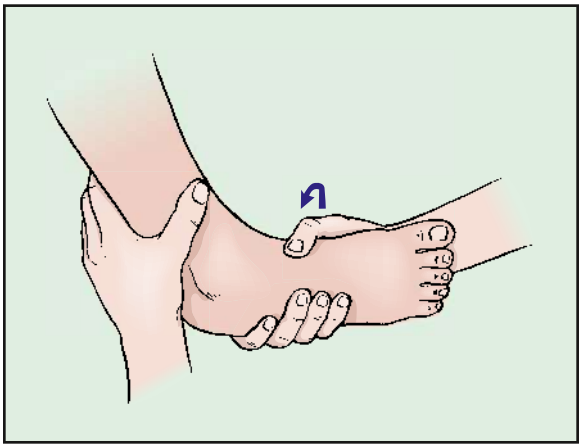

Fig. 728.13 Inversion stress tilt test for ankle instability. *(From Hergenroeder AC. Diagnosis and treatment of ankle sprains: a review. Am J Dis Child. 1990;144:809–814.)*

flexion, and the tendon pops anteriorly. If either a significant syndesmotic injury or an acute peroneal dislocation is suspected, orthopedic consultation should be sought.

RADIOGRAPHS

AP, lateral, and mortise views of the ankle are obtained when patients have pain in the area of the malleoli, are unable to bear weight, or have focal bone tenderness over the distal tibia or fibula. The **Ottawa ankle rules** help define who requires radiographs (Fig. 728.14). A foot series (AP, lateral, and oblique views) should be obtained when patients have pain in the area of the midfoot or bone tenderness over the navicular or fifth metatarsal, and/or an inability to bear weight. It is important to differentiate an **avulsion fracture** of the fifth metatarsal base (dancer's fracture) from the more distal **Jones fracture** of the proximal fifth metatarsal (located about 2 cm distal to the proximal end). The former is treated like an ankle sprain; the latter fracture has an increased risk of nonunion and requires orthopedic consultation. Injury to the deltoid ligament of the medial ankle is rare but should raise the question of proximal fibular fracture. In this circumstance more proximal tibial imaging may be necessary. A **talar dome fracture** may present as an ankle sprain that does not improve. Radiographs on initial presentation can have subtle abnormalities. Any suspicion on the initial radiographs of a talar dome fracture warrants orthopedic consultation and further imaging. In the early adolescent, always look carefully at the tibial epiphysis. Nondisplaced Salter III fractures can be subtle and need to be recognized early and referred to an orthopedic surgeon promptly. Diagnostic ultrasound, when available at the point of care, can efficiently provide prognostic information by direct visualization of injured ligaments. Additionally, dynamic stress can be applied during ligament visualization to assess for gaping of the joint, which is indicative of more complete tearing with an increased duration of expected recovery.

INITIAL TREATMENT OF ANKLE SPRAINS

Ankle sprains need to be treated with PRICE principles. This should be followed for the first 48-72 hours after the injury to minimize bleeding and edema. For an ankle injury, this may consist of crutches and an elastic wrap, although other compression devices, such as an air stirrup splint, are also effective. This allows early weight-bearing with protection and can be removed for rehabilitation. It is important to start a rehabilitation program as soon as possible.

Rehabilitation

Rehabilitation should begin the day of injury; for patients who have pain with movement, isometric strengthening can be started. Early-phase intervention includes restoration of functional range of motion, strengthening with emphasis on peroneal musculature, and early sensory proprioceptive training. Later intervention includes higher-level balance activities, advanced proprioception exercises, and endurance training. When determining when an athlete is ready for running, there must be full range of motion and nearly full strength compared to the uninjured side. While standing on the uninjured side only, the athlete is instructed to hop 8-10 times, if possible. When this can be achieved without pain on the injured side, the athlete can begin to run, starting out with jogging and gradually progressing in speed. The athlete must stop if there is significant pain or limp. Finally, before returning to sport, the athlete must be able to sprint and change directions off the injured ankle comfortably. Performing some sport-related tasks is also helpful in determining readiness for return to play.

Recurrent ankle injuries are more likely in patients who have not undergone complete rehabilitation. Ankle sprains are less likely in players wearing high-top shoes or lace-up ankle braces. Proper taping of the ankle with adhesive tape can provide functional support but loosens with use and is often unavailable. Surgery is a consideration for chronic mechanical instability with lateral complex ligamentous laxity in the failure of more conservative care. Salter-Harris grade I distal fibular fractures need careful consideration, particularly in the child younger than 12 years of age. The physeal plates are generally the weakest link in the musculoskeletal chain and tend to slide or pull apart before the surrounding soft tissue and/or ligaments tear in this younger population.

OTHER CAUSES OF ANKLE PAIN

Toddler's fracture needs to be considered in young children with ankle pain, especially in those younger than 6 years (see Chapter 724.4). The proposed mechanism involves sheer stress with lack of displacement because of the periosteum that is relatively strong compared to the elastic bone in younger children. Initial radiographs may be inconspicuous (a faint spiral oblique line) or even normal. The condition can be mistaken for osteomyelitis, transient synovitis, or even child abuse. Toddler's fracture usually occurs in the lower third of the tibia, whereas nonaccidental injury typically affects the upper two-thirds or midshaft

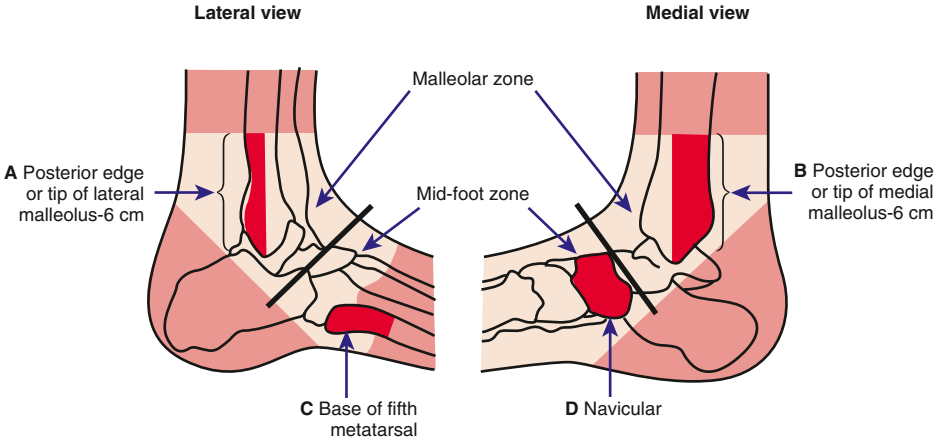

Fig. 728.14 Ottawa ankle rules. *(From Bachmann LM, Kolb E, Koller MT, et al. Accuracy of Ottawa ankle rules to exclude fractures of the ankle and mid-foot; systematic review. BMJ. 2003;326:417–419.)*

of the tibia. Other less common conditions that cannot be excluded include os fibulare, a congenital unfused secondary ossification center of the distal fibula. This can be seen in younger patients with recurrent ankle sprains, particularly as their body weight and activity increase during the early academic years. Undiagnosed tarsal coalitions can also be seen in the presence of ankle sprains in younger children (most commonly talocalcaneal and calcaneal navicular). Muscular strains and/or tendinoses are more prevalent in the older child and adolescent, and include peroneal, posterior tibialis, and gastrocnemius/Achilles types. Tarsal tunnel syndrome (entrapment of the posterior tibial nerve) is more prevalent in the adolescent/younger adult and is commonly associated with medial ankle pain and burning or tingling into the sole of the foot.

728.9 Foot Injuries

Gregory L. Landry and Andrew M. Watson

Metatarsal stress fractures can occur in any running athlete. The history is often one of insidious pain with activity that is getting worse. Examination reveals point tenderness over the mid-shaft of the metatarsal, most commonly the second or third metatarsal. Radiographs might not show the periosteal reaction before pain has been present for 2 weeks or more. Treatment is relative rest for 6-8 weeks. Shoes with good arch supports reduce stress to the metatarsals.

Vague dorsal foot pain in an athlete in a running sport can represent a **navicular stress fracture**. Unlike other stress fractures, it might not localize well on examination. If there is any tenderness around the navicular, a stress fracture should be suspected. This stress fracture can take many weeks to show up on plain radiographs, so MRI should be done to confirm the diagnosis. Because this fracture is at high risk of nonunion, immobilization and non–weight-bearing for 8-12 weeks is the usual treatment. A CT scan should be obtained to document full healing after the period of immobilization.

Sever disease (calcaneal apophysitis) occurs at the insertion of the Achilles tendon on the calcaneus and manifests as activity-related pain (see Fig. 728.3). It is more common in males, is often bilateral, and usually occurs between ages 8 and 13 years. Tenderness is elicited at the insertion of the Achilles tendon into the calcaneus, especially with squeezing the heel (positive squeeze test). Sever disease is associated with tight Achilles tendons and mid-foot hyperpronation that puts more stress on the plantar flexors of the foot. Treatment includes relative rest, ice, massage, stretching, and strengthening the Achilles tendon. Correcting the mid-foot hyperpronation with orthotics, arch supports, or stabilizing shoe wear is important in most athletes with Sever disease. If the foot is neutral or there is mild hyperpronation, cushioned heel lifts can be helpful to unload the Achilles tendon and its insertion. With optimal management, symptoms frequently improve in 4-8 weeks. Generally, if there is no limp during the athletic activity, young athletes with Sever disease should be allowed to play.

Plantar fasciitis is an overuse injury resulting in degeneration of the plantar aponeurosis. Rare in prepubertal children, this diagnosis is more likely seen in the adolescent or young adult. Athletes report heel pain with activity that is worse with the first steps of the day or after several hours of non–weight-bearing. Tenderness is elicited on the medial calcaneal tuberosity. Relative rest from weight-bearing activity is helpful. Athletes get plantar fasciitis when shoes are worn with inadequate arch supports. New shoes or use of semirigid arch supports often lessen the pain. Stretching the calves and plantar fascia helps, assisted at times with therapeutic ultrasound treatment. Some patients benefit from night splints even though they can make sleep difficult. As long as there is no limping with athletic activity, the athlete may continue participation. Complete recovery is usually seen at 6 months. Corticosteroid injection, extracorporeal shock-wave therapy, or injections of platelet-rich plasma can be considered in those cases recalcitrant to conservative treatments.

Calcaneal stress fracture is seen in the older adolescent or young adult involved in a running sport. There is heel pain with any weight-bearing activity. The physical examination reveals pain with squeezing the calcaneus. Sclerosis can show up on the AP and lateral radiographs after 2-3 weeks of pain. MRI may need to be performed to confirm the diagnosis in some cases. The calcaneus is an uncommon location for a stress fracture and is often associated with osteopenia. Treatment is rest from running and other weight-bearing activity for at least 8 weeks. Immobilization is rarely necessary.

Pes planus, or "flat feet," may be termed "flexible" or "rigid." Flexible pes planus is usually asymptomatic and is the most common type found in children (see Chapter 715.5). Foot orthotics may be helpful for older children with foot pain or associated muscle cramping. Rigid pes planus is a congenital deformity associated with other anomalies in 50% of cases. It is caused by failure of the tarsal bones to separate, leaving a bony cartilaginous or fibrous bridge or coalition between two or more tarsal bones (see Chapter 715.6). Talocalcaneal coalitions are more symptomatic between 12 and 16 years of age, whereas calcaneonavicular coalitions are more symptomatic between 8 and 12 years of age. Symptoms are insidious with occasional acute arch, ankle, and mid-foot pain, which is at times brought on with sports-related activities. The hindfoot often does not align in its normal varus position on tiptoe maneuvers. Patients are predisposed to ankle sprains secondary to limited subtalar motion, and stress to the subtalar and transverse tarsal joints frequently causes pain. CT scans are diagnostic, and initial treatment is conservative with short leg casting and/or molded orthoses and rest. In the case of failure of conservative care, surgical intervention is usually necessary. Rigid cavus feet can also be associated with metatarsalgia, clawing, and intrinsic muscle atrophy, which are all possible in the young athlete (see Chapter 715.7). With a cavus foot, undiagnosed neurologic conditions, such a Charcot-Marie-Tooth disease, spinal dysraphism, Friedrich ataxia, or spinal tumor, need to be considered. Custom-molded orthotics may be helpful, and family history can be critical. Symptomatic, accessory navicular bones and sesamoiditis can be considered when these areas are painful and do not have evidence of fracture or prior trauma. These conditions are more common in the adolescent or younger adult and can be exacerbated with sporting activities.

Other conditions causing foot pain include **Lisfranc sprain** and/or dislocation, which is more common in football linemen or other athletes requiring heavy loading on the mid-foot and forefoot joints, and gymnasts using the balance beam. The Lisfranc joint is the tarsal metatarsal articulation of the three cuneiform bones and the cuboid with the five proximal metatarsals. Turf toe can be seen, particularly in the older child and/or adolescent running on artificial or synthetic surfaces. It results from hyperextension through the first metatarsal phalangeal joint, spraining the ligaments surrounding the joint often in a football and/or soccer activity.

Iselin apophysitis is an apophysitis that occurs at the tuberosity of the fifth metatarsal. The apophysis at this site appears between the ages of 9 and 14 years and is located within the insertion of the peroneus brevis tendon. This condition can be a predisposing factor to dancer's fracture (see Chapter 728.8). **Freiberg disease**, which involves the collapse of the articular service and subchondral bone, usually of the second metatarsal, and **Kohler disease**, which involves irregular ossification of the tarsal navicular joint with localized pain and increased density, should always be considered in the evaluation **osteochondroses of the foot** (see Chapter 715.8). Freiberg disease is more common in girls between the ages of 12 and 15 years, whereas Kohler disease occurs in younger individuals, age 2-9 years, and is frequently reversible with conservative care, including orthoses and casting.

Chapter 729

Sports-Related Traumatic Brain Injury (Concussion)

Alex M. Taylor, William P. Meehan III, and Mark R. Proctor

Concussion is a form of **traumatic brain injury** (TBI) caused by sudden acceleration, deceleration, or rotational forces to the brain, which can occur with a blow to the head, neck, face, or body. The resulting pathophysiologic state is associated with a constellation of signs and symptoms that, for **sport-related concussions (SRCs)**, typically self-resolve within 7-10 days. A minority of children can experience **persistent postconcussion symptoms** (PPCS) that extend beyond 28 days and limit functional ability, cause social isolation, reduce school attendance and performance, and can lead to anxiety, mood alteration, and lower quality of life. Accurate diagnosis and appropriate management of concussion is needed to safely return children to school and sports and to avoid the potential for worse outcomes.

DEFINITION/TERMINOLOGY

The spectrum of TBI ranges from mild to severe. Classification is typically determined by score on the Glasgow Coma Scale (see Chapter 79), with severe = ≤8, moderate = 9-12, and mild = 13-15. Although concussion and **mild TBI (mTBI)** are sometimes used interchangeably, concussion may be best understood as the *clinical syndrome* that is associated with mTBI. There are several agreed on features:

- Concussion may be caused by a direct blow to the head, face, neck, or elsewhere on the body with an "impulsive" force transmitted to the head.
- Concussion typically results in the rapid onset of short-lived impairment of neurologic function that resolves spontaneously. However, in some cases, signs and symptoms may evolve over minutes to hours.
- Concussion may result in neuropathologic changes, but the acute clinical signs and symptoms largely reflect a *functional* disturbance rather than a structural injury and, as such, no abnormality is seen on standard structural neuroimaging studies.
- Concussion results in a range of clinical signs and symptoms that may or may not involve loss of consciousness (Fig. 729.1). Resolution of the clinical and cognitive features typically follows a sequential course. However, in some cases, symptoms may be prolonged.

To be defined as a concussion, the clinical signs and symptoms cannot be explained by drug, alcohol, or medication use, other injuries (such as cervical injuries, peripheral vestibular dysfunction), or other comorbidities (e.g., psychologic factors or coexisting medical conditions).

EPIDEMIOLOGOY

According to the Centers for Disease Control and Prevention (CDC), as many as 3.8 million sport-related TBIs may occur in the United States annually with 70–90% of these injuries classified as concussion. One study suggested that current surveillance systems may capture only one out of every nine concussions.

Approximately 20% of middle and high school children report a lifetime prevalence of concussion. Sports participation is the most common mechanism of injury. An estimated 1.1-1.9 million recreational and sports-related concussions occur each year in children 18 years or younger. In gender comparable sports, female athletes report higher rates of concussion than males, and both groups are more likely to suffer a concussion in competition than at practice. Among males, the incidence of concussion is highest in collision (contact) sports, including rugby, American football, ice hockey, lacrosse, basketball, soccer, and wrestling. Among females, the incidence of concussion is highest in soccer, lacrosse, and field hockey. Other sports and recreational activities in which concussions frequently occur include bicycling, skateboarding, skiing, and snowboarding. Younger children may have playground-associated concussions.

PATHOPHYSIOLOGY

The constellation of symptoms associated with concussion are not caused by observable structural injury or hemorrhage; clinical imaging studies (MRI/CT) typically are normal. However, there is a proposed cascade of events that lead to the clinical syndrome. A sudden acceleration, deceleration, or rotation of the brain is thought to result in parenchymal shear stress and strain that disrupts neuronal function in a cascade of ionic and metabolic fluctuations. Affected neurons experience massive depolarization and then require additional adenosine triphosphate (ATP) to restore cellular homeostasis. Glucose levels dramatically increase to fuel ATP production, which ultimately causes lactic acid accumulation. At the same time this process occurs, there is a decrease in cerebral blood flow, which may persist for several weeks. Consequently, less glucose is available when it is most needed to fuel ATP for ionic recovery. The signs and symptoms of concussion are thought to reflect the energy crisis or mismatch between the demand and availability of fuel in the brain after trauma.

SIGNS AND SYMPTOMS

Signs and symptoms of concussion can be classified into five categories, including somatic, vestibular, cognitive, emotional, and sleep related (Table 729.1). Acutely, headache is the most commonly reported symptom, followed by dizziness, difficulty concentrating, and confusion. Sleep disturbance, anxiety, and mood-related symptoms are more likely to occur several weeks post-injury. Brief loss of consciousness occurs in less than 5% of SRCs and is not associated with injury severity or time to recover. The most reliable predictor of recovery is initial symptom burden; children who experience greater symptom load and severity are at increased risk of PPCS. However, several noninjury–related factors can also affect recovery, including female sex, history of migraines, history of prior concussion, poorer preinjury child adjustment, family dysfunction, neurodevelopmental disorder (e.g., learning disability, attention-deficit/hyperactivity disorder [ADHD]), and psychiatric illness (e.g., anxiety, depression).

Although concussion typically results in an immediate onset of short-lived neurologic dysfunction that resolves spontaneously, signs and symptoms may develop over several minutes to hours. The diagnosis can be challenging and further complicated by the presence of concussion-like symptoms in noninjured athletes. Children with preexisting neurodevelopmental disorders, mental health concerns, history of prior concussion, or headaches/migraines may endorse concussion-like symptoms in the absence of injury. A reasonable mechanism of injury needs to be identified as well as a measurable change from baseline symptoms. To this end, age-appropriate symptom scales or checklists may be useful in assessing SRC and monitoring recovery (Table 729.1). Many symptom rating scales are available, and some are incorporated into sideline assessment tools, including the Sport Concussion Assessment Tool version 6 (SCAT6), which is approved for age 13 years and older. It is important to use a developmentally appropriate scale for younger children (e.g., Child-SCAT6 for children age 5-12 years) and to use the same tool in subsequent assessments to allow for tracking of symptoms over time.

INITIAL ASSESSMENT AND TOOLS

The initial diagnosis and management of concussion often begins on the field, rink, or court. Whether on the sideline and/or at a medical clinic, the first step is to rule out an injury that requires immediate attention. Acute care should include cervical spine stabilization, evaluation of airway, breathing, and circulation, and motor and sensory neurologic testing. Once a spinal cord injury or more severe injury to the brain is ruled out, it is important to: (1) perform a detailed evaluation of the athlete's mental status, (2) assess signs and symptoms, and (3) identify risks for delayed recovery (i.e., neurodevelopmental disorders, mental health concerns, history of prior concussion, or headaches/migraines). *This process is facilitated by use of a validated sideline*

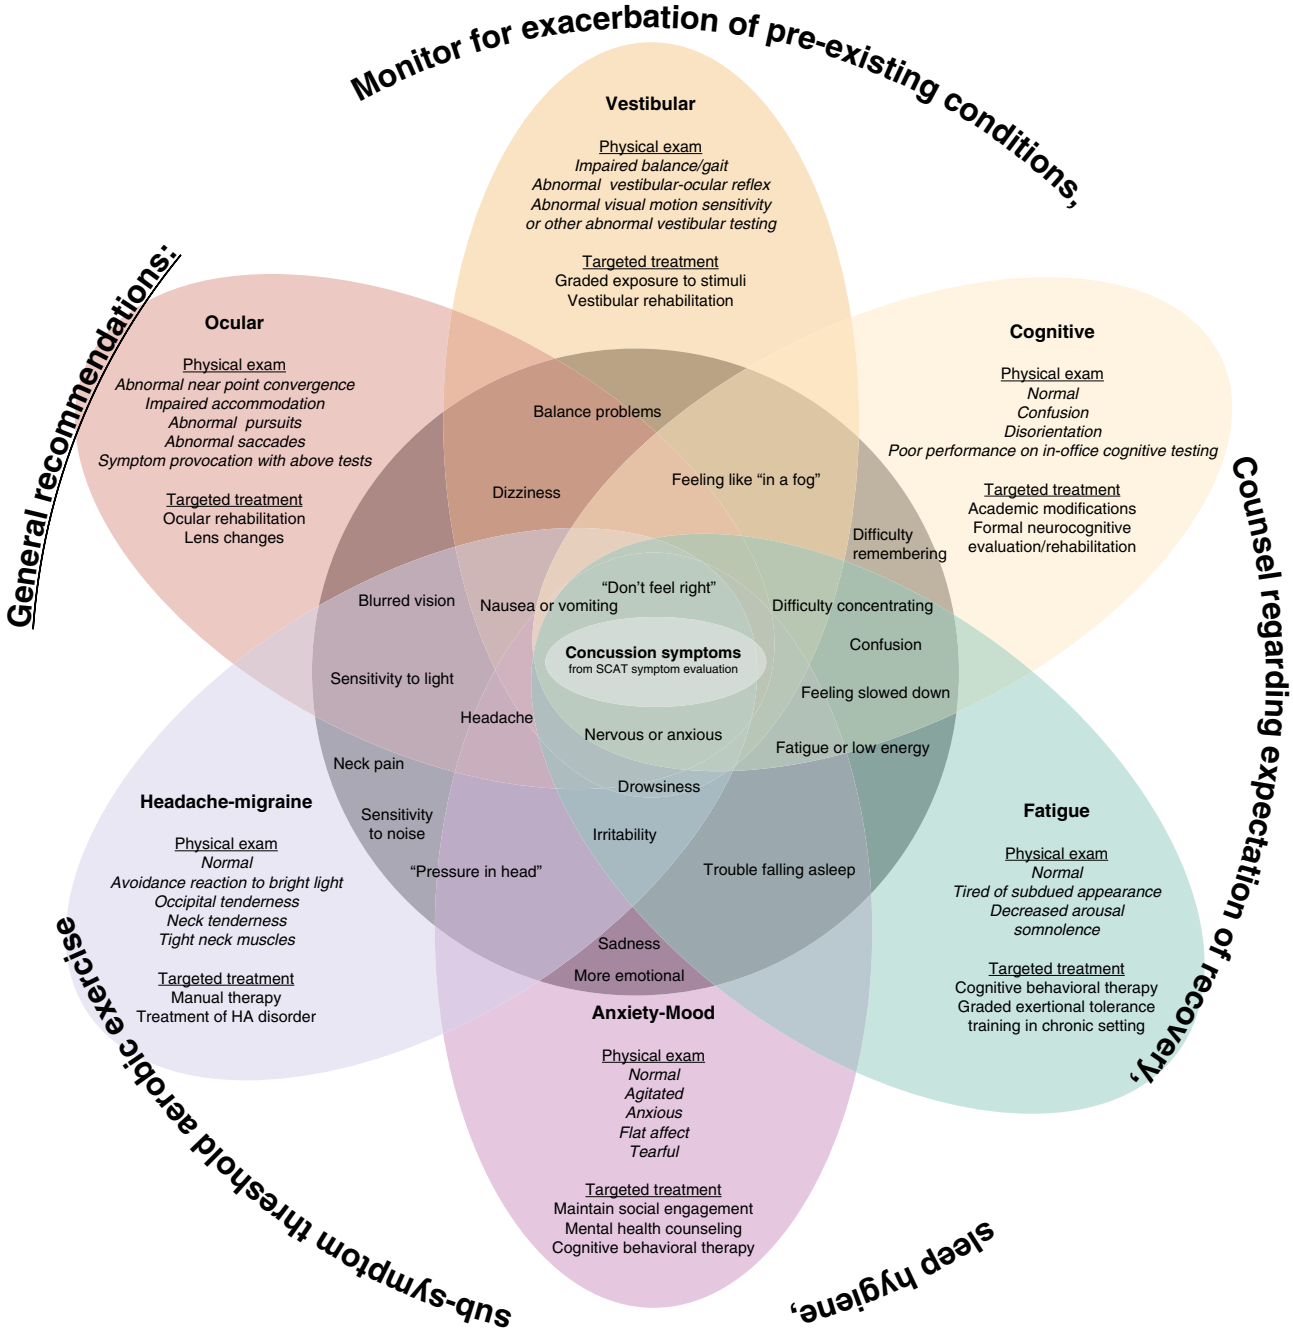

Fig. 729.1 Constellation of symptoms after concussion. Overlapping clinical domains to monitor and facilitate individualized management after concussion. *(From Harmon KG, Clugston JR, Dec K, et al. American Medical Society for Sports Medicine position statement on concussion in sport. Br J Sports Med. 2019;53[4]:213–225.)*

assessment tool. SCAT6 is recommended and includes standardized methods for recording relevant demographics, observable signs of injury, postconcussion symptoms, and memory function (excluding children <12 years), as well as the GCS, cervical spine assessment, brief neurologic exam, and the modified Balance Error Scoring System (m-BESS). Another often-used sideline assessment is the Sideline Assessment of Concussion, which includes a mental status exam, brief neurologic exam, and cognitive screen.

The Balance Error Scoring System (BESS) measures postural stability or balance and consists of six stances, three on a firm surface and the same three stances on an unstable (medium density foam) surface. The modified BESS (m-BESS) is frequently used because it does not rely on availability of medium-density foam for administration. Both include three stances: feet shoulder width apart, a tandem stance (one foot in front of the other), and a single-leg stance on the person's nondominant leg, which are performed for 20 seconds with eyes closed and hands on the iliac crests. An error is recorded each time athletes lift their hands off their hips, open their eyes, step, stumble, fall, remain out of the test position for more than 5 seconds, move hips into more than 30 degrees of flexion or abduction, or lift their forefoot or heel. Normative data are available for comparison, although preseason balance screening provides more precise, individualized data. Furthermore, most evidence suggests that balance impairments generally resolve within 3 days postinjury.

Clinicians should screen for vision problems after concussion. In addition to visual acuity and visual field testing, the Vestibular Ocular Motor Screening Assessment (VOMS) is another tool that is increasingly used to evaluate concussion. It involves a standardized method to

Table 729.1 Postconcussion Symptom Scale

	NONE	MILD		MODERATE		SEVERE

assess smooth pursuits, horizontal and vertical saccades, convergence, horizontal vestibular ocular reflex, and visual motion sensitivity. Findings on the VOMS have been shown to distinguish children with concussion from uninjured controls, and vestibular-ocular dysfunction may have a particularly deleterious effect on academics.

Neuropsychologic assessment quantifies cognitive symptoms of concussion and can help to identify comorbidities that can complicate the diagnosis. The areas identified as most vulnerable to injury include attention and executive function (e.g., speed of processing), new learning and memory, and reaction time. Obtaining preseason or "baseline" data enables clinicians to accurately detect cognitive impairment after injury and aids interpretation of data for athletes with preexisting or contextual factors that affect cognitive function (e.g., neurodevelopmental disorder, sleep, anxiety, and depression). Computer-administered neurocognitive tests are frequently used because the cost and availability of trained neuropsychologists to administer and interpret more comprehensive tests are prohibitive. Further, testing may be of additional benefit in determining appropriate school and home interventions for children who go on to experience PPCS.

The application of neuropsychologic assessment varies depending on the time of referral. Research generally supports the use of brief cognitive screens acutely (~3 days postinjury) such as those incorporated into the SCAT and SAC. Computerized administered neurocognitive assessment or a hybrid approach that includes paper and pencil measures of function are most often administered subacutely (~4-30 days postinjury) to assist in return-to-play decision-making, documenting lingering cognitive deficits, and providing rationale for academic supports or accommodations. The purpose of neuropsychologic assessment for patients with prolonged or chronic postconcussion symptoms (30+ days) is to provide the referring clinician and patient with additional insight into injury and noninjury factors affecting recovery, as well as their impact on cognitive function. Symptoms of comorbidities, including sleep deprivation, deconditioning, and pain, closely resemble postconcussion symptoms and similarly influence health-related status and cognition. Research also indicates that anxiety and depression, family functioning, and caregiver adjustment, as well as neurodevelopmental disorders (e.g., learning disability or ADHD) are strong predictors of prolonged symptoms.

In addition to ruling out more severe injury, the primary goal of both sideline assessment and/or office-based assessment is to prevent concussed athletes from returning to play prematurely. The brain is likely more vulnerable to reinjury immediately after concussion and until ionic and metabolic functioning normalizes. Consistent with this, most reinjuries occur within the first 10 days of an initial concussion. Thus, if a concussion is suspected, it is often wise to remove younger athletes from play for 24 hours or until the diagnosis of concussion can be confidently ruled out. Athletes who experience prolonged loss of consciousness, focal neurologic deficits, excessive somnolence, progressively worsening headache pain, repeated vomiting, slurred speech, and significant confusion may need to be seen in the emergency department where brain imaging can be conducted to rule out more severe head injury.

A blood test (Brain Trauma Indicator) is FDA approved for patients ≥18 years of age with concussion who have normal mental status) to help identify patients in need of cranial imaging. The test measures brain proteins, glial fibrillary acid protein, and ubiquitin C-terminal hydroclase-1, and may also be useful in detecting concussion in children.

MANAGEMENT

After diagnosis and removal from play, the initial management strategy is education of the child and parents about concussion, including the signs and symptoms, effects on cognition, and expected trajectory of recovery. Early limited, subsymptom levels of physical activity may improve recovery, whereas complete rest beyond 2-3 days is associated with delayed recovery. Children (symptomatic or asymptomatic) who can tolerate light exercise soon after injury should be encouraged to do so because it prevents deconditioning and can help with sleep and mood regulation. Importantly, early moderate and intense exercise is associated with symptom exacerbation and longer recovery times, and exercise of any intensity is deferred if it provokes symptoms in the first few days postinjury. Most children will begin to achieve some level of activity tolerance within 2-3 days. Management plans should then focus on gradually and progressively resuming noncontact, low-risk physical activity until full recovery (Table 729.2).

Most children who sustain a concussion will experience full recovery with adherence to relative rest, followed by graduated return to physical and cognitive activity. Nonetheless, some athletes require targeted symptom management, particularly when they are slow to improve (Table 729.3; see Fig. 729.1). Acetaminophen or NSAIDs may help to reduce acute headache pain. Prescription medications are sometimes warranted, including topiramate, amitriptyline, or cyproheptadine for posttraumatic headaches, peripheral nerve blocks for occipital or cervicogenic headaches, and gabapentin for headaches with a neuropathic component. Otolaryngology referral or vestibular therapy is recommended for management of dizziness, vertigo, and imbalance. For children with visual disturbance, assessment and visual rehabilitation therapy managed by an optometrist or ophthalmologist is appropriate. Psychologic assessment and intervention, particularly cognitive behavioral therapy, is recommended

Table 729.2 Graduated Return to Play Protocol

STAGE	AIM	ACTIVITY	GOAL OF EACH STEP
1	Symptom-limited activity	Daily activities that do not provoke symptoms	Gradual reintroduction of work/school activities
2	Light aerobic exercise	Walking or stationary cycling at slow to medium pace. No resistance training	Increase heart rate
3	Sport-specific exercise	Running or skating drills. No head impact activities	Add movement
4	Noncontact training drills	Harder training drills (e.g., passing drills). May start progressive resistance training	Exercise, coordination, and increased thinking
5	Full contact practice	After medical clearance, participate in normal training activities	Restore confidence and assess functional skills by coaching staff
6	Return to sport	Normal game play	

NOTE: An initial period of 24-48 hr of both relative physical rest and cognitive rest is recommended before beginning the return to sport progression.
There should be at least 24 hr (or longer) for each step of the progression. If any symptoms worsen during exercise, the athlete should go back to the previous step. Resistance training should be added only in the later stages (stage 3 or 4 at the earliest). If symptoms are persistent (e.g., more than 10-14 days in adults or more than 1 mo in children), the athlete should be referred to a healthcare professional who is an expert in the management of concussion.
From Patricios JS, Schneider KJ, Dvorak J, et al. Consensus statement on concussion in sport: the 6th International Conference on Concussion in Sport–Amsterdam, Oct 2022. *Br J Sports Med.* 2023;57:695.

Table 729.3 Common Potential Interventions for Specific Symptoms After Pediatric Concussion

SPECIFIC SYMPTOMS	POTENTIAL INTERVENTIONS
Headache	Lifestyle modifications (water intake, meal schedule, sleep, and exercise), cervicovestibular therapy, acute medications, preventive medications, and avoiding overuse of acute medications
Light-Headedness or Exercise Intolerance	Increase water and salt intake and gradual increase in exercise
Dizziness or Neck Pain	Vestibular therapy and cervical spine therapy
Balance or Coordination Difficulties	Neuromuscular training
Sleep Difficulties	Lifestyle modifications (bedtime routine, white noise, avoid caffeine, and exercise earlier), and melatonin
Anxiety or Mood Problems	Counselling, antidepressants, and anxiolytics
Cognitive Difficulties	Cognitive testing and academic accommodations

From Beauchamp MH, Degeilh F, Rose SC: Improving outcome after paediatric concussion: challenges and possibilities. *Lancet Child Adolesc* 2023;7:728-738 (Panel 2, p. 733).

for athletes who experience worsening or newly developed symptoms of anxiety or depression. Both are potentially heightened as a direct consequence of concussion as well as the resulting limitations on everyday activities and social interaction. A multidisciplinary and collaborative approach to target specific treatments is advised for children whose symptoms do not show improvement with standard behavioral interventions.

Return to School

Of particular importance to children and their families is the effect of concussion on cognitive function and school performance. Children and adolescents exposed to greater levels of cognitive stress endorse worse symptoms and experience longer recovery after concussion. Students who experience postconcussion symptoms report difficulty in school. There is also evidence that overly restricting cognitive exertion and school participation can delay recovery. Current recommendations focus on using self-reported symptoms to determine school readiness, followed by increasing exposure to classroom learning, tests, and assignments (Table 729.3). In general, children and adolescents are encouraged to attend school, even if on a modified schedule, in 2-3 days or sooner, with a program of academic adjustments and modifications that allow for ongoing learning to occur with minimal symptom provocation. Clinicians should provide documentation to schoolteachers and administrators requesting compressed assignments, more time to complete tests or assignments, deferred examinations, rest breaks, audiobooks, oral teaching, large font printed material, or preprinted notes where indicated.

Return to Play

There is a six-stage return-to-play (RTP) protocol for a safe return to activities (see Table 729.2). Starting with physical rest, athletes are progressed to light aerobic exercise, moderate levels of sport-specific exercise, noncontact training drills, full contact practice, and normal game play. Athletes should be completely asymptomatic, free of medications used to treat concussion symptoms, at full school, and back to baseline functioning on all domains tested before the injury before returning to contact or collision sports. Children and adolescents should remain at each stage of rehabilitation for no less than 24 hours before advancing to the next level. Thus a minimum of 5 days should pass before consideration of full return to competition. If symptoms return at any stage of exertion, the athlete should rest until the symptoms resolve and then return to the previous level of exertion. The final decision for RTP should be made by a licensed clinical provider with experience in the evaluation and management of sports-related concussions. Note that some states or schools require an extended minimum number of symptom-free days before RTP, so clinicians need to be aware of the laws or local recommendations regarding RTP.

Risks for Persistent Postconcussion Symptoms

From 80–90% of children and adolescents diagnosed with concussion will clinically recover within 4 weeks. Factors associated with prolonged recovery include a history of prior concussions, female

Table 729.4 Graduated Return to School Strategy

STAGE	AIM	ACTIVITY	GOAL OF EACH STEP
1	Daily activities at home that do not give the child symptoms	Typical activities of the child during the day as long as they do not increase symptoms (e.g., reading, texting, screen time). Start with 5-15 min at a time and gradually build up	Gradual return to typical activities
2	School activities	Homework, reading, or other cognitive activities outside of the classroom	Increase tolerance to cognitive work
3	Return to school part-time	Gradual introduction of schoolwork. May need to start with a partial school day or with increased breaks during the day	Increase academic activities
4	Return to school full time	Gradually progress school activities until a full day can be tolerated	Return to full academic activities and catch up on missed work

From Patricios JS, Schneider KJ, Dvorak J, et al. Consensus statement on concussion in sport: the 6th International Conference on Concussion in Sport–Amsterdam, Oct 2022. *Br J Sports Med.* 2023;57:695.

sex, history of migraines, neurodevelopmental disorder (e.g., ADHD, learning disability), successive concussion soon after recovery, and acute symptom severity and burden. Female sex and initial symptom severity are the factors associated with more persistent symptoms in adolescents.

Retiring Young Athletes

Retirement from contact sports is rare but sometimes indicated, even in younger athletes. Indications for retirement include chronic neuropsychologic deficit, increased recovery times for successive injuries, decreased threshold for repeat concussions, and multiple concussions over the course of an athletic career.

COMPLICATIONS/LONG-TERM EFFECTS

Second impact syndrome, seen more frequently in younger athletes than adults, refers to a rare, catastrophic neurologic injury involving diffuse cerebral swelling that purportedly occurs in athletes who sustain a second head injury before full recovery from a concussion. Although second impact syndrome is rare, its occurrence highlights the importance of removing children with concussion from play and other activities that place them at increased risk of head injury until fully recovered. Pathogenic variants in *CACNA1A* have been associated with delayed and severe cerebral edema after minor head trauma.

Some literature suggests that young athletes who suffer repetitive head impacts and multiple concussions may be at risk for neurodegenerative diseases, such as chronic traumatic encephalopathy (CTE) or Alzheimer disease. CTE describes pathologic changes in the brain observed postmortem, which are hypothesized to be associated with changes in mood, behavior, and cognition function. At present, there is no way to diagnose CTE in living persons and its incidence and prevalence are unknown.

PREVENTION

The strongest evidence for concussion prevention is in support of concussion education initiatives, age limits on contact, fair play, and adherence to rules of the game or competition. Additionally, there is some evidence that neck strengthening may reduce the risk of concussion. Current research shows no proven benefit to personal protective equipment (i.e., helmets, mouthguards) or dietary supplements in reducing the risk of concussion or its severity, although it is important for athletes to wear properly fitted sport specific protective equipment to prevent *more serious* head injury and maxillofacial and dental trauma.

Chapter 730

Cervical Spine Injuries

Julie M. Kerr and Joseph A. Congeni

Sports participation has surpassed motor vehicle crashes as the number one cause of cervical spine injuries (primarily involving soft tissue) in youth older than 8 years of age. American football, hockey, wrestling, and gymnastics have the highest incidence in the United States; internationally, rugby is nearly as high. Catastrophic cervical spine injuries fortunately are rare but can occur as a result of the scrum or tackling in rugby and tackling plays in American football.

The normal cervical spine has a lordotic curve, allowing it to absorb shock and dissipate force with application of an axial force. When the neck is flexed forward, the spine straightens, losing this shock-absorbing property. An axial load to the top of the head in this flexed position transmits force through the spine.

SOFT TISSUE INJURY

The most frequent injury resulting from trauma to the head and neck involves the muscles, tendons, and ligamentous structures. Even though strains, sprains, and contusions are common and are managed with cervical, scapulothoracic, and shoulder-strengthening exercises, thorough evaluation is required to rule out more serious injuries. Even without bony abnormalities, the cervical spine may become unstable secondary to soft tissue injury.

Spinal laxity results when most restraining ligaments are injured. When compared with adjacent vertebra, laxity should horizontally be less than 3.5 mm and angular displacement less than 11 degrees on plain flexion/extension films. However, younger athletes have more baseline laxity, making the criteria less applicable, and muscle spasm can acutely mask instability. If subluxation is remotely suspected, a hard cervical collar should be placed and flexion/extension views obtained again at 2-4 weeks when inflammation and spasm have subsided. A loss of lordosis on lateral x-ray is associated with significant weakness of cervical muscles, particularly the cervical extensors. Disk injuries are rare in pediatric patients. Rupture or herniation must be considered in any cervical pain differential (see Chapter 81).

SPEAR TACKLER'S SPINE

This clinical entity is characterized by progressive spinal changes secondary to incorrect tackling form. Findings on plain x-ray consist of (1) narrowing of cervical spinal canal, (2) loss or reversal of normal cervical lordosis, and (3) preexisting minor posttraumatic x-ray evidence of bony

or ligamentous injury. Although rule changes in collision and contact sports have limited the practice of contacting an opponent with a "head-down" neck position, this condition persists. Most experts argue that this condition disqualifies athletes from return to play.

CERVICAL FRACTURES

All significant neck injuries should be treated seriously until cleared with appropriate examination and imaging. Although many cervical fractures are stable, improper management or inadequate evaluation could produce catastrophic results. *Until formally evaluated, the patient should be immobilized and treated as if the patient has an unstable cervical fracture* (see Chapter 81).

STINGERS (BURNERS)

Stingers are unilateral *(never bilateral)* peripheral nerve injuries occurring at an anatomic location between the cervical nerve root and the brachial plexus. Three proposed mechanisms include traction or tensile stretch injury, compressive injury, and direct trauma. A typical presentation is a transient episode of unilateral burning pain, with or without numbness, that radiates from the shoulder, down the upper arm, and into the hand. Symptoms of C5 and C6 root injury with deltoid and biceps weakness are the most common presentation. These symptoms may last for several minutes to days but do not result in permanent neurologic deficit or abnormal imaging evaluations. Examination should assess for weakness, especially shoulder abduction, external rotation, and elbow flexion. The cervical spine should have full and pain-free range of motion and no tenderness to palpation.

The Spurling Compression test helps to assess for cervical radiculopathy as a cause of upper extremity pain. The patient is seated with their neck tilted to the affected side. In a positive test, the pain is reproduced with gentle axial compression. The test has high specificity (~93%) but relatively low sensitivity (~30%), meaning that positive tests indicate likely cervical radiculopathy but many patients with cervical radiculopathy will not have a positive test.

Return to play may be considered the same day if the exam is reassuring. This requires complete resolution of symptoms, full range of motion, and normal strength. Multiple stingers, bilateral symptoms, or symptoms persisting for longer than one hour should prompt further evaluation with cervical spine radiographs and other imaging modalities as indicated before resumption of any physical activities.

BURNING HANDS SYNDROME

The athlete with this syndrome presents with intense paresthesia and associated hand and arm weakness in both upper extremities. This is suggestive of a central cord syndrome with cord compression of the spinothalamic and corticospinal tracts. As with stingers, most of these episodes resolve in minutes to days. Persistent symptoms or repeated episodes warrant further evaluation and imaging.

TRANSIENT QUADRIPARESIS

Transient quadriparesis is a temporary neurologic episode encompassing sensory symptoms with or without motor changes. Transient quadriparesis is also known as *cervical cord neurapraxia*, *commotio spinalis*, and *spinal cord concussion*. Transient quadriparesis can be divided into three types: plegia (complete loss of motor function), paresis (motor weakness), and paresthesia (sensory symptoms only). There is also a three-part grading system: grade 1 symptoms lasting less than 15 minutes, grade 2 symptoms lasting 15 minutes to 24 hours, and grade 3 symptoms persisting beyond 24 hours. Transient quadriparesis must be differentiated from a stinger, and the player should be removed from activity and spinal cord injury considered.

Mechanisms of injury include hyperextension, hyperflexion, and axial loading. Anatomically, when the neck is hyperflexed or hyperextended, the spinal canal is narrowed by up to 30%, increasing the likelihood of cord injury.

Evaluation should start with plain flexion and extension films if stable. CT should be used if cervical fracture is suspected. MRI should then be used to evaluate for intrinsic spinal cord abnormalities or ongoing cord or root compression.

Table 730.1 Return to Play

NO CONTRAINDICATION TO RTP	
Healed fractures	Healed C1 or C2 fracture with normal cervical spine ROM Healed subaxial fracture without sagittal plane deformity Asymptomatic clay-shoveler's (C7) spinous process avulsion fracture
Congenital conditions	Klippel-Feil (single-level anomaly not C0/C1 articulation) Spina bifida occulta
Degenerative/ postsurgical conditions	Cervical disk disease (no change in baseline neurologic status) Single-level ACF with/without instrumentation Single- or multiple-level posterior cervical laminotomy
Recurrent stingers	Fewer than three episodes lasting <24 hours Must have full cervical range of motion No persisting neurologic deficit
Transient quadriparesis	Single episode Full cervical range of motion Normal neurologic exam No radiologic instability Normal spinal reserve (as evidenced on MRI)
RELATIVE CONTRAINDICATION TO RTP	
Stingers/burners	Prolonged symptomatic burner/stinger Three or more stingers
Transient quadriparesis	Transient quadriparesis lasting >24 hours More than 1 episode with symptoms of any duration
Postsurgical	Healed two-level ACF PCF with/without instrumentation
ABSOLUTE CONTRAINDICATION TO RTP	
Transient quadriparesis and any one or more of	Cervical myelopathy Continued neck discomfort Reduced ROM Neurologic deficit from baseline after injury
Surgical procedures	C1 + C2 fusion Cervical laminectomy Three-level ACF or PCF
Soft tissue injuries	Asymptomatic ligamentous laxity (>11 degrees of kyphotic deformity) C1 + C2 hypermobility with anterior dens >3.5 mm (adult), >4 mm (child), i.e., Down syndrome Symptomatic cervical disk herniation
Other conditions	Spear tackler's spine Multilevel Klippel-Feil anomaly (see Chapter 721.2) Healed subaxial fracture with sagittal kyphosis, coronal plane abnormality, or cord encroachment Ankylosing spondylitis Rheumatoid arthritis with spinal abnormalities Spinal cord abnormality (cord edema, compression, etc.) Arnold-Chiari syndrome Basilar invagination Occipital-C1 assimilation (occipitalization or connection) Spinal stenosis (canal width <13 mm between C3 and C7)

ACF, Anterior cervical fusion; PCF, posterior cervical fusion; ROM, range of motion; RTP, return to play.

Adapted from Cantu R, Li YM, Abdulhamid M, et al. Return to play after cervical spine injury in sports. *Curr Sports Med Rep*. 2013;12:14–17.

Fig. 730.1 An MRI (sagittal) demonstrating spinal cord contusion (edema in central portion of spinal cord). *(From Krabak BJ, Kanarek SL. Cervical spine pain in the competitive athlete. Phys Med Rehabil Clin N Am. 2011;22:459–471. Fig. 2).*

Return to play for transient quadriparesis is heavily debated and lacks data to guide decision-making. Some experts argue that one episode is a contraindication to return to contact sports, whereas others agree with using the Return to Play Table (Table 730.1) for absolute and relative contraindications for return. If allowed to return to play and a second episode of transient quadriparesis occurs, the complete workup must be repeated.

CONGENITAL SPINAL STENOSIS

Developmental narrowing of the cervical spinal canal predisposes an athlete to higher risk of spinal cord injury. This condition can be found incidentally while working up other conditions. Currently, the "gold standard" imaging modality is an MRI measuring a canal width of <13 mm between C3 and C7 to define stenosis, with "normal" being greater than 15 mm.

Functional stenosis can be seen with dynamic MRI in flexion and extension to determine whether the canal space decreases with movement. The positioning of the canal in flexion or extension causes narrowing from movement of the vertebra and ligament, respectively. The measured diameter may be irrelevant if disk protrusion or ligament hypertrophy causes compression. This narrow "reserve space" around the spinal cord puts the athlete at greater risk for injury as compared with the same force applied to a normal spine.

SPINAL CORD INJURY

Spinal cord injury is the most devastating complication of cervical trauma. Hemorrhage and transection are considered irreversible and associated with complete cord injury, whereas contusion and edema are considered to have more potential for recovery (Fig. 730.1). These severe injuries should be managed by providers with expertise in this area.

Chapter 731

Heat Injuries

Gregory L. Landry and Andrew M. Watson

Heat illness is among the leading causes of death in U.S. high school athletes. It is a continuum of clinical signs and symptoms that can be mild (heat stress) to fatal (heat stroke). Children are more vulnerable to heat illness than adults because they have a greater ratio of surface area to body mass and produce greater heat per kilogram of body weight during activity. The sweat rate is lower in children, and the temperature at which sweating occurs is higher. Although there is considerable interindividual variability, children can take longer to acclimatize to warmer, more humid environments (typically 8-12 near-consecutive days of 30- to 45-minute exposures). Children also have a blunted thirst response compared with adults and might not consume enough fluid during exercise in hot, humid environments to prevent dehydration. In addition, certain medications may predispose to heat-related injury (Table 731.1).

Three major categories for heat illness are generally used: heat cramps, heat exhaustion, and heat stroke (Table 731.2). However, symptoms of heat illness overlap and progress as the core temperature rises. **Heat cramps** are the most common heat injury and usually occur in mild dehydration and/or salt depletion, typically affecting the calf and hamstring muscles. They tend to occur later in activity, as muscle fatigue is reached and water loss and sodium loss worsen. Heat cramps will normally respond to oral rehydration with electrolyte solution and with gentle stretching. The athlete can return to play when the ability to perform is not impaired. Other minor heat illnesses include heat syncope, heat edema, and heat tetany. **Heat syncope** is fainting after prolonged exercise, attributed to poor vasomotor tone and depleted intravascular volume; it responds to fluids, cooling, and supine positioning. **Heat edema** is mild edema of the hands and feet during initial exposure to heat; it resolves with acclimatization. **Heat tetany** is carpopedal tingling or spasms caused by heat-related hyperventilation during short periods of exposure to intense heat. It responds to moving to a cooler environment and decreasing respiratory rate (or rebreathing by breathing into a bag).

Heat exhaustion is a moderate illness with a core temperature of 37.7–40°C (100–104°F). It is manifested as weakness, fatigue, headache, nausea, vomiting, dizziness, orthostasis, piloerection, and possibly syncope. Central nervous system dysfunction is mild, if present. Treatment includes moving to a cool environment, cooling the body with fans, removing excess clothing, and placing ice over the groin and axillae. If a patient is not able to tolerate oral rehydration, IV fluids are indicated. Patients should be monitored, including rectal temperature, for signs of heat stroke. If rapid improvement is not achieved, transport to an emergency facility is recommended.

Heat stroke is a severe illness manifested by central nervous system disturbances and potential tissue damage. It is a medical emergency; *the mortality rate is up to 50%*. Sports-related heat stroke is characterized by profuse sweating and is related to intense exertion, whereas "classic" heatstroke with dry, hot skin is of slower onset (days) in elderly or chronically ill persons. Rectal temperature is usually >40°C (104°F). Significant damage to the heart, brain, liver, kidneys, and muscle occurs, with possible fatal consequences if untreated. Treatment is immediate whole-body cooling via cold water immersion (Table 731.3). Airway, breathing, circulation, core temperature, and central nervous system status should be monitored constantly. Rapid cooling should be ceased when core temperature is approximately 38.3–38.9°C (101–102°F). IV fluid at a rate of 800 mL/m^2 in the first hour with normal saline or lactated Ringer solution improves

Table 731.1 Medications and Drugs That May Increase the Risk of Heat-Related Injury

MEDICATIONS
Anticholinergic agents (including antihistamines)
β Blockers
Antipsychotics (including SSRIs, TCAs)
Lithium
Diuretics
Salicylates
Sympathomimetic agents
Calcium channel blockers
Antiseizure medications (topiramate, zonisamide)
DRUGS OF MISUSE/SUPPLEMENTS
Amphetamines (including ephedra)
Cocaine
Ecstasy
Phencyclidine
Cathinone (synthetic marijuana) agents
LSD
Alcohol
Anabolic steroids

SSRI, selective serotonin reuptake inhibitors; LSD, lysergic acid diethylamide; TCA, tricyclic antidepressants.

Table 731.2 Spectrum of Heat Illness

HEAT CRAMPS AND DEHYDRATION: *CAUTIOUS RETURN TO PLAY*

Thirst
Fatigue
Light-headedness
Sweating
Flushed face
HEAT EXHAUSTION: *REMOVE FROM PLAY*
Dizziness
Rapid pulse
Headaches
Nausea
Vomiting
Loss of coordination
Profuse sweating
Core temperature less than 40°C (104°F)
HEAT STROKE: *MEDICAL EMERGENCY, CALL 911*
Core temperature of 40°C (104°F) or higher
Hot dry skin
Multiple system failure
Delirium
Convulsions
Abnormal vital signs

From Merkel DL, Molony JT Jr. Medical sports injuries in the youth athlete: emergency management. *Int J Sports Phys Ther.* 2012;7:242–251. Table 4.

Table 731.3 Current Therapy for Heat-Related Illness

- Acclimatization is key for prevention of exertional heat illness.
- Heat illness is most effectively managed by immediate recognition of the signs and symptoms and proper diagnosis.
- Core body temperature measurement *must* be done with a rectal thermometer.

EXERCISE-ASSOCIATED COLLAPSE

- Continue walking after race to prevent development.
- Position the patient in the supine or Trendelenburg position and start fluid administration.

HEAT EXHAUSTION

- Provide rapid cooling with ice bags to areas adjacent to large vasculature (groin, neck, axilla).
- Administer oral or intravenous (IV) fluid to correct for hydration deficit.

HEAT STROKE

- Ensure the ability to maintain adequate circulation, airway, and breathing.
- *Ice-water immersion is the most effective way to provide rapid cooling.*
- The goal of cooling is to reduce and maintain a temperature below 38.3°C (101°F).
- Transport to the hospital may be required if the patient's temperature is not reduced effectively or the patient does not return to normal mental status after 30 minutes of medical treatment.

From Cleland P. Heat illness. In: Kellerman RD, Rakel DP, Heidelbaugh JJ, Lee EM, eds. *Conn's Current Therapy 2023.* Philadelphia: Elsevier, 2023: p. 1390.

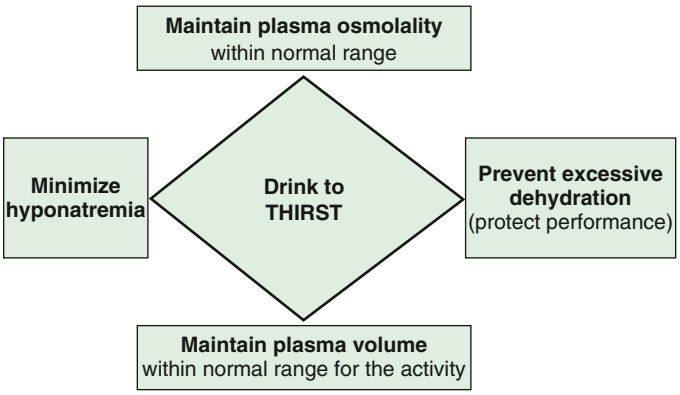

Fig. 731.1 Primary recommended fluid intake strategy to prevent symptomatic exercise-associated hyponatremia. *(From Hew-Butler T, Rosner MH, Fowkes-Godek S, et al. Statement of the third international exercise-associated hyponatremia consensus development conference, Carlsbad, California, 2015. Clin J Sport Med. 2015;25:303–320. Fig. 1.)*

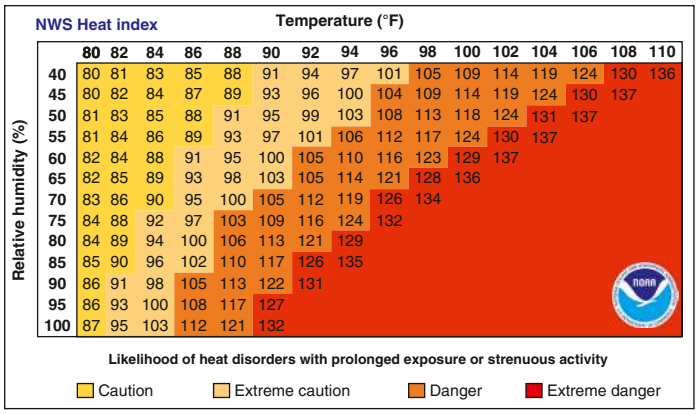
intravascular volume and the body's ability to dissipate heat. Immediate transport to an emergency facility is necessary. Physician clearance is required before return to exercise.

Dehydration is common to all heat illness; consequently, measures to prevent dehydration may also prevent heat illness. Thirst is usually an adequate indicator of hydration status; excessive hypotonic fluid replacement beyond sweat and urine losses can lead to hyponatremia. Endurance athletes should be cautioned not to drink beyond thirst. Mild dehydration (2–3%) does not usually affect performance and itself does not cause cramping, fatigue, or heat stroke.

Exercise-associated hyponatremia (Na < 135 mmol/L) may be asymptomatic or symptomatic (lightheadedness, nausea, headache, confusion, cerebral edema) and is often seen in endurance sports (marathon, triathlon, cycling, swimming), hiking, football, and police or military drills. Major risk factors include overdrinking water or hypotonic sports drinks, weight gain during exercise, exercise duration >4 hours, readily available fluids, and inexperienced or slow pace. Athletes are advised to be hydrated before exercise and should drink to thirst (Fig. 731.1). Fluids should contain sodium and not be ingested in excess.

During a football practice, for example, scheduled breaks every 20-30 minutes with helmets off can decrease the cumulative amount of heat exposure. Practices and competitions should be scheduled in the early morning or late afternoon to avoid the hottest part of the day. Guidelines have been published about modifying activity related to temperature and humidity (Fig. 731.2). Proper clothing such as shorts and T-shirts without helmets can improve heat dissipation. Prepractice and postpractice weight can be helpful in determining the amount of fluid necessary to replace (8 oz for each pound of weight loss). When practicing or performing in a warm environment, gradual acclimatization is recommended.



Classification	Heat index	Effect on the body
Caution	80°F - 90°F	Fatigue possible with prolonged exposure and/or physical activity
Extreme danger	90°F - 103°F	Heat stroke, heat cramps, or heat exhaustion possible with prolonged exposure and/or physical activity
Danger	103°F - 124°F	Heat cramps or heat exhaustion likely, and heat stroke possible with prolonged exposure and/or physical activity
Extreme danger	125°F or higher	Heat stroke highly likely

Fig. 731.2 Heat index. To determine the heat index using this chart, air temperature and the relative humidity need to be known. For example, if the air temperature is 100°F and the relative humidity is 55%, the heat index will be 124°F. When the relative humidity is low, the apparent temperature can actually be lower than the air temperature. *(Courtesy National Weather Service, United States National Oceanic and Atmospheric Administration. https://www.weather.gov/ama/heatindex.)*

Fluids with electrolytes and carbohydrates are important during exercise lasting longer than 1 hour. Salt supplements should not be used by most people because of the risk of causing hypernatremia and delayed gastric emptying. If excessive fluid intake contributes to hyponatremia, salt supplements will not avoid the decline in serum sodium. They may be useful in a person with a high sweat rate or recurrent heat cramps.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

Chapter 732

Nutrition and Endocrine Conditions in Athletes

Gregory L. Landry and Andrew M. Watson

Excessive physical training in young women can adversely affect reproductive function and bone mineral status, especially when combined with calorie restriction (Fig. 732.1; see Chapters 41 and 159).

The majority of bone mass is acquired by the end of the second decade of life (see Chapter 749). Approximately 60–70% of adult bone mass is genetically determined, and the remaining is influenced by three modifiable factors: exercise, calcium intake, and sex steroids (primarily estrogen). Exercise promotes bone mineralization in the majority of young women and should be encouraged. In females with eating disorders and those who exercise to the point of excessive weight loss with **amenorrhea** or **oligomenorrhea**, exercise can be detrimental to bone mineral acquisition, resulting in reduced bone mineral content, or **osteopenia**. In males, prolonged negative energy balance can similarly result in bone demineralization, although this may be more occult without the obvious sign of menstrual cycle disruption.

Specifically, bone mineralization is negatively affected by amenorrhea (absence of menstruation for 3 or more consecutive months). This may be influenced by abnormal eating patterns, or disordered eating, that results in insufficient caloric intake. When occurring together, disordered eating, amenorrhea, and osteoporosis represent the **female athlete triad**. A more inclusive definition refers to the interrelationships among energy availability, endocrine function, and bone mineral

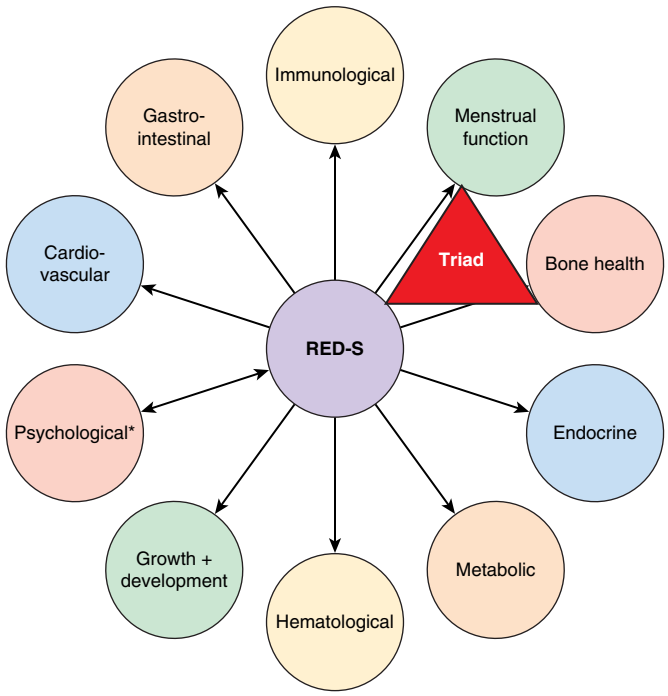


Fig. 732.1 Health consequences of relative energy deficiency in sport (RED-S) showing an expanded concept of the Female Athlete Triad to acknowledge a wider range of outcomes and the application to male athletes. *Psychologic consequences can either precede RED-S or be the result of RED-S. *(Courtesy Dr. Naama W. Constantini, Shaare Zedek Medical Center, Hebrew University, Israel.)*

density, as athletes are distributed along a spectrum of health and disease. The **male athlete triad** describes the impact of these interrelated problems in male athletes. In addition, the International Olympic Committee introduced the concept of **relative energy deficiency in sport** (RED-S), outlining the myriad physiologic, psychologic, and performance consequences of low energy availability in both male and female athletes (see Fig 732.1). At health supervision visits and the preparticipation physical examination, special attention should be given to screening for any unhealthy features of the female or male athlete triads (Tables 732.1 and 732.2).

In both male and female athletes, low energy availability can result in disruption of the hypothalamic-pituitary-gonadal axis. Menstrual abnormalities (including amenorrhea) result from

Table 732.1 Recommended Screening Questions for the Female Athlete Triad*

- Have you ever had a menstrual period?
- How old were you when you had your first menstrual period?
- When was your most recent menstrual period?
- How many periods have you had in the past 12 months?
- Are you presently taking any female hormones (estrogen, progesterone, birth control pills)?
- Do you worry about your weight?
- Are you trying to or has anyone recommended that you gain or lose weight?
- Are you on a special diet or do you avoid certain types of foods or food groups?
- Have you ever had an eating disorder?
- Have you ever had a stress fracture?
- Have you ever been told you have low bone density (osteopenia or osteoporosis)?

*The Triad Consensus Panel recommends asking these screening questions at the time of the sport preparticipation evaluation.

From Constantini NW. Medical concerns of the dancer. Book of Abstracts. XXVII FIMS World Congress of Sports Medicine, Budapest, Hungary, 2002. p. 151.

Table 732.2 Recommended Screening Questions for the Male Athlete Triad

- Do you worry about your weight?
- Are you trying or has anyone recommended that you lose or gain weight?
- Are you on a special diet, or do you avoid certain types of foods or food groups?
- Have you ever had an eating disorder?
- Have you ever had a stress fracture?
- Have you ever been told that you have low bone density or osteoporosis?
- Have you ever been diagnosed with low testosterone levels?
- Do you have low libido (sex drive)?
- Do you have morning erections?*
- Do you need to shave your facial hair less frequently?*

*Recommend inclusion on only preparticipation physical examinations for postpubertal athletes.

From Fredericson M, Kussman A, Misra M, et al. The male athlete triad – a consensus statement from the Female and Male Athlete Triad Coalition part II: diagnosis, treatment, and return-to-play. *Clin J Sport Med.* 2021;31(4):349–366. Box 1.

suppression of the spontaneous hypothalamic pulsatile secretion of gonadotropin-releasing hormone (Fig. 732.2; see Chapter 159.1). It is believed that the amenorrhea results from reduced energy availability, defined as energy intake minus expenditure. Energy availability below a threshold of 30 kcal/kg/day lean body mass is thought to result in menstrual disturbances, whereas availability at or above 45 kcal/kg/day is generally considered sufficient for optimal physiologic function. Other causes of menstrual cycle irregularities to be ruled out are pregnancy (see Chapter 161), pituitary tumors, thyroid abnormalities, polycystic ovary syndrome (see Chapter 589), anabolic-androgenic steroid use (see Chapters 157 and 733), and other medication side effects. Negative energy balance also appears to disrupt thyroid function and appetite-regulating hormones (e.g., leptin, ghrelin), increase resistance to growth hormone, decrease insulin and insulin-like growth factor 1, and increase cortisol levels. Although a threshold has yet to be established, low energy availability in males may also lead to decreased levels of testosterone and luteinizing hormone.

The low estrogen state of amenorrhea predisposes the female athlete to osteopenia and increases the risk of stress fractures, especially of the spine and lower extremity. If left unchecked, bone loss may be partially irreversible despite resumed menses, estrogen replacement, or calcium supplements. Similarly, low energy availability in males reduces bone turnover and can contribute to bone demineralization. Routine bone mineral density screening is not recommended but can help guide treatment and return to activity in severe cases.

Three eating disorders can occur in athletes, contributing to low energy availability. **Anorexia nervosa** manifests as weight <85% of estimated ideal body weight with evidence of starvation manifesting as bradycardia, hypothermia, and orthostatic hypotension or orthostatic tachycardia. **Bulimia nervosa** manifests as recurrent episodes (at least once weekly) of binge eating with a sense of lack of control over eating during an episode with recurrent episodes of compensatory behaviors, such as induced vomiting or excessive exercise. A third category, **unspecified feeding or eating disorder (UFED)**, is a general description for disorders failing to meet the criteria for the two previous disorders. Many young people who previously were diagnosed with UFED have a specific diagnosis of anorexia or bulimia. Signs of an eating disorder are weight loss, food restriction, depression, fatigue, worsened athletic performance, and preoccupation with calories and weight. The athlete might avoid events surrounding food consumption or might hide and discard food. Signs and symptoms include fat depletion, muscle wasting, bradycardia worsened from baseline, orthostatic hypotension, constipation, cold intolerance, hypothermia, gastric motility problems, and in some cases lanugo (see Chapter 41). Electrolyte abnormalities can lead to cardiac dysrhythmias. Psychiatric problems (depression [see Chapter 39], anxiety [see Chapter 38], and suicide risk [see Chapter 40]) are of higher incidence in this population.

For treatment of eating disorders, control of the symptoms is a central theme. The first step is confronting the athlete about the abnormal behavior and unhealthy weight. In general, exercise is not recommended if body weight is <85% of estimated ideal body weight, although there are exceptions, especially if the athlete is eumenorrheic. If the athlete is unable to gain weight with nutrition and medical counseling alone, then psychologic consultation is sought (Fig. 732.3).

Most athletes will not initially admit a problem, and many are unaware of the serious physical consequences. In some cases, athletes may have pursued athletic participation (e.g., in endurance activities) as a means to reduce or maintain a low body weight. A helpful technique in talking to these athletes is to sensitively point out performance issues. Education about decreased strength, endurance, and concentration can be a motivating factor for treatment. Often, the athlete's family needs to be involved, and the athlete should be encouraged to reveal necessary information to them. Psychology or psychiatry referral is important in the multidisciplinary approach to treatment of disordered eating. It is important for the physician to monitor the athlete's physical health while the mental health professional is caring for the mental aspects of the eating disorder.

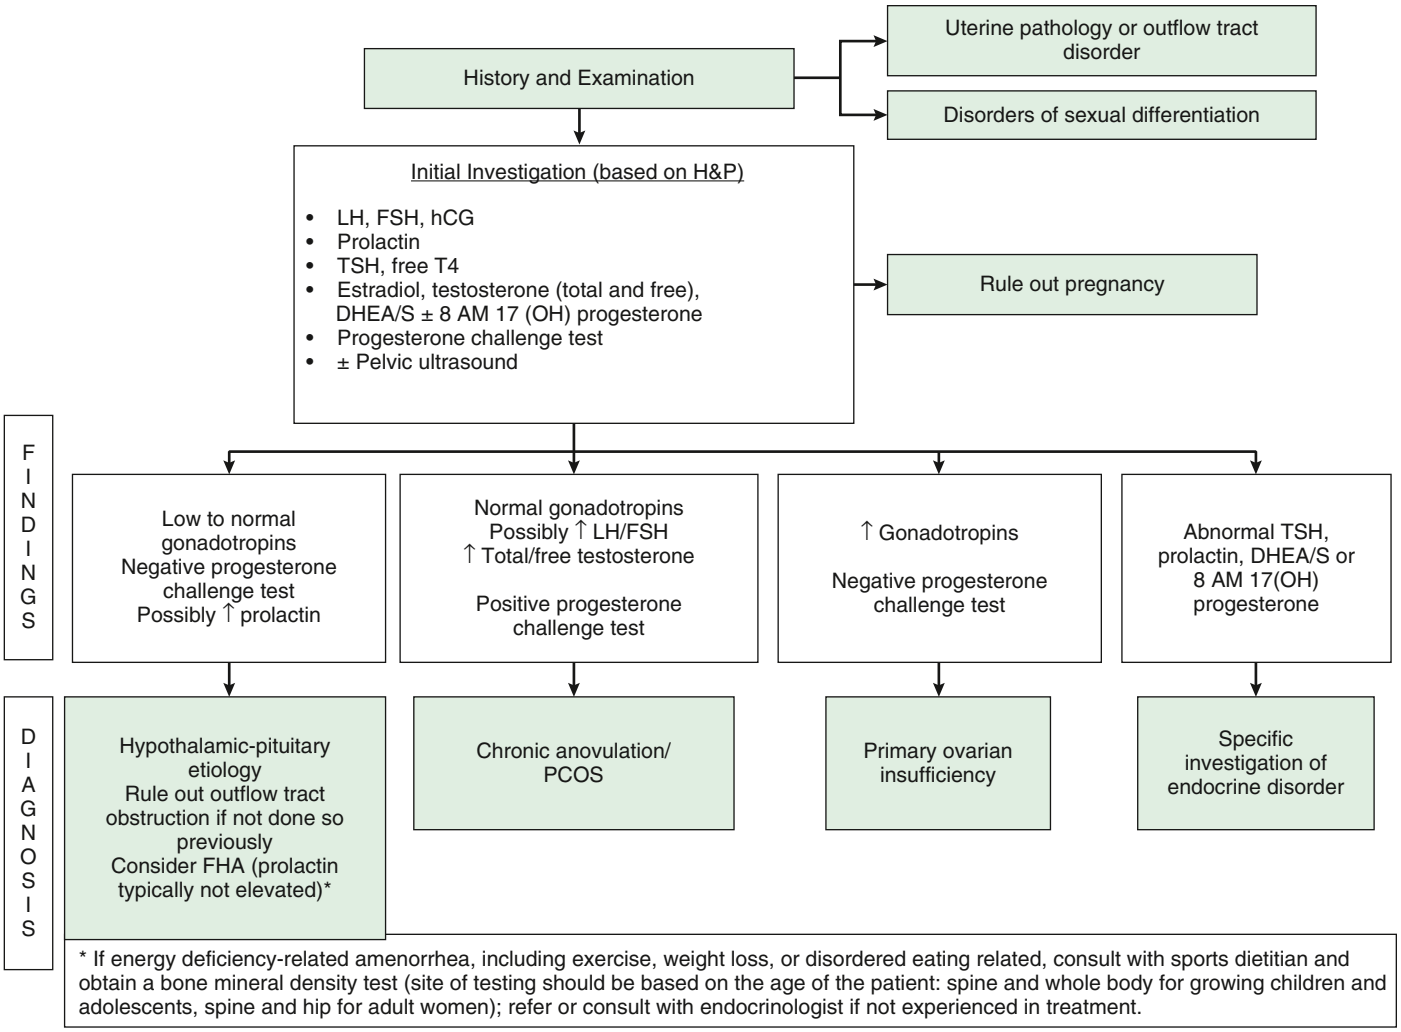

Fig. 732.2 Amenorrhea algorithm. Recommended clinical evaluation of an athlete with primary or secondary amenorrhea, or prolonged oligomenorrhea, includes a history and physical examination, initial and follow-up laboratory testing, and diagnosis by a physician. Referral or consultation with endocrinology is recommended if the diagnosing physician is not experienced with treatment of functional hypothalamic amenorrhea or other etiologies of amenorrhea. DHEA/S, Dehydroepiandrosterone sulfate; FHA, functional hypothalamic amenorrhea; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; PCOS, polycystic ovarian syndrome; TSH, thyroid-stimulating hormone. *(Modified from Jameson JL, De Groot LJ, Illingworth P. Amenorrhea, anovulation, and dysfunctional uterine bleeding. In: Jameson JL, De Groot LJ, eds. Endocrinology Adult and Pediatric, 6th ed. St. Louis: Saunders, 2010: pp. 2341–2355.)*

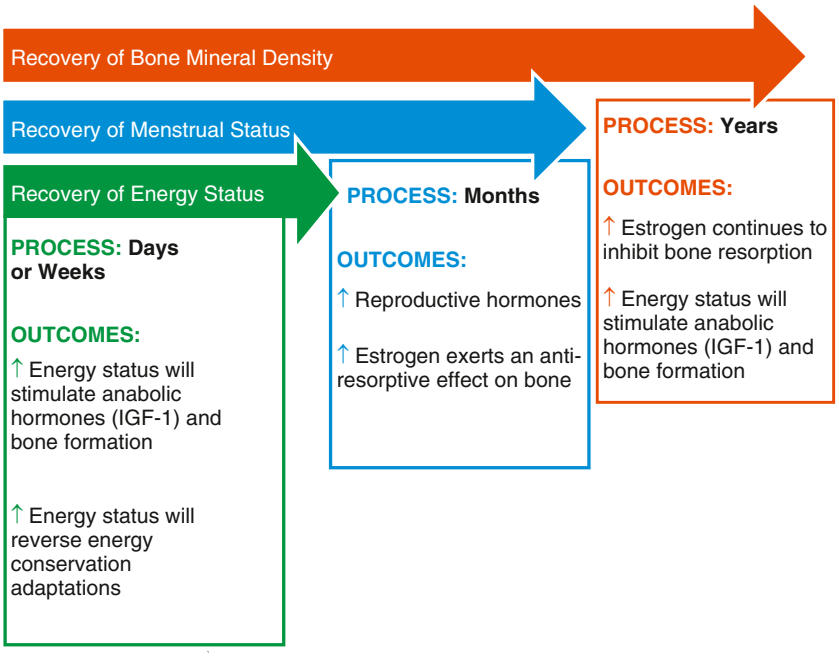

Fig. 732.3 Treatment of the female athlete triad. The three components of the triad recover at different rates with the appropriate treatment. Recovery of energy status is typically observed after days or weeks of increased energy intake and/or decreased energy expenditure. Recovery of menstrual status is typically observed after months of increased energy intake and/or decreased energy expenditure, which improves energy status. Recovery of bone mineral density may not be observed until years after recovery of energy status and menstrual status has been achieved. IGF-1, Insulin-like growth factor-1. *(From De Souza MJ, Nattiv A, Joy E, et al. 2014 Female Athlete Triad Coalition consensus statement on treatment and return to play of the female athlete triad. Br J Sports Med. 2014;48:289. Fig. 3.)*

Chapter 733

Performance-Enhancing Aids

Gregory L. Landry and Andrew M. Watson

See also Chapter 157.

Ergogenic aids are substances used for performance enhancement, most of which are unregulated supplements (Table 733.1). Many agents have significant side effects without proven ergogenic properties. The 2004 Controlled Substance Act outlawed the purchase of steroidal supplements, such as androstenediol and androstenedione, with the exception of dehydroepiandrosterone (DHEA).

The prevalence of lifetime steroid use is highest among males in the United States; among a large representative sample, 3–4% of males in middle school and 5–6% of those in high school report having used steroids for muscle enhancement. The European School Survey Project on Alcohol and Other Drugs found that 1% of European youth reported any use of steroids. Steroids in oral, injectable, and skin cream form are taken in various patterns. *Cycling* is a term used to describe taking multiple doses of steroids for a period, ceasing, and then starting again. *Stacking* refers to the use of different types of steroids in both oral and injectable forms. *Pyramiding* involves slowly increasing the steroid dose to a peak amount and then gradually tapering down.

Anabolic-androgenic steroids have been used in supraphysiologic doses for their ability to increase muscle size and strength and decrease body fat. An evidence base does support the increase in muscle mass and strength; the effects appear to be related to the myotrophic action at androgen receptors, as well as competitive antagonism at catabolism-mediating corticosteroid receptors. However, they have significant endocrinologic side effects, such as decreased sperm count and testicular atrophy in men and menstrual irregularities and virilization in women. Hepatic problems include elevated aminotransaminases and γ-glutamyl transferase, cholestatic jaundice, peliosis hepatitis, and a variety of tumors, including hepatocellular carcinoma. There is evidence that anabolic-androgenic steroids might predispose to a number of cardiovascular risk factors as well, including higher blood pressure, lower high-density lipoprotein, higher low-density lipoprotein, higher homocysteine, and decreased glucose tolerance. The possible psychologic effects include aggression, several personality disorders, and a variety of other psychologic problems (anxiety, paranoia, mania, depression, psychosis). Physical findings that may accompany anabolic-androgenic steroid use in males include gynecomastia, testicular shrinkage, jaundice, male pattern baldness, acne, and marked striae. Women can develop hirsutism, voice deepening, clitoral hypertrophy, male-pattern baldness, acne, and marked striae.

Testosterone precursors (also known as *prohormones*) include androstenedione and DHEA. Their use in the adolescent population has increased markedly in conjunction with reports of high-profile athletes' use. They are androgenic but have not been proven to be anabolic. If they are anabolic at all, they work by increasing the production of testosterone. They also increase production of estrogenic metabolites. The side effects are similar to those of anabolic-androgenic steroids and far outweigh any ergogenic benefit. These substances cannot be sold without prescription.

Creatine is an amino acid mostly stored in skeletal muscle as creatine phosphate or phosphocreatine. Phosphocreatine has the ability to rephosphorylate adenosine diphosphate through the donation of its phosphate group, yielding creatine and adenosine triphosphate. Creatine phosphate is then reconstituted through oxidative phosphorylation. The exogenous provision of creatine can therefore allow for a greater concentration of phosphocreatine in muscle, increasing muscle performance. The use of creatine as an ergogenic aid has increased, especially since other supplements have been withdrawn from the market. Thirty percent of high school football players have used creatine. There is evidence that creatine, as a source of increased energy, enhances strength and maximal exercise performance when used during training.

Caffeine is an active ingredient in energy drinks and some endurance sport supplements that has been shown to have ergogenic effects in both aerobic and anaerobic efforts. It acts primarily as an antagonist at the adenosine receptor, resulting in a number of potentially ergogenic effects such as reduced fatigue and increased muscle power. Although moderate doses of caffeine are considered relatively safe, when included in an energy drink combined with alcohol, excessive caffeine ingestion may result in tachycardia, gastritis, nausea, vomiting, and central nervous system excitation. Overdoses of caffeine may result in seizures, arrhythmias, and hypotension.

Table 733.1 Characteristics of Common Performance-Enhancing Substances

PERFORMANCE-ENHANCING SUBSTANCE	DESIRED EFFECTS	MAJOR ADVERSE EFFECTS	MINOR ADVERSE EFFECTS	STATUS	ROUTE OF ADMINISTRATION
Anabolic-androgenic steroids*	Increase muscle size, strength, lean body mass; decrease body fat	Testicular atrophy, CV disease, atherosclerosis, myocardial disease, liver dysfunction, cancer	Acne, gynecomastia	Banned by IOC and all major sporting bodies	Oral, topical, injectable
Creatine	Increase in strength, power output, sprint performance, total work to fatigue, peak force/power; decrease lactate threshold; increase weight and lean body mass	Heatstroke	Dehydration	Allowed	Oral

Continued

Table 733.1 Characteristics of Common Performance-Enhancing Substances—cont'd

PERFORMANCE-ENHANCING SUBSTANCE	DESIRED EFFECTS	MAJOR ADVERSE EFFECTS	MINOR ADVERSE EFFECTS	STATUS	ROUTE OF ADMINISTRATION
Human growth hormone[†]	May increase lean body mass and decrease fat mass	Carpal tunnel syndrome, intracranial hypertension, CV disease, hyperlipidemia, insulin resistance	Arthralgias	Banned by IOC and International Federations	Injectable
Amphetamines/ stimulants[‡,§]	Increase in alertness and metabolism; may increase strength, muscular power, speed, acceleration, aerobic power, anaerobic capacity, endurance	Arrhythmias, heat exhaustion, seizures, myocardial infarction, sudden death	Agitation, GI upset, nausea, headaches, insomnia, hallucinations	Banned by IOC, NCAA, NFL	Oral, injectable, inhalable
Erythropoietin/blood doping	Increase in oxygen-carrying capacity, endurance	Hypertension, myocardial infarction, pulmonary embolism, immune reaction	Headaches	Banned by IOC and all major sporting bodies	Injectable
Beta-hydroxy-beta-methylbutyrate	May increase lean body mass, muscle strength, power; enhance recovery	Unknown	Unknown	Allowed	Oral
Protein supplements	Increase lean body mass, improve healing	Unknown in previously healthy athletes	Unknown	Allowed	Oral

*Including selective androgen receptor modulators and aromatase inhibitors or estrogen receptor modulators.
[†]Including various growth factors (IGF-1, etc.).
[‡]Caffeine is commonly used and remains permitted by WADA.
[§]Includes various beta-2-agonists prohibited by WADA, except when needed for therapy of asthma but within therapeutic limits.
CV, Cardiovascular; GI, gastrointestinal; IOC, International Olympic Committee; LDH, lactate dehydrogenase; N/A, not applicable; NCAA, National Collegiate Athletic Association; NFL, National Football League; WADA, World Anti-Doping Agency.

Chapter 734

Specific Sports and Associated Injuries

Gregory L. Landry and Andrew M. Watson

SPORTS PARTICIPATION, EARLY SPECIALIZATION, INJURY RISK, AND BURNOUT

It is estimated that 60 million youth, age 6-18 years, participate in organized athletics, with 44 million participating in multiple sports. It has also been estimated that 69% of females and 75% of males age 8-17 years participate in at least one organized sport team or club. Participating in sport gives children the opportunity to develop self-esteem and leadership skills, promote peer socialization, and improve general health and fitness. Some parents encourage their children to participate in a *single sport* because they think this will allow the athlete more time to focus on sport-specific skills and will increase the likelihood that their child will be selected for elite teams, a college scholarship, or professional contract. They may also feel pressure from coaches. However, only 0.2–0.5% of U.S. high school athletes rise to the professional level; Olympic-level athletes start training in their main sport at an older age than their less elite peers and on average participate in two other sports before, or in parallel with, their main sport. A study at the collegiate level revealed that 70% of surveyed athletes did not specialize in their sport until 12 years of age, and 88% participated in more than one sport at some point during childhood. *Multisport* athletes, in general, have a more diverse skill set, can transfer skills from one sport to another, have a decreased risk of **overuse injury**, have lower rates of **burnout**, and thus are less likely to quit sports at a younger age. Exposure to multiple sports also allows these athletes to identify the sport they most enjoy.

Risk of injury in sports increases with age and training volume. In general, there is an increased risk of injury if young athletes participate in more weekly organized sport hours than their age. When young athletes exceed a 2:1 ratio of weekly hours in organized sports to weekly hours in unorganized free play, they are more likely to suffer a serious overuse injury. Overuse injuries unique to young athletes include apophyseal injuries and physeal stress injuries secondary to decreased muscle mass, increased joint hypermobility, and imbalances in growth and strength (see Chapter 728). Overuse injuries and fractures are more likely to occur during adolescent growth spurts as physes, apophyses, and articular surfaces in a rapid phase of growth are less resistant to tensile, shear, and compressive forces than either mature bone or more immature prepubescent bone, and because of decreased blood flow to

the physes. When this underlying vulnerable physiology is combined with overscheduling secondary to participation in a large number of competitive events at young ages, the risk of overuse injury increases. These events often include tournaments, which may consist of multiple games in a short period of time. This type of schedule does not allow enough time for rest and recovery.

Sports specialization is traditionally defined as "participating in a single sport for greater than eight months per year, choosing a single main sport, and/or quitting all other sports to focus on one sport." Athletes who specialize early sometimes report increased anxiety and stress secondary to worrying about failure, trying to meet adult expectations, or experiencing parental pressure to participate or perform at a certain level, and often feel as though they have a lack of control in sport decision-making. These feelings can contribute to burnout, which can lead to quitting sports early and ultimately increased inactivity as an adult. To reduce the risk of overuse injury and burnout, one should limit weekly and yearly participation time, limit sport-specific repetitive movements, and ensure adequate rest and recovery periods. Thus it has been recommended that "intense training in a single sport to the exclusion of others should be delayed until adolescence in order to optimize success while minimizing injury, stress, and burnout."

FOOTBALL

Football is the sport with the greatest number of participants in the United States, especially at the high school level, and with the highest number and rate of injuries. Most of these injuries are relatively minor, and compared with injuries in many other sports, are less severe, as evidenced by fewer days lost from injury. Age, weight, and position played contribute to injury risk, with older and heavier players, running backs, and linebackers having higher injury rates. The most common football injuries include joint sprains, muscle strains, and contusions, with the lower extremities injured most frequently.

Although the majority of catastrophic sports injuries in the United States have occurred in football, these injuries are rare. Catastrophic injury is defined as a fatal injury or a severe injury with or without permanent severe functional disability. Disabling injuries include cervical spine and cerebral injuries.

Head and neck injuries in football include concussion, neck sprain, and brachial plexopathy. Compared to other sports, brain injury (concussion) (see Chapter 729) occurs with the highest rate in football, a result of the frequent exposure to contact during practices and games, although more concussions occur in games than practices. When compared to other sports, cervical spine injuries occur at higher rates in football given the increased risk of high-velocity contact, neck flexion, and axial loading. Proper blocking and tackling form with the neck extended rather than flexed is essential to help reduce the risk of cervical spine injury. Although not shown to reduce the concussion rate, helmets can help reduce facial and dental trauma and provide some protection from side head blows. A **"stinger"** or **"burner"** represents a brachial plexus neurapraxia (see Chapter 730). This is the most common nerve injury in football and results from traction, compression, or a direct blow to the upper cervical nerve roots of the brachial plexus caused by forceful lateral neck bending.

Heat illness is possible in pediatric athletes given physiologic factors, including increased heat production per body weight, less efficient heat dissipation, and higher body temperatures associated with dehydration. Dehydration and associated electrolyte abnormalities and poor acclimatization increase the risk of heat illness. Heat illness risk can be reduced with proper hydration prepractice, during, and postpractice, avoiding practice in high heat or humidity, wearing breathable, light-colored clothing, removing the helmet between plays, and avoiding certain medications such as antihistamines, anticholinergics, stimulants, and supplements (see Chapter 731).

Contusions to the arm or thigh muscles can result in the development of a large hematoma if not treated aggressively in the acute stage, resulting in prolonged time away from football. Large hematomas and those allowed to persist are at risk for development of **myositis ossificans**.

Low back pain can be caused by **spondylolysis**, especially in players with repetitive hyperextension of the spine (see Chapter 720.6). Education on tackling mechanics, core strengthening, and hamstring flexibility are important in prevention of and/or recovery from a spondylolysis injury. Shoulder trauma can cause glenohumeral joint dislocations, the majority of which are anterior dislocations and have a high rate of recurrence; acromioclavicular joint sprains; and fractures to the clavicle or humerus (see Chapter 724). Knee injuries (see Chapter 728.6) are common and include **anterior cruciate ligament (ACL)** tears and, less frequently, medial collateral ligament (MCL) tears. Knee bracing in high school football players is controversial and lacks significant evidence.

Ankle sprains occur frequently, with lateral ankle sprains resulting in less time away from the sport than high ankle sprains. The risk of re-injury may be reduced by rehabilitation, including strengthening and range of motion, and the use of a lace-up ankle brace (see Chapter 728.8). **Turf toe**, a sprain to the first metatarsophalangeal joint, is caused by forceful dorsiflexion of the toe while wearing soft, lightweight, flexible shoes. Calcaneal apophysitis at the insertion of the Achilles tendon on the calcaneus, also known as **Sever disease**, is an overuse injury that typically presents as heel pain in a cleated athlete who is still growing (typically age 7-10 years).

BASEBALL/SOFTBALL

Baseball- and softball-related injury sites are most commonly the shoulder, elbow, ankle, and hip. Facial injuries and concussions are also seen. The most common mechanisms of injury include pitching repetition and being hit by a ball or a bat.

Throwing injuries of the shoulder and elbow are typically seen in pitchers secondary to overuse, with contributory factors, including high pitch count, pitch type, and inadequate rest. **Little League shoulder** is a repetitive microtrauma injury to the open proximal humeral physis, and **Little League elbow** is a repetitive microtrauma injury to one or more of the six ossification centers in the elbow (see Chapter 728.3). Little League shoulder is the most common injury seen in softball windmill pitching, with similar shoulder stress as seen in overhand pitching. Poor core strength and alteration in biomechanics, especially when fatigued, may contribute to injury risk (Fig. 734.1). Age-related **pitch count** and rest guidelines, "Pitch Smart," are available online and are endorsed by the Little League. Curve balls and sliders should not be thrown by players younger than 14 years of age. Current recommendations also advise against participating in multiple leagues and participating in year-round baseball, given the increased risk of injury with this volume of play. Adherence to the guidelines is the responsibility of the athlete, parents, and coaches. Counseling athletes (and coaches) to stop all throwing activities if the player experiences shoulder or elbow pain, with medical evaluation if no resolution with rest, is essential. If injured, a gradual return to throwing protocol under the direction of a physical therapist with additional focus on strengthening and throwing mechanics should be considered. Catchers are more vulnerable to traumatic sprains of the interphalangeal and metacarpal phalangeal joints, head injuries, including concussions from the ball striking the mask, and knee injuries associated with the deep squatting posture. Knee savers are pads attached to the shin guards that increase the angle between the knee and thigh and prevent hyperflexion of the knees. No scientific studies have been done to assess their effectiveness.

Death or serious injury in baseball is rare but may result from direct contact by the ball or bat, causing serious head injury or **commotio cordis**, which is a direct blow to the chest during a critical time in the cardiac cycle resulting in a possibly fatal arrhythmia. Batting helmets, with consideration of faceguards, must be worn properly to help prevent face and head injuries. Modifications to the hardness of baseballs used with younger athletes may also be helpful. Chest protectors have not been shown to reduce the risk of commotio cordis.

Sliding causes the most injuries in base runners, including head injury and lower limb injuries. If sliding is allowed, correct sliding technique must be taught because many injuries are secondary to timing

issues. Head-first sliding is controversial and is not recommended for players younger than 10 years of age.

BASKETBALL/VOLLEYBALL

When combining male and female sports participation, basketball has one of the highest injury rates, even though it is considered a "safe sport" from a contact perspective. Common maneuvers of basketball and volleyball include jumping, pivoting, running, and sudden acceleration and deceleration, which increase the risk for knee and ankle injuries. Similarly, injury to the fingers may result from the passing, catching, and striking of the ball inherent in these sports. Scaphoid fractures may result from falling on an outstretched hand. Injuries to the face and eyes can also occur.

Ankle sprains are the most common injury and are usually caused by inversion with plantar flexion, placing the lateral ligaments at risk. An avulsion fracture of the base of the fifth metatarsal at the insertion of the peroneus brevis tendon is another sequela of inversion ankle injuries. A **high ankle sprain** or syndesmosis ligament injury typically results from an excessive external rotation in a dorsiflexed position, and these athletes have pain out of proportion to examination findings.

Foot pain may be secondary to calcaneal apophysitis (Sever disease), retrocalcaneal bursitis, posterior tibialis tendinosis, accessory tarsal navicular, sesamoiditis, blisters, subungual hematoma, and paronychia (see Chapter 704). Achilles tendinosis is also a common overuse injury.

Knee injuries include those caused by overuse, such as traction apophysitis at the insertion of the patella tendon on the tibial tubercle **(Osgood-Schlatter disease)** (see Chapter 718.4), traction apophysitis at the distal patella **(Sinding-Larsen-Johansson syndrome)** and patellar tendinosis **(jumper's knee)** (see Chapter 728.6).

ACL injury occurs in both male and female participants; however, among children 12-17 years old, the frequency of ACL injury in female participants is slightly higher. The exact reason for this discrepancy is unclear; however, some data suggest that female athletes do not exhibit the same neuromuscular adaptions that male athletes exhibit during pubertal growth spurts. Multiple studies on the effect of neuromuscular training and strengthening programs focused on ACL injury prevention in females suggest that these types of programs may reduce the risk of ACL injury. As with other jumping sports, other acute ligament sprains (MCL with or without ACL) can occur. For all participants, a program focused on the sport-specific strengthening of hip, core, and hamstring muscles to prevent dynamic valgus when landing can help to reduce knee injury rates.

The overhead nature of volleyball can result in overuse shoulder injuries, including rotator cuff tendinosis, shoulder impingement syndrome, labral tears, and glenohumeral instability. Players may want to limit the number of overhead spikes and serves they perform, similar to pitch count limits in baseball, to help reduce the risk of overuse injuries. Finger injuries seen in both basketball and volleyball participants include sprains, dislocations, and fractures.

Eye injuries, although rare, can be reduced by wearing protective eyewear. Facial injuries typically result from an elbow or hand hitting the opponent's face during rebounding or defending. Head injury can occur in both sports when the player makes contact with another player, the floor, or equipment (such as the net pole in volleyball).

TENNIS

Injury rates in high-level youth tennis players are higher than in adults. Tennis injuries occur twice as often in the lower extremity as in the upper extremity. Lower extremity injuries tend to be more acute, whereas upper extremity and trunk injuries tend to be more chronic, and the incidence of overuse injury is high. Overall injury rates are similar for males and females. However, male players age 5-10 years were more likely to sustain injuries to the head and neck and suffer injuries as a result of contact with the net, ball, or racket than other groups.

The most common injury in tennis players is to the ankle, although the knee and thigh are vulnerable as well. Lower extremity injuries are related to the frequent directional changes, creating significant concentric and eccentric loads. Overuse injuries include iliopsoas tendonitis or bursitis, patellofemoral stress syndrome, patellar tendinosis, Osgood-Schlatter disease, medial gastrocnemius strain (**"tennis leg"**), Achilles tendonitis, and Sever disease. Stress fractures in the lower extremity in elite players are most common at the tarsal navicular, metatarsals, and tibia.

In the upper extremities, **tennis elbow** (lateral epicondylosis with extensor carpi radialis brevis tendinosis) and **extensor carpi ulnaris (ECU) tendinosis** with or without subluxation, are particularly prevalent in the recreational player and are thought to be most likely related to overuse and improper technique (see Fig. 728.11). With repetitive overload of the wrist flexor–pronator muscle groups, traction apophysitis at the medial humeral epicondyle and medial epicondylar fragmentation of the humerus, especially in younger males, can occur. This can secondarily involve the ulnar collateral ligament and ulnar nerve. Shoulder pain often results from **labral injury**, a common site of injury for overhead athletes. Anteroposterior glenohumeral instability, glenohumeral internal rotation deficit with impingement, rotator cuff strain, and scapular dyskinesis are all possible. Wrist problems include an enlarged dorsal ganglion cyst, radiocarpal joint capsular impingement or synovitis, chronic degenerative tears of the triangular fibrocartilage complex, and acute fracture of the hook of the hamate. Stress fractures may occur in the metacarpals (second metacarpal in particular) and less commonly in the humerus, ulna, and radius.

It has been hypothesized that repeated loading during service, particularly using a "topspin" serve at a young age, may contribute to the

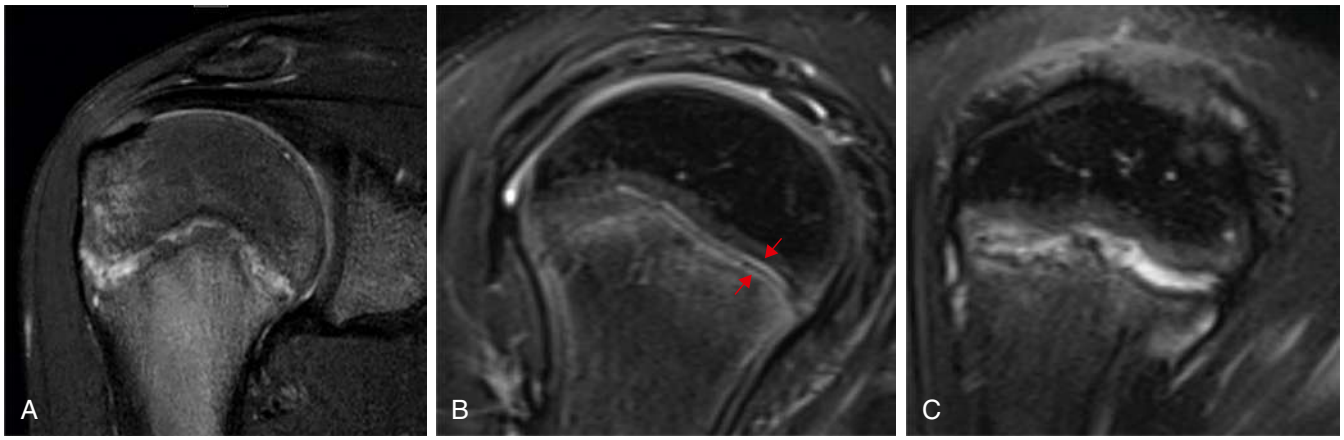

Fig. 734.1 Little League shoulder MRI findings. A, Coronal oblique fat-saturated T2 weighted image in a 12-yr-old pitcher demonstrates diffuse proximal humeral primary physeal widening and undulation with bone marrow edema within the metaphysis and lateral epiphysis. B and C Sagittal oblique fat-saturated T2 weighted images obtained in a 13-yr-old pitcher demonstrate preservation of the normal anterior medial humeral physis *(arrows)* in contrast to the widened irregular physis posteriorly and laterally. *(From Braithwaite KA, Marshall KW. The skeletally immature and newly mature throwing athlete. Radiol Clin N Am. 2016;54:841–855.)*

development of **spondylolysis (pars interarticularis fracture)** or spondylolisthesis. However, the most common back injury in tennis is lumbar muscle strain.

LACROSSE

Lacrosse is one of the fastest growing sports for both male and female youth, high school, and college level athletes. Protective equipment and rules are different for male and female players. Required equipment for male players includes mouth guard, helmet, gloves, and elbow and shoulder pads. Required equipment for female players includes eye wear and mouth guard. **Checking** is allowed in men's lacrosse but is not permitted in youth or women's games.

Injury rates are nearly three times higher in competition than in practice. The most common injuries for all players include lower extremity injuries, primarily ankle and knee sprains, and head injuries. Ankle sprains typically occur in the setting of cutting, dodging, and twisting activities. The likelihood of subsequent injury may be reduced with bracing. ACL tears are a common knee injury and typically occur in noncontact cutting or pivoting. Prepractice training should include balance, lower extremity strengthening, and neuromuscular feedback activities, as these have been proven to help reduce the ACL injury rate.

Head injury occurs in both male and female players. Player-to-player contact is the typical mechanism for head injury in male players. Incidental contact with the stick is the typical mechanism for head injury in female players. Eyewear for female athletes has been shown to reduce the risk of significant eye injury.

Upper extremity injuries include **acromioclavicular sprains** and hand and thumb fractures, particularly in games that permit contact and checking. Shoulder and elbow injuries are typically secondary to contact injury.

As with any sport with significant protective equipment that impedes heat loss, heat illness can occur. Players and coaches should be mindful of hydration, temperature, humidity, and duration of play. Commotio cordis is a rare but possible risk. The use of chest protectors has been evaluated and has not been shown to reduce risk.

SWIMMING/DIVING

In competitive swimming, injuries to the shoulder are most common and are generally a result of chronic overuse. **Swimmer's shoulder** is a general term for shoulder overuse in a swimmer and is typically a combination of subacromial impingement/bursitis and tendinosis of the rotator cuff and long head of the bicep tendon. Commonly, a narrowed subacromial space, increased laxity of the shoulder capsule, and relative weakness of the scapular stabilizers result in protracted shoulder posture, which contributes over time to the insidious onset of shoulder pain and possible **scapulohumeral dyskinesis**. Freestyle, back, and butterfly strokes tend to exacerbate the pain. Prevention includes monitoring training load, proper technique, and strengthening exercises. The multiaxial instability of the glenohumeral joint common in swimmers is addressed with rehabilitation focusing on strengthening of the rotator cuff and scapular stabilizer musculature. Knee and hip/groin pain can be exacerbated with breaststroke given the whip kick motion required in this stroke.

Swimmer's ear, or **otitis externa**, presents with pain and often drainage from the external auditory canal. It is caused by bacterial, or less commonly, fungal infection of the external auditory canal as a result of chronic, excessive wetness (see Chapter 679).

Diving is a sport that many athletes start at a young age with early sport-specific, specialized training. The most common injury for divers is shoulder strain, given overhead activity and the significant force taken by the shoulder, which is dependent on the angle of entry into the water. Low back pain can be seen in divers and may be associated with lumbar hyperextension to compensate for limited shoulder flexibility when entering the water, which can lead to spondylolysis. Diving is also associated with a risk of cervical spinal cord injury secondary to axial loading; according to the National Spinal Cord Injury Statistical Center, diving is the fifth leading cause of spinal cord injury in the United States.

SOCCER

Soccer enjoys a very high level of popularity and participation among youth worldwide. In the United States, the annual rate of injury in soccer more than doubled between 1990 and 2014, and almost three million children were seen in U.S. emergency departments for injuries related to soccer during those years. Mechanisms of injury include noncontact, body-to-body contact, falls, or ball-to-body contact. Although lower extremity injuries are by far the most common, younger children are more likely to injure an upper extremity, and upper extremity injuries are most likely to be fractures. Torso and significant abdominal injuries can occur. Low back symptoms are relatively less common and are most often muscular in nature.

Injuries in youth soccer occur predominately in the lower extremity and include joint and ligament injuries, abrasions, contusions, muscle strains, and fractures of the ankle, knee, and thigh. Ligamentous injuries to the ACL and MCL at the knee and the **anterior talofibular ligament** at the ankle can occur because of the cutting and pivoting maneuvers required during play or as a result of contact with another player. ACL injuries, particularly in females, have gained attention in recent years. ACL injuries are more common in high school girls' soccer than in other girls' sports. Risk factors may include genetics, hormones, age, sex, previous injury, and anthropomorphic factors. **Overuse syndromes** such as patellofemoral dysfunction, Osgood-Schlatter, Sinding-Larsen-Johansson, and Sever disease frequently occur. Hip problems include the **hip pointer (iliac crest contusion)**, iliac crest apophysitis, and chronic groin pain (muscle strain, **sports hernia**, **osteitis pubis**). The terms *sportsman's hernia, inguinal insufficiency,* and *conjoint tendon tear* may comprise a constellation of different pathologic processes producing similar groin pain. These injuries may occur with the combined forceful rotation of the torso and kicking motion. Femoral neck stress fractures, slipped femoral capital epiphysis, and avulsion fractures of the pelvis or femur should also be considered in the differential. Neuromuscular factors, such as quadriceps dominance, muscle activation patterns and dynamic stability, may be modifiable; thus the American Academy of Pediatrics (AAP), and other organizations support neuromuscular training programs aimed at risk reduction for both sexes.

Concussion is common in soccer, primarily as a result of contact between players, player and goal post, and player and ground. Recent evidence suggests that intentional heading of the ball rarely results in a concussion, although the long-term effect of repeated subconcussive impacts for intentional heading remains unknown. The U.S. Soccer Concussion Initiative updated recommendations to reduce head injury risk in youth soccer players, including a ban on heading the ball for age 10 and under and limited heading of the ball for 11-13 year olds. It remains unknown if this has reduced the number or severity of concussions. Padded headbands have not been shown to reduce the risk of concussion in youth soccer players.

ICE HOCKEY

Ice hockey is a fast-paced collision sport associated with injuries caused by contact from other players, the ice, or the boards, as well as from the puck or stick. With injury rates similar to other high school full-contact sports, concussions, contusions, fractures, ligament sprains, muscle strains, lacerations, joint separations, dislocations, and subluxations are commonly reported. Injuries are more likely to occur in competition than in practice, and overall injury rates appear to be on the rise, possibly related to increased participation.

Concussion was the most commonly reported injury in U.S. high school ice hockey athletes, with head and face injuries accounting for 34% of all of the reported injuries. Injuries to the shoulder and arm are also common and include contusions, strains, acromioclavicular separations, and clavicle fractures. Over 50% of upper extremity fractures occur in the forearm, wrist, and hand. Other specific hockey injuries include hip pain secondary to **femoroacetabular impingement (FAI)**, high ankle sprains, hip adductor strain, and osteitis pubis.

The role of factors such as age, size, level of skill, player position, and sex in injury risk is inconclusive, although evidence suggests that concussion may be more frequent in females and fractures more common in males.

Body checking is the single most common mechanism of injury. In Canada, 11- and 12-year-old Pee Wee hockey players who were allowed

to body check had a threefold greater risk of injury than those who were not. USA Hockey rules of play do not allow body checking in the 12-year and under youth leagues. Body checking is not allowed in girls'/women's leagues of any age. The AAP recommends the expansion of nonchecking programs and the restriction of body checking to elite levels of boys' play after 15 years of age. AAP recommendations also include the use of protective equipment (helmets and full-face shields or cages), rules to eliminate dangerous play with a zero-tolerance policy for head contact and body contact from behind, and safer play education for coaches and athletes.

FIELD HOCKEY

Field hockey is played worldwide by both male and female athletes. Protective equipment, including mouth, shin, and ankle guards, is recommended but not required. Players are twice as likely to be injured in game versus practice. Lower limb injuries, particularly inversion ankle sprains, are the most common. Bracing may help with ankle re-injury rates. Other lower extremity injuries include hamstring strain, ACL tears, and contusions. The most common upper limb injury occurs when the hand is struck by a stick or a ball, as field hockey does not require the use of padded gloves for protection. Head injury and facial lacerations occur at a very high rate and are typically caused by contact with the stick or ball. Injury types and rates may differ based on the position played; however, specific data are lacking.

Injury prevention is important in this sport and can be attained via the use of protective equipment, including permitted head or face protection, and sport-specific training, including balance, strengthening, and proprioceptive training activities.

SKIING AND SNOWBOARDING

Injury frequency in skiing, snowboarding, and related winter sports has declined over the past several decades, largely secondary to improved equipment (boots, bindings, poles) and slope conditions. Of concern, however, is that severe head and spinal cord injuries are on the rise due to increased speed and the addition of acrobatic maneuvers (terrain parks, half pipes, aerial tricks). Head and neck injuries are the primary cause of fatal injury. Of the World Cup events, freestyle skiers (particularly aerials and slope style) have a higher incidence of head injury than snowboard and alpine events. Overall, the risk of injury is higher in snowboarders, males, beginners, and those with improper equipment.

Lower extremity injuries are more commonly associated with skiing, while head, internal organ, upper extremity, and ankle injuries are more common in snowboarders. The most common lower extremity injury in skiing is ligamentous (ACL, MCL, and LCL) at the knee. Lower-extremity injuries in skiers also include contusions, knee dislocation, femur fractures, spiral fractures of the tibia **("boot top" fractures)**, and high ankle sprains. Snowboarders are at a unique risk for fracture of the lateral process of the talus, which is often initially misdiagnosed as an ankle sprain.

Upper-extremity injuries are more common in snowboarding because both of the snowboarder's feet are strapped onto the same board and, without poles, there is an increased risk of falls on outstretched arms. Common injuries include distal radial, ulnar, and metacarpal fractures, sprains, and contusions. Other high-incidence upper extremity injuries in snowboarding include shoulder soft tissue injuries, clavicle fractures, acromioclavicular sprains, and glenohumeral joint dislocations. A unique skiing injury is **skier's thumb**, a sprain of the ulnar collateral ligament of the thumb, which typically results from a fall with the thumb in abduction and hyperextension around a ski pole. Phalanx fractures and bony avulsions can also be associated with this injury.

Snow sport athletes may experience visceral injuries to the spleen, liver, and kidney. Spine injuries, including fracture and strain, may also occur.

It is strongly advised that individuals of all ages wear helmets for skiing and snowboarding. Wrist protectors are also recommended for snowboarders. Care should be taken to ensure up-to-date and properly fitted and adjusted equipment. Preventive measures endorsed by the AAP include participation in formal instruction, such as in a ski school, having adequate supervision, and exercising responsible speed and technique. Cardiovascular fitness, endurance, and muscle strength are believed to be critical components in injury prevention; however, there is limited supportive literature.

SKATEBOARDING

Injuries associated with skateboarding are predominantly acute, including contusions, lacerations, sprains, and fractures, affecting the wrists, forearms, and to a lesser extent, the ankles and head. Fractures involving the upper extremities are more common in younger skateboarders, often from a fall onto an outstretched arm. Lower-extremity fractures and head injuries predominate in the adolescent population, which is likely because of higher complexity of the airborne maneuvers and tricks often attempted. Loss of balance leading to a fall when failing to perform a particular maneuver, especially when catching a wheel, is generally the primary cause of injury. These falls can occur at high velocities (up to 40 mph), placing the skateboarder at risk for serious injuries.

Traumatic brain injuries do occur within this sport; the incidence increases with age and is more common in males than females. In older children and adolescents, the neglected use of helmets and the increased speed of their skating contribute to this fact.

In addition to helmet use, other safety measures recommended include wrist guards as well as elbow and knee pads. The building of skateboard parks has been a recent strategy to remove skateboarders from pedestrians, bicyclists, and motor vehicle traffic, while also encouraging adult supervision.

CYCLING AND MOTOCROSS

Bicycle riding has been a beloved childhood recreational activity for decades. Cycling options have expanded to include a variety of events such as track and road racing as well as mountain biking, mountain bike terrain parks or "free-riding," cyclo-cross, and freestyle BMX. As increased speed, jumps, and other human-made obstacles have been added, risk for injury has increased. Motocross, beginning as early as 4 years of age, adds further complexity as it uses two-wheeled motorized cycles racing through designed outdoor courses.

Recreational bicycling injuries include abrasions, lacerations, contusions, and fractures. Head and face as well as genitourinary injuries are common. Helmet use is strongly encouraged to reduce the risk of serious head injury. Upper extremity fractures predominate in mountain bikers and mountain terrain park riders. Risk of injury is increased in mountain biking males between 10 and 14 years and in those who admit to riding faster than usual. Motocross riders sustain more serious injuries. Head injuries include skull fractures and a variety of intracranial bleeds that may occur even when using a helmet.

WRESTLING

Wrestlers may have great fluctuations in weight to meet weight-matched competition standards. Such fluctuations are sometimes associated with fasting, dehydration, and then binging. Counseling wrestlers and their parents regarding impaired performance from these components of disordered eating, especially with respect to decreased speed and strength, is important to deter athletes from incorporating them into routine practice. Most states have rules in place to mitigate this risk by limiting the amount of weight loss for each wrestler.

Wrestling moves apply a variety of torques or forces to the extremities and spine, potentially resulting in a number of common injuries. Takedown maneuvers and subsequent impact with the mat can produce concussions, neck strain/sprain, or spinal cord injury. Spondylolysis (see Chapter 720.6) is a concern in wrestlers given repetitive lumbar extension.

Stingers and **burners**—also seen among football players—are caused by stretching or pinching of the brachial plexus (see Chapter 730). Overall, the two most common sites of injury in wrestling are the shoulder and knee.

At the shoulder, subluxation is common. This generally occurs anteriorly with the shoulder forcibly abducted and extended. Patients are commonly aware of their shoulder slipping in and out. Injuries to the hand are less common and typically include metacarpophalangeal and proximal interphalangeal joint sprains.

Knee injuries (see Chapter 728.6) are also common, and include **prepatellar bursitis**, medial and lateral collateral ligament sprains, and medial and lateral meniscus tears. Acute or recurrent traumatic impact to the mat can result in prepatellar bursitis. If the overlying skin is broken, septic bursitis may occur, resulting in swelling, redness, and warmth over the anterior knee.

Dermatologic problems associated with wrestling include herpes simplex (see Chapter 299: **herpes gladiatorum**), impetigo (see Chapter 706.1), staphylococcal furunculosis or folliculitis, superficial fungal infections, and contact dermatitis. Herpes gladiatorum and superficial bacterial skin infections are contraindications to wrestling until the lesions have resolved. Washing of the wrestling mats with appropriate antibacterial and antifungal solution is required after daily wrestling sessions to keep the mats disinfected and prevent the spread of dermatologic contagion.

Auricular hematoma is caused by friction or direct trauma to the auricle (see Chapter 683). If allowed to remain without evacuation, irreversible deformity of the auricle often results, termed cauliflower ear. Properly fitted headgear is the best means of prevention, and early aspiration of the accumulated blood may reduce the risk of deformity.

RUNNING

Running for sport and exercise has increased in popularity for children and adolescents. Running problems are typically caused by overuse injury related to muscle imbalance; a minor skeletal deformity; repetitive overload; and/or poor flexibility, strength, endurance, or proprioception. With each step while running, the foot impact ranges from 3-8 times the athlete's body weight. Errors in training, including increasing the distance or intensity of workouts too rapidly, often result in injury to the runner. Minor variations (e.g., malalignment) in anatomy that do not cause problems at rest can predispose to injury at specific sites, such as **over-pronation** contributing to increased **patellofemoral stress**. Muscle fatigue, environmental temperature (see Chapter 731), and running surface (grass vs unyielding concrete) also contribute to injury. **Barefoot** or **minimalist running** shoes may promote greater weight distribution through the forefoot during running, and biomechanical research suggests reduced joint forces through the knee and hip. However, increased forces can occur through the foot, ankle, and lower leg in individuals not accustomed to this style of running. Prevention of injuries is possible by muscle-strengthening exercises, incorporating periods of rest into training plans, and the use of good-quality running shoes that match an athlete's foot type.

Shin splints, or **medial tibial stress syndrome**, is a descriptive term for pain located diffusely over the distal medial tibia and should be distinguished from tibia stress fracture and chronic exertional compartment syndrome. Medial tibial stress syndrome is a periosteal stress reaction at the insertion of the soleus muscle. It can be seen in new runners, runners that have markedly increased their training duration in a short period of time, and runners with higher body mass indices (BMIs). Continued loading and stress of medial tibial stress syndrome can lead to a **stress fracture**. Stress fractures in runners (see Chapter 724.4) have been documented at the femoral neck, inferior pubic rami, subtrochanteric area, proximal femoral shaft, proximal tibia, fibula, calcaneus, tarsal navicular, metatarsals, and sesamoids. The most common are in the metatarsals, tibia, and fibula. The anterior proximal tibia, femoral neck (tension or superior side), tarsal navicular, and sesamoids are most at risk for nonunion.

Muscle strains most frequently affect the hamstrings, followed by the quadriceps, hip adductors, soleus, and gastrocnemius muscles. Lower extremity tendon injuries are more common than apophyseal injuries in young, skeletally immature runners. Tendon injury is most common in the Achilles tendon, followed by the posterior tibial, peroneal, iliopsoas, and proximal hamstring tendons. Achilles tendinosis should be distinguished from retrocalcaneal bursitis.

Knee pain in the runner is frequently anterior in location and is commonly caused by **patellofemoral pain syndrome (runner's knee**), which results from excessive dynamic, usually lateral, motion of the patella in relationship to the femoral intracondylar groove (see Chapter 728.6). The athlete's body habitus (i.e., increased Q-angle, over-pronation) and presence of core and hip abductor weakness may contribute to this overuse injury. Posterior knee pain can be caused by gastrocnemius strain, while posteromedial pain may be caused by proximal tibial stress fracture or semimembranosus/semitendinosus tendinosis. Lateral knee pain is commonly caused by **iliotibial band syndrome** and less so by **popliteal tendinosis**, which may be precipitated by running downhill. Iliotibial band syndrome may combine a component of both bursitis and tendinosis owing to mechanical friction of the iliotibial band (an extension of the tensor fasciae latae) over the lateral femoral epicondyle. Vague knee pain that worsens with activity or traumatic event, particularly if associated with joint swelling, should raise suspicion for **osteochondritis dissecans**, most commonly located at the lateral aspect of the medial femoral condyle.

Chronic exertional compartment syndrome can involve any of the muscle compartments, but the most common is the anterior compartment. There is typically poorly localized throbbing pain that begins 10-15 minutes into a run. Pain typically prevents further training, thus limiting the risk of nerve injury (see Chapter 728.7).

Plantar fasciitis is an inflammation of the supporting structures of the longitudinal arch of the foot due to repetitive cyclic loading with foot strike. Pain is typically worst with the first step out of bed in the morning and with running and is located on the medial aspect of the heel. Pes planus and over-pronation are common in these patients. Calcaneal stress fracture should be considered, especially in the amenorrheic distance runner (see Chapter 732).

The **female and male athlete triads (or relative energy deficiency in sport)**, referring to abnormalities in energy availability, endocrine function, and bone health, are well documented in adolescent running literature and are important education topics for the runner, parents, and coaches (see Chapter 732).

CHEERLEADING

Like other sports, cheerleading has become increasingly popular and evolved to become more competitive and athletic. Cheerleading can begin as early as 3-6 years of age and includes skill levels ranging from recreational to sideline, competition to professional. The sport includes advanced gymnastic tumbling and "stunts" involving athletes lifting and throwing other athletes overhead. This requires repetitive flexion, hyperextension, and rotation of the spine as well as compressive loading on landings, and the risk of athlete contact and falls.

Stunting injuries account for the majority of injuries, with bases (the athletes who lift, throw, and catch another athlete) at higher risk of injury than fliers (athletes who are lifted and thrown). The primary mechanism of injury is contact with another athlete. Injuries sustained in tumbling are the second most common.

The overall injury rate in cheerleading is low at 1/1,000 athletic exposures. However, injuries may be severe; of all female sports, the risk of catastrophic injury is the highest in cheerleading. Following a period of increasing incidence of injury, it appears that injury rates have stabilized.

Head and facial injury accounts for almost one third of injuries sustained. Head trauma primarily results from falls while stunting or from a pyramid formation, which includes the base cheerleaders as well. After concussion, strains and sprains account for the most likely injuries, with ankle the most common site followed by wrist and trunk. Fractures are more likely to occur in the upper extremity. Overuse injuries are common.

Strategies to reduce the risk of injury include designating cheerleading as an official sport, ensuring athletes undergo preparticipation exams, participating in conditioning and strength training, using proper lifting technique, avoiding stunting over hard surfaces, and educating coaches and trainers about sport safety, including specific rules for the execution of technical skills. The American Association of Cheerleading Coaches and Administrators and others have also set up rules to limit the type of stunts performed, and the National Federation of State High School Associations annually updates rules for spirit events with the intent of improving cheerleading safety.

GYMNASTICS

Typically, males and females begin gymnastics participation at 4-5 years of age. The highest level of competition is in the mid-teens followed by retirement, often by 20 years of age for females and mid-20s for males. Both acute and chronic injuries, with a high incidence of overuse-related injuries, are seen in gymnasts and commonly involve the wrists, shoulders, ankles, and back. Injury types and rates in the acrobatic and circus arts are similar to those seen in traditional gymnastics.

The injury rate is similar in male versus female gymnasts. Lower-extremity injuries are more common in female gymnasts, whereas upper body injuries occur with higher frequency in male gymnasts.

Apparatus competed upon accounts for this discrepancy, such as the horizontal bar and ring exercises for male gymnasts, which place a great deal of stress upon the shoulders, and floor exercise, vault, and balance beam for female gymnasts, stressing the feet and ankles. In addition to mechanical or traumatic injuries, female gymnasts may have delayed menarche and can be at risk for hypothalamic amenorrhea or oligomenorrhea, as well as low body weight for height, which is related to disordered eating. Despite the presence of these two components of the **female athlete triad** (see Chapter 732), the third component, reduced bone density or osteoporosis, is not commonly seen. In fact, bone density tends to be high in most gymnasts, which is thought to be secondary to their performance involving repetitive high-impact activities. Nevertheless, **stress fractures**, in both the upper and lower extremities, are a significant problem. The short stature associated with male and female gymnasts is probably caused by selection bias and not the result of gymnastics training.

The amount of weight bearing through the upper extremities in gymnastics can contribute to the development of both traumatic and overuse injuries. During upper extremity weight bearing, the wrist, particularly over the radial physis, is subjected to a force almost twice the athlete's body weight and up to 16 times the body weight during high-impact loading activities. This, along with repetitive motion, axial compression, and torsional forces, contributes to the increasing frequency of wrist pain and injury in gymnastics and acrobatics. Wrist pain and injury is also correlated with training intensity, based on skill level and number of hours of training per week. Wrist injuries typically seen include **distal radial epiphysitis (gymnast's wrist)**, triangular fibrocartilage complex tears, scaphoid fractures, **scapholunate dissociation**, dorsal ganglion cysts, and wrist sprains (see Chapter 722). Individualized training regimens, including gradual increase in training load and reduced training during growth spurts, as well as the use of wrist orthoses, should be considered for these athletes.

Ankle sprain remains the most common injury in gymnastics, secondary to forces seen in landing and dismounting. Ankle sprains that have not responded to conservative management should be further evaluated for osteochondral defects of the talar dome. Heel pain may be secondary to plantar fasciitis, Sever disease, or calcaneal stress fracture. Patellar tendinopathy may contribute to knee pain in a gymnast.

Spine injuries are notable for a high incidence of **spondylolysis**, a stress fracture of the pars interarticularis, and, in less frequent cases, spondylolisthesis, both related to repetitive extension loading of spine (see Chapter 720.6). Other potential sources of back pain in a gymnast include intervertebral disk pathology, **Scheuermann disease** (juvenile kyphosis) (see Chapter 720.4), and mechanical back pain secondary to biomechanical imbalances.

DANCE

Dance, including ballet, modern dance, or drill line, is a highly demanding activity that may be associated with delayed menarche in females and disordered eating in both female and male dancers (see Chapter 732). Acute injuries commonly involve the lower extremities. Overuse injuries are common, due to the repetitive nature of maneuvers incorporated into training and performance and occur at the same rate in amateur male and female dancers. Injuries seen in modern/contemporary dance are similar in type and incidence to those seen in traditional ballet.

Frequently, kinetic chain dysfunction contributes to injury and should be considered when evaluating the dancer. Common mistakes in technique can cause injury, such as forcing excessive "turnout" (external rotation at the hip) in ballet resulting in undue stress placed upon the hip and knees (see Chapter 728.6).

Foot problems are common and include metatarsal stress fractures, subungual hematomas, **sesamoiditis**, **tenosynovitis** (especially of the flexor digitorum longus), plantar fasciitis, Achilles tendinitis, retrocalcaneal bursitis, calluses, and bunions (see Chapter 728.7). A **dancer's fracture** is an avulsion fracture of the distal shaft of the fifth metatarsal. This fracture is at risk for delayed healing as a result of the tenuous blood supply in the area and may necessitate surgical fixation. Common ankle injuries and pain include acute sprains, anterior and posterior impingement syndromes, and osteochondral defects of the talus. Soft tissue impingement between the lateral malleolus and talus can cause persistent pain after an inversion injury. Medial tibial stress syndrome ("shin splints") and tibial stress fractures are noted in the lower leg. Achilles tendinopathy is seen due to the demands of running and jumping. Patellar malalignment or hypermobility can result in patellofemoral pain syndrome or, less frequently, patellar subluxation/dislocation. Patellar tendinopathy is widely reported. **Internal snapping hip syndrome**, caused by the iliopsoas tendon riding over the anterior hip capsule and iliopectineal eminence, and hip flexor (rectus femoris and iliopsoas) tendinosis are commonly noted in traditional ballet. Gluteal region pain with sciatica may be a result of piriformis syndrome, which occurs because of the repetitive external hip rotation required in ballet (see Chapter 728.5).

The proper time to allow a ballet dancer to go en pointe is a common question asked by dancers and parents alike. The average age to go en pointe is 12 years. A functional test should be part of that decision: if the young dancer is able to perform a passé steadily away from the barre and maintain an en pointe position without pain or instability, the dancer is likely ready to begin dancing en pointe. **Posterior impingement syndrome** of the ankle can be seen with dancing en pointe, given compression between bony or soft tissue structures during terminal plantarflexion. An **os trigonum** is commonly the cause of bony-related posterior impingement syndrome.

ADAPTIVE SPORTS

Participation in sports and recreational activities helps to minimize deconditioning; improve strength, endurance, and cardiopulmonary fitness; and promote companionship, sense of achievement, and self-esteem (see Chapter 756). Participation can also support the development of the child's motor coordination and adjustment to physical limitations. However, children with disabilities tend to participate less in physical activity for myriad reasons, including lack of access to activities or opportunities for participation, lack of self-confidence, and fear of injury by the child, parent, or physician. Direction into appropriate sports/physical activity rather than excluding them should be guided by the child's physical or mental challenge, physical abilities, preparticipation exam, and consideration of the American Academy of Orthopedic Surgeons "participation possibility chart," which outlines recommended sports and recreation based on physical disability.

Fear of injury remains a barrier to participation for many; however, the risk of injury for an adaptive sport athlete is no greater than for an athlete without disability. Injuries in the adaptive sport athlete are influenced by the specific disability, equipment used, and prosthetic or orthotics worn. Acute soft tissue injuries, including skin abrasions, contusions, sprains, and strains, tend to be the most common injuries; fractures and dislocations tend to be uncommon, given the lower participation in contact sports. Overuse injuries commonly occur in this athlete population. Lower limb injuries are more common in athletes with amputations or cerebral palsy, and upper limb injuries are more common in spinal cord injury and wheelchair-based athletes. Appropriate training to support muscle balance and avoid muscle imbalance, as well as the management of **spasticity** and properly fitting prosthetics and orthotics can help to reduce the risk of overuse injuries. Pressure sores are common in wheelchair-based athletes and can be avoided with vigilant skin care and monitoring and weight shifting.

Consideration of the athlete's disability and medications is essential because they may have increased propensity for abnormalities in, for example, thermoregulation, resulting in heat illness, and fluid and electrolyte derangements. This should be discussed and monitored with the athlete, parents, athletic trainers, and coaches, as appropriate.

Section 3

The Skeletal Dysplasias

Chapter 735

General Considerations in Skeletal Dysplasias

Julie E. Hoover-Fong and Daniah Albokhari

Genetic skeletal disorders include skeletal dysplasias, as well as metabolic bone conditions, dysostoses, and other skeletal malformations (Table 735.1).

The **chondroosteodysplasias**, also known as **skeletal dysplasias** or bone dysplasias, are a genetically and clinically heterogeneous group of disorders with an estimated prevalence of 1/4,000 births. The chondroosteodysplasias can be divided into the chondrodysplasias and osteodysplasias. The former includes genetic disorders of cartilage and results in deficient linear growth, typified by achondroplasia. The **osteodysplasias** are marked by abnormal bone structure, with a classic example of osteogenesis imperfecta (see Chapter 742). The clinical picture of the chondroosteodysplasias is dominated by generalized skeletal abnormalities with frequent involvement of nonskeletal elements. The disorders range in severity from lethal in utero to such mild features as to go undetected. Metabolic bone conditions, such as rickets or hypophosphatasia, are because of abnormal bone mineralization, whereas the dysostoses affect a single bone (e.g., craniosynostosis). Many complex genetic syndromes include skeletal malformations as part of the overall phenotype.

The chondrodysplasias are distinguished from other forms of short stature by skeletal disproportion between the length of the torso and the limbs. There are two basic categories of skeletal dysplasias: those with predominantly short limbs versus short trunks. Figure 735.1 notes the importance of cartilage in bone formation. Efforts to define the extent of clinical heterogeneity has resulted in the delineation of well

Table 735.1 Nosology of Genetic Skeletal Disorders: 2023

GROUP #	NAME	EXAMPLES*
01	FGFR3 chondrodysplasias	Achondroplasia, hypochondroplasia, thanatophoric dysplasia type 1, 2
02	Type 2 collagen disorders	Achondrogenesis (*COL2A1*), Kniest dysplasia, Stickler syndrome (*COL2A1* related)
03	Type 11 collagen	Stickler syndrome (*COL11A1*, *COL11A2*), Marshall syndrome
04	Sulfation disorders	Achondrogenesis (*SLC26A2*), diastrophic dysplasia, spondyloepimetaphyseal dysplasia
05	Dysplasias with multiple joint dislocations	Ehlers-Danlos syndrome types 1 and 2, SEMD with joint laxity
06	Filamins and related disorders	Frontometaphyseal dysplasias (multiple types), Larsen syndrome
07	Proteoglycan core protein disorders	Spondyloepiphyseal dysplasias (multiple types)
08	TRPV4 disorders	Metatropic dysplasia, spondyloepiphyseal dysplasia, SEMD
09	Pseudoachondroplasia and the multiple epiphyseal dysplasias	Sticker syndromes (multiple types), MED (multiple types)
10	Skeletal disorders caused by abnormalities of cilia or ciliary signaling	Short-rib polydactyly syndromes (Jeune syndromes multiple types), Ellis-Van-Creveld syndrome, Meckel syndrome
11	Metaphyseal dysplasias	Metaphyseal dysplasia (multiple types)
12	Spondylometaphyseal dysplasias	Spondylometaphyseal dysplasias (multiple types)
13	Spondyloepi(meta)physeal dysplasias	Multiple types
14	Severe spondylodysplastic dysplasias	Achondrogenesis (*TRIP11*), spondylometaphyseal dysplasia (*GPX4*, *SBDS*, *PAM16*)
15	Mesomelic and rhizo-mesomelic dysplasias	Robinow syndrome (multiple types), mesomelic dysplasia (multiple types)
16	Acromesomelic dysplasias	Multiple types
17	Acromelic dysplasias	Geleophysic dysplasias, acromicric dysplasias, Weill-Marchesani syndrome (multiple types)
18	Brachydactylies (isolated)	Multiple types
19	Brachydactylies (syndromic)	Multiple types, Coffin-Siris syndrome (multiple types)
20	Bent bones dysplasias	Campomelic dysplasia, bent bone dysplasia
21	Primordial dwarfism and slender bones	Microcephalic osteodysplastic primordial dwarfism (multiple types)
22	Lysosomal storage diseases with skeletal involvement	Mucopolysaccharidosis types 1, 2, 3, 4, 6, 7, 10
23	Chondrodysplasia punctata (CDP)	Rhizomelic CDP (multiple types)

Continued

Table 735.1 Nosology of Genetic Skeletal Disorders: 2023—cont'd

GROUP #	NAME	EXAMPLES*
24	Osteopetrosis and related osteoclast disorders	Osteopetrosis (multiple types)
25	Osteosclerotic disorders	Caffey disease and dysplasia, craniometaphyseal dysplasias
26	Osteogenesis imperfecta (OI) and bone fragility	OI (multiple types), osteoporosis (multiple types)
27	Disorders of bone mineralization	Hypophosphatasia, hypophosphatemic rickets (multiple types)
28	Skeletal disorders of parathyroid hormone signaling	Metaphyseal dysplasia (*PTHR1*, *SIK3*)
29	Osteolysis	Progeria, mandibuloacral dysplasias (multiple types)
30	Disorganized development of skeletal components	Cherubism, fibrodysplasia ossificans progressiva
31	Overgrowth and segmental overgrowth	Marfan syndrome, Loey-Dietz syndrome, Sotos syndrome, Proteus syndrome
32	Genetic inflammatory or rheumatoid-like osteoarthropathies	Neonatal onset multisystem inflammatory disease
33	Cleidocranial dysplasias (CD)	CD (*RUNX2*, *CBFB*)
34	Syndromes with craniosynostosis	Carpenter syndromes, Crouzon syndromes, Pfeiffer syndromes
35	Craniofacial dysostosis	Treacher Collins syndrome (multiple types), frontonasal dysplasias; mandibulofacial dysostosis (multiple types)
36	Vertebral and costa dysostosis	Spondylocostal dysostosis (multiple types), Klippel-Feil syndrome (multiple types)
37	Patellar dysostosis	Nail patella syndrome, Holt-Oram syndromes
38	Limb hypoplasia (reduction defects)	Holt-Oram, Cornelia de Lange syndrome (multiple types) Rothmund-Thompson syndrome, Poland syndrome, TAR syndrome
39	Split hand / foot ± other manifestations	Ectrodactyly-ectodermal dysplasia-cleft palate, split hand-foot malformation (multiple types)
40	Polydactyly-syndactyly triphalangism	Preaxial polydactyly (multiple types), syndactyly types 1, 3, 4, 5
41	Defects in joint formation and synostosis	Multiple synostosis syndrome (multiple types), radio-ulnar synostosis (multiple types)

*Examples are not all inclusive; incomplete list.
SEMD, spondyloepimetaphyseal dysplasia; MED multiple epiphyseal dysplasia; ( ) gene notations in italics; TAR, thrombocytopenia absent radius.
Data from Unger S, Ferreira CR, Mortier GR, et al. Nosology of genetic skeletal disorders: 2023 revision. *Am J Med Genet* 2023;1-46 (Table 1).

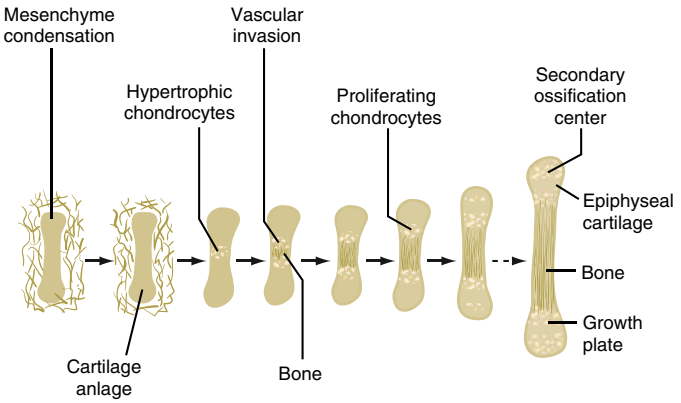

Fig. 735.1 The importance of cartilage in bone formation. *(From Horton WA. Skeletal development: insights from targeting the mouse genome. Lancet. 2005;362:560.)*

over 200 distinct entities (Table 735.2). Many of these disorders result from pathogenic variants of a relatively small group of genes, the *chondrodysplasia genes*. The better-defined chondrodysplasia groups, such as the *FGFR3* and type II collagenopathy groups, contain graded series of disorders that range from severe to mild. This severity spectrum is increasingly appreciated in other skeletal dysplasia groups as more pathogenic variants have been discovered and their associated phenotypes defined. For some genes, such as *COL2A1*, pathogenic variants are distributed throughout the gene, and the clinical phenotypes merge into one another across a broad range. There is much less phenotypic overlap in other genes, such as *FGFR3*, in which the distribution of pathogenic variants is more discrete.

Most chondrodysplasias require the analysis of information from the history, physical examination, skeletal radiographs, family history, and laboratory testing to make a diagnosis. The process involves recognizing complex patterns that are characteristic of the different disorders (Tables 735.3-735.6). Metaphyseal dysplasias, for example, often are characterized by short stature, bowing of the legs, and a waddling gait. Most metaphyseal dysplasias have normal serum levels of calcium and phosphate, alkaline phosphatase activity, and vitamin D metabolites. In addition, subtypes of metaphyseal dysplasias exist and have their own unique features. Metaphyseal chondrodysplasia (**Jansen type;** see Chapter 737) is typified by cupped and ragged metaphyses, which develop mottled calcification at the distal ends of bone over time (Fig. 735.2). Hypercalcemia can occur. The **Schmid type** of metaphyseal chondrodysplasia is less severe, although the radiographic appearance of the knees and extreme bowing of the lower limbs resemble that in patients with familial hypophosphatemia. This condition is associated with defects in collagen type X (*COL10A1*), and the hip abnormalities are more debilitating than in Jansen metaphyseal chondrodysplasia. Patients with both types of metaphyseal chondrodysplasia have short stature.

Table 735.2 Genetics of Some Skeletal Dysplasias

GENE LOCUS	PROTEIN	PROTEIN FUNCTION	CLINICAL PHENOTYPE	INHERIT
COL2A1	Type II collagen α_1 chain	Cartilage matrix protein	Achondrogenesis II	AD*
			Hypochondrogenesis	AD*
			SED congenita	AD
			Kniest dysplasia	AD
			Late-onset SED	AD
			Stickler dysplasia	AD
ACG1	Aggrecan	Cartilage matrix protein	SED Kimberley	AD
			SEMD Aggrecan type	AR
SEDL	Sedlin	Intracellular transporter	X-linked SED tarda	XLR
COL11A1	Type XI collagen α_1 chain	Cartilage matrix protein	OSMEDA	AD
COL11A2	Type XI collagen α_2 chain	Cartilage matrix protein	OSMEDB	AR
COMP	Cartilage oligomeric matrix protein	Cartilage matrix protein	Pseudoachondroplasia	AD
			EDM1 (MED)	AD
COL9A2	Type IX collagen α_2 chain	Cartilage matrix protein	EDM2 (MED)	AD
COL9A3	Type IX collagen α_3 chain	Cartilage matrix protein	EDM3 (MED)	AD
MATN3	Matrilin-3	Cartilage matrix protein	EDM5 (MED)	AD
COL10A1	Type X collagen α_1 chain	Hypertrophic cartilage matrix protein	Schmid metaphyseal chondrodysplasia	AD
FGFR3	FGF receptor 3	Tyrosine kinase receptor for FGFs	Thanatophoric dysplasia I	AD*
			Thanatophoric dysplasia II	AD*
			Achondroplasia	AD
			Hypochondroplasia	AD
PTHR1	PTHrP receptor	G protein–coupled receptor for PTH and PTHrP	Jansen metaphyseal chondrodysplasia	AD
DTDST	DTD sulfate transporter	Transmembrane sulfate transporter	Achondrogenesis 1B	AR*
			Atelosteogenesis II	AR*
			Diastrophic dysplasia	AR
SOX9	SRY box 9	Transcription factor	Campomelic dysplasia	AD
RUNX2†	Runt-related transcription factor 2	Transcription factor	Cleidocranial dysplasia	AD
LMX1B		Transcription factor	Nail-patella dysplasia	AD
CTSK	Cathepsin K	Enzyme	Pyknodysostosis	AR
RMPR	Mitochondrial RNA-processing endoribonuclease	RNA-processing enzyme	CHH	AR
DYNC2H1	Dynein, cytoplasmic two, heavy chain 1	Cytoplasmic cilia-related protein	ATD	AR
			SRPIII	AR
TRPV4	Calcium-permeable TRP ion channel	Transmembrane channel protein	Brachyolmia type 3	AD
			SMDK	AD
			Metatropic dysplasia	AD

*Usually lethal.
†Also called CBFA1.
AD, Autosomal dominant; SED, spondyloepiphyseal dysplasia; SEMD, spondyloepimetaphyseal dysplasia; AR, autosomal recessive; EDM (MED), multiple epiphyseal dysplasia; FGF, fibroblast growth factor; OSMEDA, otospondylomegaepiphyseal dysplasia autosomal dominant; OSMEDB, otospondylomegaepiphyseal dysplasia autosomal recessive; PTHrP, parathyroid hormone-related protein; PTH, parathyroid hormone; DTD, diastrophic dysplasia; SRY, sex-determining region of the Y chromosome; CHH, cartilage-hair hypoplasia; ATD, Jeune asphyxiating thoracic dystrophy; SRPIII, short rib polydactyly syndrome type III; TRPV4, transient receptor potential vanilloid family 4; SMDK, spondyloepimetaphyseal dysplasia Kozlowski type.

Table 735.3 Major Problems Associated with Skeletal Dysplasias

PROBLEM	EXAMPLE
Lethality*	Thanatophoric dysplasia
Associated anomalies†	Ellis-van Creveld syndrome
Short stature	Common to almost all
Cervical spine dislocations	Larsen syndrome
Severe limb bowing	Metaphyseal dysplasia, Schmid type
Spine curvatures	Metatropic dysplasia
Clubfeet	Diastrophic dysplasia
Fractures	Osteogenesis imperfecta
Pneumonias, aspirations	Campomelic dysplasia
Spinal cord compression	Achondroplasia
Joint problems (hips, knees)	Most skeletal dysplasias
Hearing loss	Common (greatest with cleft palate)
Myopia/cataracts	Stickler syndrome
Immunodeficiency	Cartilage-hair hypoplasia, Schimke immunoosseous dysplasia, spondyloenchondromatosis, pathogenic variants in *PEM3, EXTL3, ADA*
Poor body image	Variable, but common to all
Sex reversal	Campomelic dysplasia

*Mostly a result of severely reduced size of thorax.
†See Table 735.4.

Table 735.4 Associated Anomalies in Skeletal Dysplasias

ANOMALY	EXAMPLE
Heart defects	Ellis-van Creveld syndrome, Jeune syndrome
Polydactyly	Short rib polydactyly, Majewski type
Cleft palate	Diastrophic dysplasia
Ear cysts	Diastrophic dysplasia
Spinal cord compression	Achondroplasia
Encephalocele	Dyssegmental dysplasia
Hemivertebrae	Dyssegmental dysplasia
Micrognathia	Campomelic dysplasia
Nail dysplasia	Ellis-van Creveld syndrome
Conical teeth, oligodontia	Ellis-van Creveld syndrome
Multiple oral frenula	Ellis-van Creveld syndrome
Dentinogenesis imperfecta	Osteogenesis imperfecta
Pretibial skin dimples	Campomelic dysplasia
Cataracts, retinal detachment	Stickler syndrome
Intestinal atresia	Saldino-Noonan syndrome
Renal cysts	Saldino-Noonan syndrome
Camptodactyly	Diastrophic dysplasia
Craniosynostosis	Thanatophoric dysplasia
Ichthyosis	Chondrodystrophia punctata
Hitchhiker thumb	Diastrophic dysplasia
Sparse scalp hair	Cartilage-hair hypoplasia
Hypertelorism	Robinow syndrome
Hypoplastic nasal bridge	Acrodysostosis
Clavicular agenesis	Cleidocranial dysplasia
Genital hypoplasia	Robinow syndrome
Tail	Metatropic dysplasia
Omphalocele	Beemer-Langer syndrome
Blue sclera	Osteogenesis imperfecta

Comprehensive descriptions of disorders and references can be found at the Online Mendelian Inheritance in Man (OMIM) website (http://omim.org/about), along with the most recent nosology for genetic skeletal conditions.

CLINICAL MANIFESTATIONS

Growth

The hallmark of the chondrodysplasias is disproportionate short stature. Although this refers to a disproportion between the limbs and the trunk, most disorders exhibit some shortening of both, and subtle degrees of disproportion may be difficult to appreciate, especially in premature, obese, or edematous infants. Disproportionate shortening of the limbs should be suspected if the upper limbs do not reach the mid-pelvis in infancy or the upper thigh after infancy. Disproportionate shortening of the trunk is indicated by a short neck, small chest, and protuberant abdomen. Skeletal disproportion is usually accompanied by short stature (length and height below the third percentile); these measurements are occasionally within the low-normal range early in the course of certain conditions.

There may also be disproportionate shortening of different segments of the limbs; the specific pattern can provide clues for diagnoses. Shortening is greatest in the proximal segments (upper arms and legs) in achondroplasia; this is termed **rhizomelic shortening.** Disproportionate shortening of the middle segments (forearms and lower legs) is called **mesomelic shortening; acromelic** shortening involves the hands and feet.

With some exceptions, there is a strong correlation between the age when shortening is appreciated and the clinical severity of the condition. Many of the lethal neonatal chondrodysplasias are evident during routine fetal ultrasound examinations performed at the end of the first trimester of gestation (see Table 735.5). Gestational standards exist for long-bone lengths, and discrepancies are often detected between biparietal diameter of the skull and long-bone lengths. Many disorders become apparent around the time of birth whereas others manifest during the first year of life. A number of disorders manifest in early childhood and a few in late childhood or later.

Non–Growth-Related Manifestations

Most patients also have problems unrelated to growth. Skeletal deformities, such as abnormal joint mobility, protuberances at and around joints, and angular deformities, are common and usually symmetric. Skeletal abnormalities can adversely affect nonskeletal tissues. Impaired growth at the base of the skull and of vertebral pedicles reduces the size of the spinal canal in achondroplasia and can contribute to spinal cord compression. Short ribs reduce thoracic volume, which can compromise breathing in patients with short trunk chondrodysplasias. Cleft palate (see Chapter 356) is common to many disorders, presumably reflecting defective palatal growth.

Manifestations may be unrelated to the skeleton; they reflect the expression of pathogenic gene variants in nonskeletal tissues. Examples include retinal detachment in spondyloepiphyseal

Table 735.5 Lethal Neonatal Skeletal Dysplasias

USUALLY FATAL*

Kniest dysplasia
Metatropic dysplasia
Langer mesomelic dysplasia

dysplasia congenita, sex reversal in campomelic dysplasia, congenital heart malformations in Ellis-van Creveld syndrome, immunodeficiency in cartilage-hair hypoplasia, and renal dysfunction in asphyxiating thoracic dysplasia. These nonskeletal problems provide valuable clues to specific diagnoses and must be managed clinically (see Table 735.4).

Family and Reproductive History

A family history might identify relatives with the condition, and a Mendelian inheritance pattern may be elicited. Because the presentation can vary in some disorders within and among families, features that might be related to the disorder should be identified. Special attention should be given to mild degrees of short stature, disproportion, deformities, and other manifestations (e.g., precocious osteoarthritis) because they may be overlooked. Physical examination of relatives may be useful, as may the review of their photographs, radiographs, and medical and laboratory records.

A reproductive history might reveal previous stillbirths, fetal losses, and other abnormal pregnancy outcomes resulting from a skeletal dysplasia. Pregnancy complications, such as polyhydramnios or reduced fetal movement, are common in bone dysplasias, especially neonatal lethal variants.

Even though most of the skeletal dysplasias are genetic, it is common for an affected individual to be the first in their family to have the diagnosis. New pathogenic variants are common for autosomal dominant disorders, especially lethal disorders in the perinatal period (e.g., thanatophoric dysplasia, osteogenesis imperfecta). In achondroplasia, the most common short stature skeletal dysplasia, ~80% of all individuals have a new pathogenic variant in *FGFR3*. Germ cell mosaicism, in which a parent has clones of mutant germ cells, has been observed in osteogenesis imperfecta, achondroplasia, and in other dominant disorders. A negative family history is usually seen in recessive disorders unless consanguinity is present. A few of the short stature skeletal dysplasias are X-linked in origin. Prenatal diagnosis is available for disorders that have a known genetic etiology. Appropriateness of the testing depends on many factors, and genetic counseling is warranted for these families.

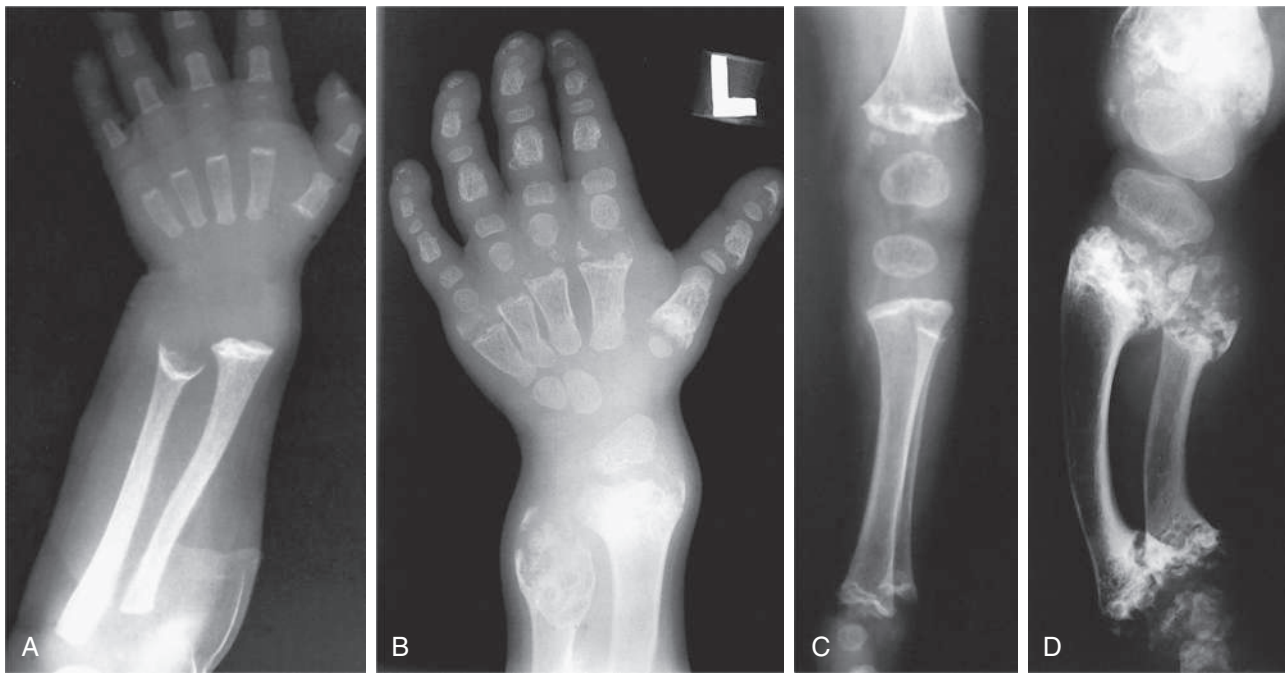

Fig. 735.2 Radiographic findings in Jansen-type metaphyseal chondrodysplasia. **A,** At age 1 yr, there is severe metaphyseal cupping and splaying at the wrists and also in the hand bones. **B,** At age 7 yr, there is increasing metaphyseal change at the wrists with enlarged epiphysis; enlarged epiphyses with wide epiphyseal plates are also present in the hands. **C,** At age 1 yr, there are severe metaphyseal irregularities at the knees and ankles (femur, tibia, and fibula) and enlarged, rounded epiphyses. **D,** At age 7 yr, there are severely fragmented, sclerotic metaphyses, wide epiphyseal plates, and enlarged epiphyses. Radiographic findings in Jansen-type metaphyseal chondrodysplasia. *(From Slovis T, ed. Caffey's Pediatric Diagnostic Imaging, 11th ed. Philadelphia: Mosby, 2008.)*

Table 735.7 Dynamic Classification of Bone Dysplasias

I. EPIPHYSEAL DYSPLASIAS
A. Epiphyseal hypoplasias
1. Failure of articular cartilage: spondyloepiphyseal dysplasia congenita and tarda
2. Failure of ossification center: multiple epiphyseal dysplasia congenita and tarda
B. Epiphyseal hyperplasia
1. Excess of articular cartilage; dysplasia epiphysealis hemimelica
II. PHYSEAL DYSPLASIAS
A. Cartilage hypoplasias
1. Failure of proliferating cartilage: achondroplasia congenita and tarda
2. Failure of hypertrophic cartilage: metaphyseal dysostosis congenita and tarda
B. Cartilage hyperplasias
1. Excess of proliferating cartilage: hyperchondroplasia
2. Excess of hypertrophic cartilage: enchondromatosis
III. METAPHYSEAL DYSPLASIAS
A. Metaphyseal hypoplasias
1. Failure to form primary spongiosa: hypophosphatasia congenita and tarda
2. Failure to absorb primary spongiosa: osteopetrosis congenita and tarda
3. Failure to absorb secondary spongiosa: craniometaphyseal dysplasia congenita and tarda
B. Metaphyseal hyperplasias
1. Excessive spongiosa: multiple exostoses
IV. DIAPHYSEAL DYSPLASIAS
A. Diaphyseal hypoplasias
1. Failure of periosteal bone formation: osteogenesis imperfecta congenita and tarda
2. Failure of endosteal bone formation: idiopathic osteoporosis congenita and tarda
B. Diaphyseal hyperplasias
1. Excessive periosteal bone formation: progressive diaphyseal dysplasia
2. Excessive endosteal bone formation: hyperphosphatasemia

From Rubin P. *Classification of bone dysplasias*. Chicago: Year Book Medical Publishers, 1964. p. 82.

Radiographic Features

Radiographic evaluation for a chondrodysplasia should include plain films of the entire skeleton. Efforts should be made to identify which bones and which parts of bones (i.e., epiphyses, metaphyses, diaphyses) are most affected (Figs. 735.3 and Fig. 735.4 and Table 735.7). If possible, films taken at different ages should be examined because the radiographic changes evolve with time. Films taken before puberty are generally more informative because pubertal closure of the epiphyses obliterates many of the signs needed for a radiographic diagnosis. Prenatal diagnosis may also be possible with fetal ultrasound.

DIAGNOSIS

If an infant or child is short with disproportionate features, a diagnosis is established by matching the observed clinical picture (defined primarily from clinical, family, and gestational histories; physical examination; and radiographic evaluation) with clinical phenotypes of well-documented disorders. A number of reference texts and online databases provide information about the disorders and comprehensive lists of current references (http://www.ncbi.nlm.nih.gov/books/NBK1116/). Consultation with experts in medical genetics, orthopedics, endocrinology, or the bone dysplasia field is recommended.

Genetic testing for chondrodysplasias is very useful, especially for disorders in which recurrent pathogenic variants occur (typical achondroplasia has the same *FGFR3* pathogenic variant). Pathogenic variant testing for achondroplasia is available, although the diagnosis can be made clinically. The greatest utility for testing may be for prenatal diagnosis for couples where both parents have typical *(heterozygous)* achondroplasia. Their children are at a 25% risk of the much more severe *homozygous* achondroplasia (also known as *double dominant*), which can be detected by pathogenic variant analysis. Preimplantation genetic testing can be used to identify zygotes with two pathogenic variants in *FGFR3*. Another example of the utility of genetic testing is in disorders resulting from pathogenic variants in *DTDST*. These disorders are inherited in an autosomal recessive manner, and a limited number of mutant alleles have been found. If the pathogenic variants are identified in the patient, they should be detectable in the parents and potentially used for prenatal diagnosis. Pathogenic variant analysis is commercially available for many of the skeletal dysplasias and is increasingly used to confirm clinical diagnosis and for future pregnancy planning.

Many of the chondrodysplasias have distinct histologic changes of the skeletal growth plate. Sometimes, such tissues obtained at biopsy or discarded from a surgical procedure are helpful diagnostically. It is uncommon to make a diagnosis histologically if it was not already suspected on clinical or radiographic grounds.

MOLECULAR GENETICS OF SKELETAL DYSPLASIAS

A number of chondrodysplasia genes have been identified (see Table 735.2). They encode several categories of proteins, including cartilage matrix proteins, transmembrane receptors, ion transporters, and transcription factors. The number of identified gene loci is smaller than anticipated from the number of recognized clinical phenotypes. The majority of patients have disorders that map to fewer than 10 loci, and

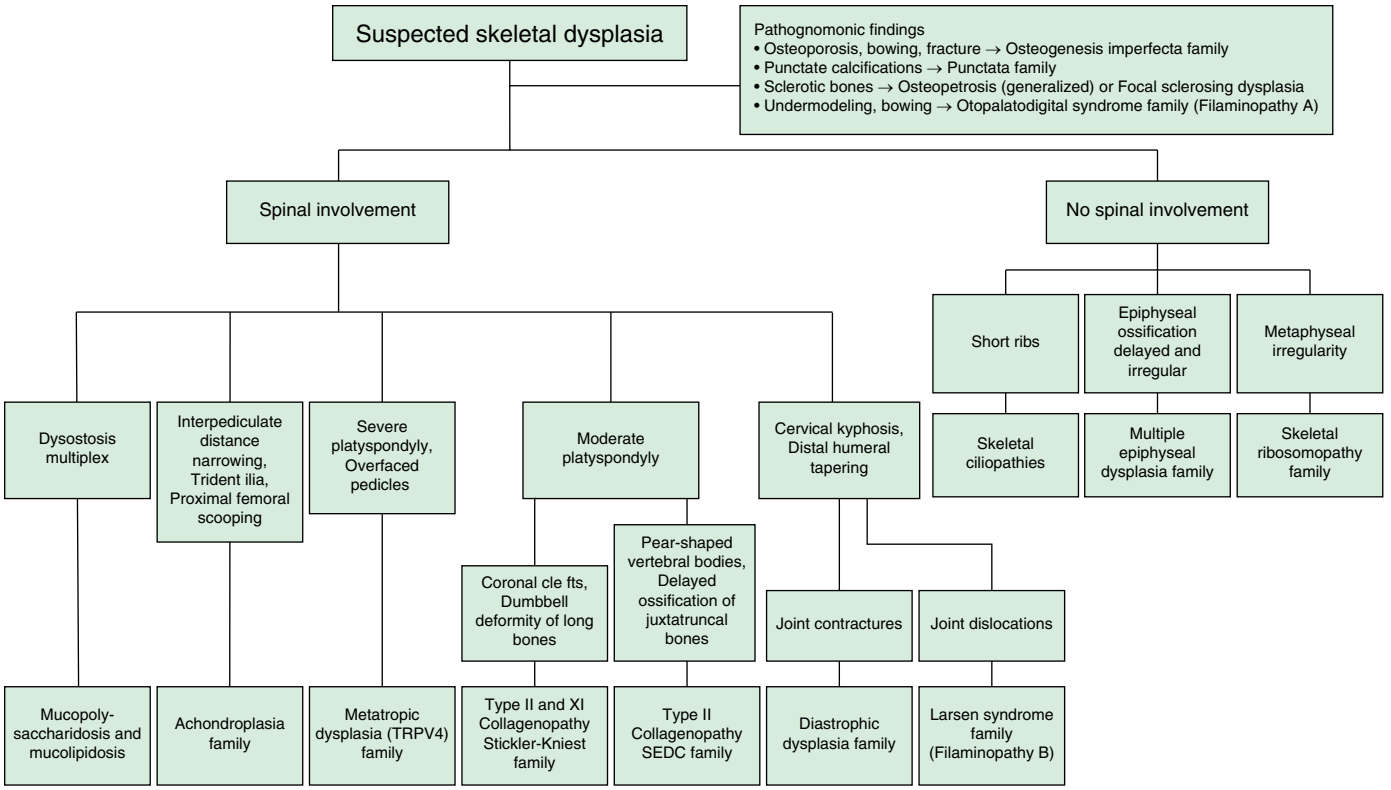

Fig. 735.4 Diagnostic algorithm for the major skeletal dysplasias. TRPV4, transient receptor potential vanilloid 4. *(From Handa A, Grigelioniene G, Nishimura G: Skeletal dysplasia families: a stepwise approach to diagnosis. RadioGraphics 2023;43(5), Fig. 1.)*

pathogenic variants at two loci (*COL2A1* and *FGFR3*) account for more than half of all cases. There may be a limited number of genes whose function is critical to skeletal development, especially linear bone growth, and pathogenic variants in these genes give rise to a wide range of chondrodysplasia clinical phenotypes. New genes harboring pathogenic variants that cause chondrodysplasias continue to be identified with advances in technology.

Pathogenic variants of *COL2A1* and *FGFR3* illustrate different genetic characteristics. *COL2A1* pathogenic variants are distributed throughout the gene, with few instances of recurrence in unrelated persons. In contrast, *FGFR3* pathogenic variants are restricted to a few locations within the gene, and the occurrence of new pathogenic variants at these same sites in unrelated persons is the rule. There is a strong correlation between clinical phenotype and pathogenic variant site for *FGFR3,* but not *COL2A1*.

PATHOPHYSIOLOGY

Chondrodysplasias are caused by pathogenic variants in genes that encode abnormal proteins and disrupt normal endochondral ossification, the biologic process responsible for the development and linear growth of the skeleton (see Fig. 735.1). These genetic variants act through different mechanisms. Most pathogenic variants involving cartilage matrix proteins cause disease when only one of the two copies (alleles) of the relevant gene is mutated. These pathogenic variants usually act through a *dominant negative mechanism* in which the protein products of the mutant allele interfere with the assembly and function of multimeric molecules that contain the protein products of both the normal and mutant alleles. The type II collagen molecule is a triple helix composed of three collagen chains, which are the products of the type II collagen gene *COL2A1*. When chains from both normal and mutant alleles are combined to form triple helices, most molecules contain at least one mutant chain. It is not known how many mutant chains are required to produce a dysfunctional molecule, but, depending on the pathogenic variant, it theoretically could be as few as one.

Pathogenic variants in the gene encoding type X collagen differ from the model above. They map to the region of the chain that is responsible for chain recognition; the chains must recognize each other before they can assemble into collagen molecules. Disease-causing variants are thought to disrupt this process. As a result, none of the mutant chains are incorporated into molecules. This mechanism is *haploinsufficiency* because the products of the mutant allele are functionally absent, and the normal allele is insufficient for normal function. Genetic variants involving ion transport genes also act through a *loss of function* of the transporters. Pathogenic variants of transmembrane receptors studied to date appear to act through a *gain of function*; the mutant receptors initiate signals in a constitutive manner independent of their normal ligands. A pathogenic variant in *FGFR3* is another example of a *gain of function* mechanism of disease. At baseline, *FGFR3* is a negative regulator of endochondral bone formation. If the pathogenic variant associated with achondroplasia is present in this gene, the clinical manifestations of this condition are caused by enhanced inhibition of endochondral bone formation and growth, independent of normal ligands.

TREATMENT

The first step is to establish the correct diagnosis. This allows one to provide a prognosis and to anticipate the medical and surgical problems associated with a particular disorder. Establishing a diagnosis helps to distinguish between lethal disorders and nonlethal disorders in a premature or newborn infant (see Tables 735.5 and 735.6). A poor prognosis for long-term survival might argue against initiating extreme lifesaving measures for thanatophoric dysplasia or achondrogenesis types Ib or II, whereas such measures may be indicated for infants with spondyloepiphyseal dysplasia congenita or diastrophic dysplasia, which have a good prognosis if the infant survives the newborn period.

Overall, management of patients with short stature skeletal dysplasias is directed at preventing and correcting skeletal deformities (spinal stenosis, kyphosis, scoliosis), treating nonskeletal complications (other anomalies, immunodeficiencies), providing genetic counseling, and

helping patients and families learn to cope. Each disorder has its own unique set of problems, and consequently, management must be tailored to each disorder.

There are a number of problems common to many chondrodysplasias for which general recommendations can be made. Children with most chondrodysplasias should avoid contact sports and other activities that cause injury or stress to joints. Good dietary habits should be established in childhood to prevent or minimize obesity in adulthood. Dental care should be started early to minimize the crowding and malalignment of teeth. Children and relatives should be given the opportunity to participate in support groups, such as the Little People of America (http://www.lpaonline.org) and Human Growth Foundation (http://www.hgfound.org).

Three controversial approaches have been used to increase bone length. Surgical limb lengthening has been employed for a few disorders. Its greatest success has been in achondroplasia in which nonskeletal tissues tend to be redundant and easily stretched. The procedure is usually performed during adolescence. Pharmacologic doses of human growth hormone comparable to those used to treat Turner syndrome have also been tried in several disorders; the results have been equivocal. Animal studies suggest that C-type natriuretic peptide (CNP) promotes linear bone growth in achondroplasia. One CNP analogue (vosoritide) is approved to increase height in children with achondroplasia (≥5 years old) before the growth plates are closed. Palovarotene is undergoing clinical trials for fibrodysplasia ossificans and resveratrol for pseudoachondroplasia. Enzyme replacement therapy is available for hypophosphatasia and Morquio A syndrome. Many new therapies are based on the gene or pathway involved in the specific disease (see Chapters 736-742). Clinicaltrials.gov is a resource to access information about these and all other clinical trials.

Chapter 736

Disorders Involving Cartilage Matrix Proteins

Daniah Albokhari and Julie E. Hoover-Fong

Disorders of cartilage matrix proteins resulting in bone and joint disorders can be classified according to the defective proteins: collagens (types 2, 9, 10, 11) and the noncollagenous proteins COMP (cartilage oligomeric matrix protein), matrilin-3, and aggrecan. The clinical phenotypes and clinical severity differ between and within the groups, especially the spondyloepiphyseal dysplasia (SED) group, which is made up largely of type collagenopathies (see also Table 735.1).

TYPE 2 COLLAGENOPATHIES

The term *spondyloepiphyseal dysplasia* refers to a heterogeneous group of disorders characterized by shortening of the trunk and, to a lesser extent, the limbs. Severity ranges from most severe and often lethal perinatally, such as achondrogenesis type II, hypochondrogenesis, and platyspondylic dysplasia, Torrance type, to severe/moderately severe neonatal presentation, such as Kniest dysplasia (which is apparent at birth and usually nonlethal) and SED congenita, to mild SED with premature-onset arthrosis (which might not be detected until adolescence or later) (Table 736.1). The radiographic hallmarks are abnormal development of the vertebral bodies and of epiphyses, the extent of which corresponds with clinical severity. Most of the SEDs result from heterozygous pathogenic variants of *COL2A1* and are autosomal dominant disorders. The pathogenic variants are dispersed throughout the gene with imperfect correlation between the variant location and resultant clinical phenotype. Molecular testing/confirmation is readily available commercially. Prenatal diagnosis is possible if the pathogenic variant is known.

Lethal Spondyloepiphyseal Dysplasias

Achondrogenesis type II is characterized by severe shortening of the neck and trunk and especially the limbs, and by a large, soft head. Fetal hydrops and prematurity are common, and infants are stillborn or die shortly after birth. **Hypochondrogenesis** refers to a clinical phenotype intermediate between achondrogenesis type II and SED congenita. It is typically lethal in the newborn period. **Platyspondylic dysplasia, Torrance type** is characterized by disproportionate short stature, short limbs, and coarse facial features. The majority of infants die at or shortly after birth.

The severity of radiographic changes correlates with clinical severity. These conditions manifest short, broad tubular bones with cupped metaphyses. The cranial bones are not well mineralized, and the vertebral bodies are poorly ossified in the entire spine in achondrogenesis type II, and in the cervical and sacral spine in hypochondrogenesis. In both conditions, the pelvic bones are hypoplastic, and the pedicles are ossified. In Torrance type, the platyspondyly is strikingly severe, with iliac hypoplasia, short sacrosciatic notches, and preserved ossification of the pubic bones. The three types can be detected prenatally and confirmed by molecular testing.

KNIEST DYSPLASIA

The Kniest dysplasia variant of SED manifests at birth with a short trunk and limbs associated with a flat face, prominent eyes, enlarged joints, cleft palate, and clubfoot (Fig. 736.1). Radiographs show vertebral defects and short tubular bones with epiphyseal irregularities and metaphyseal enlargement that gives rise to a dumbbell appearance.

Motor development is often delayed because of the joint deformities, although intelligence is normal. Hearing loss and myopia commonly develop during childhood, and retinal detachment is a common complication. Joint enlargement progresses during childhood and becomes painful. It is accompanied by flexion contractures and muscle atrophy, which may be incapacitating by adolescence.

Spondyloepiphyseal Dysplasia Congenita

The phenotype of this group, SED congenita, is apparent at birth. The hands and feet are usually normal. Craniofacial features may present, including malar hypoplasia, hypertelorism, and cleft palate. The neck is short, and the chest is barrel shaped (Fig. 736.2). Kyphosis and exaggeration of the normal lumbar lordosis are common. The proximal segments of the limbs are shorter than the hands and feet, which often appear normal. Some infants have clubfoot and/or exhibit hypotonia.

Skeletal radiographs of the newborn reveal short tubular bones, delayed ossification of vertebral bodies, and proximal limb bone epiphyses (Fig. 736.3). Hypoplasia of the odontoid process, a short, square pelvis with a poorly ossified symphysis pubis, and mild irregularity of metaphyses are apparent.

Infants usually have normal developmental milestones with a waddling gait typically appearing in early childhood. Childhood complications include respiratory compromise from tracheomalacia, spinal deformities, and spinal cord compression because of cervicomedullary instability. The disproportion and shortening become progressively worse with age, and adult heights range from 95-128 cm. Myopia is typical; adults are predisposed to retinal detachment. Precocious osteoarthritis (OA) occurs in early adulthood and requires surgical joint replacement.

Table 736.1 Collagen Disorders

DISORDER	INHERITANCE	GENE
TYPE 2 COLLAGEN DISORDERS		
Achondrogenesis (formerly type 2, type Langer-Saldino)	AD	*COL2A1*

Data from Unger S, Ferreira CR, Mortier GR, et al. Nosology of genetic skeletal disorders: 2023 revision. *Am J Med Genet*. 2023;191A:1164-1209 (Table 1, Group 2 and 3, pp 1166-1167).

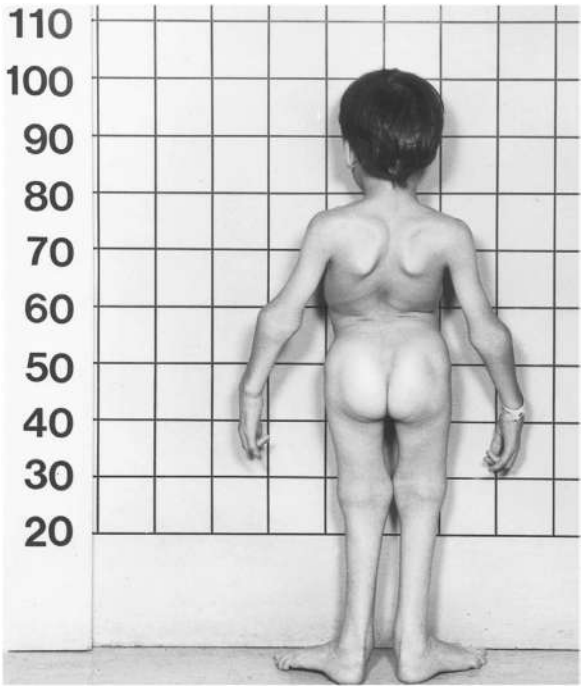

Fig. 736.1 Patient with Kniest dysplasia. The trunk is short, the epiphyses are broad, and there is contracture of the fingers. *(From Traboulsi EI. Skeletal and connective tissue disorders with anterior segment manifestations. In Krachmer JH, Mannis MJ, Holland EJ, eds. Cornea, 3rd ed. Philadelphia: Elsevier, 2011. Fig. 60.9.)*

Mild Spondyloepiphyseal Dysplasia with Premature-Onset Arthrosis

Late-onset SED is a mild clinical phenotype characterized by slightly short stature, progressive joint pain, and diminished range of movement, associated with mild epiphyseal and vertebral abnormalities on radiographs. It is typically detected during childhood or adolescence but can go unrecognized until adulthood when precocious OA appears. The vision and hearing are usually normal. This designation is nosologically distinct from SED tarda, which is clinically similar but results from pathogenic variant of the X-linked gene *SEDL (TRAPPC2)*.

Stickler Syndrome/Dysplasia (Hereditary Progressive Arthro-Ophthalmopathy)

Short stature is not a feature of Stickler dysplasia. This condition resembles SED because of its joint and eye manifestations. Pathogenic variants of genes encoding type II *(COL2A1)*, type XI *(COL11A1, COL11A2)*, and type IX *(COL9A1, COL9A2, COL9A3)* collagens have been identified in Stickler-like disorders. Stickler dysplasia is often identified in the newborn because of cleft palate and micrognathia (**Pierre Robin** anomaly; see Chapter 357). Of patients with Stickler syndrome, 25% have Pierre Robin anomaly, and 18% of patients with Pierre Robin anomaly have Stickler syndrome. Children with Stickler syndrome are often identified in craniofacial clinics. Infants typically have severe myopia and additional ophthalmologic complications, including cataracts, glaucoma, and choroidoretinal and vitreous degeneration, with retinal detachment common during childhood requiring multiple surgical interventions (Fig. 736.4). Special attention must be given to eye complications even in childhood to preserve vision for these individuals. Hearing loss is a common feature that arises during adolescence. Sensorineural hearing loss is the most common form; however, conductive hearing loss may also be seen. Osteoarticular manifestations include joint hypermobility (especially hip), which resolves in adulthood, metaphyseal broadening of the femoral neck, hypoplastic iliac wings, Schmorl nodes, muscle hypotonia, metaphyseal-epiphyseal dysplasia, precocious progressive OA of the spine and peripheral joints (which may require hip replacement surgery before age 30 years), and decreased bone density. Similar manifestations may be seen in other diseases with pathogenic variants in type II and XI collagen genes (Table 736.2).

PSEUDOACHONDROPLASIA AND MULTIPLE EPIPHYSEAL DYSPLASIA

Pseudoachondroplasia and the most common form of multiple epiphyseal dysplasia (MED) are two distinct phenotypes that are grouped together because they result from pathogenic variants of the gene encoding COMP. The pathogenic variants are heterozygous in both, and they are autosomal dominant traits. The clinical phenotypes are restricted to musculoskeletal tissues. Newborns with pseudoachondroplasia are average in size and appearance. Gait abnormalities and short stature mainly affect the limbs and become apparent in late infancy. Short stature becomes marked as the child grows and is associated with generalized joint laxity (Fig. 736.5). The hands are short, broad, and deviated in an ulnar direction; the forearms are bowed. Developmental milestones and intelligence are usually normal. Lumbar lordosis and deformities of the knee develop during childhood; the latter often requires surgical correction. Pain is common in weight-bearing joints during childhood and adolescence, and OA develops late in the second decade of life, which may require hip replacement by mid-30s. Adult height ranges from 105-128 cm. Skeletal radiographs show distinctive abnormalities of vertebral bodies and of both epiphyses and metaphyses of tubular bones (Fig. 736.6).

The MED phenotype has skeletal abnormalities that predominantly affect the epiphyses as noted on radiographs. Two forms, the severe Fairbank type and the mild Ribbing type, are no longer used in classification. Because of overlap in clinical features, and because COMP pathogenic variants are found in both types, they are now considered part of a clinical spectrum. The more severe clinical

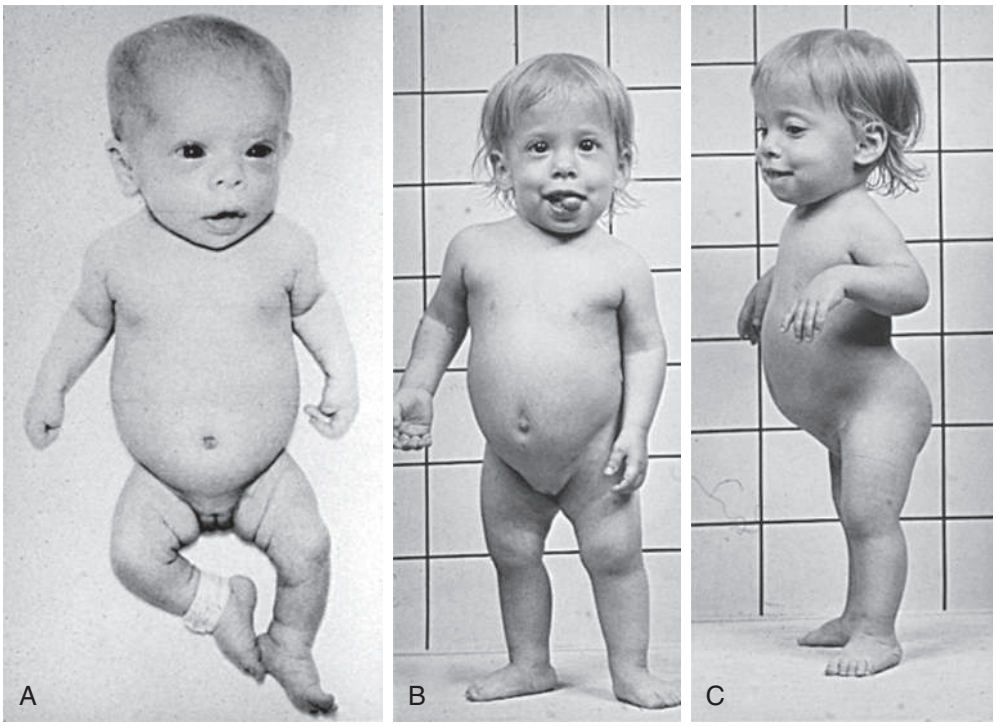

Fig. 736.2 Spondyloepiphyseal dysplasia congenita is shown in infancy (**A**) and early childhood (**B, C**). Note the short extremities, relatively normal hands, flat facies, and exaggerated lordosis.

Fig. 736.3 Spondyloepiphyseal dysplasia. Platyspondyly, delayed epiphyseal ossification (especially femoral heads), dens hypoplasia. *(From Campeau P, Schlesinger AE. Skeletal dysplasias. [Updated 2017 Jan 30]. In: De Groot LJ, Chrousos G, Dungan K, et al., eds. Endotext [internet]. South Dartmouth, MA, 2000, MDText.com, Inc. Fig. 5. Available from https://www.ncbi.nlm.nih.gov/books/NBK279130/.)*

phenotype of MED has its onset during childhood, with mild short-limbed short stature, pain in weight-bearing joints, and a waddling gait. Radiographs show delayed and irregular ossification of epiphyses. A typical finding is the double-layered patella (pathognomonic). In more mildly affected patients, the disorder might not be recognized until adolescence or adulthood. Radiographic changes may be limited to the capital femoral epiphyses. In the latter case, mild MED must be distinguished from bilateral Legg-Calvé-Perthes disease (see Chapter 719.3). Precocious OA of hips and knees is the major complication in adults with MED. Adult heights range from 136-151 cm.

There are families with clinical and radiographic manifestations of MED that are not caused by pathogenic variants of COMP. Pathogenic variants in the genes encoding all three of the type IX collagen chains have been reported. It has been suggested that COMP and type IX collagen interact functionally in cartilage matrix, thus explaining why pathogenic variants of different genes produce similar pictures. Pathogenic variants of the genes coding for another cartilage matrix protein, matrilin-3 *(MATN3)*, and the diastrophic dysplasia sulfate transporter *(SLC26A)* have also been found in patients with autosomal dominant and recessive MED, respectively. For familial cases of pseudoachondroplasia and MED resulting from pathogenic variant in COMP, prenatal diagnosis is available.

Spondyloepimetaphyseal dysplasia, Borochowitz-Cormier-Daire type

Spondyloepimetaphyseal dysplasia, Borochowitz-Cormier-Daire type is a rare more severe spondylo-epi-metaphyseal dysplasia (SEMD)-like phenotype characterized by short-limb dwarfism with spinal,

Fig. 736.4 Face and profile of a mother and daughter with Stickler syndrome type I. Note in the daughter the flat nasal bridge, the mild epicanthal folds, and discrete micrognathia. At first sight, the mother shows no clear facial characteristics of Stickler syndrome. *(From Baijens LWJ, De Leenheer EMR, Weekamp HH, et al. Stickler syndrome type I and Stapes ankylosis. Int J Pediatr Otorhinolaryngol. 2004;68:1573–1580. Fig. 2.)*

Nosology and classification of genetic skeletal disorders: 2019 revision. *Am J Med Genet A.* 2019;179(12):2393–2419.

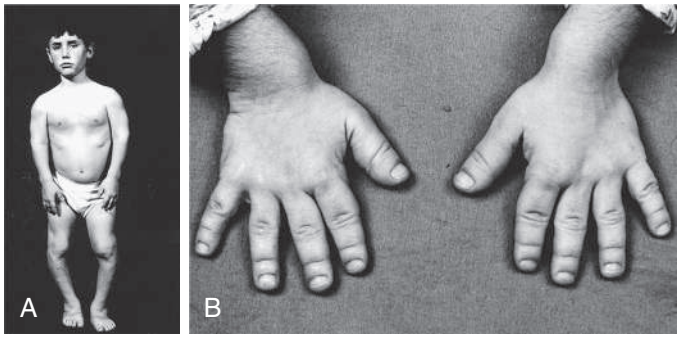

Fig. 736.5 Pseudoachondroplasia in an adolescent male. **A,** The facies and head circumference are normal. There is shortening of all extremities and bowing of the lower extremities. **B,** Photograph of hands, demonstrating short stubby fingers.

epiphyseal, and metaphyseal abnormalities. There are only three families described in the literature caused by autosomal recessive pathogenic variant in the gene encoding matrilin-3 (*MATN3*). Radiographic examination showed flat, ovoid vertebral bodies, short with a stocky appearance, long tubular bones, wide metaphysis with lateral spurs, irregular epiphysis of knee, unossified proximal femur epiphysis, squaring of pelvis, and narrow greater sciatic notch.

SCHMID METAPHYSEAL DYSPLASIA

Schmid metaphyseal dysplasia is one of several chondrodysplasias in which metaphyseal abnormalities dominate the radiographic features. It typically manifests in early childhood with mild short stature, bowing of the legs, and a waddling gait (Fig. 736.7). Joints, such as the wrist, may be enlarged. Radiographs show flaring and irregular mineralization of the metaphyses of tubular bones of the proximal

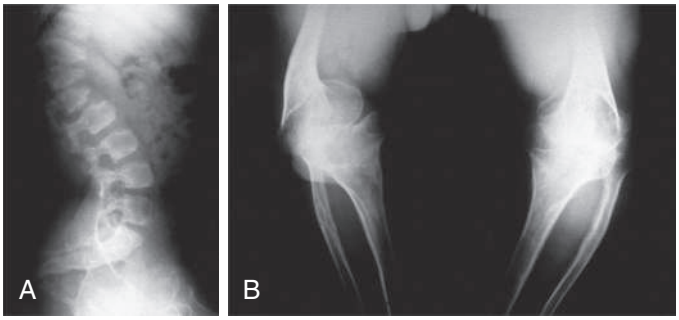

Fig. 736.6 A, Lateral thoracolumbar spine radiograph of a patient with pseudoachondroplasia showing central protrusion (tonguing) of the anterior aspect of upper lumbar and lower thoracic vertebrae. Note reduced vertebral body heights (platyspondyly) and secondary lordosis. B, Lower-extremity radiograph of a patient with pseudoachondroplasia showing large metaphyses, poorly formed epiphyses, and marked bowing of the long bones.

Fig. 736.7 Female patient with metaphyseal dysplasia, type Schmid. The facies are normal, and the stature is mildly reduced. Mild tibia vara is present.

limbs (Fig. 736.8). Coxa vara is usually present and can require surgical correction. Short stature becomes more evident with age and affects the lower extremities more than the upper extremities. Overall, manifestations are limited to the skeleton. Schmid metaphyseal chondrodysplasia is caused by heterozygous pathogenic variants

Fig. 736.8 Radiograph of lower extremities in Schmid metaphyseal dysplasia showing short tubular bones and metaphyseal flaring and irregularities, abnormal capital femoral epiphyses, and femoral necks. The epiphyses are normal. Coxa vara is present.

in the gene encoding type X collagen *(COL10A1)* as an autosomal dominant condition. The distribution of type X collagen is restricted to the region of growing bone in which cartilage is converted into bone. This might explain why radiographic changes are confined to the metaphyses.

Aggrecan-Related Spondyloepiphyseal Dysplasias

Pathogenic variants of aggrecan have been detected in three SED-like conditions. SED-Kimberley is relatively mild, with short stature, stocky build, and early-onset OA of weight-bearing joints. Autosomal dominant pathogenic variants are etiologic. Autosomal recessive pathogenic variants cause a more severe and generalized clinical phenotype, **spondyloepimetaphyseal dysplasia–aggrecan type**. Radiographic changes include irregular epiphyses and widened metaphyses. A mild condition, **familial osteochondritis dissecans,** is characterized by multiple osteochondritic lesions (separation of cartilage and subchondral bone from the surrounding tissue and primarily affecting the knee, ankle, and elbow joints) in knees and/or hips and/or elbows, disproportionate short stature, and early-onset OA. Autosomal dominant pathogenic variants have been found in familial cases.

Chapter 737

Disorders Involving Transmembrane Receptors

Daniah Albokhari and Julie E. Hoover-Fong

Heterozygous pathogenic variants of genes encoding *FGFR3* (fibroblast growth factor receptor 3) and *PTHR1* (parathyroid hormone-1 receptor) result in disorders involving transmembrane receptors. The pathogenic variants cause the receptors to become activated in the absence of physiologic ligands, which accentuates normal receptor function of negatively regulating bone growth. The pathogenic variants act by gain of negative function. In the *FGFR3* pathogenic variant group, in which the clinical phenotypes range from severe to mild, the severity appears to correlate with the extent to which the receptor is activated. *PTHR1* and especially *FGFR3* pathogenic variants tend to recur in unrelated individuals (Table 737.1; see also Table 735.1).

FGFR3 CHONDRODYSPLASIA GROUP

The achondroplasia group represents a substantial percentage of patients with chondrodysplasias and contains thanatophoric dysplasia (TD), the most common lethal chondrodysplasia, with a birth prevalence of 1 in 35,000 births and achondroplasia, the most common nonlethal chondrodysplasia, with a birth prevalence of 1 in 15,000–25,000 births. Also in this group are severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN), hypochondroplasia, and camptodactyly, tall stature, and hearing loss syndrome (CATSHL). All five have pathogenic variants in a small number of locations in the *FGFR3* gene. There is a strong correlation between the pathogenic variant site and the clinical phenotype.

Thanatophoric Dysplasia

TD manifests before or at birth. In the former situation, ultrasonographic examination in mid-gestation or later reveals a large head and very short limbs; the pregnancy is often accompanied by polyhydramnios and premature delivery. Very short limbs, short neck, long narrow thorax, and large head with midfacial hypoplasia dominate the clinical phenotype at birth (Fig. 737.1). The cloverleaf skull deformity known as **kleeblattschädel** is sometimes found. If the affected fetus survives pregnancy, the newborn will have severe respiratory distress because of the small thorax. Although this distress can be treated by intense respiratory care, the long-term prognosis is poor.

Skeletal radiographs distinguish two slightly different forms called TD I and TD II. In the more common TD I, radiographs show large calvarium with a small cranial base, marked thinning and flattening of vertebral bodies (platyspondyly) visualized best on lateral view, very short ribs, severe hypoplasia of pelvic bones, and very short and bowed tubular bones with flared metaphyses (Fig. 737.2). The femurs are curved and shaped like a telephone receiver. TD II differs mainly in that there are longer and straighter femurs.

The TD II clinical phenotype is associated with pathogenic variants that map to codon 650 of *FGFR3*, causing the substitution of a lysine with glutamic acid. This activates the tyrosine kinase activity of a receptor that transmits signals to intracellular pathways. The pathogenic variant of the same lysine 650 to methionine is also associated with a clinical phenotype intermediate between TD and achondroplasia, referred to as **SADDAN (severe achondroplasia with developmental delay and acanthosis nigricans)**, where affected cases often do not require ventilatory support and survive beyond infancy. Pathogenic variants of the TD I phenotype mainly map to two regions in the extracellular domain of the receptor, where they substitute cysteine residues for other amino acids. Free cysteine residues are thought to form disulfide bonds promoting dimerization of receptor molecules, leading to activation and signal transmission. TD I and TD II typically present as new pathogenic variants in offspring born to unaffected, average stature parents. The recurrence risk is low. Because the variant codons in TD are pathogenic for unknown reasons and because of the theoretical risk of germ cell mosaicism, parents are offered prenatal diagnosis for subsequent pregnancies.

Table 737.1 *FGFR3* Chondrodysplasia Group

GROUP/NAME OF DISORDER	INHERITANCE	OMIM	GENE
Thanatophoric dysplasia type I (TD I)	AD	187600	*FGFR3*
Thanatophoric dysplasia type II (TD II)	AD	187601	*FGFR3*
Severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN)	AD	616482	*FGFR3*
Achondroplasia	AD	100800	*FGFR3*
Hypochondroplasia	AD	146000	*FGFR3*
Camptodactyly, tall stature, and hearing loss syndrome (CATSHL)	AD	610474	*FGFR3*

Achondroplasia

Achondroplasia is the prototype chondrodysplasia. It typically manifests at birth with short limbs, a long narrow trunk, and a large head with midfacial hypoplasia and prominent forehead (Fig. 737.3). The limb shortening is greatest in the proximal segments (rhizomelia), and the fingers often display a trident configuration. Most joints are hyperextensible, but extension is restricted at the elbow. A thoracolumbar gibbus is typically found in newborns but improves as they start walking with no intervention in 90% of the cases. Birth length may be slightly less than normal but often plots within the low-normal range.

Diagnosis

Skeletal radiographs confirm the diagnosis (Fig. 737.4; see also Fig. 737.3). The calvarial bones are large, whereas the cranial base and facial bones are small. The vertebral pedicles are short throughout the spine as noted on a lateral radiograph. The interpedicular distance, which normally increases from the first to the fifth lumbar vertebra, decreases in achondroplasia. The iliac bones are short and round, and the acetabular roofs are flat. The tubular bones are short with mildly irregular and flared metaphyses. The fibula is disproportionately long compared with the tibia, which is often bowed, causing genu varum.

Clinical Manifestations

Infants usually exhibit delayed motor milestones, often not walking alone until 18-24 months. This is because of hypotonia and mechanical difficulty balancing the large head on a normal-sized trunk and short extremities. Intelligence is normal unless central nervous system complications develop. As the child begins to walk, the gibbus usually gives way to an exaggerated lumbar lordosis.

Infants and children with achondroplasia progressively fall below normal standards for length and height. They can be plotted against standards established for achondroplasia. Adult heights typically are 118-145 cm for men and 112-136 cm for women. C-type natriuretic

Fig. 737.1 Identical twins with type I thanatophoric dysplasia. Disproportionately large head, bell-shaped chest, and micromelia. *(From Gilbert-Barness E, Kapur RP, Oligny LL, Siebert JR, eds. Potter's Pathology of the Fetus, Infant and Child, 2nd ed. Philadelphia: Elsevier, 2007. Fig. 20-47.)*

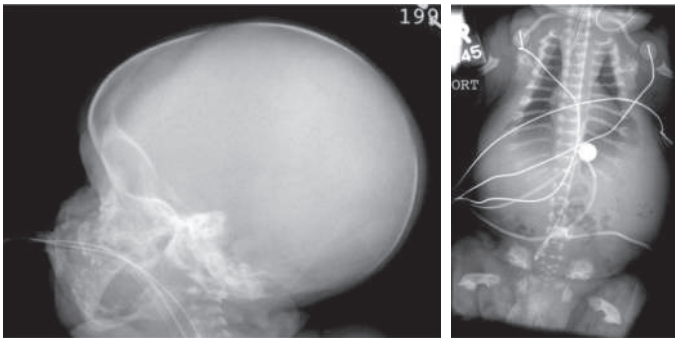

Fig. 737.2 Thanatophoric dysplasia type I. Severe platyspondyly, very short ribs, narrow thorax, short broad pelvis, large skull, very short and bent long bones. *(From Campeau P, Schlesinger AE. Skeletal dysplasias. [Updated 2017 Jan 30]. In De Groot LJ, Chrousos G, Dungan K, et al., eds. Endotext [internet]. South Dartmouth, MA, 2000, MDText.com, Inc., Fig. 1. Available from https://www.ncbi.nlm.nih.gov/books/NBK279130/.)*

Fig. 737.3 Achondroplasia phenotype at different ages. **A**, Infant with achondroplasia with macrocephaly, frontal bossing, midface hypoplasia, small chest, rhizomelic shortening of all the limbs, redundant skinfolds, and extreme joint laxity. Note the trident hand with short fingers and abducted hips. **B**, Typical radiographic findings from a child with achondroplasia. All of the tubular bones are short, but the fibula is relatively long compared with the tibia. There is protrusion of the epiphysis into the metaphysis of the distal femur, creating the chevron deformity, and—to a lesser extent—of the proximal tibia. The iliac bones are rounded, the acetabular roof is horizontal, and the sacrosciatic notches are small. **C**, A 3-yr-old with achondroplasia with the typical features shown in **(A)**. Note that the redundant skinfolds are no longer present and that joint laxity has improved. Rhizomelic shortening of the extremities is more pronounced and accompanied by tibial bowing. *(From Horton WA, Hall JG, Hecht JT. Achondroplasia. Lancet. 2007;370:162–172.)*

peptide analogue (vosoritide), administered as a daily subcutaneous injection is the first approved treatment for children ≥5 years of age with achondroplasia; treatment with vosoritide produced an increase of annual growth velocity with no significant side effect. In addition, vosoritide maintains this annual growth velocity up to 2 years along with an improvement in body segment proportion. Clinical trials are underway to study other compounds such as soluble FGFR3 decoy receptors, and tyrosine kinase inhibitors, which may restore bone growth in achondroplasia based on studies in animal models. Other possible future treatments of achondroplasia include fibroblast growth factor aptamers and meclizine, which showed improvement of the skeletal phenotype of the mutant mice. Surgical limb lengthening and human growth hormone treatment have been used to increase height; however, both are controversial.

Virtually all infants and children with achondroplasia have large heads, although only a fraction have true hydrocephalus. Head circumference should be carefully monitored using standards developed for achondroplasia, as should neurologic function in general. The spinal canal is stenotic, and spinal cord compression can occur at the foramen magnum and in the lumbar spine. The former usually occurs in infants and small children and may be associated with hypotonia, failure to thrive, quadriparesis, central and obstructive apnea, and sudden death. Surgical correction may be required for severe stenosis. Lumbar spinal stenosis usually does not occur until early adulthood. Symptoms include paresthesias, numbness, and claudication in the legs. Loss of bladder and bowel control may be late complications. Bowing of the legs is common in patients with achondroplasia and might need to be corrected surgically. Other common problems include dental crowding, articulation difficulties, obesity, and frequent episodes of otitis media, which can contribute to hearing loss.

Genetics

All patients with typical achondroplasia have pathogenic variants at *FGFR3* codon 380. This pathogenic variant is located in the transmembrane domain of the receptor and is thought to stabilize receptor dimers that enhance receptor signals, the consequences of which inhibit linear bone growth. Achondroplasia behaves as an autosomal dominant condition; most cases arise from a new pathogenic variant to average stature parents.

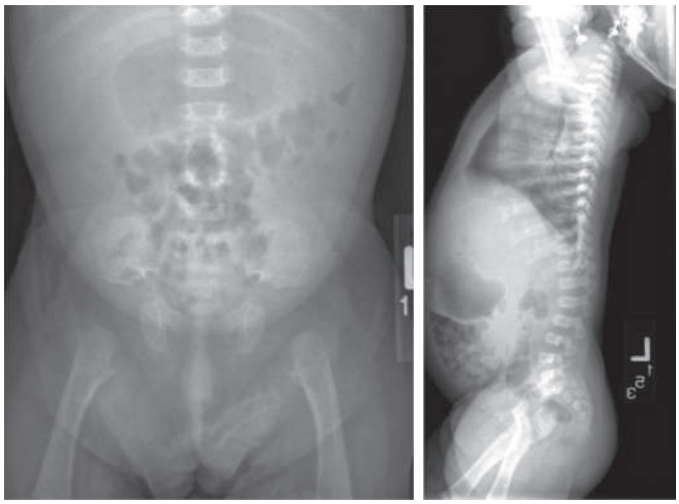

Fig. 737.4 Achondroplasia. Small rounded iliac bones, horizontal acetabula, decreasing interpediculate distance, normal vertebral body height, short ribs. *(From Campeau P, Schlesinger AE. Skeletal dysplasias. [Updated 2017 Jan 30]. In De Groot LJ, Chrousos G, Dungan K, et al., eds. Endotext [internet]. South Dartmouth, MA, 2000, MDText.com, Inc., Fig. 2. Available from https://www.ncbi.nlm.nih.gov/books/NBK279130/.)*

Because of the high frequency of achondroplasia among short stature skeletal dysplasias, it is relatively common for adults with achondroplasia to marry. Such couples have a 50% risk of transmitting their condition, heterozygous achondroplasia, to each offspring, as well as a 25% risk of **homozygous achondroplasia**. The latter condition exhibits intermediate severity between TD and heterozygous achondroplasia and is usually lethal in the newborn period and is often referred to as "double dominant" inheritance. Prenatal diagnosis is available and has been used to diagnose homozygous achondroplasia. Preimplantation genetic testing can be used to identify double dominant pathogenic variants.

Hypochondroplasia

Hypochondroplasia resembles achondroplasia but is milder. Usually, it is not apparent until childhood, when mild short stature affecting the limbs becomes evident. Children have a stocky build, disproportionately short extremities, and slight frontal bossing of the head. Learning disabilities may be more common in this condition. Radiographic changes are mild and consistent with the mild achondroplastic phenotype. Complications are rare; in some patients, the condition is never diagnosed. Adult heights range from 131-154.5 cm for men and 124-138 cm for women. An *FGFR3* pathogenic variant at codon 540 is the most pathogenic variant found in patients with more severe hypochondroplasia. Genetic heterogeneity exists in hypochondroplasia; that is, *SHOX* pathogenic variants are associated with a very similar clinical phenotype. Recombinant growth hormone therapy may enhance growth and improve body disproportion but is still considered controversial with limited evidence of increased final adult height.

JANSEN METAPHYSEAL DYSPLASIA

Jansen metaphyseal chondrodysplasia is a rare, dominantly inherited chondrodysplasia characterized by severe shortening of limbs associated with an unusual facial appearance (see Chapter 735). Sometimes it is accompanied by clubfoot and **hypercalcemia** with serum calcium values of 13-15 mg/dL. At birth, a diagnosis can be made from these clinical findings, and radiographs that show short tubular bones with characteristic metaphyseal abnormalities that include flaring, irregular mineralization, fragmentation, and widening of the physeal space. The epiphyses are normal. The joints become enlarged and limited in mobility with age. Flexion contractures develop at the knees and hips, producing a bent-over posture. The spine can also be deformed by the irregular growth of vertebrae. Intelligence is normal, although there may be hearing loss.

Jansen metaphyseal chondrodysplasia is caused by activating pathogenic variants of *PTHR1*. This G-protein–coupled transmembrane receptor serves as a receptor for both parathyroid hormone and parathyroid hormone-related peptide. Signaling through this receptor serves as a brake on the terminal differentiation of cartilage cells at a critical step in bone growth. Because the pathogenic variants activate the receptor, they enhance the braking effect and thereby slow bone growth. In contrast, loss-of-function pathogenic variants of *PTHR1* are observed in Blomstrand chondrodysplasia, whose clinical features are the mirror image of Jansen metaphyseal chondrodysplasia.

Chapter 738

Disorders Involving Ion Transporters

Daniah Albokhari and Julie E. Hoover-Fong

Five genes related to ion transporters have been reported to be involved in skeletal dysplasia conditions, including the *SLC39A13* gene causing Ehlers-Danlos syndrome, spondylodysplastic type, the *SLCO2A1* gene causing hypertrophic osteoarthropathy (OA), the *SLC10A7* gene causing multiple joint dislocations with amelogenesis imperfecta, and the *SLC34A3* gene causing hypophosphatemic rickets with hypercalciuria (HHRH). This chapter will focus on pathogenic variants in the sulfate transporter gene *(SLC26A2)*, also known as **diastrophic dysplasia sulfate transporter *(DTDST),*** which is the most common ion transporter gene causing sulphation disorders skeletal dysplasia. It encompasses a spectrum of both lethal and nonlethal chondrodysplasia, including, in order of decreasing severity, achondrogenesis type 1B, atelosteogenesis type II, diastrophic dysplasia, and a rare recessive form of multiple epiphyseal dysplasia (rMED). The gene product sulfate transporter is important to uptake sulfate ions into cells and is important for cartilage cells that add sulfate moieties to newly synthesized proteoglycans destined for cartilage extracellular matrix. Matrix proteoglycans are responsible for many of the properties of cartilage that allow it to serve as a template for skeletal development. The clinical manifestations result from defective sulfation of cartilage proteoglycans (see also Table 735.1).

A number of pathogenic alleles have been found for the *DTDST* gene; they variably disturb transporter function. The disorders are recessive traits requiring the presence of bi-allelic pathogenic variants. The phenotype is determined by the combination of abnormal alleles with some alleles present in more than one disorder.

Achondrogenesis Type 1B and Atelosteogenesis Type 2

Achondrogenesis type 1B and atelosteogenesis type 2 are rare recessive lethal chondrodysplasias. The most serious is achondrogenesis type 1B, which demonstrates a severe lack of skeletal development usually detected in utero or after a miscarriage. The limbs are extremely short, the head is soft, the thorax is narrow, and the abdomen protuberant. Skeletal radiographs show poor to missing ossification of skull bones, vertebral bodies, fibulas, and ankle bones. The pelvis is hypoplastic, and the ribs are short and slightly thin. The femurs are short and exhibit a trapezoid shape with irregular metaphyses.

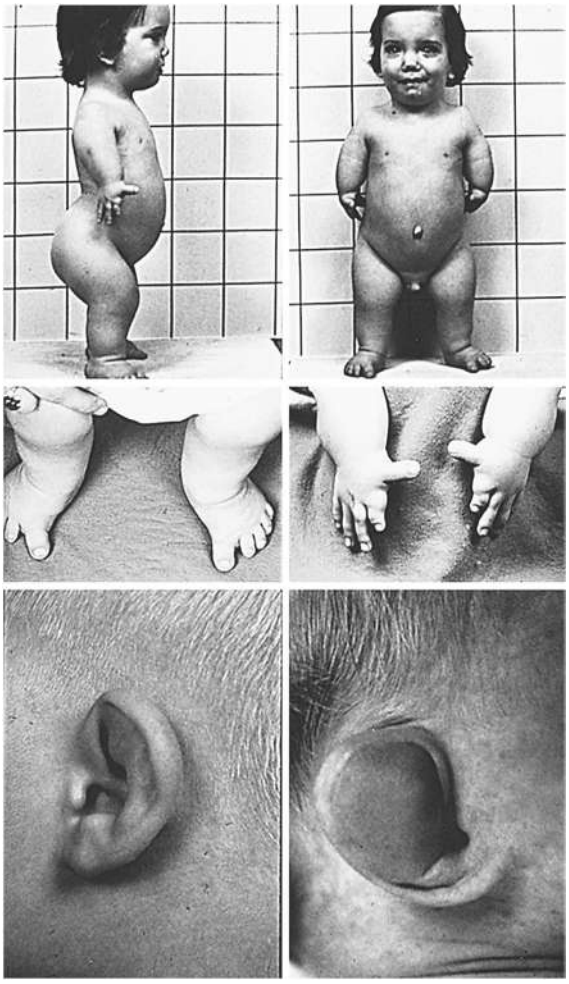

Fig. 738.1 Child with diastrophic dysplasia. The extremities are dramatically shortened *(top)*. Clubfoot is commonly observed *(middle left)*. The fingers are short, especially the index finger; the thumb characteristically is proximally placed and has a hitchhiker appearance *(middle right)*. The upper helix of the ears becomes swollen 3-4 wk postnatally *(lower left)*, and this inflammation spontaneously resolves, leaving a cauliflower deformity of the pinnae *(lower right)*.

Infants with atelosteogenesis type II are stillborn or die soon after birth; prematurity is common. They exhibit very short limbs, especially the proximal segments with normal size head and midface hypoplasia. Clubfoot and dislocations of the elbows and knees may be detected. Hypoplasia of vertebral bodies, especially in the cervical and lumbar spine, and hypoplastic ilia with flat acetabulum are found on radiographs. The femora and humeri are hypoplastic and display a club-shaped appearance. The distal limb bones, including the ulna and fibula, are poorly ossified.

Both disorders have a 25% recurrence risk and are potentially detectable in utero by pathogenic variant analysis if the mutant alleles are identified in the parents. Prenatal diagnosis is possible with fetal imaging and/or pathogenic variant testing, which is commercially available.

Diastrophic Dysplasia

Diastrophic dysplasia is a well-characterized disorder recognized at birth by the presence of very short extremities, normal head size, clubfoot, and short hands, with proximal displacement of the thumb producing a hitchhiker appearance (Fig. 738.1). The hands are usually deviated in an ulnar direction. Bony fusion of the metacarpophalangeal joints (symphalangism) is common, as is restricted movement of many joints, including the hips, knees, and elbows. The external ears often become inflamed soon after birth. The inflammation resolves spontaneously but leaves the ears fibrotic and contracted (cauliflower ear deformity). Many newborns have a cleft palate.

Fig. 738.2 Radiograph of hands in diastrophic dysplasia. The metacarpals and phalanges are irregular and short. The first metacarpal is ovoid.

Radiographs reveal short and broad tubular bones with flared metaphyses and flat, irregular epiphyses (Fig. 738.2). The capital femoral epiphyses are hypoplastic, and the femoral heads are broad. The ulnas and fibulas are disproportionately short. Carpal centers may be developmentally advanced with the first metacarpal typically ovoid, and the metatarsals twisted medially. There may be vertebral abnormalities, including clefts of cervical vertebral lamina and narrowing of the interpedicular distances in the lumbar spine.

Complications are primarily orthopedic and tend to be severe and progressive, leading to joint contractures, spine deformity and early onset OA. The clubfoot deformity in the newborn resists usual treatments, and multiple corrective surgeries are common. Scoliosis typically develops during early childhood. It often requires multiple surgical procedures to control, and it sometimes compromises respiratory function in older children. Despite the orthopedic problems, patients typically have normal intelligence, have normal life span, and reach adult heights in the 105-130 cm range, depending on the severity of scoliosis. Growth curves are available for diastrophic dysplasia. Respiratory insufficiency may present in neonates because of the small rib cage and tracheal instability and collapsibility. In these cases, supportive measures such as mechanical ventilation may be required. Cervical kyphosis is seen in most newborns, which improves spontaneously in childhood. However, some may experience severe cervical kyphosis leading to spinal cord compression.

Some patients are mildly affected and exhibit slight short stature and joint contractures, no clubfoot or cleft palate, and correspondingly mild radiographic changes. The mild phenotype tends to recur within families. The recurrence risk of this autosomal recessive condition is 25%. Ultrasonographic examination can be employed for prenatal diagnosis, but if *DTDST* pathogenic variants can be identified in the patients or parents, molecular genetic diagnosis is possible.

AUTOSOMAL RECESSIVE MULTIPLE EPIPHYSEAL DYSPLASIA

Although previously regarded as a multiple epiphyseal dysplasia, according to the new nosology, rMED is now classified among other sulfation disorders. rMED typically presents during adolescence with the gradual onset of hip and knee pain that might resemble rheumatoid arthritis. Later on, patients present with hand, feet, and knee deformities and scoliosis. Fifty percent of individuals present during infancy with club feet and external ear abnormalities. Stature is normal during childhood, but final height might be slightly decreased compared with unaffected siblings and ranges from 150-180 cm. Radiographic findings include flat epiphysis, mild brachydactyly, and double-layered patella. Diagnosis is clinical, based on presentation and radiologic findings, but molecular confirmation is available with a detection rate over 90%. Management includes physical therapy, pain control, and orthopedic interventions.

Chapter 739

Disorders Involving Transcription Factors

Julie E. Hoover-Fong and Daniah Albokhari

Transcription factors are proteins that control the transcription of DNA into RNA to make proteins essential for cellular function. Pathogenic variants in the genes that make transcription factors can result in disease by "turning on" or "turning off" downstream genes to result in disease. Of the estimated 1,500 known transcription factors in humans, four are associated with well-delineated bone dysplasias. Campomelic dysplasia (CD), cleidocranial dysplasia (CCD), and SHOX gene-related conditions are considered dysplasias, whereas nail-patella syndrome (NPS) is classified as a dysostosis (meaning a skeletal disorder limited to individual bones or group of bone rather than the entire skeleton, as in a skeletal dysplasia) (see also Table 735.1).

Pathogenic variants in genes that encode transcription factors that cause disease are *SOX9, RUNX2 (CBFA1)*, *SHOX,* and *LMX1B*, respectively. *SOX9* is a member of the SOX family of transcription factors related to the SRY (sex-determining region of the Y chromosome) gene; *RUNX2 (CBFA1)* belongs to the runt family of transcription factor genes; *SHOX* is part of the homeobox gene family; and *LMX1B* is part of the LIM homeodomain gene family. Each results in a disorder caused by haploinsufficiency of the respective gene products. CD, CCD, and NPS are all autosomal dominant conditions, whereas *SHO*X-related conditions are inherited in a pseudoautosomal fashion.

CAMPOMELIC DYSPLASIA

Campomelic dysplasia is apparent in newborn infants and characterized by short, bowed long bones (especially in the lower legs), respiratory distress, cervical spine anomalies, Pierre-Robin sequence, and variable involvement of the central nervous system, heart, and kidneys. In some cases, femoral bowing is minimal (i.e., acampomelic campomelic dysplasia). Additionally, 75% of XY individuals have some degree of gonadal dysgenesis that ranges from normal female phenotype through ambiguous genitalia and lack of determination of testicular tissue with undervirilization. 46,XX individuals have an expected female phenotype with normal ovarian differentiation. *Therefore karyotype analysis is indicated in every female with campomelia*. These features are because of the role of *SOX9* in the differentiation of testicular tissue downstream of *SRY*. Compared with SOX9 haploinsufficiency, duplications cause gonadal tissue to differentiate into testicular tissue in 46,XX individuals, highlighting the dosage sensitivity of *SOX9* in gonadal differentiation. Radiographs confirm long bone bowing and often show hypoplasia of the scapulae and pelvic bones (Fig. 739.1). Affected infants often die of respiratory distress in the neonatal period because of tracheomalacia, small thoracic volume, and early scoliosis. Complications in children and adolescents who survive include cervical instability, short stature with progressive kyphoscoliosis, recurrent apnea and respiratory infections, hearing loss, and learning difficulties. Because of a deficiency of gonadal differentiation, 46,XY individuals with female genitalia often present with absent thelarche and primary amenorrhea. Pathogenic variant testing is commercially available and has a >95% detection rate. Nearly all individuals with CD represent a de novo pathogenic variant in *SOX9*.

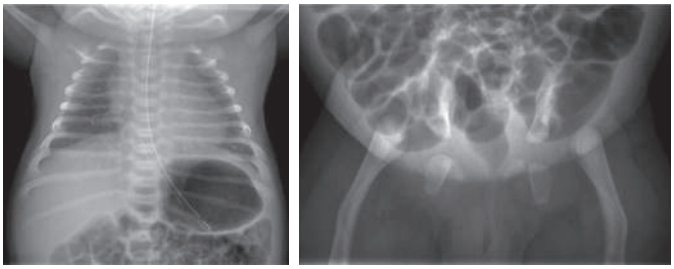

Fig. 739.1 Campomelic dysplasia. Bell-shaped thorax, hypoplastic scapula, bowed femurs, widely spaced ischial bones. *(From Campeau P, Schlesinger AE. Skeletal dysplasias [Fig. 12]. [Updated 2017 Jan 30]. In: De Groot LJ, Chrousos G, Dungan K, et al., eds. Endotext [internet]. South Dartmouth, MA, 2000, MDText.com, Inc. Fig 12. Available at https://www.ncbi.nlm.nih.gov/books/NBK279130/.)*

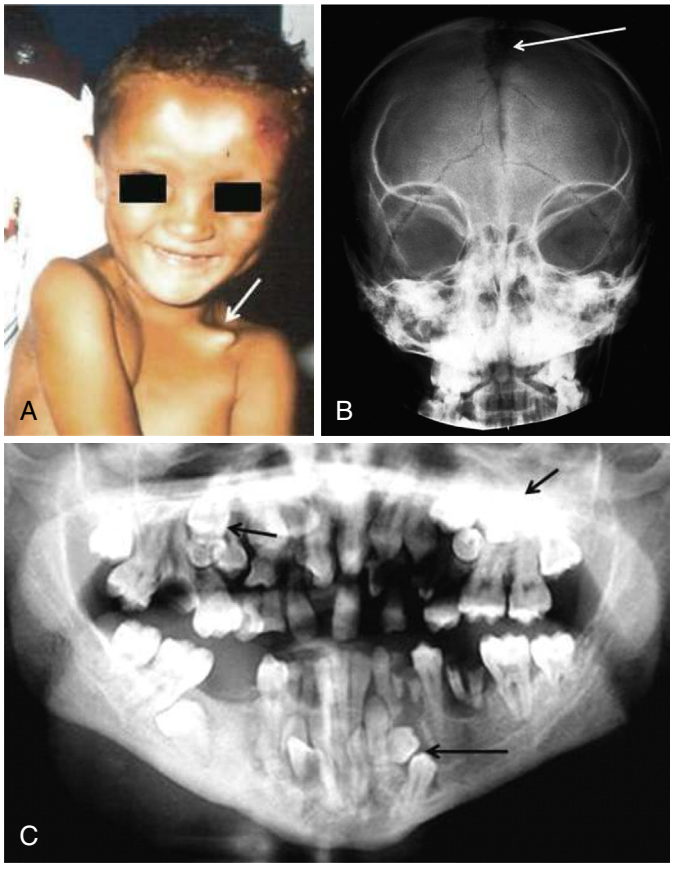

Fig. 739.2 Features of cleidocranial dysplasia displayed. **A,** The forehead is bulky with a central depression, the eyes are widely spaced, and the jaw is pointed. The clavicle is misshapen *(arrow)*. **B,** Note patency of the anterior fontanelle. **C,** Hyperdontia pantomogram of an affected male showing supernumerary teeth. *(From Roberts T, Stephen L, Beighton P. Cleidocranial dysplasia: a review of the dental, historical, and practical implications with an overview of the South African experience. Oral Surg Oral Med Oral Pathol Oral Radiol. 2013;115[1]:46–55. Figs. 1, 4, and 6.)*

CLEIDOCRANIAL DYSPLASIA

Cleidocranial dysplasia can be recognized in infants because of sloping shoulders, wide fontanelles, and prominent forehead. Birth length is normal, but mild short stature and dental abnormalities are evident during childhood (Fig. 739.2). The shoulders of patients

Fig. 739.3 Nail-patella syndrome. **A,** Adolescent showing nail hypoplasia, especially of thumbs, and displacement of small patellae. **B,** Two affected children showing nail dysplasia. **C,** Incomplete extension of the elbows. *(From Jones KL, Jones MC, Del Campo M, eds. Smith's Recognizable Patterns of Human Malformation, 7th ed. Philadelphia: Saunders, 2013. Fig. 1, p. 574.)*

with CD can collapse to meet in the midline because of hypoplasia or absence of the clavicles. Radiographs will reveal the abnormal clavicles, delayed ossification of cranial bones with multiple ossification centers (Wormian bones), and delayed ossification of pelvic bones. The anterior fontanelle is wide and may remain open into adulthood. The course is relatively uncomplicated except for dislocations and variable diffuse joint pain (especially of the shoulders), dental anomalies (e.g., supernumerary and/or retained primary teeth) that require dental treatment, and risk of hearing loss because of infections. Affected individuals are shorter than unaffected siblings and have an increased risk of genu valgum, pes planus, and scoliosis. Diagnosis is based on clinical and radiographic presentation, but molecular confirmation is available with a detection rate of >70%. The proportion of cases caused by de novo pathogenic variants is high. Management includes prevention of ear infections, speech therapy, dental, and orthopedic interventions as indicated.

SHOX GENE-RELATED CONDITIONS

The *SHOX* gene is located on the pseudoautosomal region of the X and Y chromosomes (i.e., Xp22.33/Yp11.32). Because of crossover during meiotic replication, a *SHOX* variant can segregate on both sex chromosomes, thereby allowing inheritance to occur from male to male, male to female, female to female, and female to male (i.e., sex chromosome gene location while appearing to have autosomal inheritance; pseudoautosomal). Haploinsufficiency of the *SHOX* gene (i.e., loss of one copy of the gene) through deletion, single nucleotide variant, or abnormal regulation of adjacent genes causes Leri-Weill dyschondrosteosis (LWD) and idiopathic short stature (ISS) and contributes to Turner syndrome features when included in the absent X-chromosome material. Features of LWD include short stature, mesomelia, and Madelung deformity of the wrists. ISS does not have other phenotypic features of an abnormal *SHOX* gene other than short stature. This distinguishes ISS from Turner syndrome in which the entire X chromosome is typically missing in affected females, causing short stature, pubertal delay/absence, cardiac anomalies, nuchal folds, and other anomalies. Growth hormone injections can provide effective treatment for short stature associated with a *SHOX* gene abnormality.

NAIL-PATELLA SYNDROME

Dysplasia of the nails, absence or hypoplasia of the patella, abnormalities of the elbow, and spurs or "horns" extending from the iliac bones characterize NPS, also called *osteo-onychodysostosis*. Penetrance is high, but clinical presentation is extremely variable with a wide spectrum of severity. Some patients present in early childhood, whereas others are asymptomatic as adults. Nail abnormalities are almost universal with a wide variety of manifestations, including absence, hypoplasia, clefts, ridged, thin, or hypertropic nails, all of which may worsen in severity moving in the ulnar to radial direction. Elbow abnormalities include limitation of movement, cubits valgus, and pterygium. The patella can be hypoplastic or absent (Fig. 739.3). Iliac horns project posterior-laterally from the center of the iliac bone. A total of 30% of patients have nephritis that resembles chronic glomerulonephritis that presents with proteinuria with or without hematuria; 5% of cases progress to end-stage renal disease. There is an increased risk of glaucoma for NPS patients. NPS is often inherited with 12% of cases being *de novo*. Diagnosis is based on clinical presentation, and molecular confirmation is available with a 95% detection rate. Management includes treatment of orthopedic complications, surveillance and treatment of renal disease, and ophthalmologic follow-up.

Chapter 740

Osteopetrosis and Other Disorders Involving Defective Bone Resorption

Julie E. Hoover-Fong and Daniah Albokhari

Bone dysplasias displaying increased bone density are rare. Osteopetrosis, which has many subtypes, pycnodysostosis, and dysosteosclerosis are the principal members of this disease category. The clinical features and complications of these conditions are the result of abnormal osteoclast formation and function, resulting in defective bone resorption (Table 740.1).

Table 740.1 Osteopetrosis and Related Osteoclast Disorders

GROUP / DISORDER	INHERITANCE	GENE OR LOCUS
Osteopetrosis, neonatal or infantile form	AR	*TCIRG, CLCN, SNX10*
Osteopetrosis, infantile form, with nervous system involvement	AR	*OSTM1*
Osteopetrosis, infantile form, osteoclast-poor with immunoglobulin deficiency	AR	*TNFRSF11A*
Osteopetrosis, intermediate form	AR	*TCIRG1, TNFSF11, PLEKHM1, CLCN7*
Osteopetrosis, late-onset, dominant form	AD	*CLCN7*
Osteopetrosis with renal tubular acidosis	AR	*CA2*
Osteopetrosis with ectodermal dysplasia and immune defect (OLEDAID)	XL	*IKBKG*
Osteopetrosis, moderate form	AR	*SLC4A2*
Osteopetrosis, moderate form with defective leucocyte adhesion	AR	*FERMT3, RASGRP2*
Osteosclerotic metaphyseal dysplasia	AR	*LRRK1*
Pyknodysostosis	AR	*CTSK*
Dysosteosclerosis	AR	*SLC29A3, TNFRSF11A*
Dysosteosclerosis with degenerative encephalopathy and brain malformation	AR	*CSF1R*

Data from Unger S, Ferreira CR, Mortier GR, et al. Nosology of genetic skeletal disorders: 2023 revision. *Am J Med Genet* 2023;191A:1164-1209 (Table 1, Group 24, pp 1184-1185).

OSTEOPETROSIS

The term *osteopetrosis* derives from the Greek root "osteo," meaning bone, and "petrosis," meaning stone. Osteopetrosis is marked by *increased* bone mass caused by abnormal osteoclast formation or function. The dense bone in osteopetrosis invades the marrow space, causing anemia and pancytopenia, and impinges on nerves traversing cranial and other skeletal foramina, causing deafness, blindness, and palsies. Although the skeleton is dense in osteopetrosis, the bone quality is poor and may be prone to fracture because of imbalanced bone turnover.

To date, genes known to cause osteopetrosis include: *CLCN7, TCIRG1, OSTM1, SNX10, CA2, PLEKHM1, TNFRSF11A, TNFSF11, IKBKG, SLC4A2, FERMT3, and RASGRP2.* Pathogenic variants in *CLCN7, TCIRG1, OSTM1, SNX10, CA2,* and *PLEKHM1* prevent normal osteoclast function to resorb bone while *TNFRSF11A, TNFSF11* encode proteins (RANK and RANKL, respectively) that are essential to the formation of osteoclasts. Pathogenic variants in *CLCN7* may cause disease in an autosomal dominant or recessive fashion and variants in *IKBKG* are X-linked, whereas all others here cause recessive osteopetrosis. CLCN7-related autosomal dominant osteopetrosis occurs in 1 in 20,000 births, while collectively, the recessive form of osteopetrosis occurs in 1 in 250,000 births. Pathogenic variants in *CLCN7* are the most common cause of osteopetrosis overall, causing a wide spectrum of disease severity ranging from late childhood/adolescent-onset autosomal dominant osteopetrosis II (ADOII) to more involved intermediate autosomal osteopetrosis (IAO) to the most severe autosomal recessive osteopetrosis (ARO) with onset at birth. In general, the other recessive forms of osteopetrosis are also severe, usually detected in infancy because of macrocephaly, hepatosplenomegaly, deafness, blindness, and severe anemia.

CLINICAL MANIFESTATIONS

Most of the manifestations of osteopetrosis are because of failure to remodel growing bones. This leads to narrowing of cranial nerve foramina and encroachment on marrow spaces, which results in secondary complications, such as optic and facial nerve dysfunction, and anemia accompanied by compensatory extramedullary hematopoiesis in the liver and spleen (Table 740.2). The unusually dense bones are weak, leading to increased risk of fractures.

In the severe recessive infancy-onset form, patients present with macrocephaly, hepatosplenomegaly, deafness, blindness, and severe anemia. Radiographs reveal diffuse bone sclerosis and *hypocalcemia* may be present. Later radiographs show the characteristic bone-within-bone appearance throughout the skeleton (Figs. 740.1 and 740.2). With time, infants typically fail to thrive and show psychomotor delay and worsening of cranial neuropathies and anemia. Dental problems, osteomyelitis of the mandible, and pathologic fractures are common. The most severely affected patients die during infancy; less severely affected patients rarely survive beyond the second decade but often only after treatment with bone marrow transplant. Those who survive beyond infancy usually have learning disabilities but might have normal intelligence despite hearing and vision loss.

The autosomal dominant form of osteopetrosis (Albers-Schönberg disease, osteopetrosis tarda, or marble bone disease) usually manifests during childhood or adolescence with fractures and mild anemia and, less often, as cranial nerve dysfunction, dental abnormalities, or osteomyelitis of the mandible. Skeletal radiographs reveal a generalized increase in bone density and clubbing of metaphyses. Alternating lucent and dense bands produce a sandwich appearance to vertebral bodies. The radiographic changes are sometimes incidental findings in otherwise asymptomatic adolescents and adults.

Table 740.2 Complications of Osteopetrosis by Subspeciality

SUBSPECIALTY	COMPLICATION
Endocrinology	Osteopetrorickets Hypocalcemia
Ophthalmology	Papilledema Ptosis Strabismus Paralysis of extraocular muscles Optic nerve atrophy Exophthalmos Nystagmus Retinal degeneration Tearing (from nasolacrimal duct obstruction)
Dentistry	Delay/failure of tooth eruption Malformed crowns/roots Periodontal ligament defects Odontoma Tooth agenesis Enamel hypoplasia Tooth decay/caries Thickened lamina dura Osteomyelitis (most frequently of the mandible)
Orthopedics	Skeletal deformities Scoliosis Spondylolisthesis Fractures (particularly of the long bones) Delayed union/nonunion Degenerative arthritis Spondylolysis
Neurology/ neurosurgery	Compressive cranial neuropathies (often optic and facial nerves, but can involve any of cranial nerves I–VIII) Increased intracranial pressure Craniosynostosis Arnold–Chiari I malformation Neuromuscular scoliosis Developmental delay/regression, seizures (*OSTM1* mutation) Calcifications of the basal ganglia, thalami (*CAII* deficiency) Hydrocephalus Cerebrovascular stenosis/occlusion Acquired encephalocele
Otolaryngology	Conductive hearing loss Recurrent otitis media Chronic congestion (poorly pneumatized sinuses) Rhinorrhea Choanal atresia Rhinosinusitis Obstructive sleep apnea
Hematology	Thrombocytopenia with bleeding Anemia Leukopenia with frequent infections Hepatosplenomegaly Transfusion dependence
Nephrology	Renal tubular acidosis, nephrocalcinosis, and nephrolithiasis (*CAII* deficiency)

From Wu CC, Econs MJ, DiMeglio LA, et al. Diagnosis and management of osteopetrosis: consensus guidelines from the osteopetrosis working group. *J Clin Endocrinol Metab* 2017;102(9):3111-3123 (Table 2, p. 3116).

TREATMENT

Most of the bone manifestations in severe osteopetrosis caused by intrinsic osteoclast defects can be prevented or reversed by hematopoietic stem cell transplantation (HSCT), if carried out before development of irreversible secondary complications, such as visual impairment. RANKL replacement therapy may be useful in patients with RANKL deficiency caused by *TNFSF11* bi-allelic pathogenic variants, who do not benefit from HSCT. Interferon-γ is used to delay progression in patients with severe malignant infantile osteopetrosis. Symptomatic care, such as dental care, transfusions for anemia, and antibiotic treatment of infections, is important for patients who survive infancy.

Fig. 740.1 Osteopetrosis. Thick dense bones, alternating bands of sclerosis, and normal density bone in long bones, rugger jersey spine, dense base of skull. *(From Campeau P, Schlesinger AE. Skeletal dysplasias. [Updated 2017, Jan 30]. In De Groot LJ, Chrousos G, Dungan K, et al, eds. Endotext [internet]. South Dartmouth, MA, 2000, MDText.com, Inc. Fig. 14. Available at https://www.ncbi.nlm.nih.gov/books/NBK279130/.)*

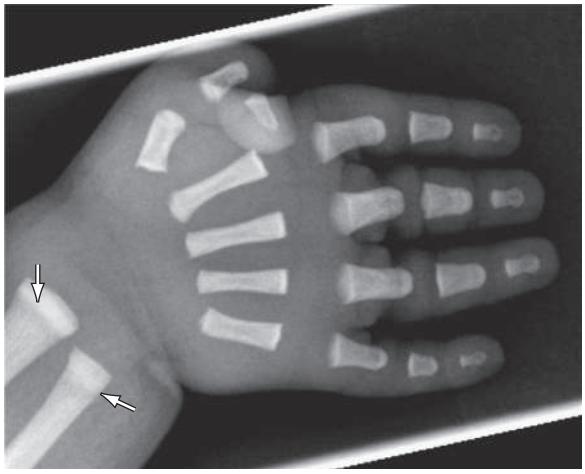

Fig. 740.2 Osteopetrosis. Right-hand radiograph obtained at 2 weeks of age. Note metaphyseal lucent bands in the distal ulna and radius *(arrows)* and short tubular bones. *(From Stark Z, Savarirayan R. Osteopetrosis. Orphanet J Rare Dis. 2009;4:5.)*

PYCNODYSOSTOSIS AND DYSOSTEOSCLEROSIS

Pycnodysostosis

An autosomal recessive bone dysplasia related to osteopetrosis, pycnodysostosis manifests in early childhood with short limbs, characteristic facies, an open anterior fontanel, a large skull with frontal and occipital bossing, acroosteolysis, and dental abnormalities. The hands and feet are short and broad, and the nails may be dysplastic. The sclerae may be blue. Minimal trauma often leads to fractures. Treatment is symptomatic and focused mainly on the management of dental problems and fractures. Although some patients have a persistently open anterior fontanelle (i.e., even into adulthood), others with pycnodysostosis have craniosynostosis. The overall prognosis for these patients is generally good, and they typically reach 130-150 cm in height. Skeletal radiographs show a generalized increase in bone density. In contrast to many disorders in this group, the metaphyses are normal. Other changes include wide sutures and Wormian bones in the skull, a small mandible, and osteolysis of the distal phalanges. Homozygous or compound heterozygous missense, nonsense, insertions, deletions, and splicing variants have been described in the gene *CTSK*, which encodes cathepsin K. This is a lysosomal protease that is involved in bone resorption and remodeling. *CTSK* is highly expressed in osteoclasts, and pathogenic variants prevent degradation of bone matrix proteins (e.g., type I and II collagen), which is necessary for normal bone remodeling and resorption. Growth hormone therapy has been used to improve growth.

Dysosteosclerosis

Dysosteosclerosis is another rare bone disease with generalized increased bone density plus widening of tubular bones and vertebral flattening. It is caused by pathogenic variants in three genes: *SLC9A3*, *CSF1R*, and *TNFRSF11A* (which is allelic with osteopetrosis). Affected individuals have short stature and cranial nerve involvement caused by impingement of the foramina by the abnormally dense bone. No disease-specific treatment has been developed.

There are several other conditions marked by hyperostotic and fragile bones but also other anomalies or conditions distinguishing them from osteopetrosis, pycnodysostosis, and dysosteosclerosis (Table 740.3).

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

Table 740.3 Other Conditions with Hyperostotic Fragile Bones

GENE	DISORDER	CLINICAL CHARACTERISTICS	FEATURES DISTINGUISHING THIS DISORDER FROM *CLCN7*-RELATED ARO
CA2	ARO w/renal tubular acidosis (RTA) (OMIM 259730)	Generalized osteosclerosis. Cerebral calcifications are typical and may be associated with ID.	Onset of ARO with RTA is usually later than in infantile malignant form of ARO and disease course is milder.
OSTM1	*OSTM1*-related ARO (OMIM 259720)	~4% of ARO is caused by pathogenic variants in *OSTM1*. Extremely severe form of ARO with CNS involvement that is indistinguishable from most severe forms of *CLCN7*-related ARO.	*OSTM1*-related ARO is frequently associated with structural brain anomalies.
PLEKHM1	*PLEKHM1*-related ARO (OMIM 611497)	Very rare, can look like ADOII.	*PLEKHM1*-related ARO appears to be very mild and can regress with ↑ age. One person with *PLEKHM1*-related ARO caused by a heterozygous pathogenic variant has been described.
SNX10	*SNX10*-related ARO (OMIM 615085)	~4% of ARO is caused by pathogenic variants in *SNX10*; in particular, "Västerbottenian osteopetrosis" is caused by *SNX10* pathogenic variants. Loss of vision, anemia, and bone fragility are frequently observed, warranting use of HSCT.	*SNX10*-related ARO appears to be slightly less severe than *CLCN7*-related ARO.
TCIRG1	*TCIRG1*-related ARO (OMIM 259700)	>50% of ARO is caused by pathogenic variants in *TCIRG1*.	Higher frequency of neurodevelopmental delay and seizures in *CLCN7*-related ARO than in *TCIRG1*-related ARO. Noncoding *TCIRG1* variants can cause milder phenotype that resembles ADOII.
TNFRSF11A	Osteoclast-poor ARO (OMIM 612301)	Characterized by onset within first year of life and typical ARO manifestations. Investigation of bone biopsy is prerequisite for reliable diagnosis.	*TNFSF11* pathogenic variants cause a slight T-cell defect, and *TNFRSF11A* pathogenic variants can lead to hypogammaglobulinemia similar to a common variable immune deficiency. It is crucial to rule out *TNFSF11*- and *TNFRSF11A*-related ARO, as HSCT is not successful in these persons.
TNFSF11	Osteoclast-poor ARO (OMIM 259710)		

ADOII, Autosomal dominant osteopetrosis type II; ARO, autosomal recessive osteopetrosis; CNS, central nervous system; ID, intellectual disability; HSCT, hematopoietic stem cell transplantation

Chapter 741

Other Inherited Disorders of Skeletal Development

Julie E. Hoover-Fong and Daniah Albokhari

Advances in understanding have led to the delineation of the genetic basis of disorders that were previously poorly understood. Some of these conditions are now classified into gene families based on their molecular and clinical findings, as outlined in the most recent nosology and classification of genetic skeletal disorders and previous chapters. Additional important skeletal dysplasias that do not fit into one of the previous categories are discussed in this chapter.

ELLIS-VAN CREVELD SYNDROME

The Ellis-van Creveld syndrome, also known as **chondroectodermal dysplasia**, is a skeletal *and* an ectodermal dysplasia. This skeletal dysplasia presents at birth with short limbs, especially the middle and distal segments, accompanied by postaxial polydactyly of the hands and sometimes of the feet (Fig. 741.1). Nail dysplasia and dental anomalies (including neonatal, absent, premature loss of teeth, and upper lip defects) constitute the ectodermal dysplasia. Additional common manifestations include atrial septal defects and other congenital heart defects.

Skeletal radiographs reveal short tubular bones with clubbed ends, especially the proximal tibia and ulna (Fig. 741.2). Carpal bones display extra ossification centers and fusion; cone-shaped epiphyses are evident in the hands. A bony spur is often noted above the medial aspect of the acetabulum.

Ellis-van Creveld syndrome is an autosomal recessive condition that occurs with increased frequency in the Amish and Finnish founder populations than in the general population. Pathogenic variants have been identified in one of two genes, *EVC (EVC1)* or *EVC2 (LIMBIN)*, which map in a head-to-head configuration to chromosome 4p. Disease-causing variants of *EVC2* are detected in the allelic condition **Weyers acrofacial dysostosis**. EVC and EVC2 proteins are thought to influence hedgehog signaling in cilia by constitutively associating in a ringlike pattern in the ciliary transition zone and transducing extracellular signals to the nucleus via hedgehog signaling. Fgf18 may also play a significant role. This disorder is classified under the **ciliopathies** with major skeletal involvement (see Chapter 101.3).

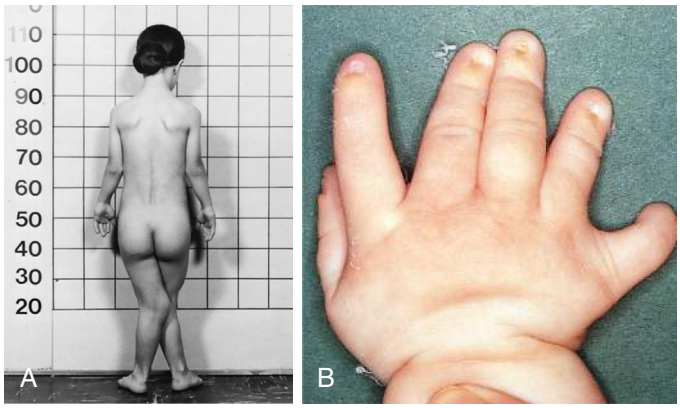

Fig. 741.1 **A,** Ellis-van Creveld syndrome in a young female. Note short stature, joint contractures at the elbows, and marked genu valgum. **B,** Multiple digits (polydactyly) in a different patient with Ellis-van Creveld syndrome. (**A** *from Zipes DP, Libby P, Bonow R, Braunwald E, eds. Braunwald's Heart Disease: a textbook of cardiovascular medicine, 7th ed. Philadelphia: WB Saunders, 2004. Fig 70.6;* **B** *from Beerman LB, Kreutzer J, Allada V. Cardiology. In: Zitelli BJ, McIntire SC, Nowalk AJ, eds. Zitelli and Davis' Atlas of Pediatric Physical Diagnosis, 6th ed. Philadelphia: Elsevier, 2012. Fig 5.6.)*

Fig. 741.2 Radiograph of lower extremities in Ellis-van Creveld syndrome. Tubular bones are short, and proximal fibula is short. Ossification is retarded in lateral tibia epiphyses, causing a knock-knee deformity.

Approximately 30% of patients die of cardiac or respiratory problems during infancy. Life span is otherwise normal; adult heights range from 119-161 cm.

ASPHYXIATING THORACIC DYSTROPHY

See also Chapter 467.3.

Asphyxiating thoracic dystrophy, or **Jeune syndrome**, is an autosomal recessive chondrodysplasia. Newborn infants present with a long, narrow thorax and respiratory insufficiency associated with pulmonary hypoplasia. Neonates often die. Other neonatal manifestations include slightly short limbs and postaxial polydactyly. This condition results from a disturbance of primary cilia, most often from pathogenic variants of the gene encoding cytoplasmic dynein 2 heavy chain 1 *(DYNC2H1)*. This disorder is classified under **ciliopathies** with major skeletal involvement (see Chapter 101.3).

Skeletal radiographs show very short ribs with anterior expansion. Tubular limb bones are short with bulbous ends; cone-shaped epiphyses occur in hand bones. The iliac bones are short and square with a spur above the medial aspect of the acetabulum (Fig. 741.3).

If infants survive the neonatal period, respiratory function usually improves as the rib cage grows. Surgery that produces lateral thoracic expansion improves rib growth and enhances chest wall dimensions. Progressive renal dysfunction often develops during childhood. Intestinal malabsorption and hepatic dysfunction have also been reported.

SHORT-RIB POLYDACTYLY SYNDROMES

These conditions, which share the clinical features of constricted thoracic cage, short ribs, polydactyly, very short extremities, lethality during the newborn period and autosomal recessive inheritance. Pathogenic variants that map to cilia-related genes—*DYNC2H1, IFT80, IFT81, WDR34, WDR60, DYNC2LI1, NEK1, IFT122, WDR19, INTU, TRAF3IP1*—are found in this group of disorders.

CARTILAGE-HAIR HYPOPLASIA-ANAUXETIC SPECTRUM DISORDERS

Cartilage-hair hypoplasia (CHH), also known as **metaphyseal chondrodysplasia–McKusick type,** is part of a spectrum of disorders with metaphyseal involvement that includes metaphyseal dysplasia without hypotrichosis and anauxetic dysplasia. All disorders are characterized by severe disproportionate short stature, which is usually recognized at birth; the short limbs can lead to prenatal detection. They all show autosomal recessive inheritance and are caused by pathogenic variants in *RMRP*, a gene coding for a large untranslated RNA component of an enzyme complex involved in processing mitochondrial RNA. Loss of this gene product interferes with processing of both messenger RNA and ribosomal RNA and correlates with the extent of bone dysplasia, whereas loss of messenger RNA processing correlates with the degree of hair hypoplasia, immunodeficiency, and hematologic abnormality. Molecular testing confirms the diagnosis, and prenatal diagnosis is available if the pathogenic variant is identified either in the patient or the parents.

CHH is recognized during the second year because of growth deficiency affecting the limbs, accompanied by flaring of the lower rib cage, a prominent sternum, and bowing of the legs. The hands and feet are short, and the fingers are very short with extreme ligamentous laxity. The hair is thin, sparse, and light colored; the nails are hypoplastic; and the skin can be hypopigmented.

Radiographs show short tubular bones with flared, irregularly mineralized, and cupped metaphyses (Fig. 741.4). The knees are more affected than are the hips, and the fibula is disproportionately longer than the tibia. The metacarpals and phalanges are short and broad. Spinal radiographs reveal mild platyspondyly.

Nonskeletal manifestations associated with CHH include immunodeficiency (T-cell abnormalities, neutropenia, leukopenia, and susceptibility to varicella zoster virus infections; children also may have complications from smallpox and polio vaccinations), malabsorption, celiac disease, and Hirschsprung disease. Adults are at risk for malignancy, especially non-Hodgkin lymphoma and skin tumors. Adult height ranges from 107-157 cm.

The highest birth prevalence is in the Amish and Finnish populations because of a founder effect. Carrier frequency in the Amish is 1:19 with 1 per 1,300 births affected compared to a carrier frequency of 1:76 and 1 per 23,000 births affected in Finland. The exact prevalence in the general population is not known, but CHH

is relatively rare. However, two allelic conditions, metaphyseal dysplasia without hypotrichosis and anauxetic dysplasia, expand the phenotypic spectrum. Children with a growth disorder and abnormal hair should be evaluated for *RMRP* pathogenic variants.

TRPV4-SPECTRUM DISORDERS

Pathogenic variants in *TRPV4* cause a spectrum of conditions including metatropic dysplasia, spondylometaphyseal dysplasia (SMD), Kozlowski type, brachyolmia, and familial digital arthropathy with brachydactyly. Metatropic dysplasia and SMD, Kozlowski type are expanded on next. **Brachyolmia** is dominated by progressive scoliosis and platyspondyly on x-rays and familial digital arthropathy with brachydactyly, which is characterized by deforming painful osteoarthritis of the interphalangeal, metacarpophalangeal, and metatarsophalangeal joints starting after the first decade of life. The rest of the skeleton is unaffected in this condition. It should also be noted that pathogenic variants in *TRPV4* are also responsible for a large group of neuromuscular disorders including **Charcot-Marie-Tooth disease type 2C**, scapuloperoneal spinal muscular atrophy, and congenital distal spinal muscular atrophy. Though there is considerable overlap of the phenotypes of the conditions within the skeletal group and the neuromuscular group, there are only rare instances currently recognized of individual patients with both features.

METATROPIC DYSPLASIA

Metatropic dysplasia is an autosomal dominant disorder resulting from heterozygous pathogenic variants of transient receptor potential vanilloid family 4 (TRPV4), which encodes a calcium-permeable cation channel. Newborn infants present with a long narrow trunk and short extremities. A tail-like appendage sometimes extends from the base of the spine. Odontoid hypoplasia is common and may be associated with cervical instability. Kyphoscoliosis appears in late infancy and progresses through childhood, often becoming severe enough to compromise cardiopulmonary function. The joints are large and become progressively restricted in mobility, except in the hands. Contractures often develop in the hips and knees during childhood. Although severely affected infants can die at a young age from respiratory failure, patients usually survive, although they can become disabled as adults from the progressive musculoskeletal deformities. Adult heights range from 110-120 cm.

Skeletal radiographs show characteristic changes dominated by severe platyspondyly and short tubular bones with expanded and deformed metaphyses that exhibit a dumbbell appearance (Fig. 741.5). The pelvic bones are hypoplastic and exhibit a halberd appearance because of a small sacrosciatic notch and a notch above the lateral margin of the acetabulum.

Fig. 741.4 Radiograph of lower extremities in cartilage-hair hypoplasia. The tubular bones are short, and the metaphyses are flared and irregular. The fibula is disproportionately long compared with the tibia. The femoral necks are short.

Fig. 741.3 Asphyxiating thoracic dystrophy. Short ribs, long and narrow chest, small pelvis, trident acetabula, no platyspondyly (helps differentiate from thanatophoric dysplasia), cystic renal disease. *(From Campeau P, Schlesinger AE. Skeletal dysplasias. [Updated 2017 Jan 30]. In: De Groot LJ, Chrousos G, Dungan K, et al., eds. Endotext [internet]. South Dartmouth, MA, 2000,* MDText.com, *Inc., Fig 6. Available at:* https://www.ncbi.nlm.nih.gov/books/NBK279130/*)*

SPONDYLOMETAPHYSEAL DYSPLASIA, KOZLOWSKI TYPE

Kozlowski type of spondylometaphyseal dysplasia is an autosomal dominant allelic disorder to metatropic dysplasia caused by *TRPV4* variants.

Kozlowski type of spondylometaphyseal dysplasia manifests in early childhood with mild short stature involving mostly the trunk and a waddling gait. The hands and feet may be short and stubby. Radiographs show flattening of vertebral bodies. The metaphyses of tubular bones are widened and irregularly mineralized, especially at the proximal femur. The pelvic bones manifest mild hypoplasia. Scoliosis can develop during adolescence. The disorder is otherwise uncomplicated, and manifestations are limited to the skeleton. Adults reach heights of 130-150 cm.

DISORDERS INVOLVING FILAMINS

Pathogenic variants of genes encoding filamin A and filamin B proteins have been detected in diverse disorders of skeletal development: filamin A pathogenic variants in otopalatodigital syndromes type 1 and 2, frontometaphyseal dysplasia, Melnick-Needles syndrome and terminal osseous dysplasia with pigmentary defects and filamin B pathogenic variants in Larsen syndrome and perinatal lethal atelosteogenesis types 1 and 3, spondylo-carpal-tarsal dysplasia and Boomerang dysplasia. Filamins functionally connect extracellular to intracellular structural proteins, thereby linking cells to their local microenvironment, which is essential for skeletal development and growth.

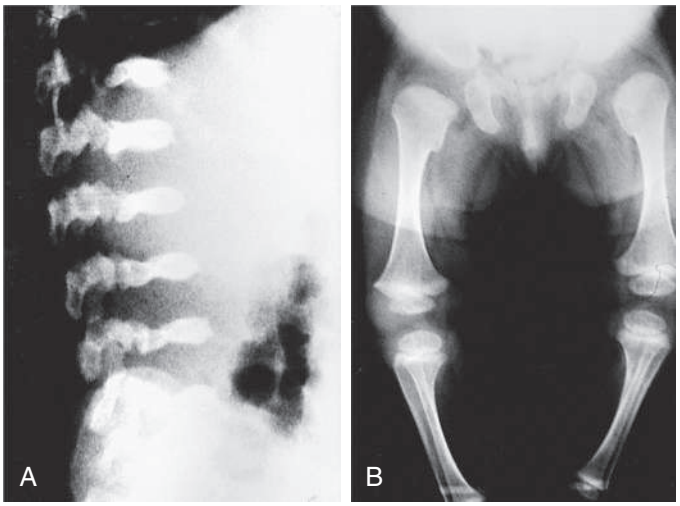

Fig. 741.5 A, Radiograph of the lateral thoracolumbar spine in metatropic dysplasia showing severe platyspondyly. B, Radiograph of lower extremities in metatropic dysplasia showing short tubular bones with widened metaphyses. The femurs have a dumbbell appearance.

JUVENILE OSTEOCHONDROSES

The juvenile osteochondroses are a heterogeneous group of disorders in which regional disturbances in bone growth cause noninflammatory arthropathies. Table 741.1 summarizes the juvenile osteochondroses. Some have localized pain and tenderness (Freiberg disease, Osgood-Schlatter disease [see Chapter 718.4], osteochondritis dissecans [see Chapter 718.3]), whereas others present with painless limitation of joint movement (Legg-Calvé-Perthes disease [see Chapter 719.3], Scheuermann disease [see Chapter 720.4]). Bone growth may be disrupted, leading to deformities. The diagnosis is usually confirmed radiographically, and treatment is symptomatic. The pathogenesis of these disorders is believed to involve ischemic necrosis of primary and secondary ossification centers. Although familial forms have been reported, these disorders usually occur sporadically.

CAFFEY DISEASE (INFANTILE CORTICAL HYPEROSTOSIS)

This is a rare disorder of unknown etiology characterized by cortical hyperostosis with inflammation of the contiguous fascia and muscle. It is often sporadic, but both autosomal dominant and autosomal recessive forms have been reported. Pathogenic variants in *FAM111A* and *TBCE* have been identified in the autosomal dominant and recessive forms, respectively. **Sanjad-Sakati syndrome** (hypoparathyroidism, intellectual disability, dysmorphism) is also caused by pathogenic variants in *TBCE*. Caffey dysplasia is classified in the slender bone dysplasia group.

Prenatal and more often postnatal onsets have been described. Prenatal onset may be mild (autosomal dominant) or severe (autosomal recessive). Severe prenatal disease is characterized by typical bone lesions, polyhydramnios, hydrops fetalis, severe respiratory distress, prematurity, and high mortality. Onset in infancy (younger than 6 months; average: 10 weeks) is most common; manifestations include the sudden onset of irritability, swelling of contiguous soft tissue that precedes the cortical thickening of the underlying bones, fever, and anorexia. The swelling is painful with a woodlike induration but with minimal warmth or redness; suppuration is absent. There are unpredictable remissions and relapses; an episode can last 2 weeks to 3 months. The most common bones involved include the mandible (75%) (Fig. 741.6), the clavicle, and the ulna. If swelling is not prominent or visible, the diagnosis might not be evident.

Laboratory features include elevated erythrocyte sedimentation rate and serum alkaline phosphatase as well as, in some patients, increased serum prostaglandin E levels. There may be

Table 741.1 Juvenile Osteochondroses

EPONYM	AFFECTED REGION	AGE AT PRESENTATION
Legg-Calvé-Perthes disease	Capital femoral epiphysis	3-12 yr
Osgood-Schlatter disease	Tibial tubercle	10-16 yr
Sever disease	Os calcaneus	6-10 yr
Freiberg disease	Head of second metatarsal	10-14 yr
Scheuermann disease	Vertebral bodies	Adolescence
Blount disease	Medial aspect of proximal tibial epiphysis	Infancy or adolescence
Osteochondritis dissecans	Subchondral regions of knee, hip, elbow, and ankle	Adolescence

Fig. 741.6 Facies in infantile cortical hyperostosis. In almost all cases, the changes have appeared before the fifth month of life. Unilateral swelling of the left cheek and left side of the jaw in an infant 12 weeks of age. *(From Slovis T, ed. Caffey's Pediatric Diagnostic Imaging, 11th ed. Philadelphia: Mosby, 2008.)*

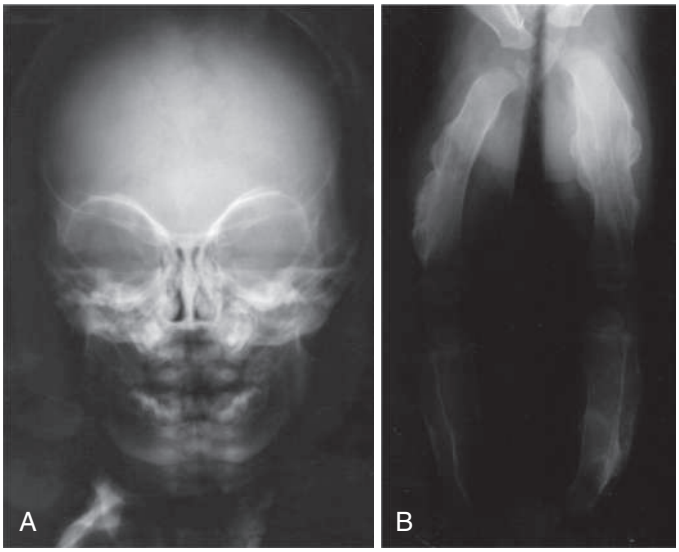

Fig. 741.7 A, Radiograph of a 5-mo-old infant showing hyperostosis of the mandible. B, Radiograph of a 5-mo-old infant showing hyperostosis of both legs. *(From Kamoun-Goldrat A, le Merrer M. Infantile cortical hyperostosis [Caffey disease]: a review. J Oral Maxillofac Surg. 2008;66:2145–2150. Figs. 1 and 2.)*

thrombocytosis and anemia. The radiographic features include soft tissue swelling and calcification and cortical hyperostosis (Fig. 741.7). All bones may be affected except the phalanges or vertebral bodies. The differential diagnosis includes other causes of hyperostosis such as chronic vitamin A intoxication, prolonged prostaglandin E infusion in children with ductal dependent congenital heart disease, primary bone tumors, and scurvy.

Complications are unusual but include pseudoparalysis with limb or scapula involvement, pleural effusions (rib), torticollis (clavicle), mandibular asymmetry, bone fusion (ribs or ulna and radius), and bone angulation deformities (common with severe prenatal onset). Treatment includes indomethacin and prednisone (if there is a poor response to indomethacin).

FIBRODYSPLASIA OSSIFICANS PROGRESSIVA

Fibrodysplasia ossificans progressiva (FOP) is a rare and severely disabling disorder characterized by progressive extraskeletal heterotopic bone formation in soft connective tissues including muscles, tendons, ligaments, fascia, and aponeuroses. With the exception of deformity of the large toes, infants are normal at birth. Episodes of painful soft tissue swelling with inflammation usually begin in early childhood initially involving the upper back and neck, and later the entire trunk and extremities. Repeated episodes (flare-ups) slowly transform the soft tissues into bands or plates of bone that span joints and progressively limit movement and mobility. Episodes are often triggered by injury, intramuscular injections, and viral infection. Most patients are wheelchair bound by their late teens. The average life span is approximately 40 years, with death usually resulting from complications of thoracic insufficiency.

FOP results from heterozygous activating pathogenic variants of the gene *(ACVR1)* encoding the bone morphogenetic protein (BMP) type I receptor, activin A receptor type I *(ALK2)*. Patients with classic FOP have the same missense *ACVR1* pathogenic variant, which enhances BMP signaling, which, in turn, induces inflammation and aberrant endochondral ossification through mechanisms that are poorly understood. Environmental factors, such as injury, play an important role in triggering these events. *ACVR1* pathogenic variants usually occur sporadically, but autosomal dominant transmission has rarely been observed. FOP is classified in the disorganized development of skeletal components group.

There is currently no definitive treatment for FOP. Supportive care includes avoidance of injury-prone physical activities, intramuscular injections including immunizations, and overstretching of the jaw during dental procedures. Corticosteroids and other anti-inflammatory agents reduce inflammation and pain during flare-ups but are unable to prevent heterotopic bone formation. Studies in FOP animal models suggest that BMP type I kinase inhibitors and retinoic acid receptor γ agonists, which block chondrogenesis—the initial step in endochondral ossification—may be useful therapies in the future. An animal FOP study has indicated that mutant ALK2 responds to activin A, induces canonical BMP signaling, and leads to heterotopic bone formation, providing an additional possible therapeutic target. The retinoic acid receptor γ agonist palovarotene was approved by the US Food and Drug Administration in 2023 for treatment of FOP for females ages 8 years and older and for males ages 10 years and older.

Chapter 742

Osteogenesis Imperfecta

Joan C. Marini

Osteoporosis is fragility of the skeletal system and a susceptibility to fractures of the long bones or vertebral compressions from mild or inconsequential trauma (see Chapter 749). **Osteogenesis imperfecta (OI)** (brittle bone disease), the most common genetic cause of osteoporosis, is a generalized disorder of connective tissue. The spectrum of OI is extremely broad, ranging from forms that are lethal in the perinatal period to a mild form in which the diagnosis may be equivocal in an adult (Table 742.1).

ETIOLOGY

Structural or quantitative defects in type I collagen cause the full clinical spectrum of OI (types I-IV). Defects in processing either the N- or C-terminal propeptides of type I collagen cause distinctive bone fragility syndromes. Type I collagen is the primary component of the extracellular matrix of bone and skin. Between 15% and 20% of patients clinically indistinguishable from OI do not have a molecular defect in type I collagen. These cases are typically caused by defects in genes whose protein products interact with type I collagen. One group of patients has overmodified collagen, with similar biochemical findings to those with collagen structural defects and severe or lethal OI bone dysplasia. These cases are caused by recessive null pathogenic variants in any of the three components of the collagen prolyl 3-hydroxylation complex, prolyl 3-hydroxylase 1 (encoded by *LEPRE1*) or its associated protein, CRTAP, or cyclophilin B (CyPB, encoded by *PPIB*). A second set of cases without collagen defects have biochemically normal collagen. Defects in *IFITM5* and *SERPINF1* account for defects in mineralization in types V and VI OI, while pathogenic variants in *SERPINH1*, encoding the collagen chaperone HSP47, and *FKBP10*, encoding the peptidyl-prolyl *cis-trans* isomerase FKBP65, cause types X and XI OI, respectively. Rare pathogenic variants in *BMP1,* the enzyme that processes the C-propeptide of type I collagen, also cause a recessive form of OI (type XIII). The newest set of genes added to the recessive OI causative panel (*SP7*, type XII OI; *TMEM38B*, type XIV OI; *WNT1*, type XV OI; *CREB3L1*, type XVI OI, *SPARC*, type XVII OI, and *MBTPS2*, type XVIII OI) are not only involved in osteoblast differentiation but also affect collagen synthesis and cross linking. There are currently very few individuals with OI whose genetic defect is not in a known causative gene.

EPIDEMIOLOGY

The autosomal dominant forms of OI occur equally in all racial and ethnic groups, whereas recessive forms occur predominantly in ethnic groups with consanguineous marriages or as a founder effect in an isolated population. The West African founder pathogenic variant for type VIII OI has a carrier frequency of 1 in 200-300 among Black individuals. The collective incidence of all types of OI detectable in infancy is approximately 1 in 20,000. There is a similar incidence of the mild form OI type I.

PATHOLOGY

The pathogenic structural collagen variants in OI cause the bones to be globally abnormal. The bone matrix contains abnormal type I collagen fibrils and relatively increased levels of types III and V collagen. Several noncollagenous proteins of bone matrix are also reduced. Bone cells also contribute to OI pathology, with abnormal osteoblast differentiation and increased numbers of active bone resorbing osteoclasts. The hydroxyapatite crystals deposited on this matrix are poorly aligned with the long axis of fibrils, and there is paradoxical hypermineralization of bone.

PATHOGENESIS

Type I collagen is a heterotrimer composed of two α_1(I) chains and one α_2(I) chain. The chains are synthesized as procollagen molecules with short globular propeptide extensions on both ends of the central helical domain. The helical domain is composed of uninterrupted repeats of the sequence Gly-X-Y, where Gly is glycine, X is often proline, and Y is often hydroxyproline. The presence of glycine at every third residue is crucial to helix formation because its small side chain can be accommodated in the interior of the helix. The chains are assembled into trimers at their carboxyl ends, and helix formation then proceeds linearly in a carboxyl to amino direction. Concomitant with helix assembly and formation, helical proline and lysine residues are hydroxylated by prolyl 4-hydroxylase and lysyl hydroxylase 1, and some of the hydroxylysine residues are subsequently glycosylated. After secretion, the propeptides are cleaved in the pericellular space by specific N- and C-terminal propeptidases.

Collagen structural defects are predominantly of two types: 80% are pathogenic missense variants causing substitutions of helical glycine residues or crucial residues in the C-propeptide by other amino acids, and 20% are single exon splicing defects. The clinically mild OI type I has a quantitative defect, with null pathogenic variants in one α_1(I) allele leading to a reduced amount of normal collagen. Deficiency of type I procollagen caused by a C-propeptide removal causes a paradoxical high bone mass form of OI with mild or severe skeletal fragility depending on whether the defect is in the cleavage site or the cleaving peptidase. Impaired removal of the N-propeptide causes an overlap syndrome of Ehlers-Danlos and OI (OI/EDS) with variable skeletal fragility.

Glycine substitutions in the two α chains have distinct genotype-phenotype relationships, but there is also striking phenotype variability caused by independent pathogenic variants at the same site. In general, glycine substitutions in the α_1 chain are more lethal than those in the α_2(I) chain. Two lethal regions in α_1(I) align with major ligand binding regions of the collagen helix.

Classical OI (Sillence types I-IV) is an autosomal dominant disorder, as is type V OI. Some familial recurrences of OI are caused by parental mosaicism for dominant collagen pathogenic variants. Recessive OI accounts for 10–15% of newly diagnosed OI in North America. Three recessive types are caused by null pathogenic variants in the genes coding for the components of the collagen prolyl 3-hydroxylation complex in the endoplasmic reticulum (*LEPRE1*, *CRTAP,* or *PPIB)*. Murine models indicate that it is the absence of the complex components, rather than the absence of the Pro986 modification, that is critical for development of OI. Other recessive types are caused by null pathogenic variants in genes whose products are involved in collagen folding *(SERPINH1, FKBP10)*, bone mineralization *(SERPINF1)*, or defects in osteoblast differentiation and function *(SP7, TMEM38B, WNT1, CREB3L1, SPARC, MBTPS2)*.

CLINICAL MANIFESTATIONS

Classical OI was described with the triad of fragile bones, blue sclerae, and early deafness, although most cases do not have all three features. The Sillence classification divides OI into four types based on clinical and radiographic criteria. Types V and VI were later proposed based on histologic distinctions. Subsequent types VII-XVIII were based on identification of the molecular defect, followed by clinical description.

Osteogenesis Imperfecta Type I (Mild)

OI type I is sufficiently mild that it is often found in large pedigrees. Many type I families have blue sclerae, recurrent fractures in childhood, and presenile (i.e., beginning in early adulthood) hearing loss (30–60%). Both types I and IV are divided into A and B subtypes, depending on the absence (A) or presence (B) of **dentinogenesis imperfecta,** a type of dentin dysplasia resulting in discolored (often blue-gray or amber), translucent teeth that wear down rapidly or break. Other possible connective tissue abnormalities include hyperextensible joints, easy bruising, thin skin, joint laxity, scoliosis, wormian bones, hernia, and mild short stature compared with family members. Fractures result from mild to moderate trauma but decrease after puberty.

Table 742.1 Osteogenesis Imperfecta

DISORDER	INHERITANCE	GENE	PREVIOUS NAMES / NOTATION
Osteogenesis imperfecta, non-deforming (Sillence type 1)	AD	*COL1A1, COL1A2*	OMIM as OI type I
Osteogenesis imperfecta, severe perinatal form (Sillence type 2)	AD	*COL1A1, COL1A2*	OMIM as OI type II
	AR	*CRTAP*	OMIM as OI type VII
	AR	*P3H1*	OMIM as OI type VIII
	AR	*PPIB*	OMIM as OI type IX
Osteogenesis imperfecta, progressively deforming (Sillence type 3)	AD	*COL1A1, COL1A2, IFITM5*	OMIM as OI type III
	AD	*SERPINF1*	In OMIM as OI type VI
	AR	*CRTAP, P3H1*	OMIM as OI type VII
	AR	*PPIB*	OMIM as OI type IX
	AR	*SERPINH1*	OMIM OI as type X
	AR	*FKBP10*	OMIM as OI type XI
	AR	*TMEM38B*	OMIM as OI type XIV
	AR	*BMP1*	OMIM as OI type XIII
	AR	*WNT1*	OMIM as OI type XV Variants may result in AD osteoporosis.
	AR	*CREB3L1*	OMIM as OI type XVI Ehlers-Danlos-like
	AR	*SPARC*	OMIM as OI type XVII
	AR	*TENT5A*	OMIM as OI type XVIII
	XLR	*MBTPS2*	OMIM as OI type XIX
	AR	*MESD*	OMIM as OI type XX
	AR	*KDELR2*	OMIM as OI type XXL
	AR	*CCD134*	OMIM as OI type XXII
Osteogenesis imperfecta, moderate form (Sillence type 4)	AD	*COL1A1, COL1A2, IFITM5*	OMIM as OI type IV
	AR	*WNT1*	OMIM as OI type XV
	AR	*CRTAP*	OMIM as OI type VII
	AD	*PP1B*	OMIM as OI type IX
	AR	*FKBP10*	OMIM as OI type XI
	AR	*SP7*	OMIM as OI type XII
Osteogenesis imperfecta with calcification of interosseous membranes and/or hypertrophic callus (OI type 5)	AD	*IFITM5*	May mimic progressively deforming or moderate OI (Sillence types 3 and 4)
Osteogenesis imperfecta with craniosynostosis (Cole- Carpenter syndrome)	AD	*P4HB*	Craniosynostosis is not well documented.
	AR	*SEC24D*	Most patients do not have craniosynostosis but rather large fontanels.
Osteoporosis – X-linked form	XL	*MBTPS2*	OMIM as OI type XIX
Osteoporosis – dominant form	AD	*WNT1*	OMIM as OI type XV

Data from Unger S, Ferreira CR, Mortier GR, et al: Nosology of genetic skeletal disorders: 2023 revision. *Am J Med Genet* 2023;191A:1164-1209 (Table 1, Group 26, pp. 1187-1190).

Osteogenesis Imperfecta Type II (Perinatal Lethal)

Infants with OI type II may be stillborn or die in the first years of life. Birthweight and length are small for gestational age. There is extreme fragility of the skeleton and other connective tissues. There are multiple intrauterine fractures of long bones, which have a crumpled appearance on radiographs. There are striking micromelia and bowing of extremities; the legs are held abducted at right angles to the body in the frogleg position. Multiple rib fractures create a beaded appearance, and the small thorax contributes to respiratory insufficiency. The skull is large for body size, with enlarged anterior and posterior fontanels. Sclerae are dark blue-gray. The cerebral cortex has multiple neuronal migration and other defects (agyria, gliosis, periventricular leukomalacia).

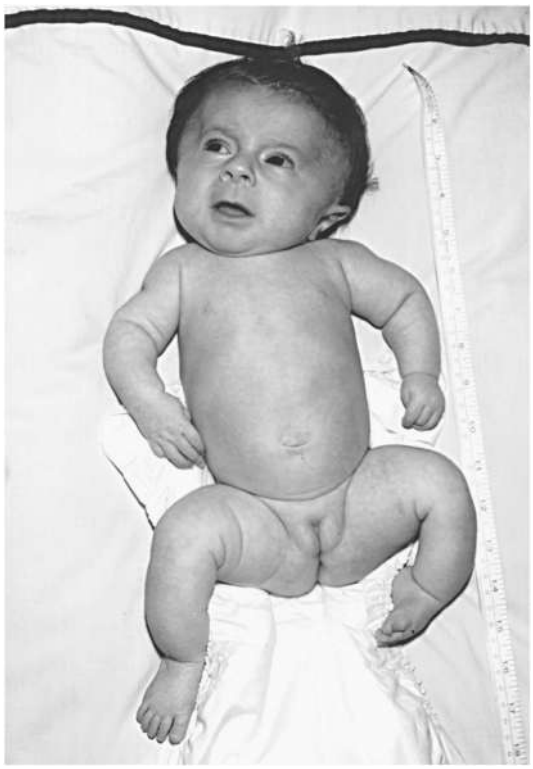

Fig. 742.1 Infant with type III osteogenesis imperfecta displays shortened bowed extremities, thoracic deformity, and relative macrocephaly.

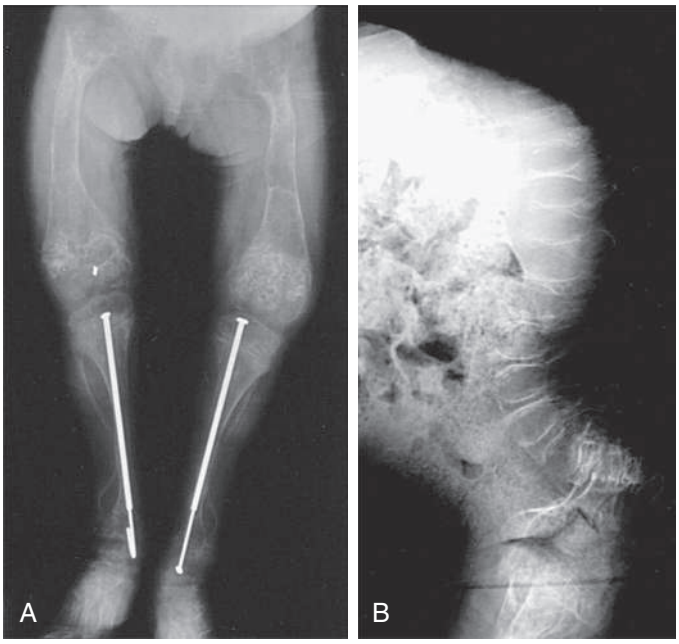

Fig. 742.2 Typical features of type III osteogenesis imperfecta radiographs in a 6-yr-old child. **A,** Lower long bones are osteoporotic, with metaphyseal flaring, "popcorn" formation at growth plates, and placement of intramedullary rods. **B,** Vertebral bodies are compressed and osteoporotic.

Osteogenesis Imperfecta Type III (Progressive Deforming)

OI type III is the most severe nonlethal form of OI and results in significant physical disability. Birthweight and length are often low normal. Fractures usually occur in utero. There is relative macrocephaly and triangular facies (Fig. 742.1). Postnatally, fractures occur from inconsequential trauma and heal with deformity. Disorganization of the bone matrix results in a "popcorn" appearance at the metaphyses (Fig. 742.2). The rib cage has flaring at the base, and pectus deformity is frequent. Virtually all type III patients have scoliosis and vertebral compression. Growth falls below the curve by the first year; all type III patients have extreme short stature. Scleral hue ranges from white to blue. Dentinogenesis imperfecta, hearing loss, and kyphoscoliosis may be present or develop over time.

Osteogenesis Imperfecta Type IV (Moderately Severe)

Patients with OI type IV can present at birth with in utero fractures or bowing of lower long bones. They can also present with recurrent fractures after ambulation and have normal to moderate short stature. Most children have moderate bowing even with infrequent fractures. Children with OI type IV require orthopedic and rehabilitation intervention, but they are usually able to attain community ambulation skills. Fracture rates decrease after puberty. Radiographically, they are osteoporotic and have metaphyseal flaring and vertebral compressions. Scleral hue may be blue or white.

Defects in the Processing of Type I Procollagen Propeptides

Autosomal dominant pathogenic variants in the C-propeptide cleavage site of procollagen or recessive defects in BMP1, the enzyme responsible for its cleavage, cause bone fragility with normal or elevated dual-energy x-ray absorptiometry bone density *z* scores. Individuals with dominant pathogenic variants have normal stature, white sclerae and teeth, and mild to moderate OI. Null pathogenic variants in *BMP1* lead to a more severe skeletal phenotype with short stature, scoliosis, and bone deformity because *BMP1* has other substrates in addition to type I collagen.

Defects in removal of the type I procollagen N-propeptide cause a distinctive combination of Ehlers-Danlos syndrome and OI. Deletion of exon six, containing the cleavage site, causes EDS type VII. Glycine substitutions near the cleavage site impair processing by altering the site configuration, causing hyperextensibility of large and small joints and variable bone fragility.

Osteogenesis Imperfecta Type V (Hyperplastic Callus) and Type VI Hyperosteoidosis (Mineralization Defect)

Types V and VI OI patients clinically have OI similar in skeletal severity to types IV and III, respectively, but they have distinct findings on bone histology. Type V patients also usually have some combination of hyperplastic callus, calcification of the interosseous membrane of the forearm, and/or a radiodense metaphyseal band. They constitute <5% of OI cases. All type V OI patients are heterozygous for the same pathogenic variant in *IFITM5*, which generates a novel start codon for the bone protein BRIL. Ligamentous laxity may be present; blue sclera or dentinogenesis imperfecta are not present. Patients with type VI OI have progressive deforming OI that does not manifest at birth. They have distinctive bone histology with broad osteoid seams and fish-scale lamellation under polarized light, caused by deficiency of pigment epithelium derived factor, encoded by *SERPINF1*. Types V and VI are connected in intracellular osteoblast pathways—*SERPINF1* transcripts are increased in type V OI, while *IFITM5* transcripts are decreased in type VI OI.

Osteogenesis Imperfecta Types VII, VIII, and IX (Autosomal Recessive)

Types VII and VIII patients overlap clinically with types II and III OI but have distinct features including white sclerae, rhizomelia, and small to normal head circumference. Surviving children have severe osteochondrodysplasia with extreme short stature and dual-energy x-ray absorptiometry L1-L2 *z* score in the −6 to −7 range. Type IX OI is very rare; most cases are lethal, but some have moderate skeletal severity without rhizomelia, and white sclerae.

Osteogenesis Imperfecta Types X and XI (Autosomal Recessive)

There have been several reports of severe to lethal type X OI caused by defects affecting the serine-type endopeptidase inhibitor domain of HSP47. This domain is responsible for the HSP47 chaperone function that helps to maintain the folded state of procollagen heterotrimers. HSP47 and FKBP65, the protein responsible for type XI OI, cooperate in collagen synthesis. Type XI OI is a more prevalent recessive form with a moderate to severe skeletal phenotype, including white sclerae and normal teeth. Congenital contractures of large joints may occur with the same pathogenic variants that cause only skeletal fragility, even in sibships. At the opposite end of the spectrum, a deletion of a single tyrosine residue causes Kuskokwim syndrome, a congenital contracture disorder with very mild vertebral findings and osteopenia. Defects in *FKBP10* decrease collagen crosslinking in matrix because FKBP65 is the foldase for lysyl hydroxylase 2, which hydroxylates collagen telopeptide residues important for cross linking.

Defects in Osteoblast Differentiation (Types XIII-XXII OI)

The most recent functional grouping of genes causing recessive OI (types XIII to XXII) affect osteoblast differentiation and are collagen related. *SP7* (type XIII OI) regulates osteoblast differentiation and is critical for bone formation. *TMEM38B* (type XIV OI) defects are clinically indistinguishable from type IV OI. *TMEM38B* encodes the endoplasmic reticulum membrane cation channel TRIC-B, which affects calcium flux from the endoplasmic reticulum to the cytoplasm. Since many enzymes involved in collagen metabolism are calcium dependent, collagen synthesis is globally dysregulated in the absence of TRIC-B, with significant intracellular retention. Collagen posttranslational modification is also impaired, leading to underhydroxylation of the collagen helix. Recessive *WNT1* (type XV OI) defects cause severe progressive deforming OI. Notably, Wnt signaling pathway activation through the Frizzled receptor on the osteoblast surface increases bone mass, and deficiency of Wnt decreases it. SPARC (type XVII OI), also known as osteonectin, is a glycoprotein component of extracellular matrix. Defects in residues important for SPARC binding to collagen were reported in two cases of moderate to severe OI.

The genes *MBTPS2* and *CREB3L1*, causing types XVIII and XVI OI, respectively, encode proteins involved in regulated intramembrane proteolysis (RIP). *MBTPS2* encodes the transmembrane Golgi protein site-2 protease (S2P), that acts in succession with S1P to activate regulatory molecules in times of cell stress. OASIS, encoded by *CREB3L1*, is an RIP substrate.

Interestingly, missense substitutions in S2P in OI patients result in underhydroxylation of the collagen lysine residue important for crosslinking of collagen in matrix, thus impairing bone strength. In OASIS-null mice, collagen transcription has been shown to be impaired.

Defects in *TENT5A, MESD, KDELR2,* and *CCDC134* have been reported in small numbers of individuals with lethal or severe OI skeletal phenotypes. The products of these genes are not known to interact directly with collagen. *TENT5A* encodes FAM46A, a cytoplasmic poly(A) polymerase with an unexpected role in bone mineralization, likely related to its role as a binding partner for SMADs, modulating BMP signaling. *MESD* acts along the Wnt pathway, serving as an endoplastic reticulum chaperone for the low-density lipoprotein receptors LRP5 and LRP6. Oligodontia and intellectual disability occur in some patients. Bone histology shows enlarged osteocytes and irregular matrix mineralization.

Pathogenic variants in *KDELR2* cause neurodevelopmental and severe skeletal defects. Pathogenic variants in *CCDC134* add to the skeletal effects by impacting the mitogen-activated protein kinase/extracellular signal-regulated kinase (MAPK/ERK) pathway. Expression of type I collagen is reduced, as is osteoblast in vitro mineralization, but histomorphometry is atypical for OI.

LABORATORY FINDINGS

DNA sequencing is the first diagnostic laboratory test, and several Clinical Laboratory Improvement Amendments (CLIA)-certified sequencing labs offer panels to test for dominant and recessive OI. Pathogenic variant identification is useful to determine the type with certainty and to facilitate family screening and prenatal diagnosis. It is also possible to screen for type VI OI by the determination of serum pigment epithelium-derived factor level, which is severely reduced in this type.

If dermal fibroblasts are obtained, they can be useful for determining the level of transcripts of the candidate gene and for collagen biochemical testing, which is positive for overmodification in most cases of types I-IV and IX OI, and in all cases of VII/VIII OI, and for undermodification in type XIV. In OI type I, the reduced amount of type I collagen results in an increase in the ratio of type III to type I collagen on gel electrophoresis.

Severe OI can be detected prenatally by level II ultrasonography as early as 16 weeks of gestation. OI and thanatophoric dysplasia may be confused. Fetal ultrasonography might not detect OI type IV and rarely detects OI type I. For recurrent cases, chorionic villus biopsy can be used for biochemical or molecular studies. Amniocytes produce false-positive biochemical studies but can be used for molecular studies in appropriate cases.

In the neonatal period, the normal to elevated alkaline phosphatase levels present in OI distinguish it from hypophosphatasia. During the school-age period, children with type VI OI have notably elevated serum alkaline phosphatase.

COMPLICATIONS

The morbidity and mortality of OI are cardiopulmonary. Recurrent pneumonias and declining pulmonary function occur in childhood, and cor pulmonale is seen in adults.

Neurologic complications include basilar invagination, brainstem compression, hydrocephalus, and syringohydromyelia. Many children with OI types III and IV have basilar invagination, but brainstem compression is uncommon. Basilar invagination is best detected with spiral CT of the craniocervical junction (Fig. 742.3).

TREATMENT

There is no cure for OI. For severe nonlethal OI, active physical rehabilitation in the early years allows children to attain a higher functional level than orthopedic management alone. Children with OI type I and

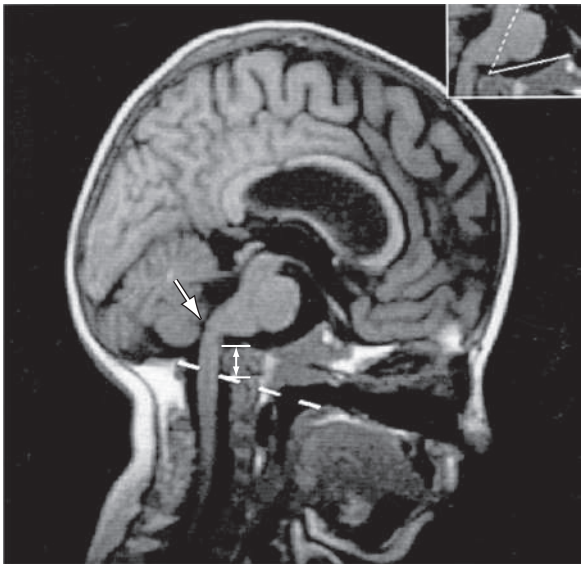

Fig. 742.3 Typical feature of basilar invagination shown in the sagittal MRI of an asymptomatic child with type III osteogenesis imperfecta. There is invagination of the odontoid above the Chamberlain line, causing compression and kinking at the pontomedullary junction *(arrow)*.

some with type IV are spontaneous ambulators. Children with types III, IV, V, VI, and XI OI benefit from gait aids and a program of swimming and conditioning. Severely affected patients require a wheelchair for community mobility but can acquire transfer and self-care skills. Teens with OI can require psychologic support with body image issues. Growth hormone improves bone histology in growth-responsive children (usually types I and IV).

Orthopedic management of OI is aimed at fracture management and correction of deformity to enable function. Fractures should be promptly splinted or cast; OI fractures heal well, and cast removal should be aimed at minimizing immobilization osteoporosis. Correction of long-bone deformity requires an osteotomy procedure and placement of an intramedullary rod.

A several-year course of treatment of children with OI with bisphosphonates (IV pamidronate or oral olpadronate or risedronate) confers some benefits. Bisphosphonates decrease bone resorption by osteoclasts; OI patients have increased bone volume that still contains the defective collagen. Bisphosphonates are more beneficial for vertebrae (trabecular bone) than long bones (cortical bone). Treatment for 1-2 years results in increased L1-L4 dual-energy x-ray absorptiometry and, more importantly, improved vertebral compressions and area. However, follow-up of bisphosphonate-treated children has shown that the incidence of scoliosis is unchanged even in children treated early, although there was a modest delay in progression in type III OI. The relative risk of long-bone fractures is modestly decreased by several years of bisphosphonates. However, the material properties of long bones are weakened by prolonged treatment and nonunion after osteotomy is increased. There is no effect of bisphosphonates on mobility scores, muscle strength, or bone pain. Limiting treatment duration to 2-3 years in mid-childhood can maximize the benefits and minimize the detriment to cortical material properties. Benefits appear to persist several years after the treatment interval, and alternation of treatment intervals and drug holidays may be beneficial. Side effects include abnormal long-bone remodeling, increased incidence of fracture nonunion, and osteopetrotic-like brittleness to bone.

Antibodies to sclerostin and TGF-β stimulate osteoblasts to produce bone matrix. They have shown promise in murine models for OI and are currently in trials for children with OI. TGF-beta signaling may be a pathogenic mechanism in OI. Fresolimumab, a TGF-beta neutralizing antibody, treatment in adults with OI type IV demonstrated increases in lumbar spine bone mineral density.

PROGNOSIS

OI is a chronic condition that may limit both life span and functional level. Infants with OI type II usually die within months to 1 year of life. An occasional child with radiographic type II and extreme growth deficiency survives to the teen years. Persons with OI type III have a reduced life span with clusters of mortality from pulmonary causes in early childhood, the teen years, and the 40s. OI types I, IV, and V OI are compatible with a full life span. The oldest reported individuals with type VIII are in their third decade, and some with type XI are in their fourth decade. The long-term prognosis for most recessive types is still emerging, and many adults with OI have not had molecular testing.

Individuals with OI type III are usually wheelchair dependent. With aggressive rehabilitation, they can attain transfer skills and household ambulation. OI type IV children usually attain community ambulation skills either independently or with gait aids.

GENETIC COUNSELING

For autosomal dominant OI, the risk of an affected individual passing the gene to the individual's offspring is 50%. An affected child usually has about the same severity of OI as the parent; however, there is variability of expression, and the child's condition can be either more or less severe than that of the parent. The empirical recurrence risk to an apparently unaffected couple of having a second child with OI is 5–7%; this is the statistical chance that one parent has germline mosaicism. The collagen pathogenic variant in the mosaic parent is present in some germ cells and may be present in somatic tissues. If a parent is a mosaic carrier, the risk of recurrence may be as high as 50%.

For recessive OI, the recurrence risk is 25% per pregnancy. No known individual with severe nonlethal recessive OI has had a child. For X-linked type XVIII OI, the risk to male offspring of carrier women is generally 50%.

Section 4

Connective Tissue Disorders

Chapter 743

Marfan Syndrome

Jefferson J. Doyle and Harry C. Dietz III

Marfan syndrome (MFS) is an inherited systemic, connective tissue disorder caused by pathogenic variants in the *FBN1* gene encoding the extracellular matrix (ECM) protein fibrillin-1. It is primarily associated with skeletal, cardiovascular, and ocular pathology. The diagnosis is based on clinical findings, some of which are age dependent.

EPIDEMIOLOGY

The incidence is estimated at 1 in 10,000 live births, and approximately 25% of cases are sporadic. The disorder shows autosomal dominant inheritance, with high penetrance but variable expression. Both interfamilial and intrafamilial clinical variation are common. There is no racial or gender preference.

PATHOGENESIS

MFS is associated with abnormal production, matrix deposition, and/or stability of fibrillin-1, a 350-kd ECM protein that is the major constituent of microfibrils, with prominent disruption of microfibrils and elastic fibers in diseased tissues. The fibrillin-1 *(FBN1)* gene is composed of 65 exons. Linkage analysis has suggested an absence of locus heterogeneity, and the involvement of *FBN1* is demonstrated in >90% of cases, with more than 1,000 disease-causing pathogenic variants identified to date (the majority of which are pathogenic missense variants unique to a given family). With the exception of early-onset and severe presentations of the disease associated with pathogenic variants in exons 26-27 and 31-32, no clear genotype-phenotype correlation has been identified. Given that there is considerable intrafamilial variability, genetic, epigenetic, environmental, or other unidentified factors may influence expression of the disease.

The transforming growth factor beta (TGF-β) family of cytokines influences a diverse repertoire of cellular processes, including cell proliferation, migration, differentiation, survival, and synthetic activity. The TGF-β ligands (TGF-β1, TGF-β2, or TGF-β3) are synthesized as inactive precursor complexes and sequestered by ECM proteins, including fibrillin-1. Mice heterozygous for a pathogenic variant in the fibrillin-1 gene, typical of those that cause MFS in humans, display many of the classic features of MFS, including aortic root aneurysm, which associates with a tissue signature for increased TGF-β signaling, suggesting that pathogenic variants in fibrillin-1 lead to increased TGF-β activation and signaling. Furthermore, pharmacologic antagonism

of TGF-β signaling initiated after the first few weeks of life ameliorates aortic aneurysm in mouse models of MFS, demonstrating that high TGF-β signaling is a cause rather than a consequence of disease progression.

Increased TGF-β signaling has been observed in other tissues in MFS mice, including the developing lung, mitral valve, and skeletal muscle. Treatment of these mice with agents that antagonize TGF-β attenuates or prevents pulmonary emphysema, myxomatous degeneration of the mitral valve, and skeletal muscle myopathy. The prominent role of TGF-β dysregulation in the pathogenesis of MFS was further validated by the discovery and characterization of another related aortic aneurysm syndrome, **Loeys-Dietz syndrome (LDS)**, in which patients have pathogenic variants in the genes encoding positive effectors of TGF-β signaling, including the ligands TGF-β2 or TGF-β3, either subunit of the TGF-β receptor (TβRI or TβRII) or the intracellular signaling intermediates SMAD2 or SMAD3. Patients with LDS share many overlapping clinical features with MFS (see the section on "Differential Diagnosis"). This is further supported by data showing that **Shprintzen-Goldberg syndrome (SGS)**, which shows phenotypic overlap with both MFS and LDS, is caused by pathogenic variants in *SKI*, a known repressor of the TGF-β transcriptional response.

CLINICAL MANIFESTATIONS

MFS is a multisystem disorder, with cardinal manifestations in the skeletal, cardiovascular, and ocular systems.

Skeletal System

Overgrowth of the long bones **(dolichostenomelia)** is often the most obvious manifestation of MFS and may produce a reduced upper segment–to–lower segment ratio (UL/LS) or an arm span–to–height ratio >1.05 times. Abnormal ratios are US/LS <1 for age 0-5 years, US/LS <0.95 for 6-7 years, US/LS <0.9 for 8-9 years, and US/LS <0.85 above age 10 years. Anterior chest deformity is likely the result of excessive rib growth, pushing the sternum either outward **(pectus carinatum)** or inward **(pectus excavatum)**. Abnormal curvatures of the spine (most commonly thoracolumbar scoliosis) may also partly result from increased vertebral growth. Other skeletal features include an inward bulging of the acetabulum into the pelvic cavity (protrusio acetabuli), flat feet (pes planus), and joint hypermobility (Fig. 743.1) or joint contractures. Long and slender fingers in relation to the palm of the hand **(arachnodactyly)** are generally a subjective finding. The combination of arachnodactyly and hypermobile joints is examined by the Walker-Murdoch or wrist sign, which is positive if there is full overlap of the distal phalanges of the thumb and fifth finger when wrapped around the contralateral wrist (see Fig. 743.1), and the Steinberg or thumb sign, which is present when the distal phalanx of the thumb fully extends beyond the ulnar border of the hand when folded across the palm (see Fig. 743.1). Contracture of the fingers **(camptodactyly)** and elbows is commonly observed. A selection of craniofacial manifestations may be present, including a long narrow skull (dolichocephaly), deeply set eyes (enophthalmos), recessed lower mandible (retrognathia) or small chin (micrognathia), flattening of the midface **(malar hypoplasia)**, a high-arching palate, and downward-slanting palpebral fissures (Fig. 743.2).

Cardiovascular System

Thickening of the atrioventricular valves is common and often associated with valvular prolapse. Variable degrees of regurgitation may be present. In children with early-onset and severe MFS, insufficiency of the mitral valve can lead to heart failure, pulmonary hypertension, and death in infancy. This manifestation is the leading cause of morbidity and mortality in young children with the disorder. Supraventricular arrhythmias may be seen in association with mitral valve dysfunction. Ventricular dysrhythmias have also been described in children with MFS, and there is an increased prevalence of prolonged QT interval. Dilated cardiomyopathy occurs with increased prevalence in patients with MFS, most often attributed to volume overload imposed by valve regurgitation. Aortic valve dysfunction is generally a late occurrence and attributed to stretching of the aortic annulus by an expanding aortic root aneurysm.

Aortic aneurysm, **dissection**, **and rupture**, principally at the level of the sinuses of Valsalva (also known as the aortic root), remain the most life-threatening manifestations of MFS, prompting lifelong monitoring by echocardiography or other imaging modalities. In severe cases, the aneurysm may be present in utero, but in mild examples it may be absent or never exceed dimensions that require clinical intervention. Aortic dimensions must be interpreted in comparison to age-dependent nomograms. The most important risk factor for aortic dissection is the maximal aortic root size and a positive family history. The characteristic histologic findings from aortas of patients with MFS include cystic medial necrosis of the tunica media and disruption of

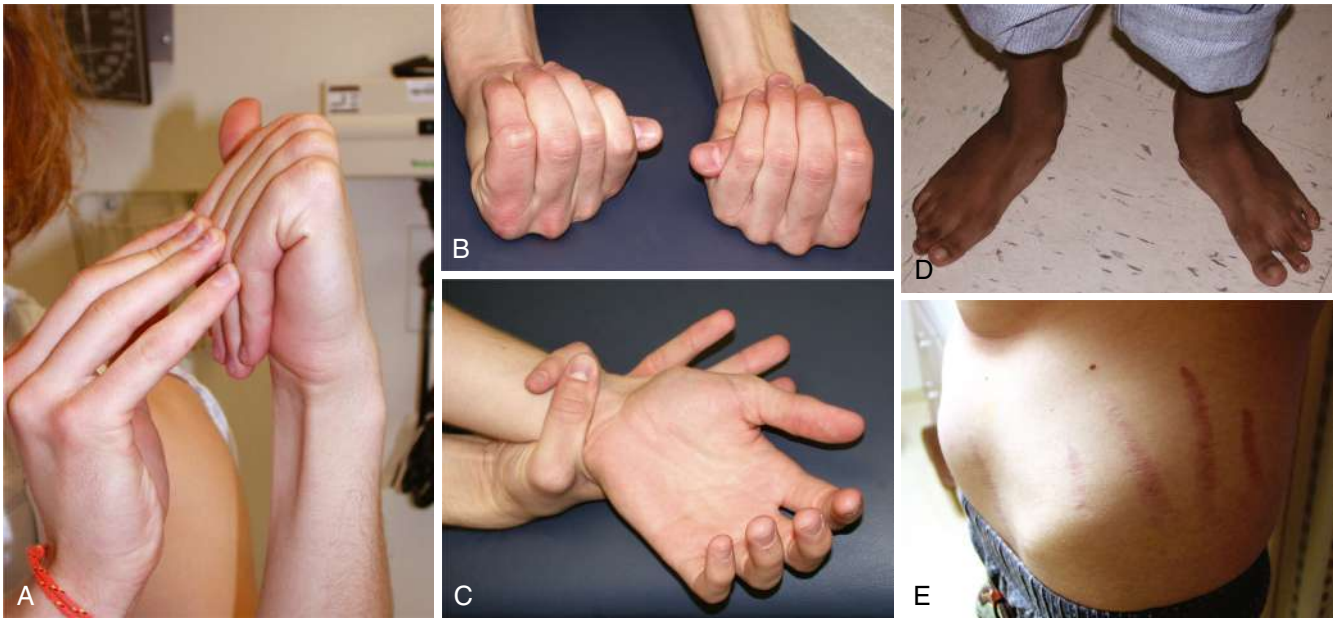

Fig. 743.1 Marfan syndrome. Note the joint laxity (A), Steinberg thumb sign (B), ability to join thumb and fifth finger around the wrist (Walker-Murdoch sign) (C), pes planus (D), and striae over hips and back (E). *(From Jones KL, Jones MC, Del Campo M. Smith's Recognizable Patterns of Human Malformation, 8th ed. Philadelphia: Elsevier, 2022; Fig. 2, p. 664.)*

Fig. 743.2 Marfan syndrome. Note the long slim limbs, pectus excavatum, narrow face, and reduced elbow extension. *(From Jones KL, Jones MC, Del Campo M. Smith's Recognizable Patterns of Human Malformation, 8th ed. Philadelphia: Elsevier, 2022: Fig. 1A, p. 662.)*

elastic lamellae. Cystic medial necrosis describes the focal apoptosis and disappearance of vascular smooth muscle cells and elastic fibers from the tunica media of the aortic wall, and subsequent deposition of mucin-like material in the cystic space. These changes produce a thicker, less distensible and stiffer aorta, which is more prone to aortic dissection. Most patients experiencing acute aortic dissection present with classic symptoms, including sudden-onset, severe, tearing chest pain, often radiating into the back. The dissection typically starts at the aortic root and may remain confined to the ascending aorta (type II) or continue into the descending aorta (type I). Acute-onset heart failure may occur if aortic valve function is compromised, and patients may suffer cerebrovascular injury, depending on the involvement of the carotid arteries. Involvement of the coronary arteries may herald sudden cardiac death, secondary to myocardial infarction or rupture into the pericardial sac with subsequent pericardial tamponade. Chronic aortic dissection usually occurs more insidiously, often without chest pain. Dilatation of the main pulmonary artery is common but does not typically cause any clinical sequelae. Enlargement of the descending thoracic or abdominal aorta can also occur, although relatively rarely.

Ocular System

Dislocation of the ocular lens **(ectopia lentis, EL)** occurs in around 60–70% of patients, although it is not unique to the disorder. Other ocular manifestations include early and severe myopia, thin and flat cornea, increased axial length of the globe, and iris dilator muscle hypoplasia, which results in poor dilation (miosis). Patients are also predisposed to retinal detachment, early cataracts, glaucoma, strabismus, and amblyopia.

Table 743.1 Diagnostic Criteria for Marfan Syndrome

IN THE ABSENCE OF A FAMILY HISTORY OF MFS, A DIAGNOSIS CAN BE ESTABLISHED IN FOUR DISTINCT SCENARIOS:
1. Aortic root *z* score ≥2 AND ectopia lentis*
2. Aortic root *z* score ≥2 AND a bona fide *FBN1* pathogenic variant (see Table 743.2)
3. Aortic root *z* score ≥2 AND a systemic score ≥7* (see Table 743.3)
4. Ectopia lentis AND a bona fide *FBN1* pathogenic variant known to cause aortic disease
IN THE PRESENCE OF A FAMILY HISTORY OF MFS, A DIAGNOSIS CAN BE ESTABLISHED IN THE PRESENCE OF:
1. Ectopia lentis
2. A systemic score ≥7*
3. Aortic root *z* score ≥2 if older than 20 years or ≥3 if younger than 20 years*
IN THE ABSENCE OF A FAMILY HISTORY OF MFS, ALTERNATIVE DIAGNOSES INCLUDE:
1. Ectopia lentis ± systemic score AND *FBN1* pathogenic variant not known to associate with aortic aneurysm or no *FBN1* pathogenic variant = Ectopia lentis syndrome
2. Aortic root *z* score <2 AND a systemic score ≥5 (with at least one skeletal feature) without ectopia lentis = MASS phenotype
3. Mitral valve prolapse AND aortic root *z* score <2 AND a systemic score <5 without ectopia lentis = Mitral valve prolapse syndrome

*Denotes caveat that features suggestive of an alternative diagnosis must be excluded and appropriate alternative molecular testing should be performed. Other syndromes include Shprintzen-Goldberg, Loeys-Dietz, or vascular Ehlers Danlos (see Table 743.4 for genes).

Other Systems

There is an increased incidence of pulmonary disease in MFS; progressive anterior chest deformity or thoracic scoliosis may contribute to a restrictive pattern of lung disease. Furthermore, a widening of the distal airspaces predisposes patients to spontaneous pneumothorax, which occurs in up to 15% of patients. Assessment of pulmonary volumes and function should account for long-bone overgrowth affecting the lower extremities, which can lead to a reduction in the normalized forced vital capacity and total lung capacity. If normalized to thoracic size or sitting height, pulmonary function testing is often normal in patients with the disorder.

MFS patients typically have normal skin texture and elasticity. The most common skin finding is stretch marks—pinkish, scarlike lesions that later become white **(striae atrophicae)**, which occur in about one third of patients (Fig. 743.1). These may occur in the absence of obesity, rapid gain in muscle mass, or pregnancy, and at sites not associated with increased skin distention (i.e., the anterior shoulder or lower back). Another common manifestation is congenital or acquired inguinal hernia. There is also an increased risk of surgical and recurrent hernias in the Marfan population.

Widening of the dural sac or root sleeves (dural ectasia) is present in 63–92% of MFS patients. Although dural ectasia can result in lumbar back pain, it is often asymptomatic and should be assessed by lumbosacral imaging with CT or MRI.

DIAGNOSIS

Given the complexity of the clinical examination in MFS and the relevant differential diagnoses, evaluation should be coordinated by a professional with extensive experience, such as a geneticist, cardiologist, or ophthalmologist. The diagnosis is based on a defined set of clinical criteria drawn up by an international panel of experts (the revised Ghent nosology for the MFS; Table 743.1).

In the absence of a conclusive family history of MFS, the diagnosis can be established in four distinct scenarios:

1. The presence of either aortic root dilatation when standardized to age and body size (an aortic root *z* score ≥2) or aortic dissection combined with ectopia lentis allows for the unequivocal diagnosis of MFS, irrespective of the presence or absence of any systemic features (see Table 743.1), except when these are indicative of an alternative diagnosis.

Table 743.2 Criteria for Causal *FBN1* Pathogenic Variant

- Pathogenic variant previously shown to segregate in a Marfan family
- Any one of the following de novo pathogenic variants (with proven parentage and absence of disease in parents):
  - Nonsense pathogenic variant
  - In-frame and out-of-frame deletion/insertion
  - Splice site pathogenic variants affecting canonical splice sequence or shown to alter splicing on mRNA/cDNA level
  - Missense pathogenic variant affecting/creating cysteine residues
  - Missense pathogenic variant affecting conserved residues of the EGF consensus sequence ((D/N)X(D/N)(E/Q)Xm(D/N)Xn(Y/F) with *m* and *n* representing variable number of residues; D aspartic acid, N asparagine, E glutamic acid, Q glutamine, Y tyrosine, F phenylalanine)
  - Other missense pathogenic variants: segregation in family if possible AND absence in 400 ethnically matched control chromosomes; if no family history, absence in 400 ethnically matched control chromosomes
  - Linkage of haplotype for $n \geq 6$ meioses to the *FBN1* locus

From Loeys BL, Dietz HC, Braverman AC, et al. The revised Ghent nosology for the Marfan syndrome. *J Med Genet*. 2010;47:476–485.

Table 743.3 Scoring of Systemic Features in Points

- Wrist AND thumb sign = 3 (wrist OR thumb sign = 1)
- Pectus carinatum deformity = 2 (pectus excavatum or chest asymmetry = 1)
- Hind foot deformity = 2 (plain pes planus = 1)
- Pneumothorax = 2
- Dural ectasia = 2
- Protrusio acetabuli = 2
- Reduced US/LS AND increased arm/height AND no severe scoliosis = 1
- Scoliosis or thoracolumbar kyphosis = 1
- Reduced elbow extension = 1
- Facial features (3/5) = 1 (dolichocephaly, enophthalmos, downslanting palpebral fissures, midface hypoplasia, retrognathia)
- Skin striae = 1
- Myopia >3 diopters = 1
- Mitral valve prolapse (all types) = 1

Maximum total: 20 points; score ≥7 indicates systemic involvement.
US/LS, Upper segment/lower segment ratio.

2. The presence of aortic root dilatation (*z* score ≥2) or aortic dissection and the identification of a bona fide *FBN1* pathogenic variant (Table 743.2) are sufficient to establish the diagnosis even if ectopia lentis is absent.
3. When aortic root dilatation (an aortic root *z* score ≥2) or aortic dissection is present, but ectopia lentis is absent and the *FBN1* status is either unknown or negative, the diagnosis may be confirmed by the presence of sufficient systemic findings (a systemic score ≥7 points; Table 743.3). However, features suggestive of an alternative diagnosis must be excluded, and the appropriate alternative molecular testing should be performed.
4. In the presence of ectopia lentis, but absence of aortic root dilatation or aortic dissection, an *FBN1* pathogenic variant, which has previously been associated with aortic disease, is required before the diagnosis can be made. If the *FBN1* pathogenic variant is not unequivocally associated with cardiovascular disease in either a related or unrelated proband, the patient should be classified as "isolated ectopia lentis syndrome" (see the section on "Differential Diagnosis").

Despite these diagnostic criteria, on occasion sporadic cases in individuals <20 years old may not fit in one of the four proposed scenarios detailed above. If insufficient systemic features (systemic score <7) and/or borderline aortic root measurements (*z* score <3) are present without documented evidence of a bona fide *FBN1* pathogenic variant, the term "nonspecific connective tissue disorder" is recommended. In those instances in which an *FBN1* pathogenic variant is identified, the term *potential MFS* should be used instead.

In an individual with a positive family history of MFS (in which a family member has been independently diagnosed using the previously described criteria), the diagnosis can be established in the presence of:

1. Ectopia lentis
2. A systemic score ≥7 points (see Table 743.3)
3. Aortic root dilatation with *z* score ≥2 in adults (≥20 years old) or *z* score ≥3 in individuals <20 years old

In the case of scenarios 2 and 3, previously, features suggestive of an alternative diagnosis must again be excluded and appropriate alternative molecular testing should be performed.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of MFS includes disorders with aortic aneurysm (LDS, familial thoracic aortic aneurysm syndrome, and SGS), ectopia lentis (ectopia lentis syndrome, Weil-Marchesani syndrome, and homocystinuria), or systemic manifestations of MFS (congenital contractural arachnodactyly [CCA] and mitral valve, aorta, skin, skeletal [MASS] phenotype); Table 743.4).

Aortic Aneurysm Syndromes

LDS is a systemic connective tissue disorder characterized by the triad of arterial tortuosity and aggressive aneurysm disease, hypertelorism, and bifid uvula or cleft palate, as well as many of the craniofacial and skeletal features found in MFS. Distinction between MFS and LDS is important because aneurysms tend to dissect at younger ages and smaller dimensions in LDS patients, necessitating more aggressive management. LDS was originally classified into type 1 or type 2, depending on whether the pathogenic variant is present in the *TGFBR1* or *TGFBR2* gene, which encode the type 1 or type 2 TGF-β receptor subunits, respectively. LDS type 3 is caused by heterozygous pathogenic variants in the gene encoding the TGF-β–dependent intracellular signaling molecule SMAD3. LDS type 4 is caused by heterozygous pathogenic variants in the extracellular TGF-β receptor ligand TGF-β2, whereas LDS type 5 is caused by heterozygous pathogenic variants in the extracellular TGF-β receptor ligand TGF-β3. LDS type 6 is caused by heterozygous pathogenic variants in the gene encoding the TGF-β–dependent intracellular signaling molecule SMAD2. As a general rule, the severity of disease associated with the different forms of LDS can be summarized: LDS1 = LDS2 > LDS3 > LDS4 = LDS5 > LDS6. There are exceptions to this rule, mandating careful monitoring of all patients with LDS. Notably, there can be wide clinical variation within each subtype, including between family members harboring the identical pathogenic variant.

Like MFS, **familial thoracic aortic aneurysm syndrome** segregates as an autosomal dominant trait characterized by aortic root aneurysm and dissection. However, other systemic manifestations of MFS are typically absent, and the disorder has reduced penetrance. Disease-causing heterozygous pathogenic variants have been identified in several genes with roles in the vascular smooth muscle contractile apparatus, including *MYH11*, *ACTA2*, and *MYLK*, which encode smooth muscle myosin heavy chain 11, vascular smooth muscle α-actin, and myosin light chain kinase. However, these genes account for only a fraction of cases of *nonsyndromic* familial thoracic aortic aneurysm. In most cases, the management principles that have been generated for MFS have proved effective for this form of familial aortic aneurysm.

SGS is a systemic connective tissue disorder that includes virtually all the craniofacial, skeletal, skin, and cardiovascular manifestations of MFS and LDS, with the additional findings of developmental delay and severe skeletal muscle hypotonia. Most cases are caused by heterozygous pathogenic variants in the *SKI* gene, which encodes an intracellular repressor of TGF-β signaling. Vascular involvement tends to be less prevalent and less severe when compared with MFS or LDS.

Table 743.4 Differential Diagnosis of Marfan Syndrome

DIFFERENTIAL DIAGNOSIS (GENES)	CARDIAC FEATURES	VASCULAR FEATURES	SYSTEMIC FEATURES
AORTIC ANEURYSM SYNDROMES			
Loeys-Dietz syndromes (types I-V) (OMIM: 609192) *TGFBR1, TGFBR2, SMAD3, TGFB2, TGFB3*	• Patent ductus arteriosus • Atrial septal defect • Bicuspid aortic valve	• Aortic root aneurysm • Arterial tortuosity • Widespread aneurysms • Vascular dissection at relatively young ages and small aortic dimensions	• Hypertelorism • Cleft palate • Broad or bifid uvula • Craniosynostosis • Midface hypoplasia • Blue sclerae • Arachnodactyly • Pectus deformity • Scoliosis • Joint hypermobility • Pes planus • Rarely easy bruising • Dystrophic scars • Translucent skin • Rarely developmental delay
Familial thoracic aortic aneurysm (OMIM: 132900) *TGFBR2, ACTA2,* others	• Generally none • Rare forms with patent ductus arteriosus	• Aortic root aneurysm • Ascending aortic aneurysm	• Generally none • Rarely livedo reticularis and iris flocculi
Shprintzen-Goldberg syndrome (OMIM: 182212) *SKI,* unknown others	None	Aortic root aneurysm	• Hypertelorism • Craniosynostosis • Arched palate • Arachnodactyly • Pectus deformity • Scoliosis • Joint hypermobility • Developmental delay
Bicuspid aortic valve with aortic aneurysm (OMIM: 109730) *ACTA2*	Bicuspid aortic valve	• Aortic root aneurysm • Ascending aortic aneurysm	
Ehlers-Danlos syndrome, type IV (OMIM: 130050) *COL3A1*	Mitral valve prolapse	• Aneurysm and rupture of any medium to large muscular artery • No predisposition for aortic root enlargement	• Joint hypermobility • Atrophic scars • Translucent skin • Easy bruising • Hernias • Rupture of hollow organs
ECTOPIA LENTIS SYNDROMES			
Familial ectopia lentis (OMIM: 129600) *FBN1, LTBP2, ADAMTSL4*	None	None	Nonspecific skeletal features
Homocystinuria (OMIM: 236200) *CBS*	Mitral valve prolapse	Intravascular thrombosis	• Tall stature • Ectopia lentis • Long-bone overgrowth • Developmental delay
SYNDROMES WITH SYSTEMIC MANIFESTATIONS OF MFS			
MASS (mitral valve, aorta, skeleton, skin) phenotype (OMIM: 604308) *FBN1*	Mitral valve prolapse	Borderline or nonprogressive	• Nonspecific skin and skeletal findings • Myopia

Ectopia Lentis Syndromes

Both **ectopia lentis syndrome** and **Weill-Marchesani syndrome (WMS)** may also be caused by heterozygous pathogenic variants in *FBN1*. Compound heterozygous or homozygous pathogenic variants at a second locus, *ADAMTSL4* cause ectopia lentis syndrome associated with slightly younger age at diagnosis. Interestingly, some *FBN1* pathogenic variants can be associated with classic MFS, ectopia lentis syndrome, and ectopia lentis combined with skin, but not cardiovascular, manifestations of MFS, suggesting that these presentations are part of a spectrum of clinical features of the same disease, and highlighting the potential contribution of genetic modifiers of disease.

WMS is a systemic connective tissue disorder characterized by skin, skeletal, and ocular abnormalities, including microspherophakia, ectopia lentis, and myopia. Features inconsistent with the diagnosis of MFS include short stature and brachydactyly. In addition to *FBN1* pathogenic variants (type 2), the syndrome may be caused by biallelic pathogenic variants in *ADAMTS10* (type 1) or in *LTBP2* (type 3), which encode ADAM metallopeptidase with thrombospondin type 1 motif 10 and latent TGF-β binding protein 2, respectively.

Homocystinuria is a metabolic disorder caused by homozygous or compound heterozygous pathogenic variants in the gene encoding cystathionine β-synthase, which leads to increases in both homocysteine and methionine. The clinical features of untreated homocystinuria include ectopia lentis and skeletal abnormalities resembling MFS. However, in contrast to MFS, affected persons often suffer from developmental delay, a predisposition to

thromboembolic events, and a high incidence of coronary artery disease. Patients with homocystinuria are not at increased risk for aortic aneurysm.

Syndromes with Systemic Manifestations of MFS

Congenital contractural arachnodactyly (CCA) is a connective tissue disorder caused by heterozygous pathogenic variants in the gene encoding fibrillin-2 *(FBN2)*. There are a number of clinical features overlapping with MFS, including dolichostenomelia, anterior chest deformity, scoliosis, joint contractures, and arachnodactyly, as well as some craniofacial malformations, including highly arched palate and retrognathia. In addition, both may suffer from severe cardiovascular abnormalities leading to premature death, but the specific cardiac anomalies are different; valvular insufficiency and aortic root dilation are common with MFS, whereas congenital heart defects are more common in CCA. Patients with CCA also suffer from crumpled auricular helices (a hallmark of this condition).

Many patients referred for possible MFS are found to have evidence of a systemic connective tissue disorder, including long limbs, deformity of the thoracic cage, striae atrophicae, mitral valve prolapse, and borderline but nonprogressive dilatation of the aortic root, but do not meet diagnostic criteria for MFS. This constellation of features is referred to by the acronym **MASS phenotype**, emphasizing the *m*itral, *a*ortic, *s*kin, and *s*keletal manifestations. The MASS phenotype can segregate in large pedigrees and remain stable over time. The diagnosis is particularly challenging in the context of a young, sporadic patient in whom careful follow-up is needed to distinguish MASS phenotype from early MFS. Familial mitral valve prolapse syndrome can also be caused by pathogenic variants in the gene encoding fibrillin-1 and include subdiagnostic systemic manifestations.

LABORATORY FINDINGS

Laboratory studies should document a negative urinary cyanide nitroprusside test or specific amino acid studies to exclude cystathionine β-synthase deficiency (homocystinuria). Although it is estimated that most, if not all, people with classic MFS have a *FBN1* pathogenic variant, the large size of this gene and the extreme allelic heterogeneity in MFS have frustrated efficient molecular diagnosis. The yield of pathogenic variant screening varies based on technique and clinical presentation. It remains unclear whether the "missing" pathogenic variants are simply atypical in character or location within *FBN1* or located in another gene. Other differential diagnoses, such as MASS phenotype, EL, and WMS have been associated with pathogenic variants in the *FBN1* gene. Furthermore, it is often difficult or impossible to predict the phenotype from the nature or location of a *FBN1* pathogenic variant in MFS. Hence molecular genetic techniques can contribute to the diagnosis, but they do not substitute for comprehensive clinical evaluation and follow-up. Consequently, the absence or presence of a *FBN1* pathogenic variant is not sufficient to exclude or establish the diagnosis, respectively.

MANAGEMENT

Management focuses on preventing complications and genetic counseling. Referral to a multidisciplinary center where a geneticist with experience in MFS works in concert with subspecialists to coordinate a rational approach to monitoring and treatment is advisable, given the complex nature of some patients' disease. Yearly evaluations for cardiovascular disease, scoliosis, or ophthalmologic problems are imperative.

CURRENT THERAPIES

Most therapies currently available or under investigation aim to diminish cardiovascular complications, which can be categorized into activity restrictions, aortic surgery, endocarditis prophylaxis, and current pharmacologic approaches.

Activity Restrictions

Physical therapy can improve cardiovascular performance, neuromuscular tone, and psychosocial health, and so aerobic exertion in moderation is recommended. However, strenuous physical exertion, competitive or contact sports, and particularly isometric activities such as weightlifting, which invoke a Valsalva maneuver, should be avoided.

Aortic Surgery

Surgical outcome is more favorable if undertaken on an elective rather than an urgent or emergent basis (mortality of 1.5% vs 2.6% and 11.7%, respectively). Therefore aortic surgery should be recommended for adult patients when their aortic root diameter approaches 50 mm, and early intervention should be considered for those with a rapid rate of enlargement (>5-10 mm/yr) or a family history of early aortic dissection. There are no definitive criteria guiding the timing of surgery in children in whom dissection is extremely rare, irrespective of aortic size. This has prompted many centers to adopt the adult criterion of 50 mm, although early surgery may be undertaken in the presence of a rapid rate of growth (>10 mm/yr) or the emergence of significant aortic regurgitation. Preserving the native aortic valve at the time of repair is desirable to avoid the need for lifelong anticoagulation. Mitral valve repair or replacement is advised for severe mitral valve regurgitation with associated symptoms or progressive left ventricular dilatation or dysfunction.

Pregnancy

There is higher risk of aortic dissection during pregnancy and particularly in the early postpartum period in women with MFS. However, improved awareness and data have indicated the risk is low in patients with an aortic root diameter <40 mm. Prophylactic aortic root replacement can minimize the risk of aortic dissection and death in women with MFS who wish to become pregnant, but the risk of more distal ascending or descending aortic dissection would not be modified by this intervention. Work in mouse models of MFS and other vascular connective tissue disorders has associated postpartum aortic rupture with lactation and specifically the activity of the hormone oxytocin. This complication can be diminished or even avoided in some mouse models by avoiding lactation through pup removal or a pharmacologic antagonist of the oxytocin receptor. Although more work needs to be done in this area, we discuss the potential negative implications of lactation with women with MFS that choose to become pregnant and are deemed to be at particularly high risk based on the personal or family history.

Endocarditis Prophylaxis

The Professional Advisory Board of the National Marfan Foundation believes that patients with MFS should continue to receive prophylaxis for bacterial endocarditis, in part because it remains unknown, but possible, that the myxomatous valves typical of MFS are a preferred substrate for bacterial infection.

Current Pharmacologic Approaches

β-Blockers

β-Adrenergic receptor blockers have historically been considered the standard of care in MFS, and multiple small observational studies have suggested there is a protective effect on aortic root growth, with the dose typically titrated to achieve a heart rate <100 beats/min during submaximal exercise. Given the putative role of hemodynamic stress in aortic dilatation and aortic dissection in MFS, these effects are attributed to the negative inotropic and chronotropic effects of β-blockade.

Angiotensin II Receptor Type 1 Blockers

There is extensive evidence linking angiotensin II signaling to TGF-β activation and signaling. In a mouse model of MFS, the angiotensin II receptor type 1 blocker (ARB) losartan was shown to completely prevent pathologic aortic root growth and to normalize both aortic wall thickness and architecture, findings that were absent in placebo-treated and propranolol-treated mice. These data suggest the potential for productive aortic wall remodeling in MFS after TGF-β inhibition.

In support of its relevance to humans, a retrospective study assessing the effect of ARBs in a small cohort of pediatric patients with MFS who had severe aortic root enlargement despite previous alternative medical therapy, showed that ARBs significantly slowed the rate of aortic root and sinotubular junction dilatation (both of which occur in MFS), whereas the distal ascending aorta (which does not normally become dilated in MFS) remained unaffected. Further evidence of a beneficial effect from losartan therapy has been provided by three prospective clinical trials demonstrating that losartan treatment alone or in combination with β-blockade slowed the progression of aortic root dilation in patients with MFS.

A comparison clinical trial assessing the therapeutic benefit of losartan versus atenolol in patients with MFS concluded that both drugs provided significant protection against aortic growth, with no significant difference in therapeutic effect between the two drugs despite the use of conventional dose losartan (FDA-approved dose for hypertension) and an atypically high dose of atenolol (average dose of atenolol was 1.5 times and the maximum dose was 2 times the FDA approved upper limit for the treatment of hypertension). Both treatment arms in this trial showed a very slow rate of aortic root growth and a significant decline in aortic root *z* score over time, a performance superior to that observed in untreated Marfan patients or in patients treated with conventional dose atenolol (1–2 mg/kg/day). These data strongly suggest that both modalities have therapeutic roles in patients with MFS.

Additional prospective studies have demonstrated therapeutic benefit of ARBs. A meta-analysis integrating seven randomized prospective trials and over 1,500 patients concluded that ARBs are both efficacious and safe in MFS, either when used alone (in comparison to placebo) or in combination with β-blockers (in comparison to β-blockers alone). An 8-year follow-up of a Dutch study exploring the use of ARBs in adults with MFS suggested that this treatment not only suppressed pathologic aortic growth but also positively influenced important patient outcomes, including risk of surgery, aortic dissection, and all-cause mortality.

PROGNOSIS

The major cause of mortality is aortic root dilatation, dissection, and rupture, with the majority of fatal events occurring in the third and fourth decades of life. A reevaluation of life expectancy in MFS suggested that early diagnosis and refined medical and surgical management has greatly improved the prognosis for patients with the condition. Nevertheless, MFS continues to be associated with significant morbidity, and selected subgroups are refractory to therapy and continue to show early mortality. In a review of 54 patients diagnosed during infancy, 89% had serious cardiac pathology, and cardiac disease was progressive despite standard care (22% died during childhood, 16% before age 1 year). In the classic form of MFS, it is estimated that more than 90% of individuals will have a cardiovascular event during their lifetime, placing both physical and mental stresses on patients and their families. Awareness of these issues and referral for support services can facilitate a positive perspective toward the condition.

GENETIC COUNSELING

The heritable nature of MFS makes recurrence risk (genetic) counseling mandatory. Fathers of these sporadic cases are, on average, 7-10 years older than fathers in the general population. This paternal age effect suggests that these cases represent new dominant pathogenic variants with minimal recurrence risk to additional future offspring of the normal parents. Owing to rare reports of gonadal mosaicism in a phenotypically normal parent, the recurrence risk for parents of a sporadic case can be reported as low but not zero. Each child of an affected parent, however, has a 50% risk of inheriting the MFS pathogenic variant and thus being affected. Recurrence risk counseling is best accomplished by professionals with expertise in the issues surrounding the disorder.

Chapter 744

Ehlers-Danlos Syndrome

Donald Basel

Ehlers-Danlos syndrome (EDS) is a heterogeneous group of heritable connective tissue disorders that are grouped into three broad pathoetiologic categories and more specifically divided into fourteen subtypes (Table 744.1). Affected individuals are considered to have an overlapping phenotype of abnormally soft, extensible skin, which often heals poorly, in association with joint hypermobility and occasional instability believed to be rooted in a disruption of normal collagen function (Tables 744.2 and 744.3). All organ systems contain connective tissue elements, and many of these elements are involved in supporting the function of feedback receptors such as mechanoreceptors in lumen or vessel walls or stretch receptors in tendons. The myriad of symptoms, variability of expression, modes of inheritance, and unique phenotypic elements distinguish the subtypes from one another while establishing their common origins. The hypermobility type (hEDS) is the most common form and has no clear molecular etiology.

The connective tissue matrix is complex (Fig. 744.1), and the interplay of cells, collagen and elastin fibers, proteins, and cell signaling molecules remains poorly understood. However, dysfunction at both structural and functional levels more than likely explains the complex medical associations typically encountered in this population, with complaints ranging from joint instability and tissue fragility to chronic pain, autonomic dysfunction, and chronic fatigue (see Table 744.3).

CLASSIFICATION OF THE SIX MOST COMMON SUBTYPES OF EHLERS-DANLOS SYNDROME

Classic (Genes: *COL5a1, COL5a2, COL1a1;* Previously EDS Type I—Gravis, EDS Type II—Mitis)

Classic EDS is the second most common form of EDS and is an autosomal dominant connective tissue disorder characterized by skin hyperelasticity (Fig. 744.2), widened atrophic scars (skin fragility), and joint hypermobility. Other features include easy bruising, which is often associated with hemosiderin staining of the tissues (particularly over regions exposed to frequent trauma, like the shins). The skin is "velvet" to the touch and is particularly fragile, with minor lacerations forming gaping wounds that leave broad, atrophic, papyraceous ("cigarette paper") scars (Fig. 744.3; see also Table 744.2). Additional cutaneous manifestations include molluscoid pseudotumors over pressure points from accumulations of connective tissue and piezogenic papules (Fig. 744.4). Joints are hypermobile, often with joint instability (Fig. 744.5). Scoliosis frequently presents in adolescence, and mitral valve prolapse is common. Life expectancy is generally not reduced, although rare rupture of large arteries has been reported. Similar noncutaneous nonarticular comorbidities, as seen in hypermobile EDS, are found, in particular pain and gastrointestinal dysfunction (see Table 744.3). Premature birth caused by rupture of membranes of an affected offspring is not uncommon. The diagnosis is made by clinical findings and sequencing of *COL5A1* and *COL5A2* genes.

Hypermobile (Cause Unknown, Previously EDS Type III)

Hypermobile EDS (hEDS) is the most prevalent form of EDS with an estimated population frequency of between 0.75–3%. It is an autosomal dominant disorder, but the causative molecular pathoetiology remains elusive. Fewer than 3% of patients with a hEDS phenotype are associated with heterozygous tenascin X gene loss of function, and likewise, only a minority of cases are linked to other findings, such as the association with mosaic type 1 collagen

Table 744.1 Classification of Ehlers-Danlos Syndrome

TYPE	GENE	SKIN FINDINGS	JOINT CHANGES	INHERITANCE	OTHER COMMENTS
Classic	*COL5A1, COL5A2* (usually haploinsufficiency)	Hyperextensibility, bruising, velvety skin, widened atrophic scars, molluscoid pseudotumors, spheroids	Hypermobility and its complications, joint dislocations	AD	Mitral valve prolapse, hernias
	COL1A1 Specific pathogenic variant; c.934C>T			AD	Blue sclerae, short stature, osteopenia/fractures; may have late arterial rupture
CLASSIC VARIANTS					
Cardiac valvular	Biallelic loss of function for *COL1A2*	Classic EDS features		AR	Severe cardiac valve issues as adult
Periodontal	*C1R* *C1S*	Can have classic EDS features	Can have hypermobility	AD	Periodontitis, marfanoid habitus, prominent eyes, short philtrum
Classic-like	*TNXB*	Hyperextensibility, marked hypermobility, severe bruising, velvety skin, no scarring tendency	Hypermobility	AR	Parents (especially mothers) with one *TNXB* pathogenic variant; can have joint hypermobility
	AEBP1	Joint hypermobility, extensible and redundant skin, abnormal scarring	Hypermobility	AR	Biallelic loss of function variants. Highly variable.
Hypermobility	Unknown	Mild hyperextensibility, scarring, textural change	Hypermobility, chronic joint pain, recurrent dislocations	AD	Sometimes confused with joint hypermobility syndrome
Vascular	*COL3A1* Rare variants in *COL1A1*	Thin, translucent skin, bruising, early varicosities, acrogeria	Small joint hypermobility	AD	Abnormal type III collagen secretion; rupture of bowel, uterus, arteries; typical facies; pneumothorax
Kyphoscoliosis	*PLOD* (deficient lysyl hydroxylase) *FKBP14*	Soft, hyperextensible skin, bruising, atrophic scars	Hypermobility	AR	Severe congenital muscle hypotonia that improves a little in childhood; congenital kyphoscoliosis, scleral fragility and rupture, marfanoid habitus, osteopenia, sensorineural hearing loss
VARIANTS WITH KYPHOSCOLIOSIS					
Spondylocheirodysplastic form	*SLC39A13,* which encodes the ZIP13 zinc transporter *B4GALT7* or *B3GALT6,* encoding galactosyltransferase I or II, key enzymes in GAG synthesis	Similar to kyphoscoliotic form		AR	Spondyloepimetaphyseal dysplasia; can have bone fragility and severe progressive kyphoscoliosis without congenital hypotonia; moderate short stature, loose facial skin, wrinkled palms with thenar and hypothenar atrophy, blue sclerae, curly hair, alopecia
Brittle cornea syndrome	ZNF469 or PRDM5	Skin hyperextensibility	Joint hypermobility	AR	Kyphoscoliosis; characteristic thin, brittle cornea, ocular fragility, blue sclera, keratoconus
Musculocontractural	*CHST14* (encoding dermatan 4-O-sulfotransferase) *DSE* (encoding dermatan sulfate epimerase)	Fragile, hyperextensible skin with atrophic scars and delayed wound healing	Hypermobility	AR	Progressive kyphoscoliosis; adducted thumbs in infancy, clubfoot, arachnodactyly, contractures, characteristic facial features, hemorrhagic diathesis
Myopathic	*COL12A1*	Soft, hyperextensible	Hypermobile small joints, large joint contractures (hip, knees, elbows)	AD or AR	Characterized by muscle hypotonia and weakness

Table 744.1 Classification of Ehlers-Danlos Syndrome—cont'd

TYPE	GENE	SKIN FINDINGS	JOINT CHANGES	INHERITANCE	OTHER COMMENTS
Arthrochalasis	Exon 6 deletion of *COL1A1* or *COL1A2*	Hyperextensible, soft skin with or without abnormal scarring	Marked hypermobility with recurrent subluxations	AD	Congenital hip dislocation, arthrochalasis, multiplex congenita, short stature
Dermatosparaxis	Type I collagen N-peptidase *ADAMTS2*	Severe fragility, sagging, redundant skin		AR	Also occurs in cattle

AD, Autosomal dominant; AR, autosomal recessive; EDS, Ehlers–Danlos syndrome; GAG, glycosaminoglycan.

defects. There are currently no diagnostic biomarkers, and the inter- and intrafamilial variation has clouded the ability to clearly define large study populations with sufficient phenotypic alignment. An editorial highlighted the impact of sex hormones and associations of certain symptom complexes to environmental exposures or "trigger events," which begs the question of a more complex gene-environment or epigenetic influence.

The primary clinical finding in hEDS is generalized joint hypermobility with less prominent skin manifestations. There is inconsistency in the literature as to what defines hypermobility, but generally a score of ≥6 on the Beighton hypermobility scale (Fig. 744.6, Table 744.4) would qualify as hypermobility in prepubertal children and adolescents, ≥5 for postpubertal individuals up to the age of 50, and ≥4 for all adults beyond the age of 50. Children <6 years of age generally tend toward a hypermobile state, and the Beighton score may not be a reliable indicator of connective tissue laxity in these children (Table 744.5). Joint instability with frequent dislocations is common but not universal; joints are predisposed to osteoarthritis in adults.

Patients with hEDS have significant nonarticular comorbidities associated with functional disorders. These present as complex pain, dysautonomia, chronic fatigue, anxiety, and sleep dysfunction (see Table 744.3). The complexity of hEDS most likely originates from the fact that it is genetically heterogeneous and represents an overlapping spectrum of disorders. Although joint hypermobility is the common denominator, symptoms may range from isolated familial joint hypermobility to the extreme multisystem disorder, which significantly impacts daily quality of life. Life expectancy is not reduced. Mild aortic root dilatation has been reported in up to 20% of affected adults. However, this mild dilatation is nonprogressive and not associated with aortic root dissection.

Vascular (vEDS) (Gene: *COL3A1*; Previously EDS Type IV)

vEDS is an autosomal dominant disorder that shows the most pronounced dermal thinning of all types of EDS. Consequently, the skin is translucent, and the underlying venous network is prominent, most notably over the chest region. The skin has minimal hyperextensibility but has a "velvet" texture and is often described as "doughy." The joints show increased mobility, often with instability. Congenital club foot and hip dislocation are frequently associated. Tissue fragility and arterial rupture cause significant morbidity and mortality. The majority of affected individuals experience a major vascular event before 20 years of age. Premature birth, extensive ecchymoses from trauma, a high incidence of bowel rupture (especially the colon), uterine rupture during pregnancy (~5% risk), rupture of the great vessels (80% by 40 years of age), dissecting aortic aneurysm, and stroke all contribute to the increased morbidity and

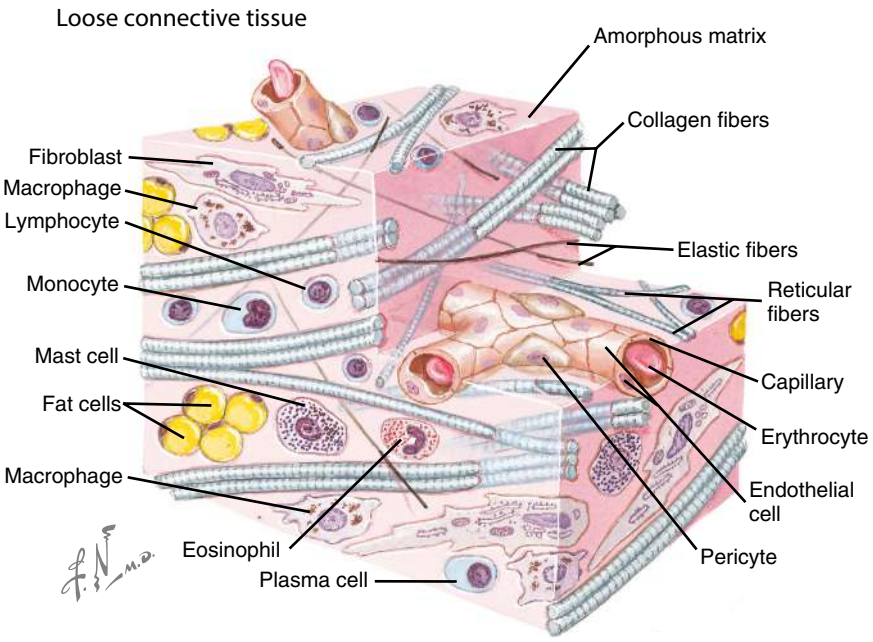

Fig. 744.1 Complex connective tissue macroenvironment illustrated by intermingled collagen and elastin fibers, nerves, mast cells, and capillaries. Fig. 744.4 Piezogenic papules on the medial aspects of the heels in a 41-yr-old patient with Ehlers-Danlos syndrome *(top)* and his 2-yr-old daughter *(bottom)*. *(From Poppe H, Hamm H. Piezogenic papules in Ehlers-Danlos syndrome. J Pediatr. 2013;63:1788.)*

shortened life span associated with this condition. The median age of death is estimated at 50 years. Patients are generally counseled regarding the risks associated with pregnancy and advised to avoid activities that raise intracranial or intrathoracic pressure as a result of a Valsalva maneuver (such as weight training or trumpet playing). Skin protection in childhood is important to minimize trauma (shin guards). Celiprolol, a β1 antagonist and a β2 agonist (vasodilator), may reduce vascular events but is not approved by the U.S. Food and Drug Administration (FDA) for use in the United States. The diagnosis is clinical and confirmed by gene sequencing of *COL3A1*.

Kyphoscoliosis (Gene: *PLOD* [Lysyl Hydroxylase Deficiency]; Previously EDS Type VI)

The kyphoscoliotic form of EDS is distinguished by the severe kyphoscoliosis that develops early in childhood. It is an autosomal recessive disorder with phenotypic overlap with the classical type of EDS in that the skin is soft and fragile, joints are hyperextensible, and easy bruising is notable from a young age. Unique characteristics include marked hypotonia and keratoconus, with corneal fragility and globe rupture also reported. In addition, there is a higher risk for rupture of medium-sized arteries. The severity of the kyphoscoliosis may lead to restrictive lung disease with secondary pulmonary hypertension and reduced life expectancy. The diagnosis is clinical and confirmed by urine screening for an increased ratio of deoxypyridinoline to pyridinoline cross linking as well as gene sequencing of *PLOD*.

Fig. 744.5 Despite joint hyperextensibility, this patient does not meet Beighton score criteria for the extreme hypermobility seen with hypermobile Ehlers-Danlos syndrome.

Arthrochalasia (Gene: *COL1a1*, *COL1a2*; Previously EDS Types VIIA and B)

This type of EDS is inherited as an autosomal dominant disorder and characterized by severe joint instability in infancy. Joints show marked hyperextensibility with painless dislocation; the skin bruises easily and is soft and hyperextensible. Congenital hypotonia with gross motor delay is common, and kyphoscoliosis can develop in childhood. The diagnosis is clinical and confirmed by gene sequencing of *COL1A1* and *COL1A2*.

Dermatosparaxis (Type 1 Collagen N-Peptidase; Previously EDS Type VIIC)

This type of EDS is a rare autosomal recessive condition characterized by redundant skin that is soft, fragile, and bruises easily. Affected children often have a characteristic facial appearance, with skin sagging into jowls and fullness around the eyes ("puffy"). Premature rupture of membranes is common; closure of fontanels is delayed. Additional unique features reported in this group include short limbs with brachydactyly (short fingers), frequent

Fig. 744.6 Beighton score. The range of motion of several key small and large joints is measured to provide an overview of joint hypermobility. Instability is not assessed. Scoring: 2 points for each bilateral measure in Nos. ***1*** to ***4*** and 1 point for No. ***5***, equaling a total possible score of 9. Hypermobility is considered significant with a score of ≥6 between the ages of 6 and 35. *(Modified from Smits-Engelsman B, Klerks M, Kirby A. Beighton Score: a valid measure for generalized hypermobility in children. J Pediatr 2011;158:119–123.e4.)*

Table 744.4 The Nine-Point Beighton Hypermobility Score

THE ABILITY TO:	RIGHT	LEFT
1. Passively dorsiflex the fifth metacarpophalangeal joint to ≥90 degrees	1	1
2. Oppose the thenar aspect of the thumb to the volar aspect of the ipsilateral forearm	1	1
3. Hyperextend the elbow to ≥10 degrees	1	1
4. Hyperextend the knee to ≥10 degrees	1	1
5. Place hands flat on the floor without bending the knees	1	
		Total: 9

One point may be gained for each side for maneuvers 1-4, so the hypermobility score will have a maximum of 9 points if all are positive.
From Hakim A, Grahame R. Joint hypermobility. *Best Pract Res Clin Rheumatol.* 2003;17:989–1004, Table 1.

Table 744.5 A Five-Part Questionnaire for Identifying Hypermobility

1. Can you now (or could you ever) place your hands flat on the floor without bending your knees?
2. Can you now (or could you ever) bend your thumb to touch your forearm?
3. As a child did you amuse your friends by contorting your body into strange shapes *or* could you do the splits?
4. As a child or teenager did your shoulder or kneecap dislocate on more than one occasion?
5. Do you consider yourself double-jointed?

Answers in the affirmative to two or more questions suggest hypermobility with sensitivity 80–85% and specificity 80–90%.

hernias (umbilical, inguinal), blue sclerae, and bladder rupture. Joints are hypermobile. The diagnosis is confirmed by sequencing of *ADAMTS2*.

DIFFERENTIAL DIAGNOSIS

EDS represents a portion of the hereditary connective tissue disorders, many of which have unique features that enable clinical differentiation. The primary differential diagnosis would include Loeys-Dietz syndrome, which has features of both vEDS and Marfan syndrome (see Chapter 743). EDS has also been confused with MASS syndrome (mitral valve prolapse, aortic root dilation, skeletal changes, skin changes), cutis laxa (see Chapter 745), and pseudoxanthoma elasticum. In general, the skin of patients with cutis laxa hangs in redundant folds, whereas the skin of those with EDS is hyperextensible and snaps back into place when stretched. Other disorders that impact the integrity of the connective tissues—such as exposure to corticosteroids and osteogenesis imperfecta or mild myopathic disorders (Bethlem myopathy, Ullrich congenital muscular dystrophy)—can be indistinguishable in the early stages of disease (Table 744.6).

GENERAL APPROACH TO MANAGEMENT

In addition to the EDS type-specific therapies discussed under each disease, there are general approaches to help improve symptoms and avoid complications.

Musculoskeletal pain, which initially involves the joints, eventually may become generalized and requires a combination of physical therapy and nonpharmacologic approaches (Fig. 744.7). Physical therapy should focus on enhancing the strength of the muscles supporting the affected joints. With severe recurrent sprains or dislocations, bracing may be necessary. Pain medication for low- to moderate-intensity pain could include nonsteroidal antiinflammatory drugs (however, their platelet-inhibiting action may increase the risk of cutaneous bleeding). Higher-intensity pain may require other agents, such as selective serotonin receptor inhibitors or low-dose tricyclic antidepressants. Muscle relaxants or antiepileptic agents should be avoided because they may increase fatigue. Surgery for joint dislocations should be avoided if possible as should prolonged periods of inactivity (which result in rapid muscle deconditioning) (Table 744.7). If surgery is needed for any complication, the sutures should approximate the margins, suture tension should be avoided, and the sutures should be retained longer than usual. Other approaches to pain include cognitive behavioral therapy, acupuncture, and transepidermal electrical nerve stimulation (TENS).

Chronic fatigue should be approached by supporting good sleep hygiene and avoiding sedating medications (see Table 744.7). Patients at risk for arterial bowel or uterine rupture should be counseled about preventive measures, appropriate medications (see specific subtype), and early warning signs of organ rupture.

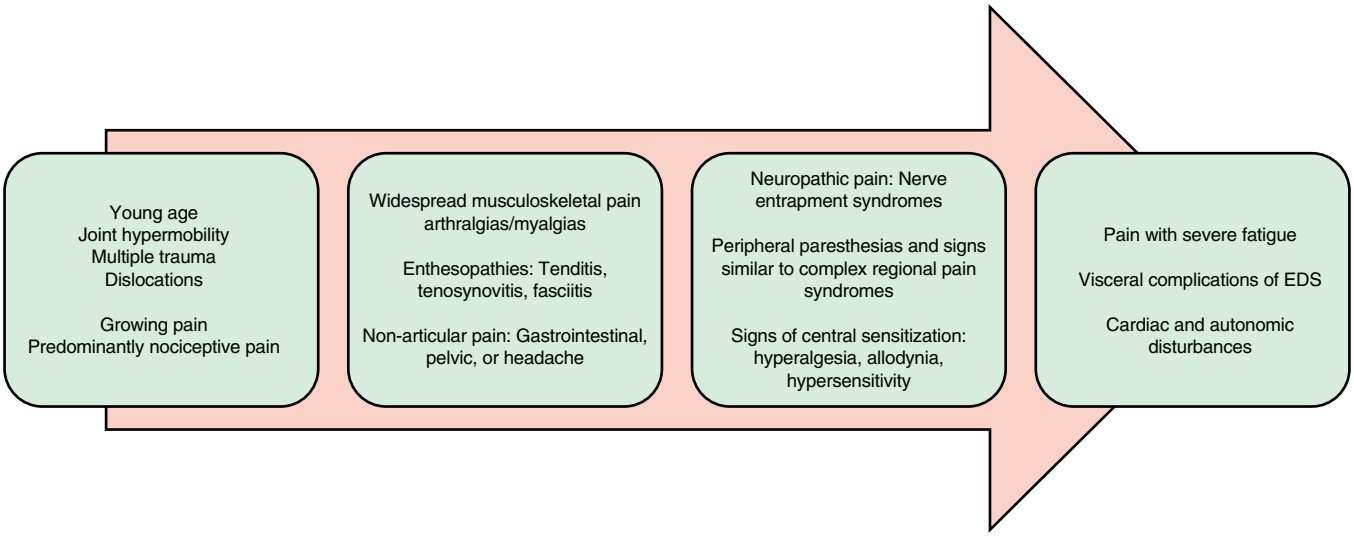

Fig. 744.7 Characteristics of pain in Ehlers-Danlos syndrome that progress in clinical stages. *(From Zhou Z, Rewari A, Shanthanna H. Management of chronic pain in Ehlers-Danlos syndrome. Medicine. 2018;97:e13115.)*

Table 744.7 Lifestyle Recommendations for Hypermobile Ehlers-Danlos Syndrome

Promote regular aerobic fitness
Promote fitness support with strengthening, gentle stretching, and proprioception exercise
Promote postural and ergonomic hygiene, especially during sleep, at school, and in the workplace
Promote weight control (body mass index [BMI] <25)
Promote daily relaxation activities
Promote lubrication during sexual intercourse
Promote early treatment of malocclusion
Avoid high-impact sports/activities
Avoid low environmental temperatures
Avoid prolonged sitting positions and prolonged recumbency
Avoid sudden head-up postural change
Avoid excessive weightlifting/carrying
Avoid large meals (especially of refined carbohydrates)
Avoid hard foods intake and excessive jaw movements (e.g., ice, gums)
Avoid bladder irritant foods (e.g., coffee and citrus products)
Avoid nicotine and alcohol intake

Note: these recommendations are intended as flexible indications for ameliorating quality of life and do not represent lifesaving solutions.
Adapted from Castori M, Morlino S, Celletti C, et al. Management of pain and fatigue in the joint hypermobility syndrome (aka Ehlers-Danlos syndrome, hypermobility type): principles and proposal for a multidisciplinary approach. *Am J Med Genet.* 2012;158:2055–2070.

Chapter 745

Cutis Laxa

Leah Lalor

Cutis laxa syndromes encompass a group of rare multisystem disorders that include loose redundant skinfolds as hallmark clinical feature (Fig. 745.1). Cutis laxa results from impaired elastic fiber assembly and homeostasis, and the known underlying gene defects affect different extracellular matrix proteins, intracellular trafficking, or cellular metabolism.

Cutis laxa (CL) may present in **autosomal recessive** (ARCL1A, ARCL1B, ARCL1C, ARCL2A, ARCL2B), **autosomal dominant** (ADCL), **X-linked** or acquired forms (Fig. 745.2, Tables 745.1 and 745.2). Acquired CL may develop after a febrile illness, inflammatory skin diseases such as lupus erythematosus or erythema multiforme, amyloidosis, urticaria, angioedema, hypersensitivity reactions to penicillin, or in neonates born to women who were taking penicillamine.

Fig. 745.1 Pendulous folds of skin of an infant with cutis laxa.

CLINICAL MANIFESTATIONS

CL may demonstrate widespread folds of **loose skin**, or changes may be mild and limited in extent, resembling anetoderma. Patients with severe cutis laxa have characteristic facial features; they present with an aged appearance with sagging jowls ("bloodhound" appearance; see Fig. 745.1), a hooked nose with everted nostrils, a short columella, a long upper lip, and everted lower eyelids. The skin is also lax elsewhere on the body and has been described as resembling an ill-fitting suit. Hyperelasticity and hypermobility of the joints as seen in the Ehlers-Danlos syndromes are not present. Many infants have a hoarse cry, probably as a result of laxity of the vocal cords. Tensile strength of the skin is normal. Other features are noted in Table 745.3.

The **autosomal dominant** form of CL (ADCL) is typically caused by pathogenic variants in *ELN*, which encodes elastin, an essential extracellular matrix protein responsible for maintenance of skin elasticity. ADCL has predominant skin involvement but can have risk for aortic aneurysm and emphysema. It typically manifests in infancy; it may be associated with intrauterine growth restriction, ligamentous laxity, and delayed closure of the fontanels.

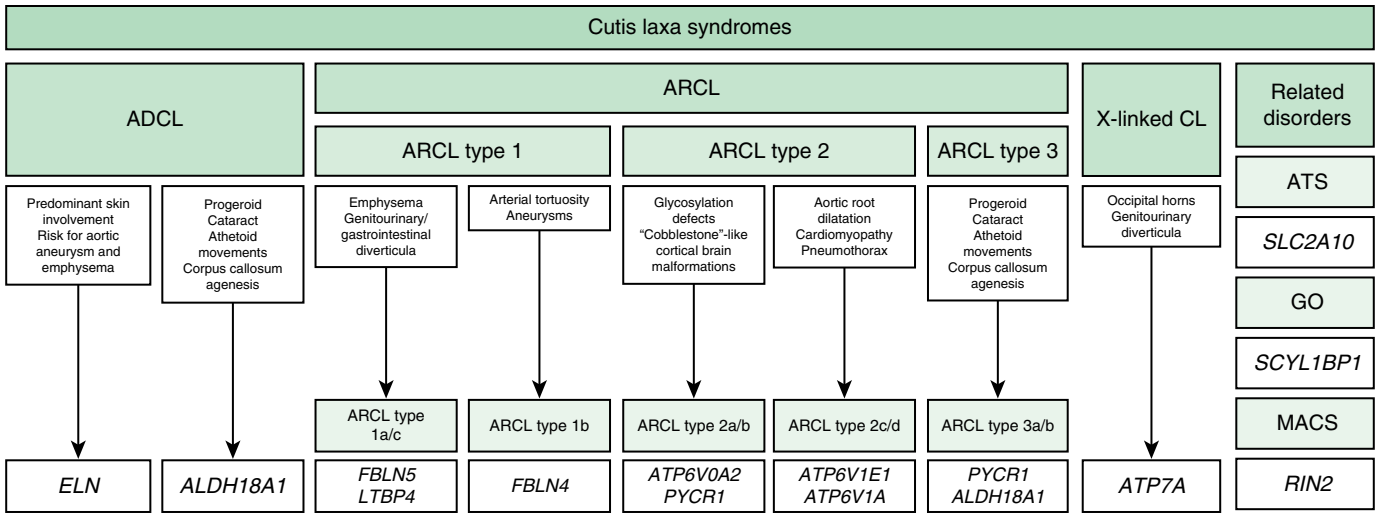

Fig. 745.2 The spectrum of cutis laxa disorders. ADCL, Autosomal dominant cutis laxa; ARCL, autosomal recessive cutis laxa; ATS, arterial tortuosity syndrome; GO, geroderma osteodysplasticum; MACS, macrocephaly-alopecia-cutis laxa-scoliosis. *(From Beyens A, Boel A, Symoens S, et al. Cutis laxa: a comprehensive overview of clinical characteristics and pathophysiology. Clin Genet. 2021;99:53–66. Fig.1.)*

GeneReviews[Internet]. Seattle (WA): University of Washington, Seattle; 1993. Available from http://www.ncbi.nlm.nih.gov/books/NBK5200/

Pathogenic variants in *ALDH18A1*, which encodes delta-1-pyrroline-5-carboxylate synthetase (P5CS), a key enzyme in the synthesis of proline (an abundant amino acid in elastin), can cause autosomal dominant or recessive CL. Notably, pathogenic variants in *PYCR1*, which encodes pyrroline-carboxylate reductase 1, another enzyme in this pathway, cause recessive CL (ARCL3). Each of these proline synthesis-related CL subtypes can also present with progeroid features, cataracts, athetoid movements, and corpus callosum anomalies.

Autosomal recessive CL is divided into three general subtypes: type 1 (ARCL1), with cardiopulmonary complications, type 2 (ARCL2), with CNS and skeletal anomalies, and type 3 (ARCL3; de Barsy syndrome), which adds ocular findings to the type 2 features. Overall, these individuals can present with multiple hernias, rectal prolapse, diaphragmatic

Table 745.3 Most Common Other Features of Cutis Laxa

- Facial dysmorphism
- Aortic dilatation
- Pulmonary artery stenosis
- Pulmonary emphysema
- Diverticulae: gastrointestinal, genitourinary
- Uterine or rectal prolapse
- Ventral, hiatal, inguinal hernias

Modified from Paller AS, Mancini AJ. *Hurwitz Clinical Pediatric Dermatology,* 6th ed. Philadelphia: Elsevier, 2022: Box 6.4, p. 148.

atony, diverticula of the gastrointestinal and genitourinary tracts, cor pulmonale, emphysema, pneumothoraces, peripheral pulmonary artery stenosis, and aortic dilation. Characteristic facial features include downward-slanting palpebral fissures, a broad, flat nose, and large ears. Skeletal anomalies, dental caries, growth retardation, and developmental delay also occur. Such patients often have a shortened life span.

ARCL1 is comprised of three subtypes. Subtypes ARCL1a and ARCL1c (Urban-Rifkin-Davis syndrome), caused by dominant pathogenic variants in *FBLN5* and *LTPB4*, respectively, are similar disorders and, in addition to skin findings, more frequently develop emphysematous lung changes and mechanical insufficiency of the gastrointestinal and genitourinary tract wall. Subtype ARCL1b, caused by pathogenic variants in *FBLN4*, in addition to skin findings, typically develops elongation, tortuosity, and aneurysms of the large- and middle-sized arteries.

ARCL2 often presents with delays in neuromotor development and can include epilepsy and cortical or cerebellar malformations. Recessive pathogenic variants in *ATP6V0A2* (ARCL 2a) are more common and include N- or O-glycosylation defects and pathogenic variants *PYCR1* (ARCL2b).

ARCL2 with recessive pathogenic variants in ATP6V1E1 (ARCL2c) and ATP6V1A (ARCL2d), genes encoding key enzymes in acidification of intracellular organelles, can include N- or O-glycosylation defects and demonstrate increased frequency of aortic root dilatation, cardiomyopathy, and pneumothorax.

X-linked CL, also referred to as **occipital horn syndrome**, is caused by pathogenic variants of *ATP7A* that encodes a Cu^{2+}-transporting adenosine triphosphatase, α-polypeptide. This clinical presentation is allelic with Menkes disease (see Chapter 639.5) but is at the milder end of that spectrum.

Cutis laxa–like skin changes may also be seen in association with multiple other syndromes, including Lenz-Majewski syndrome, hyperostotic dwarfism, SCARF (**s**keletal abnormalities, **c**utis laxa, craniostenosis, **a**mbiguous genitalia, **r**etardation, **f**acial abnormalities) syndrome, wrinkling skin syndrome, arterial tortuosity syndrome (ATS), gerodermia osteodysplasia, macrocephaly alopecia cutis laxa scoliosis syndrome (MACS), and Costello syndrome.

HISTOLOGY

Histologically, elastic tissue is reduced throughout the dermis, with fragmentation, distention, and clumping of the elastic fibers. This often results in bare microfibrils of random directionality. The light microscopic appearance of elastic fibers in CL patients is typically not able to discern between different subtypes as they appear reduced and fragmented in all.

TREATMENT

Treatment of the skin findings in cutis laxa is largely supportive, although textural improvement and symptomatic relief using resurfacing lasers for acquired CL has been reported.

Regarding medical management, as a general rule, unrelated to the underlying subtype, elastic fiber defects warrant regular assessment of pulmonary, cardiovascular, and urinary systems. Yearly echocardiography is recommended in dominant CL, ARCL1a/c, and ARCL2c. More intensive echocardiographic follow-up is needed in ARCL1b and ATS (every 3 months in ARCL1b; every 3 months until the age of 5 in ATS), while in the remaining subtypes an examination every 3-5 years is sufficient. In ARCL1, MRI head-to-pelvis should be repeated yearly (ARCL1b) or every 3-5 years (ARCL1a/c and ATS).

Section 5
Metabolic Bone Disease

Chapter 746
Bone Structure, Growth, and Hormonal Regulation

Rebecca J. Gordon and Catherine M. Gordon

See also Chapters 69 and 610.

Bone is a rigid organ but metabolically active in that it is constantly being formed **(modeled)** and reformed **(remodeled)**. It is capable of rapid turnover, bearing weight, and withstanding the stresses of various physical activities. Bone is the major body reservoir for calcium, phosphorus, and magnesium. Other functions of bone include organ protection, structure, movement, and sound transmission. It is also an endocrine organ that produces fibroblast growth factor 23 (FGF23), which regulates renal phosphate handling. Disorders that affect this organ and the process of mineralization are designated **metabolic bone diseases**.

The human skeleton consists of a protein matrix, largely composed of a collagen-containing protein, osteoid, on which is deposited a crystalline mineral phase. Collagen-containing osteoid accounts for 90% of bone protein; other proteins, including osteocalcin, which

contains γ-carboxyglutamic acid, are also present. Synthesis of osteocalcin depends on vitamin K and vitamin D; in states with high bone turnover, serum osteocalcin values are often elevated. Osteocalcin appears to enhance insulin secretion and sensitivity and reduce fat stores.

The microfibrillar matrix of osteoid permits deposition of highly organized calcium phosphate crystals, including hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] and octacalcium phosphate [$Ca_8H_2(PO_4)_6{\cdot}5H_2O$], plus less-organized amorphous calcium phosphate, calcium carbonate, sodium, magnesium, and citrate. Hydroxyapatite is deep within bone matrix, whereas amorphous calcium phosphate coats the surface of newly formed or remodeled bone.

Because bone growth and turnover rates are high during childhood, many clinical and osseous features of metabolic bone diseases are more prominent in children than in adults. The growth pattern of bones is an acceleration of bone growth (length) of the limbs during prepubescence, increased growth (length) of the trunk (spine) during early adolescence, and increased bone mineral deposition in late adolescence.

The use of dual-energy x-ray absorptiometry (DXA) or quantitative CT permits measurement of both mineral content and bone density in healthy subjects and children with metabolic bone disease. DXA exposes the patient to less radiation than a chest radiograph and significantly less than quantitative CT and is therefore most commonly used in clinical practice (see Chapter 749). **Bone growth** occurs in children by the process of calcification of the cartilage cells present at the ends of bone. In accord with the prevailing extracellular fluid calcium and phosphate concentrations, mineral is deposited in chondrocytes or cartilage cells set to undergo mineralization. The main function of the vitamin D–parathyroid hormone (PTH)–FGF23–endocrine axis is to maintain the extracellular fluid calcium and phosphate concentrations at appropriate levels to permit mineralization.

Other hormones also appear to regulate the growth and mineralization of cartilage, including growth hormone acting through insulin-like growth factors, thyroid hormones, insulin, leptin, ghrelin, and androgens and estrogens during the pubertal growth spurt. Supraphysiologic concentrations of glucocorticoids impair cartilage function and bone growth and augment bone resorption.

Rates of bone formation are coordinated with alterations in mineral metabolism in both the intestine and kidneys, where a number of hormones regulate the processes. Inadequate dietary intake or intestinal absorption of calcium causes a fall in serum levels of calcium and its ionized fraction. This decrease serves as the signal for PTH synthesis and secretion, resulting in greater bone resorption (which raises the serum calcium level) and enhanced distal tubular reabsorption of calcium. It also promotes higher rates of renal synthesis of 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] or calcitriol, the most active metabolite of vitamin D (Fig. 746.1). **Calcium homeostasis** is thus controlled by the intestine because the availability of 1,25$(OH)_2$D ultimately determines the fraction of ingested calcium that is absorbed.

Phosphate homeostasis is regulated by the kidneys because intestinal phosphate absorption is nearly complete, and renal excretion determines the serum level of phosphate. Excessive intestinal phosphate absorption causes a fall in serum levels of ionized calcium and a rise in PTH secretion, resulting in phosphaturia, thus lowering the serum phosphate level and permitting the calcium level to rise. Hypophosphatemia blocks PTH secretion and promotes renal 1,25$(OH)_2$D synthesis. This latter compound also promotes greater intestinal phosphate absorption. The important role of FGF23 in phosphate homeostasis is described later.

Vitamin D can be synthesized in the skin under the influence of ultraviolet (UV) irradiation, or it can be absorbed from the diet. It is converted to 25(OH)D3 (vitamin D3) in the liver and then further converted by the kidney. The skin contains 7-dehydrocholesterol, which is converted to vitamin D3 [25(OH)D3] by UV radiation; other inactive vitamin D sterols are also produced (see Chapter 69). Vitamin D3 is then transported in the bloodstream to the liver by a vitamin D–binding protein (DBP); DBP binds all forms of vitamin D. The plasma concentration of free or nonbound vitamin D is much lower than the level of DBP-bound vitamin D metabolites.

Vitamin D also can enter the metabolic pathway by ingestion of dietary vitamin D2 (ergocalciferol) or vitamin D3 (cholecalciferol), the latter of which is more potent, and both of which are absorbed from the intestine because of the action of bile salts. After absorption, ingested vitamin D is transported by chylomicrons to the liver, where, along with skin-derived vitamin D3, it is converted to 25-hydroxyvitamin D [25(OH)D]. The 25(OH)D is next transported by DBP to the kidneys, where it undergoes further metabolism. 25(OH)D is the main circulating vitamin D metabolite in humans (Table 746.1). Because the synthesis of 25(OH)D is weakly regulated by feedback, its plasma level rises in summer and decreases during winter. High vitamin D intake raises the plasma level of 25(OH)D to many times above normal, but the parent vitamin D compound itself is absorbed by adipose tissue.

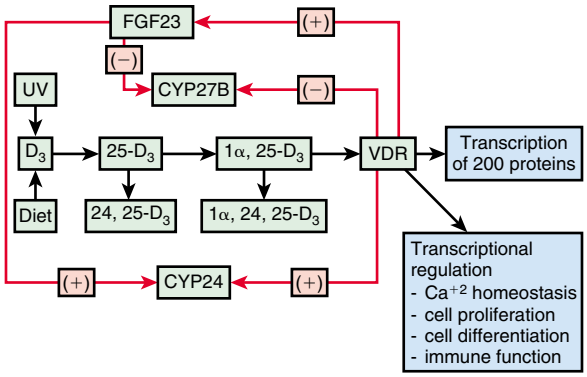

Fig. 746.1 Vitamin D metabolism. Vitamin D can be synthesized in the skin under the influence of ultraviolet (UV) irradiation, or it can be absorbed from the diet. It is converted to 25(OH)D3 (vitamin D3) in the liver and then further converted by the kidney. The enzyme cytochrome P450 (CYP) 27B converts 25(OH)D3 to 1α,25-$(OH)_2$D3. 1,25$(OH)_2$D3 binds to vitamin D receptor (VDR), which, after transport to the nucleus, acts to induce the transcription of more than 200 proteins. The functions of some of the proteins are indicated. VDR activation leads to productions of fibroblast growth factor 23 (FGF23). FGF23 induces phosphaturia (not shown), upregulates CYP 24, and downregulates CYP 27B.

In the kidneys, 25(OH)D undergoes further hydroxylation, depending on the prevailing serum concentration of calcium, phosphate, PTH, and FGF23. If the calcium or phosphate level is reduced or the PTH level is elevated, the enzyme 25(OH)D-1-hydroxylase is activated and 1,25$(OH)_2$D is formed. 1,25$(OH)_2D_3$ binds to a vitamin D receptor, which after transport to the nucleus, acts to induce the transcription of 200-400 proteins and peptides. The functions of some of the proteins are known.

Another class of proteins important in the regulation of mineral balance and vitamin D synthesis are the **phosphatonins**. Among these are FGF23, sFRP-4 (secreted Frizzled-related protein 4), and MEPE (matrix extracellular phosphoglycoprotein). Overexpression of FGF23 results in hypophosphatemia, phosphaturia, reduced serum 1,25$(OH)_2$D values, and some forms of rickets. Disorders of phosphate balance, including hyper- and hypophosphatemia, can relate to loss or gain of function of these phosphatonins (see Fig. 746.1).

Vitamin D receptor activation by 1,25$(OH)_2$D leads to production of FGF23. FGF23 is produced by osteocytes and targets another organ, the kidney, to promote phosphaturia. FGF23 reduces expression/insertion of two sodium phosphate transporters into the renal proximal tubule, resulting in higher levels of urinary phosphate excretion. This bone-derived hormone also inhibits renal hydroxylase activity (CYP 27B1) and promotes 24-hydroxylase activity, with resultant decrease in 1,25$(OH)_2$D levels.

The active metabolite, 1,25$(OH)_2$D, circulates at a level that is only 0.1% of the level of 25(OH)D (see Table 746.1) and acts on the intestine to increase the active transport of calcium and stimulate phosphate absorption. Because 1α-hydroxylase is a mitochondrial enzyme that is tightly feedback regulated, the synthesis of 1,25$(OH)_2$D declines after serum calcium or phosphate values return to normal. Excessive 1,25$(OH)_2$D is converted to an inactive metabolite. In the presence of normal or elevated serum calcium or phosphate concentrations, the renal 25(OH)D-24-hydroxylase is activated, producing 24,25-dihydroxyvitamin D [24,25$(OH)_2$D], which is a pathway for the removal of excess vitamin D; serum levels of 24,25$(OH)_2$D (1-5 ng/mL) increase after ingestion of large amounts of vitamin D (see Fig. 746.1) or in the presence of increased concentrations of FGF23. Although hypervitaminosis D and production of

Table 746.1 Vitamin D Metabolic Values in Plasma of Normal Healthy Subjects

METABOLITE	PLASMA VALUE
Vitamin D2	1-2 ng/mL
Vitamin D3	1-2 ng/mL
25(OH)D2	4-10 ng/mL
25(OH)D3	26-70 ng/mL
TOTAL 25(OH)D	20-80 ng/mL*
24,25(OH)2D	1-4 ng/mL
1,25(OH)2D	
Infancy	70-100 pg/mL
Childhood	30-50 pg/mL
Adolescence	40-80 pg/mL
Adulthood	20-35 pg/mL

*The Institute of Medicine states that a value of 25(OH)D of 20 ng/mL is the lower limit of normal for the general population. In contrast, the Endocrine Society defines vitamin D *deficiency* as having a serum level of less than 20 ng/mL, and *insufficiency* as a serum level between 21-29 ng/mL.

inactive metabolites can occur after oral dosing, extensive skin exposure to sunlight does not usually produce toxic levels of 25(OH)D3, suggesting natural regulation of the production of this metabolite in cutaneous tissue.

Serum 1,25(OH)$_2$D levels are higher in children than in adults, are not as subject to seasonal variability, and peak during the first year of life and again during the adolescent growth spurt. These values must be interpreted in light of the prevailing serum calcium, phosphate, and PTH values, and with regard to the entire vitamin D metabolite profile.

Mineral deficiency prevents the normal process of bone mineral deposition. If mineral deficiency occurs at the growth plate, growth slows and bone age is retarded, a condition called **rickets**. Poor mineralization of trabecular bone resulting in a greater proportion of unmineralized osteoid is the condition of osteomalacia. Rickets is found only in growing children before fusion of the epiphyses, whereas osteomalacia is present at all ages. All patients with rickets have osteomalacia, but not all patients with osteomalacia have rickets. These conditions should not be confused with osteoporosis, a condition of equal loss of bone volume and mineral (see Chapter 749).

Rickets may be classified as calcium-deficient or phosphate-deficient rickets. Because both calcium and phosphate ions constitute bone mineral, the insufficiency of either type in the extracellular fluid that bathes the mineralizing surface of bone results in rickets and osteomalacia. The two types of rickets are distinguishable by their clinical manifestations (Table 746.2). Rickets can also occur in the face of mineral

deficiency, despite adequate vitamin D stores. True dietary calcium deficiency rickets are found in some parts of Africa but rarely in North America or Europe. A form of phosphate-deficiency rickets can occur in infants, given prolonged administration of phosphate-sequestering aluminum salts as a treatment for colic or gastroesophageal reflux. This results in the phosphate depletion syndrome.

Chapter 747

Hypophosphatasia

Nourah N. Almutlaq and Linda A. DiMeglio

Hypophosphatasia (HPP) is a rare inborn error of metabolism in which tissue-nonspecific (liver, bone, kidney) alkaline phosphatase isoenzyme (TNSALP) activity is deficient, although activity of the intestinal and placental isoenzymes is normal. Decreased serum alkaline phosphatase (ALP) concentrations are the hallmark of HPP.

Pathogenic variants in the *ALPL* gene reduce the TNSALP enzyme activity to below the level essential for normal bone and teeth mineralization. More than 340 variants have been identified to date. Missense variants are the most common; however, splice-site, small deletions, and frameshift variants also have been found. The high heterogeneity of the disease is related to the inheritance pattern and different missense variants' varied TNSALP activity effects. Although the genotype/phenotype correlation is not very consistent, the more severe forms are recessively inherited and milder disease is dominantly inherited.

The clinical spectrum of HPP ranges from a very severe, typically lethal, perinatal form to a mild form with late-adult onset presenting with nonpathognomonic symptoms such as arthropathy and musculoskeletal pain. A nosology describing seven forms of the condition, ranging from neonatal lethal disease to odontohypophosphatasia, which only affects teeth with no skeletal deformities, is employed. (Subtypes and features of HPP are shown in Table 747.1.) The most common signs across subtypes are bone demineralization and premature loss of teeth with intact roots in the setting of low ALP.

The most severe **perinatal HPP** cases are lethal in utero or shortly after birth in untreated newborns. Infants have profound skeletal hypomineralization with short bones that lead to chest deformities and subsequent hypoplastic lungs. Infants may also have anemia with intracranial hemorrhage, periodic apnea, and pyridoxine-dependent seizures (Fig. 747.1A). **Infantile HPP** is next on the continuum. These infants present before 6 months of age with overlapping symptoms to perinatal HPP, including respiratory distress from severe lung hypoplasia. They can also have irritability and failure to thrive explained by the hypercalcemia/hypercalciuria (leading to nephrocalcinosis) and premature craniosynostosis (can lead to increased intracranial pressure). X-rays reveal irregular ossification, punched-out areas, and metaphyseal cupping. Before the availability of enzyme replacement therapy with asfotase alfa, mortality was estimated at 50% and survivors had significant disability. This subset of patients can also improve spontaneously as affected children mature, although early death from renal failure or flail chest leading to pneumonia can occur.

Of note, a **benign prenatal** form of hypophosphatasia also exists. It is seen in newborns with low ALP and skeletal abnormalities in utero or at birth that improve spontaneously over time.

The next category of hypophosphatasia manifests in childhood (after 6 months of life) or late adolescence **(hypophosphatasia tarda)** (see Fig. 747.1B). These children present with premature exfoliation of primary teeth (with the root intact because of poorly mineralized dental cementum), mild skeletal deformities, fracture, and variable short stature. Some children have symptoms of skeletal pain and muscle weakness. Long bones can have characteristic "tongues" of radiolucency (Fig. 747.2).

An **adult hypophosphatasia** form manifests in middle age (although some patients recount a history of early deciduous tooth loss or rickets). It is characterized by nonspecific symptoms and a milder course than pediatric forms. This form may be diagnosed after affected individuals present with osteopenia/osteoporosis, recurrent metaphyseal stress fractures (particularly of the metatarsals and tibiae), and femoral pseudofractures. Affected individuals can also have psychiatric symptoms (depression/anxiety) chondrocalcinosis, osteoarthritis, myopathy, nephrocalcinosis, and permanent tooth loss between 40-60 years of age.

Rarely, patients presenting with identical clinical and radiographic patterns have normal serum alkaline phosphatase activity but increased concentrations of phosphoethanolamine, inorganic phosphate, and pyridoxal-5-phosphate. Their disease has been labeled **pseudohypophosphatasia** and might represent the presence of a variant alkaline

Table 747.1 Hypophosphatasia Main Subtypes and Features

SUBTYPE	ONSET	INHERITANCE	CLINICAL FEATURES
Perinatal severe	Perinatal	Recessive	• Lethal in all cases without enzyme replacement • Prenatal US: absent skeletal mineralization, bowed/short long bones, fractures, osteochondral spurs, and pretibial dimpling • Death from respiratory distress from chest deformities and lung hypoplasia • Vitamin B6-dependent seizures
Prenatal benign	Perinatal	Dominant and recessive	• Skeletal deformity in utero without fractures ("bent not broken") • Improves spontaneously, benign course
Infantile	≤ 6 mo	Recessive	• Lethal in approximately 50% of cases without enzyme replacement • Appear normal at birth • Severe bone demineralization leads to rachitic chest deformities and resultant pulmonary hypoplasia • Hypercalcemic hypercalciuria (leads to nephrocalcinosis) • Craniosynostosis
Childhood	6 mo-18 yr	Dominant and recessive	• Premature loss of deciduous teeth with root intact in children <5 yr • Rickets/fractures/skeletal deformities • "Tongues" of radiolucency on x-ray • Chronic joint/bone pain • Short stature
Adult	Adulthood	Dominant and recessive	• Mild • Osteoporosis • Stress fractures, osteomalacia, and chondrocalcinosis
Odontohypophosphatasia	Childhood	Dominant and recessive	• Mildest form of HPP • No skeletal deformities; premature exfoliation of primary and/or permanent teeth • Severe dental caries

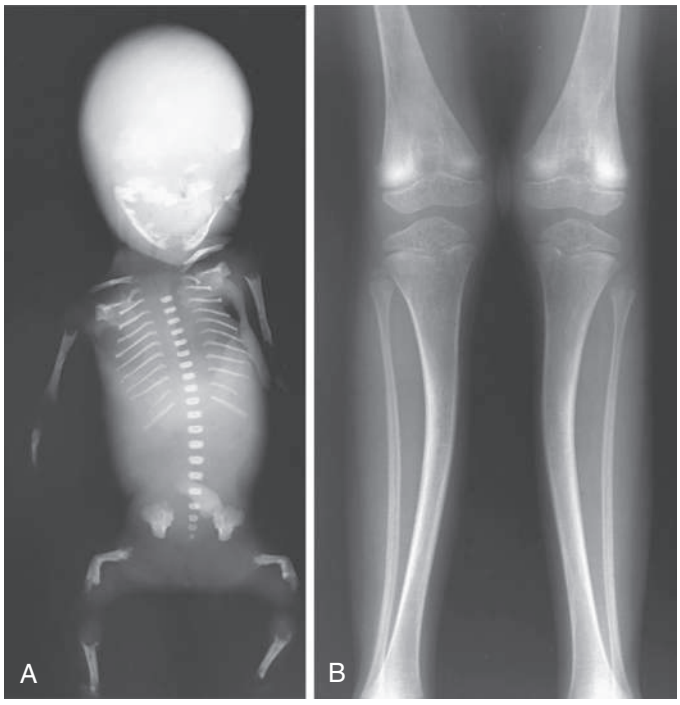

Fig. 747.1 A, Fetus with congenital lethal hypophosphatasia showing thin wavy ribs, platyspondyly, missing cervical vertebrae, ossification, and bent femurs. B, A 7-yr-old with hypophosphatasia tarda showing osteopenia, bent tibias, and punched-out metaphyseal lesions.

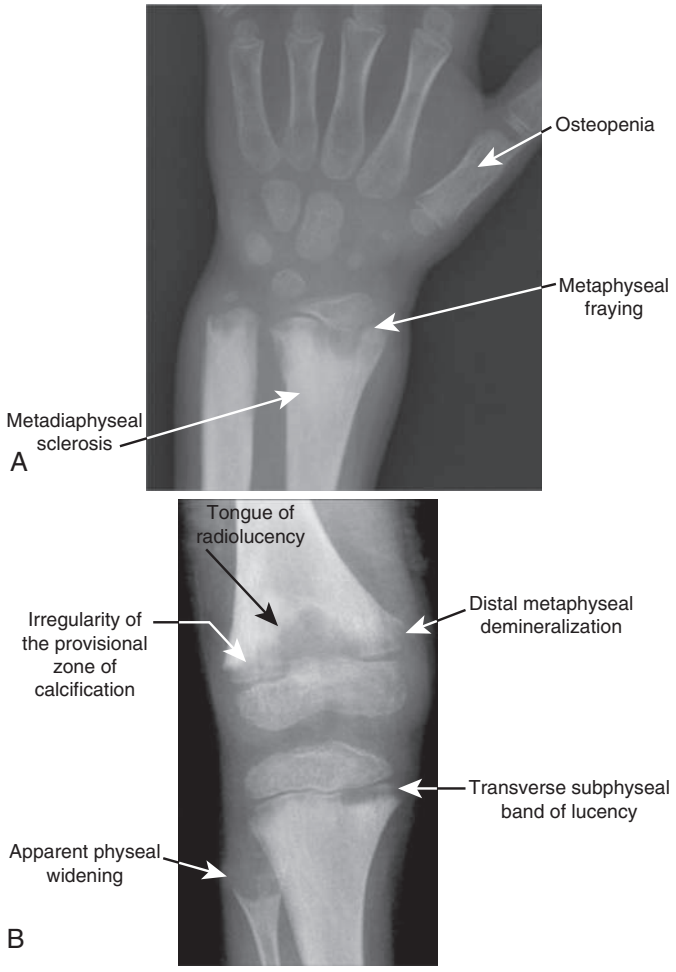

Fig. 747.2 Skeletal features of untreated hypophosphatasia. Untreated, the radiographic features of hypophosphatasia of the wrist (A) and knee (B) in children include osteopenia, metaphyseal fraying, metaphyseal flaring, metadiaphyseal sclerosis, characteristic "tongues" of radiolucency, irregularity of the provisional zone of calcification, distal metaphyseal demineralization, transverse subphyseal band of lucency, and apparent physeal widening. *(From Whyte MP, Madson KL, Phillips D, et al. Asfotase alfa therapy for children with hypophosphatasia. JCI Insight.2016;1:e85971, Fig. 2.)*

phosphatase isoenzyme that catalyzes artificial substrates in an alkaline environment (e.g., a test tube), but not in vivo with natural substrates.

Because of the heterogenous clinical manifestations of HPP, which often mimics other skeletal disorders, delays and misdiagnosis are common. Clinical features and radiologic findings in the setting of low ALP for age or other biomarkers of the disorder should raise suspicion. Initially the diagnosis might be suspected in the presence of a low serum ALP (adjusted for age and natal sex) and supported with an increased urinary phosphoethanolamine PEA level or high vitamin B6 concentrations. However, other etiologies for low ALP should be ruled out (Fig. 747.3 and Table 747.2).

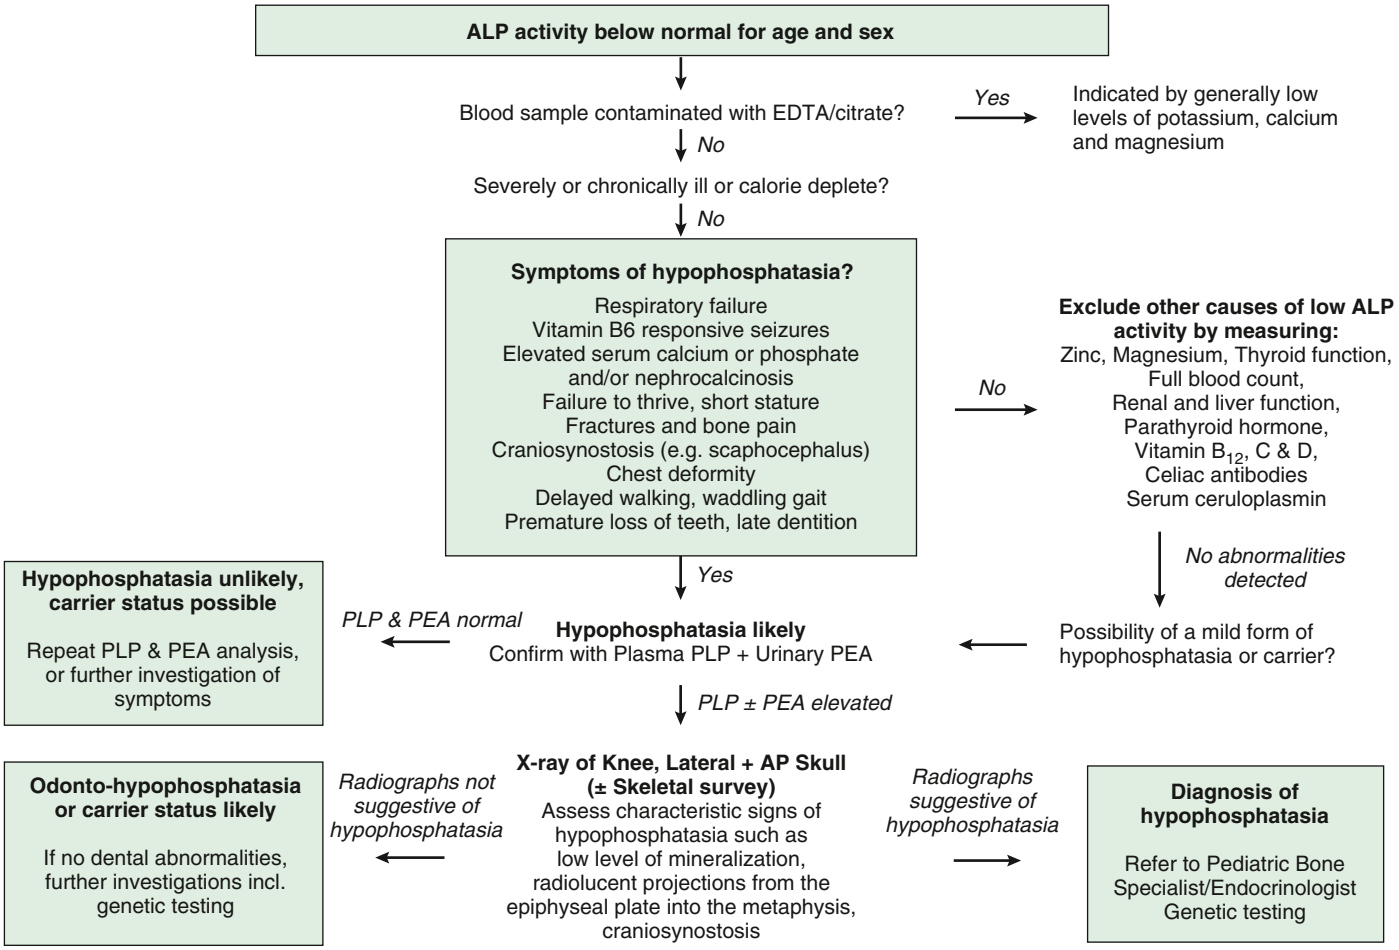

Fig. 747.3 Diagnostic algorithm for the investigation of children presenting with low ALP activity and/or symptoms of hypophosphatasia. For patients with low ALP, other conditions such as nutritional deficiencies (protein/calorie, zinc, folic acid, magnesium, vitamins B6, B12, and C), vitamin D excess, hypothyroidism, hypoparathyroidism, celiac disease, recent significant blood transfusions, renal osteodystrophy, cardiac surgery and cardiopulmonary bypass, posthepatic resection and transplantation, achondroplasia, and Wilson disease need to be excluded. AP, Anteroposterior; PEA, phosphoethanolamine; PLP, pyridoxal-5′-phosphate. *(From Saraff V, Narayanan VK, Lawson AJ, et al. A diagnostic algorithm for children with low alkaline phosphatase activities: lessons learned from laboratory screening for hypophosphatasia. J Pediatr. 2016;172:181–186. Fig. 3.)*

Table 747.2 Causes of Hypophosphatasemia

Cardiac bypass surgery	Milk-Alkali syndrome
Celiac disease	Multiple myeloma
Clofibrate therapy	Osteogenesis imperfecta, type II
Cleidocranial dysplasia	Pernicious or profound anemia
Cushing syndrome	Radioactive heavy metals
Hypophosphatasia	Starvation
Hypothyroidism	Vitamin C deficiency
Improperly collected blood (oxalate, EDTA)	Vitamin D intoxication
Inappropriate reference range	Wilson's disease
Massive transfusion	Zn^{++} or Mg^{++} deficiency

EDTA, Ethylenediaminetetraacetic acid
From Whyte MP. Hypophosphatasia: an overview for 2017. *Bone.* 2017;102:15–25. Table 1.

Some mild HPP forms require only symptomatic and supportive treatment. The primary treatment for more severe HPP is enzyme replacement therapy with recombinant human TNSALP (asfotase alfa). This therapy decreases the mortality rate in prenatal HPP and improves skeletal healing and mineral content, pulmonary status, and overall physical activity in other symptomatic forms.

Chapter 748

Hyperphosphatasia

Nourah N. Almutlaq and Linda A. DiMeglio

Hyperphosphatasia is a set of conditions characterized by hyperphosphatasemia (elevated serum alkaline phosphatase [ALP]). Increases in alkaline phosphatase are most commonly because of hepatobiliary disease or bone disorders characterized by high osteoblast activity, including nutritional rickets. Distinguishing liver from bone etiologies requires fractionating alkaline phosphatase isoenzymes or measuring bone-specific alkaline phosphatase as well as other laboratory assessments of liver function and bone turnover/vitamin D status. ALP activity varies by age and gender; therefore, specific reference ranges should be employed. It is usually higher in pediatric populations than adults, peaking at times of high bone formation including in the first 6 months and during pubertal growth.

In children younger than 5 years, marked increases in alkaline phosphatase without clinical or laboratory evidence of liver or bone disease is most often because of **benign transient hyperphosphatasemia** generally detected as an incidental finding during screening laboratory evaluations or evaluations performed to assess a specific complaint. The cause may be related to excess sialylation of alkaline phosphatase, which slows clearance. Cases often follow viral illness, including SARS-CoV-2 infection. Serum alkaline phosphatase values as high as 3,000-6,000 IU/L may be encountered. Liver and bone isoenzyme fractions are both elevated; there are no other clinical or laboratory signs of hepatic or bone disease. Diagnosis is confirmed by a careful clinical history plus laboratory assessments of calcium, phosphorus, creatine, AST, ALT, GGT, bilirubin, PTH, and 25-hydroxyvitamin D. A CBC should also be drawn to rule out oncologic processes. Alkaline phosphatase should be followed serially (every 2-3 months) until resolution is documented. The condition usually resolves within 16 weeks without intervention and does not recur.

Juvenile Paget disease (familial hyperphosphatasemia, idiopathic hyperphosphatasia or IHH) is a rare autosomal recessive bone disease hallmarked biochemically by marked serum ALP activity elevation. Most cases are because of loss-of-function variants in the tumor necrosis factor receptor superfamily, member 11B gene (TNFRSF11B) that encodes osteoprotegerin (OPG). OPG inhibits osteoclastogenesis and osteoclast activity by preventing receptor activator of nuclear factor κ-B (RANK) ligand (RANKL) from binding to its receptor RANK. Affected children are asymptomatic at birth and gradually develop progressive long bone deformity (including kyphoscoliosis), bone pain, and significant fractures. X-rays show bowing and diaphyseal thickening, along with osteopenia (Fig. 748.1). Radiographically, the bony texture is variable; dense areas (showing a teased cotton-wool appearance) are interspersed with radiolucent areas and general demineralization. Long bones appear cylindrical, lose metaphyseal modeling, and contain pseudocysts that show a dense, bony halo. Children with juvenile Paget disease have short stature, large skulls with a thickened cranium (widened diploë) that may be deformed, and progressive and profound hearing loss. There is substantial phenotype variability; some cases are diagnosed in infancy and others in late childhood. This disorder is distinct from adult Paget disease (osteitis deformans) because bone histology reveals a lack of normal cortical bone remodeling and an absence of the classic mosaic pattern of lamellar bone found in the adult condition. Given the rarity of this disorder, there is no strong evidence surrounding optimal clinical management; however, antiresorptive therapy with bisphosphonates is associated with clinical, biochemical, and radiographic improvement.

Fig. 748.1 Juvenile Paget disease showing bowing and thickening of the diaphyses and osteopenia. *(From Slovis T, ed. Caffey's Pediatric Diagnostic Imaging, 11th ed. Philadelphia: Mosby, 2008. Fig. 167–226, p. 2744.)*

Other rare forms of hyperphosphatasia include **expansile skeletal hyperphosphatasia (ESH)** caused by dominant variants in the *TNFRSF11A* gene encoding receptor activator of RANK, which regulates osteoclastogenesis, and **hyperphosphatasia-mental retardation syndrome** caused by recessive variants in *PIGV* in the glycosylphosphatidylinositol (GPI)-anchor biosynthesis pathway.

Chapter 749

Osteoporosis

Rebecca J. Gordon and Catherine M. Gordon

Osteoporosis, the most common bone disorder in adults, is relatively uncommon in children and adolescents; the criteria that underlie this diagnosis in young patients are a source of debate. This disorder is characterized by diminished bone volume and a marked increase in the prevalence of fractures. In contrast to osteomalacia, which shows undermineralization and normal bone volume, histologic sections of bone in all forms of osteoporosis reveal a normal degree of mineralization but a reduction in the volume of bone, especially trabecular bone (vertebral bone). The **diagnosis of osteoporosis in children and adolescents** requires evidence of skeletal fragility with: (1) a clinically significant fracture history, which is defined as at least two long bone fractures in children less than 10 years old, at least three long bone fractures by 19 years old, or any vertebral fractures; and (2) low bone density, with age, sex, and ancestry-matched bone mineral density (BMD) Z-score ≤ –2.0, assessed by dual-energy x-ray absorptiometry (DXA).

Blood values of minerals (e.g., calcium, phosphorus), vitamin D metabolites, alkaline phosphatase, and parathyroid hormone are usually normal. Evaluation of bone mineral content and areal bone density by DXA is the clinical gold standard for measuring BMD. DXA evaluation in patients 15 years of age or younger includes total body less head and lumbar spine, and in those 16 years and older includes lumbar spine and hip. In certain clinical scenarios, it may be useful to obtain alternative sites, such as the distal femur or forearm scan. Additional research modalities allow for the assessment of bone microarchitecture (e.g., trabecular versus cortical bone), quality, and strength, such as peripheral quantitative CT and trabecular bone score.

In the pediatric age group, osteoporosis may be primary or secondary (Table 749.1, Fig. 749.1). The primary osteoporoses can be divided into heritable disorders of connective tissue, including osteogenesis imperfecta (see Chapter 742), Bruck syndrome, osteoporosis-pseudoglioma syndrome, Ehlers-Danlos syndrome (see Chapter 744), Marfan syndrome (see Chapter 743), homocystinuria, and idiopathic juvenile osteoporosis. Secondary forms of osteoporosis include various neuromuscular disorders, chronic illness, endocrine disorders, and drug-induced and inborn errors of metabolism, including lysinuric protein intolerance and Gaucher disease.

When no obvious primary or secondary cause can be detected, **idiopathic juvenile osteoporosis** should be considered, especially if the following clinical features are evident: onset before puberty, long bone and lower back pain, vertebral fractures, long bone and metatarsal fractures, a washed-out appearance of the spine and appendicular skeleton on standard radiographs, and improvement of bone density after puberty. Trabecular bones such as the spine and metatarsals are particularly affected by atraumatic fractures. Several modes of therapy (including oral calcium supplements, calcitriol, bisphosphonates, and calcitonin) have been used with some success in individual conditions, but the effect of these treatments is difficult to gauge because spontaneous recovery occurs after the onset of puberty in more than 75% of cases.

Osteoporosis-pseudoglioma syndrome is an autosomal recessive disorder manifested by variable age at onset, low bone mass, fractures in childhood, and abnormal eye development. It is caused by pathogenic loss of function variants in *LRP5*, which encodes the low-density lipoprotein receptor-related protein 5. Interestingly, gain-of-function pathogenic variants to this gene result in increased bone density.

The life-cycle implications of either significant demineralization or osteoporosis in childhood need to be stressed. Events in childhood influence peak bone mass, and late adolescence is a period of rapid bone mineral accretion. Peak bone mass is typically achieved by 20-25 years of age (depending on the bone measured), and the contribution during childhood is considerable. A number of measures influence bone mass including adequate calcium intake, vitamin D sufficiency, weight-bearing physical activity, and body mass index (BMI) within a healthy range. General recommendations include achieving the recommended daily allowance (RDA) of calcium for age. Excellent and convenient sources of dietary calcium include dairy products, but also bony fish, green vegetables, and calcium-supplemented drinks (e.g., orange juice). Yogurt and hard cheeses can be used in many lactase-deficient children. Also, a serum 25-hydroxyvitamin D level between 30-50 ng/mL in those with known threats to bone health can be beneficial to maximize calcium absorption and ensure normal range parathyroid hormone. Weight-bearing exercise

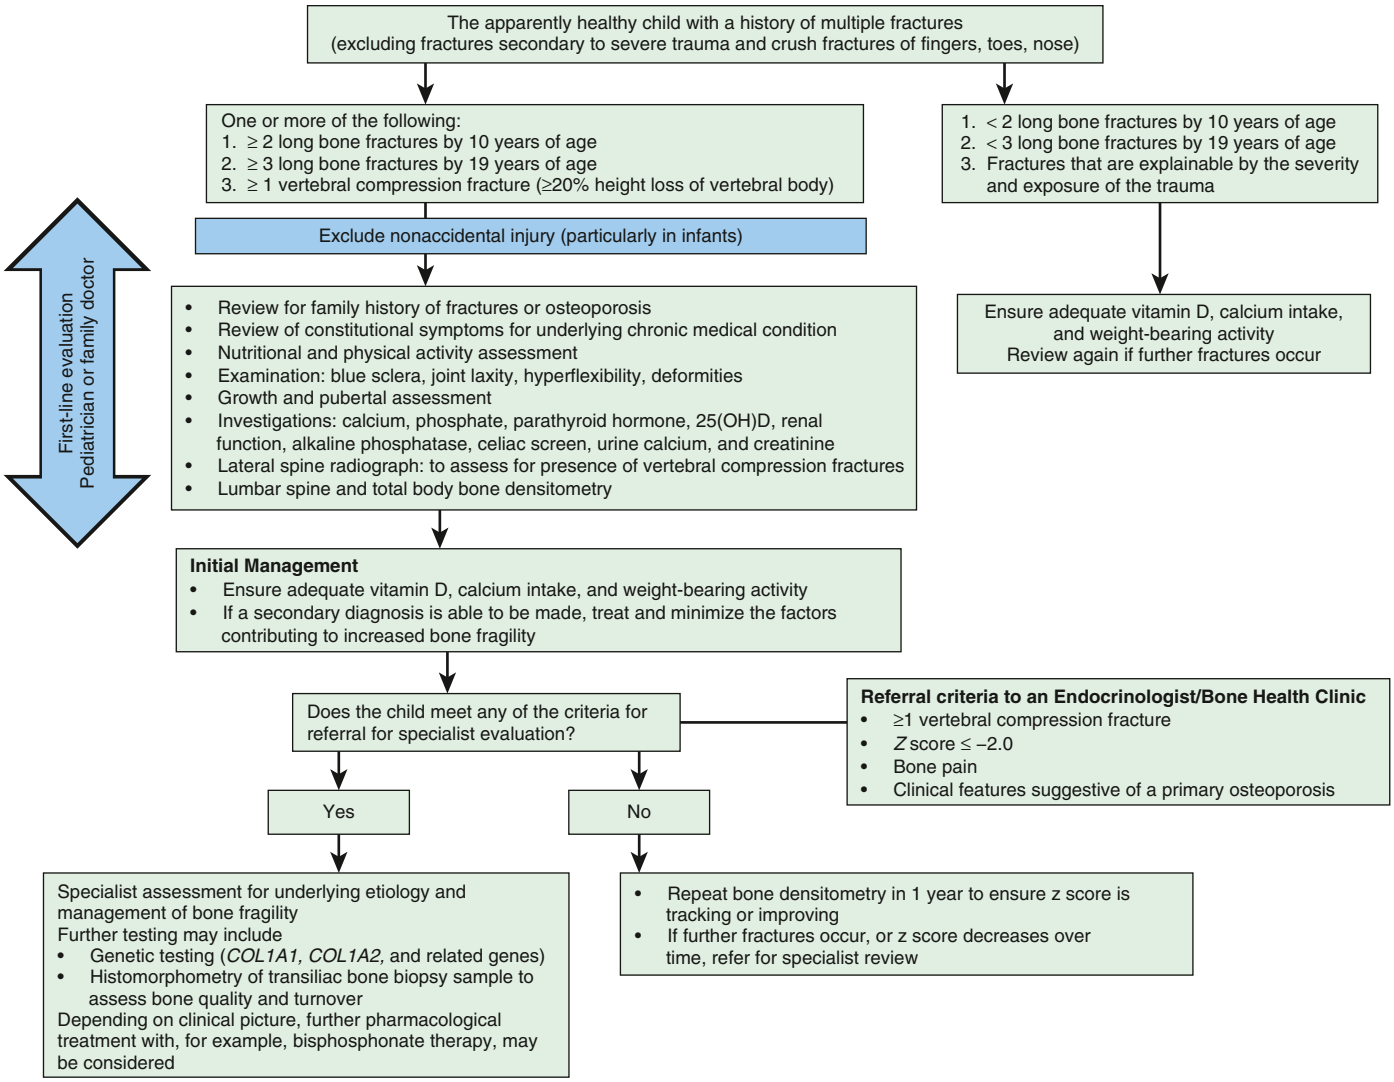

Fig. 749.1 An algorithm for the management of a child presenting with a clinically significant fracture history. The algorithm outlines the initial evaluation, management, and when to consider referral for specialist review. *(Data from Mayranpaa MK, Viljakainen HT, Toiviainen-Salo S, et al. Impaired bone health and asymptomatic vertebral compressions in fracture-prone children: a case-control study. J Bone Miner Res. 2012;27:1413–1424; and Bishop N, Arundel P, Clark E, et al. Fracture prediction and the definition of osteoporosis in children and adolescents: the ISCD 2013 pediatric official positions. J Clin Densitom. 2014;17:275–280.)*

enhances bone formation and reduces bone resorption. Factors that can prevent acquisition of peak bone mass include the use of alcohol and tobacco. Because it appears that adult-onset osteoporosis stems primarily from genetic factors, representing a complex trait interaction, specific interventions during childhood to augment bone mass are not available.

The treatment of secondary osteoporosis is best achieved by treating the underlying disorder when feasible (see Fig. 749.1). Hypogonadism should be treated with hormone replacement therapy, but in adolescent girls, nutritional issues should first be addressed and, ultimately, prescription of transdermal over oral estrogen (see Chapter 732). Calcium intake should be increased to 1,500-2,000 mg/day. In glucocorticoid-induced osteoporosis, an emphasis is placed on the lowest possible dose to prevent disease activity (e.g., in children with inflammatory bowel disease) with alternate-day dosing or, when appropriate, topical (e.g., eczema) or inhaled (e.g., asthma) glucocorticoids. Special diets for inborn errors of metabolism are also appropriate, as well as enzymatic replacement for diseases such as hypophosphatasia, a genetic disorder leading to deficient endogenous alkaline phosphatase production and defective bone mineralization. Screening for celiac disease should be carried out in unexplained cases of low bone mass, as adherence to a gluten-free diet can significantly enhance bone health in these patients (see Chapter 384).

Treatment with bisphosphonates that inhibit bone resorption in certain secondary (e.g., glucocorticoid-induced) and adult-onset osteoporosis has been successful. Bisphosphonate therapy can also be beneficial for children and adolescents and has historically been used with osteogenesis imperfecta and cerebral palsy. The use of bisphosphonates has expanded to additional patient populations with secondary osteoporosis, such as recurrent fractures and low bone mineral density, and high risk for skeletal fragility because of their underlying medical conditions. In consultation with a metabolic bone expert, bisphosphonate treatment should be considered in the following patient populations: Duchenne muscular dystrophy, spinal muscular atrophy, and other nonambulatory patients (i.e., cerebral palsy, metabolic disorders). All modifiable risk factors should be addressed, including adequate calcium intake; sufficient vitamin D; weight-bearing physical activity, such as time within a stander and physical therapy; healthy range BMI; and evaluation of overall heath (i.e., regular menstrual periods in adolescent girls, no other endocrinopathies, and optimizing the treatment status of the underlying medical condition).

Rehabilitation Medicine

PART XXXI

Chapter 750

Rehabilitation for Traumatic Brain Injury

Chong-Tae Kim and J. Michael King

Traumatic brain injury (TBI) is a major cause of pediatric disability in children older than 1 year old in the United States (see Chapter 82). According to data from the Centers for Disease Control and Prevention (2006–2010), TBI due to falls (72.8%) is most common in the 0-4 age range. **Nonaccidental TBI** remains a significant cause of TBI at this age (20-30 cases/100,000) (see Chapter 17). Falls (35.1%) and being struck by or against an object (34.9%) are most common in those 5-14 years of age. Assaults, falls, and motor vehicle injuries make up to 85% of the TBI experienced in those 15-24 years of age. TBI is more common in males than females at all ages.

PATHOPHYSIOLOGY

TBI is the consequence of primary and secondary injury (see Chapter 82). Primary injury results from direct physical impact. Secondary injury is the consequence of aberrant neurochemical homeostasis after primary injury (Fig. 750.1). This injury mechanism helps explain why individuals may experience global dysfunction of the brain despite relatively small or focal brain lesions on imaging studies. Minimizing secondary injury is critical to preventing further brain insult after the primary injury.

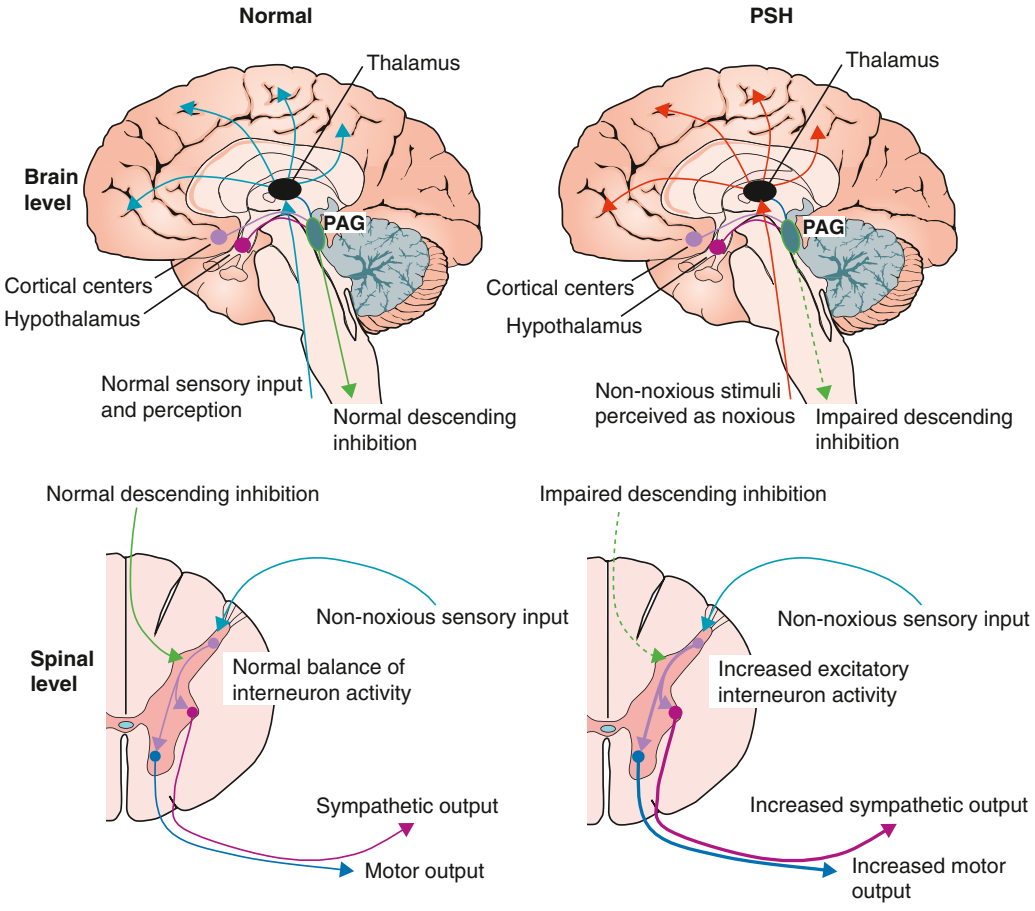

Fig. 750.1 Excitatory:inhibitory ratio model of the pathogenesis of PSH. In normal circumstances, various cortical, hypothalamic, thalamic, and other subcortical inputs modulate activity within brainstem centers—the PAG is shown here as one of the key brainstem hubs in this process. These brainstem nuclei provide inhibitory drive to spinal-reflex arcs, thereby maintaining balance between inhibitory and excitatory interneuron influences on motor and sympathetic efferents, allowing normal sensory stimuli to be perceived as nonnoxious. In the excitatory:inhibitory ratio model of PSH, disconnection of descending inhibition produces maladaptive dendritic arborization and spinal-circuit excitation, with nonnoxious stimuli triggering increased motor and sympathetic output (spinally) and potentially becoming perceived as noxious (centrally). PAG, Periaqueductal grey. PSH, paroxysmal sympathetic hyperactivity. *(From Meyfroidt G, Baguley IJ, Menon DK. Paroxysmal sympathetic hyperactivity: the storm after acute brain injury. Lancet. 16:721–729, 2017 [Fig. 2].)*

Very young children who have not yet closed their cranial sutures accommodate some increase in intracranial pressure that may result from TBI. However, young children have a relatively large head size compared with their body, higher brain water content, and less myelination, all of which may contribute to greater brain distortion and injury than from a comparable injury experienced by an adult.

SEVERITY

The acute severity of TBI is typically classified with the **Pediatric Glasgow Coma Scale** (GCS) (see Chapter 82). GCS scores of 13-15 are considered mild TBI, 9-12 moderate TBI, and 3-8 severe TBI. Additional parameters may be helpful in classifying severity. The longer the duration of loss of consciousness (i.e., <30 min, <24 hr, or >24 hr), the more severe the TBI. Longer duration of posttraumatic amnesia (<1 day, 1-7 days, or >7 days) is also reflective of a more severe TBI. Biomarkers (chemicals sensitive to nerve tissues) are being investigated as potential indicators of severity.

MEDICAL COMPLICATIONS

Disorders of Consciousness

Children with severe TBI manifest various levels of altered consciousness (Table 750.1). They may progress from coma to unresponsive wakefulness syndrome (formerly vegetative state) and/or minimally conscious state. The longer the period of impaired consciousness, the poorer the functional recovery. Rapid transition from coma/unresponsive wakefulness syndrome to a minimally conscious state increases the possibility of better recovery. As patients recover from impaired consciousness, they may have altered circadian sleep–wake patterns. In this phase, it is particularly important to **avoid overstimulation at night**, such as with procedures, and to avoid sedative medications during the day. **A sleep diary** over a period of several days to a week is a useful measure to monitor sleep patterns and determine the effectiveness of medications. **Neurostimulators** (e.g., amantadine, bromocriptine, methylphenidate, or L-dopa) may be used to improve arousal during the day. Trazodone or melatonin may help facilitate sleep onset or maintenance at night, respectively. Modafinil or donepezil can be tried if the above neurostimulators are ineffective. Paradoxically zolpidem has been reported to improve alertness in several cases.

Cognitive-Behavioral Disorders

The management and outcome of mild TBI (concussion) are discussed in Chapter 729. As patients with severe TBI recover from initial low levels of consciousness, they may demonstrate significant cognitive-behavioral disorders, such as agitation, aggression, decreased frustration tolerance, impulsivity, inattention, emotional lability, perseveration, impaired working memory, and poor safety awareness and judgement. Agitation is common in the early stages of recovery. The first line of management for agitation is to decrease excessive environmental, visual, auditory, and tactile stimulation. Physical constraint is typically implemented as a last resort to prevent harm to the patient and others, and it should be removed as soon as the danger has resolved. The **Rancho Los Amigo scale** (RLAS) (Table 750.2) may be used to evaluate the level of this impairment. It is important to exclude potential exacerbating factors or medical causes of impaired mental status and behavior, including electrolyte abnormalities, infection, and concomitant injuries in patients who incur multiple traumas including severe TBI. Posttraumatic amnesia can be particularly debilitating because it may limit the acquisition and retention of new learning skills. The **Children's Orientation and Amnesia Test** may be helpful in determining when a patients' posttraumatic amnesia has ended, after which these children may be candidates for cognitive rehabilitation. This test assesses **general orientation** (name, age, birthdate, school, etc.), **temporal orientation** (current time, day of the week, year, etc.), and **memory** (verbal and nonverbal).

Most patients who have moderate or severe TBI will have varying degrees of long-term residual cognitive impairments, which can include impaired judgment, attention deficits, and impaired working memory (see Chapter 49). The most rapid recovery in cognitive skills tend to occur in the first year after the TBI. Children with more severe injuries and children from lower socioeconomic status (SES) families tend to have more significant long-term deficits after a TBI.

Table 750.1 Level of Consciousness

	COMA	UNRESPONSIVE WAKEFULNESS SYNDROME	MINIMALLY CONSCIOUS STATE (–)	MINIMALLY CONSCIOUS STATE (+)
Eye opening	None	Spontaneous or to stimulus	Spontaneous	Spontaneous
Brain stem reflexes	None	Present	Present	Present
Orientation	None	None	Inconsistent	Consistent
Purposeful response	None	None	Trivial responses with localization (visual fixation or tracking, localization to pain)	Evident reliable responses with verbal, behavioral, and/or motor

Table 750.2 Rancho Los Amino Scale

LEVEL	COGNITIVE-BEHAVIORAL CHARACTERISTICS	CLINICAL FEATURES
I	No response	Comatose state
II	Generalized response	Nonpurposeful, reflexive, stereotyped response to simulations
III	Localized response	Specifically localized (head turn, blink eye, grasp), consistent response to stimulations
IV	Confused-agitated	Confused and hyperactive or bizarre behavior
V	Confused-inappropriate	Less agitated and able to follow simple instructions consistently but difficult to follow complicated ones
VI	Confused-appropriate	Still impaired recent memory, needs assistance for unfamiliar situations
VII	Automatic-appropriate	Able to do daily routine independently but has difficulty solving problems
VIII	Purposeful-appropriate	Independent and functional in activities at home and community but may have some difficulties in stressful situations

Posttraumatic Seizure

The incidence of posttraumatic seizure (PTS) is dependent on injury severity and age. About 30–35% of children with severe TBI will experience a PTS. Very early-onset PTS may develop within 24 hours after a TBI, early-onset PTS within 7 days, and late onset more than 7 days after a TBI. Early-onset PTS is more common in children, and late-onset PTS is more common in adults. The risk of late-onset PTS is increased in particularly severe TBI, those caused by penetrating injury, the presence of subdural hematoma, in injuries occurring in children younger than 5 years, and in patients with a history of early-onset PTS. Prophylactic treatment with an antiepileptic medication for 7 days after a TBI is commonly prescribed (see Chapter 82). However, treatment with an antiepileptic medication beyond 1 week offers no further benefit as a prophylactic agent. The risk of PTS decreases to the same incidence as in the general population after 5 years from TBI.

Paroxysmal Sympathetic Hyperactivity

Paroxysmal sympathetic hyperactivity (PSH) is a constellation of symptoms manifested by hyperthermia, tachycardia, tachypnea, diaphoresis, and increased tone, including dystonic posturing. It is primarily attributable to autonomic dysregulation. The mechanism has not been clearly defined but is thought to be because of disruption of the inhibitory function of the mesencephalon on the diencephalon (see Fig. 750.1). Some drug-related symptoms may mimic the features of PSH and may require discontinuation and the use of alternative medication; for example, haloperidol and chlorpromazine may cause neuroleptic malignant syndrome, and phenytoin may precipitate a fever. The assessment measure pediatric PSH-AM is suggested to improve diagnostic sensitivity (Tables 750.3, 750.4, and 750.5). There is no current established standard of care for management of PSH, but bromocriptine, propranolol or labetalol, clonidine, amantadine, intrathecal baclofen, morphine, benzodiazepine, and gabapentin have been prescribed with variable success. Morphine, fentanyl, propofol, propranolol, and gabapentin have consistently been effective in adult patients for both prevention and treatment. Most patients require more than one class of medication (opioid, beta blockers, alpha 2 agonists, neuromodulators, benzodiazepines, sarcolemmal calcium release blockers). Oral baclofen, Dilantin, and carbamazepine are reported to be ineffective for PSH. PSH is a negative factor for short-term but not long-term functional outcomes.

Neuroendocrine Disorders

Hypothalamic-pituitary injury that occurs with TBI can cause various endocrine disorders. Growth hormone deficiency is the most common and results in growth retardation. Precocious puberty, more common in females than males, may result from loss of neural inhibition on gonadotropin release. Three different types of salt and water metabolism derangements, diabetes insipidus (DI), syndrome of inappropriate secretion of antidiuretic hormone (SIADH), and cerebral salt wasting (CSW) can develop after a severe TBI (see Chapter 82).

Spasticity

Spasticity is a major complication that develops in children with severe TBI (see Chapter 752).

OUTCOME ASSOCIATED WITH SEVERE TRAUMATIC BRAIN INJURY

Given different mechanisms of injury, younger children who incur a severe brain injury tend to have better functional outcomes than older children. However, given the same severity of TBI, the outcome of very young children is poorer than that of older children. The age defined as "very young children" (2-5 years) is variable depending on the studies. The specific reason for this difference in outcomes has not been identified, but a plausible explanation is that although very young children demonstrate a higher potential for neuroplasticity with focal brain injuries, their immature and developing brains are more vulnerable to the diffuse effects on the brain of most forms of TBI.

The GCS score is a strong prognostic factor for mortality and functional outcome in the acute injury phase but not for functional outcome in the subacute or chronic phase for children within the severe TBI group. Duration of posttraumatic amnesia or time to follow commands are better prognostic factors for long-term functional outcomes.

Cognitive and behavioral impairments (poor memory-learning and executive skills, hyperactivity, depression, awareness deficits) are the most common and long-lasting sequelae of TBI. These deficits can inhibit successful school reentry and participation in social activities.

Given the same severity, the long-term functional outcome of children who sustain nonaccidental (inflicted) trauma is worse than that of children with other forms of TBI. Children who incur nonaccidental trauma are typically very young. If developmentally delayed before their brain injury, they are likely to have poorer long-term functional outcomes. The

Table 750.3 Pediatric PSH-AM Pediatric Clinical Feature Scale (PCFS)

Chapter 751

Spinal Cord Injury and Autonomic Dysreflexia Management

Ashlee M. Jaffe and Abigail Case

See Chapter 81.

Individuals from birth to 21 years of age account for 25% of all cases of traumatic **spinal cord injury (SCI)**. Children are more susceptible to lap-belt injuries, upper cervical injuries, SCIs without radiologic abnormalities **(SCIWORA)**, and delayed onset of neurologic deficits, ranging from 30 minutes to 4 days. A population-based study found the epidemiology of pediatric spinal injury in the US varies greatly by age, ethnicity, and payor. Low-income populations are more likely to sustain spinal cord injury due to firearms than other populations.

The most accurate way to evaluate a patient who has sustained an SCI is by performing a standardized physical examination, as endorsed by the International Standards for Neurological and Functional Classification of SCI, recommended for children 6 years of age and older (Fig. 751.1). Life expectancy is related to the neurologic level of injury and the American Spinal Injury Association (ASIA) impairment scale classification.

CLINICAL MANIFESTATIONS

Immediately after an SCI, there is typically a period of **spinal shock** with low tone and absent reflexes. Eventually, signs of an **upper motor neuron** lesion may emerge, including spasticity and involuntary muscle spasms. However, if there is a substantial segment of spinal cord infarction present, patients may have persistent flaccid paralysis.

Children with neurologic levels of injury at T6 or above are at particular risk for interruption and decentralization of the autonomic nervous system. The most common manifestations include bradycardia, hypotension, temperature dysregulation, and, once spinal shock has resolved, **autonomic dysreflexia (AD)**. AD is a sustained sympathetic response as a result of a noxious stimulus *below* the level of injury. Symptoms resulting from AD typically include hypertension, bradycardia, headache, and flushing of the skin above the level of injury, although vague symptoms such as fatigue, irritability, or crying may be the presenting symptoms in younger patients. Noxious stimuli resulting from bladder or rectal distention is a common cause of AD, but there are a large number of other causes that need to be considered (Table 751.1). Children and adolescents with cervical and upper thoracic level SCI have lower baseline blood pressures (BPs) compared with the general population. Therefore caution should be used when referencing age-appropriate BPs because BP elevations of even 20-40 mm Hg above this lower baseline may be suggestive of AD. *Identification and treatment of the noxious stimulus is typically associated with resolution of symptoms without the use of antihypertensive medication.* If necessary, antihypertensive agents with a rapid onset and short duration, such as nifedipine and nitropaste, are advocated to treat elevated BP while the underlying cause is identified (Fig. 751.2). Emergent management of AD is necessary because of the risk of stroke and additional organ damage resulting from sustained hypertension. Consideration of a medical alert bracelet, education of supervising adults, and carrying of an AD emergency reference card is recommended (Fig. 751.3).

Patients with SCI are particularly vulnerable to **deep venous thrombosis** and **pulmonary embolism** because of immobilization of their affected limbs and venous stasis during the first 90 days after an injury. Deep venous thromboses are more common in postpubertal children >14 years old than in younger children. Mechanical prophylaxis (graduated compression stockings and sequential calf compression devices) are recommended for all children with acute SCI; adolescents should also start anticoagulant thromboprophylaxis, especially if additional risk factors like lower extremity fractures are present (unless contraindicated because of the risk of bleeding or prior allergic response). Late-occurring deep venous thrombosis most commonly occurs with prolonged immobilization related to illness or surgery, and prophylactic measures should be continued during these situations as well.

Consequent of SCI, patients often present with varying degrees of bowel and bladder incontinence. After an SCI, the bladder can be areflexic or hyperreflexic, and detrusor sphincter dyssynergia may occur. Clean intermittent catheterization (CIC) of the bladder is typically performed up to 4-6 times/day to prevent urinary retention and vesicoureteral reflux. Constipation can negatively impact the success of a CIC program. Anticholinergic medications may improve bladder storage capacity and prevent urinary incontinence between bladder catheterizations. *Antibiotics are only recommended for symptomatic urinary tract infections; asymptomatic bacteriuria, without vesicoureteral reflux, is generally due to colonization and typically not treated.* If intermittent catheterization is required, one can begin teaching the skills necessary for independent catheterization as early as 3 years of age with a goal of obtaining complete independence by 5-7 years old reflecting the progression toward independent bladder management of the child's able-bodied peers.

Bowel continence programs can be successfully introduced around 2-4 years old. There should be an attempt to distinguish between upper motor neuron (UMN) and lower motor neuron (LMN) bowel dysfunction because the management and bowel agents chosen may vary

Low-income populations are more likely to sustain spinal cord injury due to firearms than other populations.

The most accurate way to evaluate a patient who has sustained an SCI is by performing a standardized physical examination, as endorsed by the International Standards for Neurological and Functional Classification of SCI, recommended for children 6 years of age and older (Fig. 751.1). Life expectancy is related to the neurologic level of injury and the American Spinal Injury Association (ASIA) impairment scale classification.

CLINICAL MANIFESTATIONS

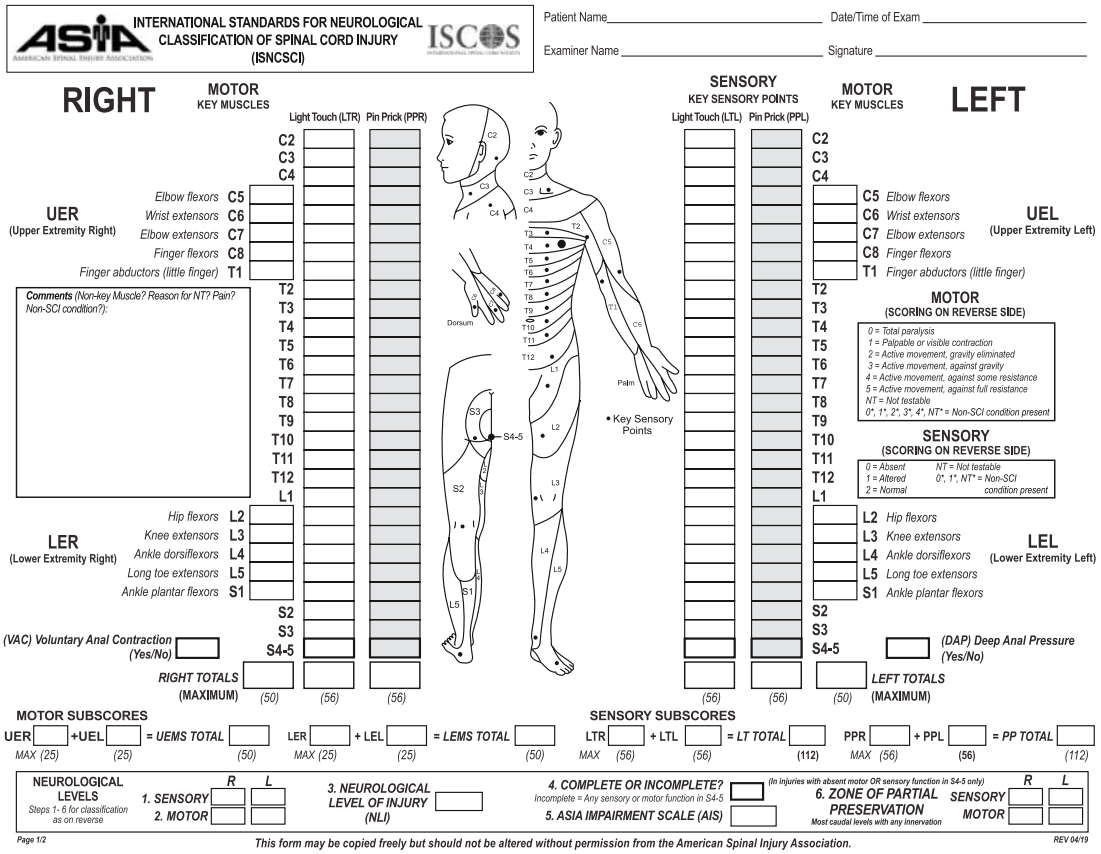
Immediately after an SCI, there is typically a period of **spinal shock** with low tone and absent reflexes. Eventually, signs of an **upper motor neuron** lesion may emerge, including spasticity and involuntary muscle spasms. However, if there is a substantial segment of spinal cord infarction present, patients may have persistent flaccid paralysis.

Children with neurologic levels of injury at T6 or above are at particular risk for interruption and decentralization of the autonomic nervous system. The most common manifestations include bradycardia, hypotension, temperature dysregulation, and, once spinal shock has resolved, **autonomic dysreflexia (AD)**. AD is a sustained sympathetic response as a result of a noxious stimulus *below* the level of injury. Symptoms resulting from AD typically include hypertension, bradycardia, headache, and flushing of the skin above the level of injury, although vague symptoms such as fatigue, irritability, or crying may be the presenting symptoms in younger patients. Noxious stimuli resulting from bladder or rectal distention is a common cause of AD, but there are a large number of other causes that need to be considered (Table 751.1). Children and adolescents with cervical and upper thoracic level SCI have lower baseline blood pressures (BPs) compared with the general population. Therefore caution should be used when referencing age-appropriate BPs because BP elevations of even 20-40 mm Hg above this lower baseline may be suggestive of AD. *Identification and treatment of the noxious stimulus is typically associated with resolution of symptoms without the use of antihypertensive medication.* If necessary, antihypertensive agents with a rapid onset and short duration, such as nifedipine and nitropaste, are advocated to treat elevated BP while the underlying cause is identified (Fig. 751.2). Emergent management of AD is necessary because of the risk of stroke and additional organ damage resulting from sustained hypertension. Consideration of a medical alert bracelet, education of supervising adults, and carrying of an AD emergency reference card is recommended (Fig. 751.3).

Patients with SCI are particularly vulnerable to **deep venous thrombosis** and **pulmonary embolism** because of immobilization of their affected limbs and venous stasis during the first 90 days after an injury. Deep venous thromboses are more common in postpubertal children >14 years old than in younger children. Mechanical prophylaxis (graduated compression stockings and sequential calf compression devices) are recommended for all children with acute SCI; adolescents should also start anticoagulant thromboprophylaxis, especially if additional risk factors like lower extremity fractures are present (unless contraindicated because of the risk of bleeding or prior allergic response). Late-occurring deep venous thrombosis most commonly occurs with prolonged immobilization related to illness or surgery, and prophylactic measures should be continued during these situations as well.

Consequent of SCI, patients often present with varying degrees of bowel and bladder incontinence. After an SCI, the bladder can be areflexic or hyperreflexic, and detrusor sphincter dyssynergia may occur. Clean intermittent catheterization (CIC) of the bladder is typically performed up to 4-6 times/day to prevent urinary retention and vesicoureteral reflux. Constipation can negatively impact the success of a CIC program. Anticholinergic medications may improve bladder storage capacity and prevent urinary incontinence between bladder catheterizations. *Antibiotics are only recommended for symptomatic urinary tract infections; asymptomatic bacteriuria, without vesicoureteral reflux, is generally due to colonization and typically not treated.* If intermittent catheterization is required, one can begin teaching the skills necessary for independent catheterization as early as 3 years of age with a goal of obtaining complete independence by 5-7 years old reflecting the progression toward independent bladder management of the child's able-bodied peers.

Bowel continence programs can be successfully introduced around 2-4 years old. There should be an attempt to distinguish between upper motor neuron (UMN) and lower motor neuron (LMN) bowel dysfunction because the management and bowel agents chosen may vary



Muscle Function Grading

0 = Total paralysis

1 = Palpable or visible contraction

2 = Active movement, full range of motion (ROM) with gravity eliminated

3 = Active movement, full ROM against gravity

4 = Active movement, full ROM against gravity and moderate resistance in a muscle specific position

5 = (Normal) active movement, full ROM against gravity and full resistance in a functional muscle position expected from an otherwise unimpaired person

NT = Not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of > 50% of the normal ROM)

0*, 1*, 2*, 3*, 4*, NT* = Non-SCI condition present [a]

Sensory Grading

0 = Absent **1** = Altered, either decreased/impaired sensation or hypersensitivity

2 = Normal **NT** = Not testable

0*, 1*, NT* = Non-SCI condition present [a]

[a] Note: Abnormal motor and sensory scores should be tagged with a '*' to indicate an impairment due to a non-SCI condition. The non-SCI condition should be explained in the comments box together with information about how the score is rated for classification purposes (at least normal / not normal for classification).

When to Test Non-Key Muscles:

In a patient with an apparent AIS B classification, non-key muscle functions more than 3 levels below the motor level on each side should be tested to most accurately classify the injury (differentiate between AIS B and C).

Movement	Root level
Shoulder: Flexion, extension, adbuction, adduction, internal and external rotation **Elbow:** Supination	C5
Elbow: Pronation **Wrist:** Flexion	C6
Finger: Flexion at proximal joint, extension **Thumb:** Flexion, extension and abduction in plane of thumb	C7
Finger: Flexion at MCP joint **Thumb:** Opposition, adduction and abduction perpendicular to palm	C8
Finger: Abduction of the index finger	T1
Hip: Adduction	L2
Hip: External rotation	L3
Hip: Extension, abduction, internal rotation **Knee:** Flexion **Ankle:** Inversion and eversion **Toe:** MP and IP extension	L4
Hallux and Toe: DIP and PIP flexion and abduction	L5
Hallux: Adduction	S1

ASIA Impairment Scale (AIS)

A = Complete. No sensory or motor function is preserved in the sacral segments S4-5.

B = Sensory Incomplete. Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-5 (light touch or pin prick at S4-5 or deep anal pressure) AND no motor function is preserved more than three levels below the motor level on either side of the body.

C = Motor Incomplete. Motor function is preserved at the most caudal sacral segments for voluntary anal contraction (VAC) OR the patient meets the criteria for sensory incomplete status (sensory function preserved at the most caudal sacral segments S4-5 by LT, PP or DAP), and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body. (This includes key or non-key muscle functions to determine motor incomplete status.) For AIS C – less than half of key muscle functions below the single NLI have a muscle grade ≥ 3.

D = Motor Incomplete. Motor incomplete status as defined above, with at least half (half or more) of key muscle functions below the single NLI having a muscle grade ≥ 3.

E = Normal. If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

Using ND: To document the sensory, motor and NLI levels, the ASIA Impairment Scale grade, and/or the zone of partial preservation (ZPP) when they are unable to be determined based on the examination results.

AMERICAN SPINAL INJURY ASSOCIATION

INTERNATIONAL STANDARDS FOR NEUROLOGICAL CLASSIFICATION OF SPINAL CORD INJURY

ISCOS

Steps in Classification

The following order is recommended for determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.
The sensory level is the most caudal, intact dermatome for both pin prick and light touch sensation.

2. Determine motor levels for right and left sides.
Defined by the lowest key muscle function that has a grade of at least 3 (on supine testing), providing the key muscle functions represented by segments above that level are judged to be intact (graded as a 5).
Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.

3. Determine the neurological level of injury (NLI).
This refers to the most caudal segment of the cord with intact sensation and antigravity (3 or more) muscle function strength, provided that there is normal (intact) sensory and motor function rostrally respectively.
The NLI is the most cephalad of the sensory and motor levels determined in steps 1 and 2.

4. Determine whether the injury is Complete or Incomplete.
(i.e. absence or presence of sacral sparing)
*If voluntary anal contraction = **No** AND all S4-5 sensory scores = **0** AND deep anal pressure = **No**, then injury is **Complete**. Otherwise, injury is **Incomplete**.*

5. Determine ASIA Impairment Scale (AIS) Grade.
Is injury Complete? If YES, AIS=A
NO ↓
Is injury Motor Complete? If YES, AIS=B
NO ↓ (No=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)

Are at least half (half or more) of the key muscles below the neurological level of injury graded 3 or better?
NO ↓ AIS=C **YES ↓ AIS=D**

If sensation and motor function is normal in all segments, AIS=E
Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact and the ASIA Impairment Scale does not apply.

6. Determine the zone of partial preservation (ZPP).
The ZPP is used only in injuries with absent motor (no VAC) OR sensory function (no DAP, no LT and no PP sensation) in the lowest sacral segments S4-5, and refers to those dermatomes and myotomes caudal to the sensory and motor levels that remain partially innervated. With sacral sparing of sensory function, the sensory ZPP is not applicable and therefore "NA" is recorded in the block of the worksheet. Accordingly, if VAC is present, the motor ZPP is not applicable and is noted as "NA".

Table 751.1 Potential Etiologies of Noxious Stimuli Causing Autonomic Dysreflexia

URINARY SYSTEM
• Bladder distention
• Bladder or kidney stones
• Blocked/kinked catheter
• Detrusor sphincter dyssynergia
• Urinary tract infection
• Urologic instrumentation
• Shock wave lithotripsy
GASTROINTESTINAL SYSTEM
• Bowel distention
• Bowel impaction
• Gallstones
• Appendicitis
• Gastric ulcers
• Gastritis
• Gastrointestinal instrumentation
• Hemorrhoids
INTEGUMENTARY SYSTEM
• Constrictive clothing, shoes, or orthotics
• Blisters
• Burns, sunburn, or frostbite
• Ingrown toenail
• Insect bites
• Pressure ulcers
MUSCULOSKELETAL SYSTEM
• Fractures
• Heterotopic ossification
• Functional electrical stimulation
REPRODUCTIVE SYSTEM—MALE
• Epididymitis
• Scrotal compression (sitting on scrotum)
• Sexual intercourse
• Sexually transmitted infections
REPRODUCTIVE SYSTEM—FEMALE
• Menstruation
• Pregnancy, especially labor and delivery
• Vaginitis
• Sexual intercourse
• Sexually transmitted infections
HEMATOLOGIC SYSTEM
• Deep vein thrombosis
• Pulmonary embolus
OTHER SYSTEMIC CAUSES
• Boosting (an episode of autonomic dysreflexia intentionally caused by an athlete with spinal cord injury in an attempt to enhance physical performance)
• Excessive alcohol intake
• Excessive caffeine or diuretic intake
• Over-the-counter or prescribed stimulants
• Substance abuse

From Consortium for Spinal Cord Medicine: Acute management of autonomic dysreflexia: individuals with spinal cord injury presenting to health-care facilities, Washington, DC, 2001, Paralyzed Veterans of America, 10–11.

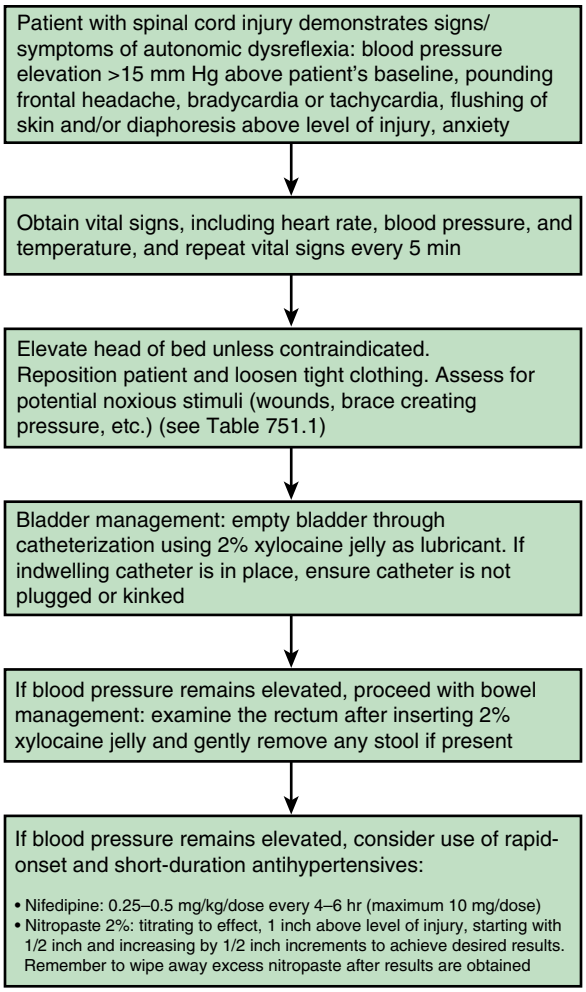

Fig. 751.2 Algorithm for the management of autonomic dysreflexia.

significantly. Lesions at or proximal to the conus medullaris typically result in UMN bowel dysfunction, whereas lesions distal to the conus typically result in LMN bowel dysfunction characterized by an areflexic bowel lacking peristalsis. Management of **bowel incontinence** requires the use of diet modifications, bowel medications, and planned evacuations. Emptying is facilitated by use of the gastrocolic reflex, digital stimulation, suppositories, and enemas in those with UMN bowel dysfunction. Individuals with LMN bowel dysfunction often require manual removal because peristalsis and reflexes are not intact.

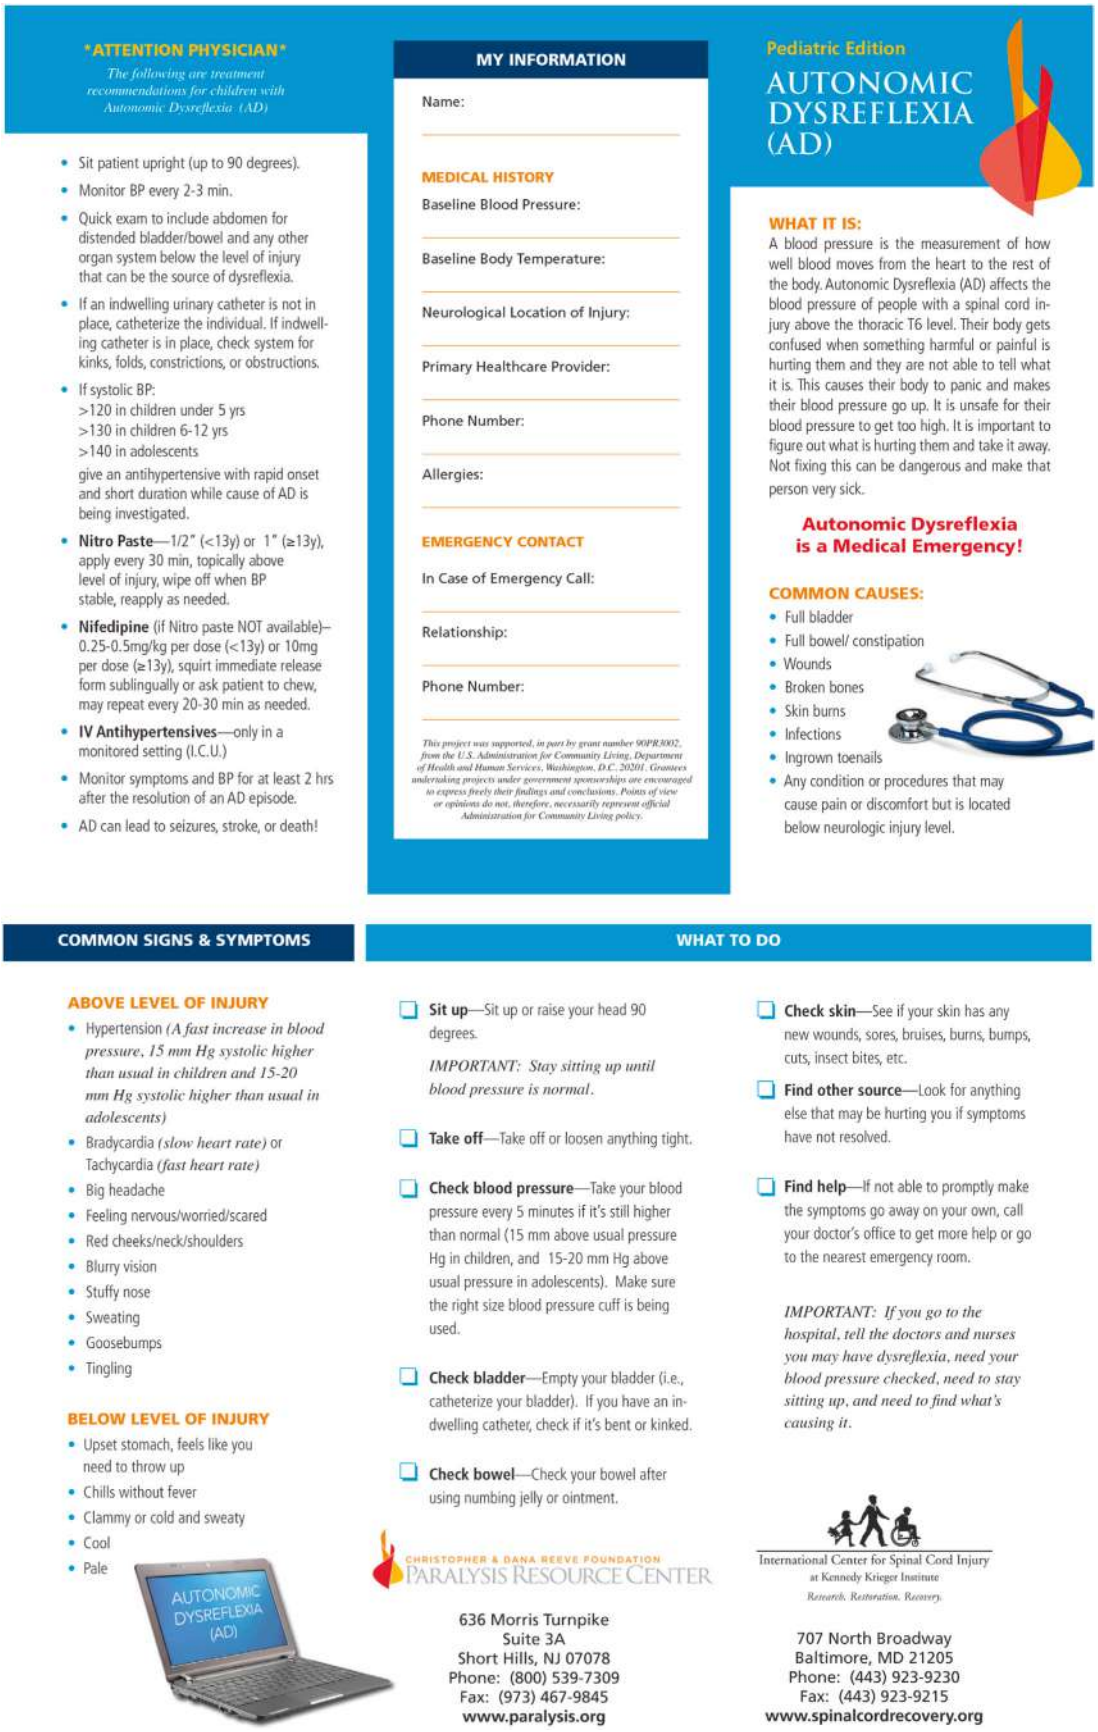
Individuals with SCI have increased risk for dysphagia, delayed gastric emptying, ileus, gastric ulcerations, pancreatitis, and superior mesenteric artery syndrome. Presentation of an acute abdomen in SCI is challenging to identify because a patient may be incapable of feeling the pain intensity typically associated with an intraabdominal disorder. As a result, an acute abdomen may be manifested by nonspecific signs and symptoms, such as vomiting, poorly localized dull pain, restlessness, fever, and leukocytosis.

Frequent monitoring for **skin breakdown** and **pressure ulcers** is necessary, both acutely as well as lifelong. Pressure ulcers may heal more slowly in patients with SCI and can significantly impact function. Common locations include the occiput, elbows, sacrum, ischium, and heels. Devices such as halo vests and splints increase the risk of developing a pressure sore. Frequent inspection and repositioning for pressure relief when in bed and when sitting are important measures to minimize the risk of pressure ulcer development.

Depending on the level of the lesion, paralysis of the diaphragm or intercostal and abdominal muscles can result in restrictive ventilatory impairment and ineffective coughing. Respiratory muscle training, abdominal binders, and noninvasive ventilation and airway clearance devices, such as the insufflator–exsufflator cough assist device, should be considered in select patients.

Spasticity typically increases with noxious stimulation and can interfere with sleep, comfort, positioning, and care (see Chapter 752). Untreated spasticity can lead to contracture development and functional limitations. Management includes pharmacologic therapy, stretching, splinting, and positioning to reduce tone. Focal spasticity can be treated with chemodenervation by injecting botulinum toxin into select hypertonic muscles or phenol perineurally. Intrathecal baclofen may be an option for severe generalized spasticity or spasticity that is predominately in the lower extremities.

Increased bone resorption occurs as a result of prolonged immobilization. If excessive calcium is not adequately excreted by the kidneys, insidious onset of abdominal pain, nausea, vomiting, lethargy, polydipsia, polyuria, and behavior changes may occur. This **immobilization**



ATTENTION PHYSICIAN

The following are treatment recommendations for children with Autonomic Dysreflexia (AD)

- Sit patient upright (up to 90 degrees).
- Monitor BP every 2-3 min.
- Quick exam to include abdomen for distended bladder/bowel and any other organ system below the level of injury that can be the source of dysreflexia.
- If an indwelling urinary catheter is not in place, catheterize the individual. If indwelling catheter is in place, check system for kinks, folds, constrictions, or obstructions.
- If systolic BP:
  >120 in children under 5 yrs
  >130 in children 6-12 yrs
  >140 in adolescents
  give an antihypertensive with rapid onset and short duration while cause of AD is being investigated.
- **Nitro Paste**—1/2" (<13y) or 1" (≥13y), apply every 30 min, topically above level of injury, wipe off when BP stable, reapply as needed.
- **Nifedipine** (if Nitro paste NOT available)–0.25-0.5mg/kg per dose (<13y) or 10mg per dose (≥13y), squirt immediate release form sublingually or ask patient to chew, may repeat every 20-30 min as needed.
- **IV Antihypertensives**—only in a monitored setting (I.C.U.)
- Monitor symptoms and BP for at least 2 hrs after the resolution of an AD episode.
- AD can lead to seizures, stroke, or death!

Pediatric Edition

AUTONOMIC DYSREFLEXIA (AD)

WHAT IT IS:

A blood pressure is the measurement of how well blood moves from the heart to the rest of the body. Autonomic Dysreflexia (AD) affects the blood pressure of people with a spinal cord injury above the thoracic T6 level. Their body gets confused when something harmful or painful is hurting them and they are not able to tell what it is. This causes their body to panic and makes their blood pressure go up. It is unsafe for their blood pressure to get too high. It is important to figure out what is hurting them and take it away. Not fixing this can be dangerous and make that person very sick.

Autonomic Dysreflexia is a Medical Emergency!

COMMON CAUSES:

- Full bladder
- Full bowel/ constipation
- Wounds
- Broken bones
- Skin burns
- Infections
- Ingrown toenails
- Any condition or procedures that may cause pain or discomfort but is located below neurologic injury level.

COMMON SIGNS & SYMPTOMS

ABOVE LEVEL OF INJURY

- Hypertension *(A fast increase in blood pressure, 15 mm Hg systolic higher than usual in children and 15-20 mm Hg systolic higher than usual in adolescents)*
- Bradycardia *(slow heart rate)* or Tachycardia *(fast heart rate)*
- Big headache
- Feeling nervous/worried/scared
- Red cheeks/neck/shoulders
- Blurry vision
- Stuffy nose
- Sweating
- Goosebumps
- Tingling

BELOW LEVEL OF INJURY

- Upset stomach, feels like you need to throw up
- Chills without fever
- Clammy or cold and sweaty
- Cool
- Pale

WHAT TO DO

- ☐ **Sit up**—Sit up or raise your head 90 degrees.
  IMPORTANT: Stay sitting up until blood pressure is normal.
- ☐ **Take off**—Take off or loosen anything tight.
- ☐ **Check blood pressure**—Take your blood pressure every 5 minutes if it's still higher than normal (15 mm above usual pressure Hg in children, and 15-20 mm Hg above usual pressure in adolescents). Make sure the right size blood pressure cuff is being used.
- ☐ **Check bladder**—Empty your bladder (i.e., catheterize your bladder). If you have an indwelling catheter, check if it's bent or kinked.
- ☐ **Check bowel**—Check your bowel after using numbing jelly or ointment.
- ☐ **Check skin**—See if your skin has any new wounds, sores, bruises, burns, bumps, cuts, insect bites, etc.
- ☐ **Find other source**—Look for anything else that may be hurting you if symptoms have not resolved.
- ☐ **Find help**—If not able to promptly make the symptoms go away on your own, call your doctor's office to get more help or go to the nearest emergency room.

IMPORTANT: If you go to the hospital, tell the doctors and nurses you may have dysreflexia, need your blood pressure checked, need to stay sitting up, and need to find what's causing it.

hypercalcemia is managed with IV normal saline and the bisphosphonate pamidronate. Failure to manage the immobilization hypercalcemia may result in nephrocalcinosis, urolithiasis, or renal failure. Loss of bone mineral density begins immediately after an SCI occurs and osteopenia plateaus 6-12 months later. This may result in **pathologic fractures,** with the most common sites of fracture including the supracondylar region of the femur and the proximal tibia. Precautions are necessary because fractures may occur with minor trauma, range of motion exercises, and gait training. Treatment should include the use of removable splints or casts that are well padded over bony prominences to prevent skin breakdown, which is more likely with insensate skin under the cast. Prevention through progressive weight bearing, if feasible and safe, and calcium and vitamin D supplementation is encouraged.

The risk of development of spinal deformities and scoliosis is about 25% in patients sustaining SCI both before and during puberty, and some of these children will require surgical correction. Because of the high incidence of scoliosis in patients younger than 15 at the time of their injury, radiographs of the thoracolumbar-sacral spine should generally be obtained every 6 months before skeletal maturity and every 12 months thereafter. Children who sustain injuries before puberty are also susceptible to hip dislocation and require periodic screening for this condition. Although neurologic **heterotopic ossification** is less prevalent in children compared with adults, it may occur on average about 4 months, but up to 14 months, after the initial injury. The most common site of heterotopic ossification is the hip, but it may also occur in the knee, elbow, and shoulder.

Children and adolescents with SCI are at risk for decreased muscle mass, insulin resistance, decreased glucose transport, dyslipidemia, obesity, and decreased bone health as they age. Long term, patients with SCI have a 3-5-fold greater odds of cardiovascular disease compared with able-bodied individuals. Nutrition education and monitoring are important for decreasing long-term morbidities. Promoting exercise and physical activity and fitness are important for well-being. Youth with SCI may develop latex allergy thought to be a result of repeated, early exposure to latex products; thus a latex-free environment and degree of suspicion for allergies to bananas, kiwis, avocados, or chestnuts is advised.

Psychologic adjustment to SCI is influenced by the developmental age at the time of injury. SCI will impact the child's psychosocial development, so adjustment should be monitored closely. Long-term outcomes related to coping, depression, and anxiety are better in adults who sustained their injury during childhood, compared with those who sustained their injuries in adulthood. Positive coping strategies and strong social supports are associated with greater social participation. Education regarding sexual development and function with SCI injury should be provided.

PROGNOSIS

Prognosis for functional recovery after an SCI depends on the neurologic level of injury and the level of completeness. Examination at least 72 hours after injury has been determined to be a better indicator of the prognosis than earlier examinations. Reexamination after recovery from spinal shock provides additional prognostic information. It is prudent for those determining and communicating the diagnosis to understand the limitations of the anorectal examinations, and thus completeness of injury, unique to children. Those individuals with an initial incomplete injury have an increased likelihood of eventual neurologic recovery. The neurologic level of injury can be helpful in determining the level of independence with functional activities (Table 751.2). The use of technology in rehabilitation encourages the pediatric patient to become more engaged in their own care and advance their

Chapter 752

Spasticity

Joyce L. Oleszek and Loren T. Davidson

Spasticity is a component of the upper motor neuron syndrome characterized by velocity-dependent resistance to passive range of motion, resulting in tonic stretch reflexes and accompanied by exaggerated tendon jerks. Spasticity management is determining what degree of spasticity may be tolerable and of functional benefit versus detrimental.

When devising a treatment plan, both the positive and negative effects of spasticity on function must be considered. Treatment should maximize function, independence, comfort, and quality of life while minimizing sedation and adverse effects. Management strategies including systemic medications, injections, and surgery are reviewed.

SYSTEMIC MEDICATIONS

Systemic medications are used as a treatment for generalized spasticity (Table 752.1). Although efficacy of certain antispasmodics has been demonstrated, their use should be contingent on functional benefit because adverse effects are quite common. Frequently used medications include baclofen, benzodiazepines, dantrolene sodium, tizanidine, clonidine, and trihexyphenidyl.

GABAergic Medications

γ-Aminobutyric acid (GABA) is an inhibitory neurotransmitter of the central nervous system. The two most relevant GABA receptors for the purposes of pharmacologic management of spasticity are $GABA_A$ and $GABA_B$. **Benzodiazepines** exert their effect by increasing the affinity of GABA for the $GABA_A$ receptor. This results in presynaptic inhibition and a net inhibitory effect at both spinal and supraspinal levels. Of the benzodiazepines, diazepam is a commonly used medication to treat spasticity because of its long half-life and need for less frequent administration. In children younger than 2 years of age, clonazepam is a good option because of the availability of a liquid formulation and dosing guidelines. Sedation and cognitive slowing limit the usefulness of this class of medications in children. However, benzodiazepines can be helpful for dystonic storms or disturbed sleep in children with cerebral palsy (CP). The use of benzodiazepines may lead to physiologic dependence; thus abrupt discontinuation should be avoided to prevent withdrawal.

Baclofen is a $GABA_B$ agonist and a preferred agent in the treatment of spasticity of spinal origin. Baclofen exerts an inhibitory effect on both monosynaptic and polysynaptic spinal reflexes, but its supraspinal receptor sites can result in sedation as is common to all GABAergic medications. Daytime dosing of oral baclofen is often better tolerated than benzodiazepines with regard to sedation. Intrathecal administration of baclofen via an intrathecal baclofen (ITB) pump (see later) allows greater selectivity of spasticity reduction while minimizing adverse cognitive effects. Oral baclofen is considered a first-line medication for the management of dystonia in CP with common indications including pain or difficulty sleeping associated with dystonia. Abrupt cessation of oral or ITB baclofen must be avoided because of withdrawal potential.

α_2-Adrenergic Agents

Clonidine and **tizanidine** are examples of centrally acting α_2-adrenergic agonists that decrease spasticity and have an antinociceptive effect. Clonidine is used more frequently as an antihypertensive. Clonidine exerts its effect on spasticity via both presynaptic inhibition of sensory afferents as well as release of glutamate at the level of the spinal cord. In comparison to clonidine, tizanidine has less-potent hemodynamic effects, which is desirable when used primarily for spasticity reduction. However, tizanidine is extensively metabolized by the liver, so hepatic impairment may have a significant effect on its pharmacokinetics. Although clonidine and tizanidine are used widely as antispasmodics in practice, there is limited evidence for their use in reducing spasticity in children with CP. Tizanidine's antispasticity effect has been demonstrated in adults with multiple sclerosis and spinal cord injury. Clonidine has been shown to be effective for disturbed sleep associated with severe hypertonia. The adverse effect profile of these agents can limit their use.

Peripherally Acting Calcium Blockers

Dantrolene sodium works at the level of skeletal muscle to block calcium release from the sarcoplasmic reticulum. Despite its peripheral site of action, dantrolene may induce sedation, although to a lesser degree than other centrally acting agents. A few small studies have shown that dantrolene decreases clonus and spasticity but can also decrease strength. Dantrolene is often well tolerated in children, but its risk of hepatotoxicity requires monitoring of liver function tests. Hepatotoxicity risk increases with age, increasing dose, and female gender (see Table 752.1).

INJECTION MANAGEMENT

Injection management of spasticity should be considered when spasticity causes significant functional impairments that are refractory to more conservative options. Combining treatment options such as injections and systemic medications can be very effective.

Botulinum toxin (BoNT) and phenol injections are used to treat localized spasticity. OnabotulinumtoxinA (Botox) and AbobotulinumtoxinA (Dysport) have obtained U.S. Food and Drug Administration (FDA) approval for both upper and lower limb spasticity in pediatrics. RimabotulinumtoxinB (Myobloc) and IncobotulinumtoxinA (Xeomin) both have FDA approval but neither have a pediatric indication. BoNT is derived from the bacteria *Clostridium botulinum,* and there are seven immunologically distinct serotypes designated A through G. Its mechanism of action involves a light chain protein binding to synaptobrevin at the neuromuscular junction, inhibiting vesicles from anchoring to the cell membrane and preventing acetylcholine release from the presynaptic membrane. This interferes with nerve impulse transmission and results in weakness of the muscle injected. Onset of action is within 2 weeks of administration, duration is 3-6 months, and effects wane as the neuromuscular junction reestablishes its original function. Injections should be administered no more frequently than every 3 months to reduce neutralizing antibody formation, which occurs in 1–2% of treated individuals. BoNT-A is a safe and effective treatment for spasticity in the upper and lower extremities in children with CP, but the effects on long-term functional improvement with repeated injections are less well known. The combination of BoNT-A injections to the gastrocnemius muscles and serial casting has been shown to improve ankle range of motion and gait. BoNT-A can also improve ease of care and comfort in nonambulatory children with CP. The most common adverse events (AEs) include localized pain and weakness, unsteadiness and increased falls, fatigue, urinary incontinence, and dysphagia. Systemic AEs

independence, which is correlated with higher quality of life. Common technology includes therapeutic and functional stimulation, EMG biofeedback and EMG-triggered stimulation, assistive technology for computer access, and implanted functional electrical stimulation system including phrenic nerve stimulators.

Chapter 752

Spasticity

Joyce L. Oleszek and Loren T. Davidson

Spasticity is a component of the upper motor neuron syndrome characterized by velocity-dependent resistance to passive range of motion, resulting in tonic stretch reflexes and accompanied by exaggerated tendon jerks. Spasticity management is determining what degree of spasticity may be tolerable and of functional benefit versus detrimental.

When devising a treatment plan, both the positive and negative effects of spasticity on function must be considered. Treatment should maximize function, independence, comfort, and quality of life while minimizing sedation and adverse effects. Management strategies including systemic medications, injections, and surgery are reviewed.

SYSTEMIC MEDICATIONS

Systemic medications are used as a treatment for generalized spasticity (Table 752.1). Although efficacy of certain antispasmodics has been demonstrated, their use should be contingent on functional benefit because adverse effects are quite common. Frequently used medications include baclofen, benzodiazepines, dantrolene sodium, tizanidine, clonidine, and trihexyphenidyl.

GABAergic Medications

γ-Aminobutyric acid (GABA) is an inhibitory neurotransmitter of the central nervous system. The two most relevant GABA receptors for the purposes of pharmacologic management of spasticity are $GABA_A$ and $GABA_B$. **Benzodiazepines** exert their effect by increasing the affinity of GABA for the $GABA_A$ receptor. This results in presynaptic inhibition and a net inhibitory effect at both spinal and supraspinal levels. Of the benzodiazepines, diazepam is a commonly used medication to treat spasticity because of its long half-life and need for less frequent administration. In children younger than 2 years of age, clonazepam is a good option because of the availability of a liquid formulation and dosing guidelines. Sedation and cognitive slowing limit the usefulness of this class of medications in children. However, benzodiazepines can be helpful for dystonic storms or disturbed sleep in children with cerebral palsy (CP). The use of benzodiazepines may lead to physiologic dependence; thus abrupt discontinuation should be avoided to prevent withdrawal.

Baclofen is a $GABA_B$ agonist and a preferred agent in the treatment of spasticity of spinal origin. Baclofen exerts an inhibitory effect on both monosynaptic and polysynaptic spinal reflexes, but its supraspinal receptor sites can result in sedation as is common to all GABAergic medications. Daytime dosing of oral baclofen is often better tolerated than benzodiazepines with regard to sedation. Intrathecal administration of baclofen via an intrathecal baclofen (ITB) pump (see later) allows greater selectivity of spasticity reduction while minimizing adverse cognitive effects. Oral baclofen is considered a first-line medication for the management of dystonia in CP with common indications including pain or difficulty sleeping associated with dystonia. Abrupt cessation of oral or ITB baclofen must be avoided because of withdrawal potential.

α_2-Adrenergic Agents

Clonidine and **tizanidine** are examples of centrally acting α_2-adrenergic agonists that decrease spasticity and have an antinociceptive effect. Clonidine is used more frequently as an antihypertensive. Clonidine exerts its effect on spasticity via both presynaptic inhibition of sensory afferents as well as release of glutamate at the level of the spinal cord. In comparison to clonidine, tizanidine has less-potent hemodynamic effects, which is desirable when used primarily for spasticity reduction. However, tizanidine is extensively metabolized by the liver, so hepatic impairment may have a significant effect on its pharmacokinetics. Although clonidine and tizanidine are used widely as antispasmodics in practice, there is limited evidence for their use in reducing spasticity in children with CP. Tizanidine's antispasticity effect has been demonstrated in adults with multiple sclerosis and spinal cord injury. Clonidine has been shown to be effective for disturbed sleep associated with severe hypertonia. The adverse effect profile of these agents can limit their use.

Peripherally Acting Calcium Blockers

Dantrolene sodium works at the level of skeletal muscle to block calcium release from the sarcoplasmic reticulum. Despite its peripheral site of action, dantrolene may induce sedation, although to a lesser degree than other centrally acting agents. A few small studies have shown that dantrolene decreases clonus and spasticity but can also decrease strength. Dantrolene is often well tolerated in children, but its risk of hepatotoxicity requires monitoring of liver function tests. Hepatotoxicity risk increases with age, increasing dose, and female gender (see Table 752.1).

INJECTION MANAGEMENT

Injection management of spasticity should be considered when spasticity causes significant functional impairments that are refractory to more conservative options. Combining treatment options such as injections and systemic medications can be very effective.

Botulinum toxin (BoNT) and phenol injections are used to treat localized spasticity. OnabotulinumtoxinA (Botox) and AbobotulinumtoxinA (Dysport) have obtained U.S. Food and Drug Administration (FDA) approval for both upper and lower limb spasticity in pediatrics. RimabotulinumtoxinB (Myobloc) and IncobotulinumtoxinA (Xeomin) both have FDA approval but neither have a pediatric indication. BoNT is derived from the bacteria *Clostridium botulinum,* and there are seven immunologically distinct serotypes designated A through G. Its mechanism of action involves a light chain protein binding to synaptobrevin at the neuromuscular junction, inhibiting vesicles from anchoring to the cell membrane and preventing acetylcholine release from the presynaptic membrane. This interferes with nerve impulse transmission and results in weakness of the muscle injected. Onset of action is within 2 weeks of administration, duration is 3-6 months, and effects wane as the neuromuscular junction reestablishes its original function. Injections should be administered no more frequently than every 3 months to reduce neutralizing antibody formation, which occurs in 1–2% of treated individuals. BoNT-A is a safe and effective treatment for spasticity in the upper and lower extremities in children with CP, but the effects on long-term functional improvement with repeated injections are less well known. The combination of BoNT-A injections to the gastrocnemius muscles and serial casting has been shown to improve ankle range of motion and gait. BoNT-A can also improve ease of care and comfort in nonambulatory children with CP. The most common adverse events (AEs) include localized pain and weakness, unsteadiness and increased falls, fatigue, urinary incontinence, and dysphagia. Systemic AEs

Table 752.1 Dosing Guidelines, Pharmacologic Actions, and Adverse Event Profile of Commonly Prescribed Oral Antispasmodic Medications for Children

MEDICATION/DOSING GUIDELINES	PHARMACOLOGIC ACTIONS	ADVERSE REACTIONS/PRECAUTIONS
BACLOFEN 0.125-1 mg/kg/day *2-7 yr:* 2.5-10 mg tid-qid (10-40 mg/day) *8-12 yr:* 5 mg-15 mg tid-qid (15-60 mg/day) *12-16 yr:* 5-20 mg tid-qid (20-80 mg/day) Note: Caution advised with renal impairment; consider reducing dose.	• Centrally acting, structural analog of GABA • Binds to $GABA_B$ receptors causing presynaptic inhibition of mono/polysynaptic spinal reflexes • Rapid absorption, blood level peaks in 1 hr, half-life 5.5 hr. • Renal excretion (70–80% unchanged) • Hepatic excretion (15%)	• CNS depression (sedation, fatigue) • Nausea • Headache • Dizziness • Confusion • Euphoria • Hallucinations • Hypotonia • Ataxia • Paraesthesias Note: Abrupt withdrawal may cause seizures, hallucinations, rebound muscle spasms, and hyperpyrexia.
DIAZEPAM 0.12-0.8 mg/kg/day *6 mo-12 yr:* 0.12-0.8 mg/kg/day PO divided q 6-8h *>12 yr:* 2-10 mg PO bid-qid Note: Starting a qhs dose only or proportionately larger dose at bedtime may limit excessive daytime sedation.	• Centrally acting, binds to $GABA_A$ receptors mediating presynaptic inhibition in brainstem reticular formation and spinal polysynaptic pathways • Rapid absorption, blood level peaks in 1 hr, with half-life of 30-60 hr	• CNS depression (sedation, impaired memory, and impaired attention) • Ataxia • Dependence/potential for substance abuse/overdose • Withdrawal syndrome (including anxiety, agitation, irritability, tremor, muscle twitching, nausea, insomnia, seizures, hyperpyrexia) • Increased potential for adverse effects with low albumin levels due to being 98% protein bound
DANTROLENE SODIUM 3-12 mg/kg /day *>5 yr:* 6-8 mg/kg/d PO divided bid-qid Start 0.5 mg/kg qd-bid for 7 days, then 0.5 mg/kg tid for 7 days, then 1 mg/kg tid for 7 days, then 2 mg/kg tid to a maximum of 12 mg/kg/d or 400 mg/day.	• Peripheral action, blocking release of calcium from sarcoplasmic reticulum with uncoupling of nerve excitation and skeletal muscle contraction • Blood level peaks in 3-6 hr (active metabolite 4-8 hr), half-life of approx. 15 hr	• Malaise • Fatigue • Nausea • Vomiting • Diarrhea • Muscle weakness with high dose **Note:** Hepatotoxicity (baseline liver function tests MUST be checked before starting dantrolene, tested weekly during dose titration and regularly every 1-2 months thereafter). Drug *should be discontinued promptly* if liver enzymes become elevated.
TIZANIDINE *<10 yr:* Initiate 1 mg orally at bedtime initially, increasing to 0.3-0.5 mg/kg in 4 divided doses *>10 yr:* Commence 2 mg orally at bedtime initially, increased according to response, maximum 24 mg/day in 3-4 divided doses	• Centrally acting, $alpha_2$ adrenoceptor agonist activity at both spinal and supraspinal sites. Prevents release of excitatory amino acids, facilitating presynaptic inhibition • Good oral absorption, blood level peaks in 1-2 hr, half-life of 2.5 hr	• Dry mouth • Drowsiness • Headache • Dizziness • Insomnia • Anxiety • Aggression • Mood swings • Visual hallucinations • Risk of hypotension (although 10 times less anti-hypertensive potency than clonidine) • Nausea/vomiting • Constipation • Liver function tests should be monitored; baseline and 1 month after maintenance dose achieved.
CLONIDINE 0.025-0.1 mg/day in 2-3 divided doses.	• Centrally acting, mixed alpha adrenoceptor agonist with predominant alpha-2 activity causing membrane hyperpolarization at multiple sites in brain, brainstem, and dorsal horns of spinal cord. • Rapidly absorbed orally, blood level peaks in 1-1½ hr, half-life of 6-20 hr.	• Drowsiness • Dry mouth • Bradycardia • Orthostatic hypotension • Abrupt cessation may result in rebound hypertension.

can occur in up to 3.6% of children with CP receiving BoNT-A, and those with a history of dysphagia and/or aspiration pneumonia are at increased risk. The FDA requires black box labeling on BoNT products, cautioning of a rare but potentially life-threatening complication of BoNT effects spreading beyond the injection site. Co-administration of BoNT and other agents interfering with neuromuscular transmission, such as aminoglycosides and curare-like agents, should be performed with caution because the effect of the toxin may be potentiated.

Phenol neurolysis can be used in combination with BoNT injections to allow treatment of more affected muscles while remaining within the safe dose range of BoNT. Phenol causes nonselective denaturing of proteins upon exposure to the nerve, thereby causing nerve injury by precipitating and dehydrating the protoplasm. This, in turn, interferes with nerve conduction and impairs innervation to muscles. Phenol injections are typically used to target nerves to large proximal muscles (musculocutaneous, obturator and sciatic nerves), and the duration of clinical effect may be longer than BoNT. There is limited evidence on the use of phenol in children with CP, but a few small studies show safety and efficacy. Phenol injection of the anterior branch of the obturator nerve in children with CP has been found to be safe and effective. AEs include pain, swelling and inflammation, and dysesthesias. The low cost of phenol incurs a significant advantage over BoNT, but the need for electrical stimulation or ultrasound guidance and general anesthesia may negate this benefit.

SURGICAL MANAGEMENT

Intrathecal baclofen (ITB) is approved to treat spasticity of cerebral origin. ITB is delivered to the intrathecal space by a catheter connected to a subfascially implanted pump. This mechanism of delivery produces much higher local concentrations in the cerebrospinal fluid at a fraction of the equivalent systemic dose of baclofen, thereby minimizing the CNS depressive effects. Catheter tips are typically positioned at C5-T2 but can be placed intraventricularly for severe dystonia. ITB pumps require refills at 2-6–month intervals depending on dose rate and pump size and need to be replaced every 5-7 years for end of battery life. The frequent maintenance required can be prohibitive to some families. Before ITB pump placement, a single bolus dose of baclofen can be delivered via lumbar puncture to evaluate responsiveness and impact on functional abilities. ITB is effective in reducing spasticity and dystonia in CP and may improve the ease of care and quality of life of children with CP. Continuous ITB treatment is superior to placebo on attainment of individual treatment goals in children with Gross Motor Function Classification System (GMFCS) level IV and V CP (Fig. 752.1). Serious AEs can occur with ITB. One 14-year study of 430 patients found at least one complication in 25% of patients: infection in 9.3%, CSF leak in 4.9%, catheter problem in 15.1%, and a pump-related problem in 1%. Electromagnetic interference and MRI may cause transient operational changes to the ITB pump and changes to the flow rate; thus the pump should be interrogated by a programmer after MRI as a precaution. **ITB withdrawal** is a medical emergency and needs to be identified early and managed aggressively. Sequelae can include high fever, altered mental status, exaggerated rebound spasticity, and muscle rigidity that, in rare cases, can advance to rhabdomyolysis, multiple organ–system failure, and death. Caregivers need to be educated on the early symptoms of baclofen withdrawal. Prevention of abrupt discontinuation of ITB requires careful attention to programming and monitoring of the infusion system, refill scheduling, and pump alarms.

Selective dorsal rhizotomy (SDR) is a surgical procedure that decreases muscle spasticity by sectioning hyperexcitatory sensory nerve rootlets that innervate the lower extremities. The surgical technique involves single or multilevel osteoplastic laminectomies exposing the L2-S1 nerve roots, and sensory rootlets are chosen for sectioning using intraoperative electromyography. The most ideal candidates are thought to be children 3-8 years of age with spastic diplegic CP, minimal upper limb involvement, good selective motor control and strength with the ability to rise from the floor independently, minimal contractures, and good cognitive skills.

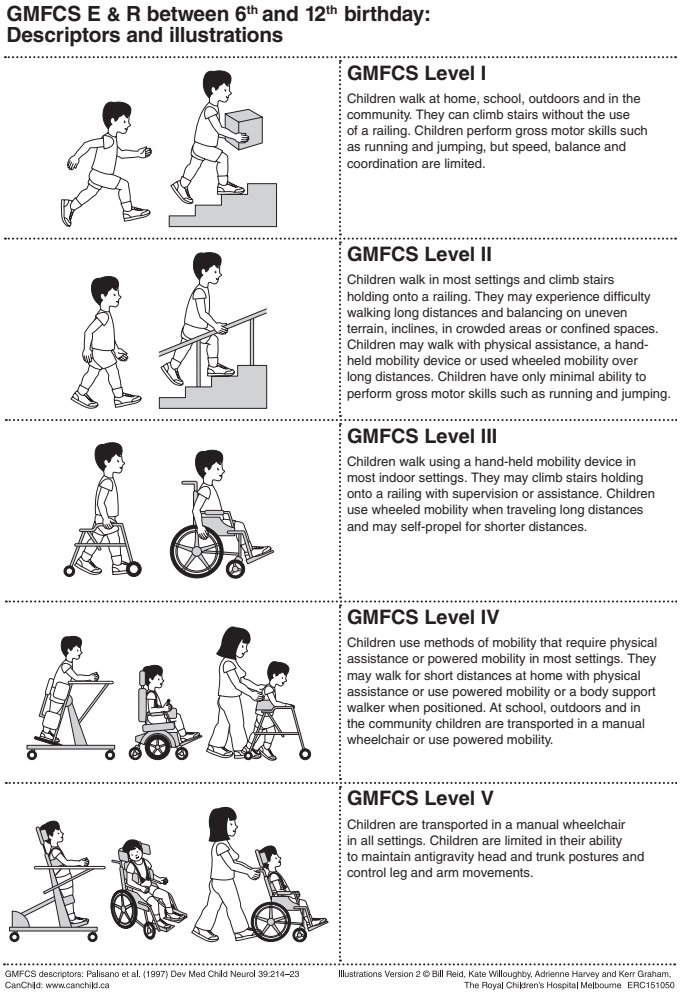

Fig. 752.1 Gross Motor Function Classification System Expanded and Revised (GMFCS E & R). *(Descriptors: ©Palisano et al, 1997 – Dev Med Child Neurol., 39:214-23 (CanChild: www.canchild.ca); Illustrations Version 2 © Bill Reid, Kate Willoughby, Adrienne Harvey and Kerr Graham, The Royal Children's Hospital Melbourne)*

Ambulatory children with CP have better function and quality of life in the 24 months after SDR. A prospective gait analysis study in adults with CP 20 years after SDR showed improved locomotor function with increased gait speed. SDRs are performed to a lesser extent in children with spastic quadriplegic CP, and goals in this population are often to decrease lower limb spasticity while improving comfort, care, and positioning. A study in nonambulatory children with severe CP showed improvements in daily care and comfort at a mean follow-up of 19 months after SDR, although unmasking of prior dystonia can occur. AEs after SDR include bladder or bowel dysfunction, sensory dysesthesias, and back pain; however, these occur infrequently and are typically transient. A systematic review of spinal deformities after SDR in children with CP found scoliosis to be the most common deformity occurring in approximately 30% of children, but this risk has never been satisfactorily shown to be higher than the risk in those children who have not undergone SDR. Studies have reported higher rates of spondylolysis and spondylolisthesis after SDR than would be expected in the general CP population. Spine radiographs should be obtained routinely after SDR to monitor for spinal deformity.

Chapter 753

Birth Brachial Plexus Palsy

Maureen R. Nelson and Nicholas L. Fleming

Birth brachial plexus palsy (BBPP) may cause significant arm weakness and subsequent functional deficits in children. The nerves to the arm are affected with variable degrees of weakness and sensory loss. Most children will have good recovery spontaneously, but functional deficits will remain in 20–30% of children with BBPP.

The mechanism for BBPP is lateral stretch of the plexus for the vast majority of cases. Anatomic variations in bones, blood vessels, and tendons lead to a very small number of cases. The incidence of BBPP is reported as 0.5-4.6 per 1,000 live births, with variability thought to be attributable to the type of obstetric care and the size of infants around the world.

Risk factors for BBPP include prior infants with BBPP, shoulder dystocia, birthweight >4 kg, multiparous mothers, mothers with excessive weight gain, and diabetic mothers. Delivering twins or triplets, as well as cesarean sections, have been described as protective from BBPP. Factors with a higher risk of poor outcome are birthweight greater than 4 kg, Horner syndrome, cephalic presentation, and induction or augmentation of labor.

Nerve injuries include neurapraxia, neurotmesis, and axonotmesis. **Neurapraxia** is the least severe of these types and is a reversible loss of nerve conduction. This type will recover. **Neurotmesis** is the most severe and is a total and complete disruption of the nerve. An *avulsion* describes a **neurotmesis** that is a preganglionic lesion, and a *rupture* describes the same event for a postganglionic lesion. **Axonotmesis** is the intermediate form and the most difficult to delineate. There is disruption of the epineurium with variable injury to the axons creating the diagnostic and prognostic difficulties (Fig. 753.1). For these reasons, it is advisable to urgently seek out consultation from specialty clinics or specializing physicians in your geographic area for close monitoring and treatment considerations, including surgical candidacy.

Not only is there variability in the degree of nerve injury, but there is also variability in location. The brachial plexus consists of the anterior primary rami, or roots, from C5, C6, C7, C8, and T1. These roots will combine and then branch to form the trunks, divisions, and branches before separating distally to individual peripheral nerves as illustrated by Figure 753.2.

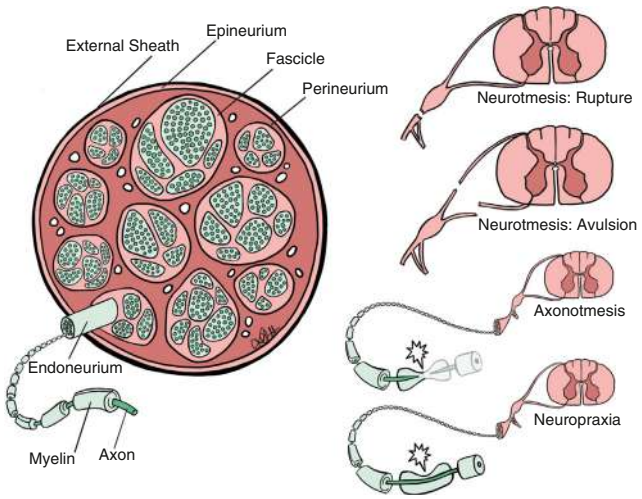

Fig. 753.1 Anatomy of peripheral nerve and injury type. *(Courtesy Kendall Hulk, DO.)*

There is variable impact on motor and sensory systems as well. The sensory fibers are relatively protected compared with the motor fibers because the sensory fibers run together until they are outside of the spinal cord into the dorsal root ganglion, where their cell bodies lie. The motor fibers have the cell bodies within the spinal cord and so are not as cohesive in their path. Therefore the sensory fibers may be spared, while motor fibers show clinical deficits.

Narakas is a commonly used classification system (Table 753.1). Erb palsy is generally described as the upper trunk or C5-C6 palsy. It is by far the most common injury seen in BBPP. When C7 is included in the injury, it may be referred to as *extended Erb palsy*. Together, these forms of Erb palsy make up 75% of all BBPP. These two groups also demonstrate the greatest recovery rate, at 80% and 60%, respectively, resulting in a functional arm. **Klumpke palsy**, C8-T1, is extremely rare in BBPP, likely not occurring except in the case of anatomic variation. If a baby presents with a C8-T1 deficit, the baby most likely originally had a complete C5-T1 BBPP and then had recovery of the upper portion of the plexus. This can happen because C4, C5, C6, and sometimes C7 are protected coming out from the spinal cord, held in a gutter along the transverse processes by connective tissue, whereas C8 and T1 are not. The phrenic nerve may also be involved with its innervation from C3, C4, and C5, with potential respiratory concerns. The differential diagnosis of an infant with a weak or less functional arm is broad, and there should be consideration for other neurologic injury (stroke, spinal cord injury, underlying congenital or metabolic diagnosis), musculoskeletal issues (fracture, muscular torticollis, anomalous rib impinging nerves), infection, tumor, and other sources of pain or pathology that could lead to developmental disregard or a learned nonuse of an extremity. **Phrenic nerve** (4th cervical and C3-C5) injury may also be present and result in ipsilateral diaphragm paralysis and respiratory distress.

PHYSICAL EXAMINATION

Motor movement evaluation is the focus of this exam. The Active Movement Scale is a reliable passive assessment of muscle strength that is widely used for infant examination of BBPP. Mallet scores, which assess shoulder abduction and external rotation deficits, are likewise useful but are more pertinent for examination of the toddler or older children. Examination for sensation, particularly sharp sensation, useful in its own right, will also frequently help with active motor evaluation in infants. Assessment of muscle stretch reflexes is important, in that infants with brachial plexus palsy will be areflexive or hyporeflexive in the involved arm. Evaluation of primitive reflexes, particularly the Moro reflex, is helpful, because most of these infants will have C5-C6 involvement, and therefore the Moro may show shoulder abduction and elbow flexion on one side but not the involved side. Range-of-motion examination is critical. Deficits are commonly seen because of the imbalance of muscles that are active and those that are not. Shoulder adduction and internal rotation is a common position, as is elbow flexion, forearm pronation, and wrist and finger flexion. Torticollis is commonly present and almost always with the face turned away from the involved arm. **Horner syndrome** (ptosis, miosis, and anhidrosis) may be present ipsilaterally and is an indicator of severity. In children with very severe deficits, the arm may be cooler because of the sympathetic nervous system outflow at T1. The size of the involved arm eventually is usually smaller, about 95% of the uninvolved arm, because of muscle atrophy and smaller diameter and length of the bone.

Among older infants and children, compensatory movements of the arm may be noted. Common examples are use of trunk momentum to move (particularly to rotate) the proximal arm, hyperlordosis of the lumbar spine to position the arm more advantageously, use of the pectoralis muscle to flex the shoulder, and use of the knee while sitting to physically flex the elbow. Examination of the back for symmetry, along with the scapulae for winging, is also relevant. Scapular winging can be problematic both socially and clinically. Having the older child manipulate buttons, snaps, or zippers, throw

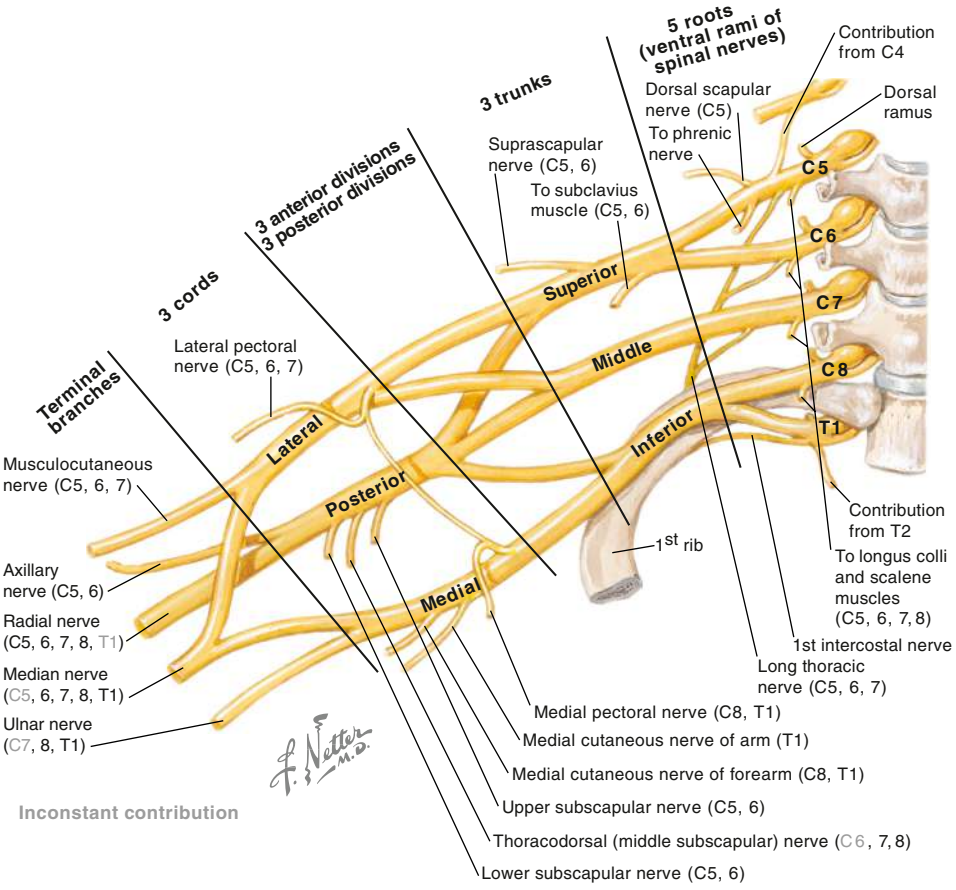

Fig. 753.2 Schematic of the brachial plexus. *(Netter illustration from www.netterimages.com. Elsevier Inc.)*

Table 753.1 Narakas Classification

GROUP	NAME	ROOTS	CLINICAL DESCRIPTION
I	Erb palsy	C5-6	Paralysis of shoulder and biceps with should abduction, external rotation, and elbow flexion
II	Extended Erb palsy	C5-7	As above with paralysis of wrist
III	Total palsy	C5-8, T1	Complete flaccid paralysis
IV	Total palsy with Horner syndrome	C5-8, T1	Complete flaccid paralysis with Horner syndrome

and catch a ball, and write, print, or color may be revealing, along with how they remove their shirt for examination.

When hand function was evaluated with testing of children with upper-plexus involvement, 80% of the children had significantly decreased performance compared with the contralateral hand. This indicates the hand function is impaired even in children who only have upper plexus involvement.

EVALUATION

Radiographic evaluation may be needed. Plain films can be viewed immediately if there is reason to consider clavicle or humerus fracture, infection, osteomyelitis, or tumor. Ultrasound (US) can be used to evaluate for shoulder dislocation. CT myelogram had been the mainstay diagnostic tool for brachial plexus evaluation despite its radiation dose and invasive lumbar puncture. However, MRI lacks these drawbacks and provides a more accurate and reliable evaluation.

US and electrodiagnostic evaluation (EDX) can also be helpful in evaluation of the brachial plexus. US is an ever-improving technology but does not yet evaluate the deeper nerve root avulsions or ruptures, making isolated US imaging inappropriate. However, US can be useful for postganglionic injury evaluation, specifically for the upper plexus. EDX may be supplemental and is especially helpful as a confirmatory test for lower plexus avulsion injuries given its strong specificity and MRI's weaker diagnostic accuracy for these lower plexus injuries.

EDX includes both nerve conduction studies (NCS) and electromyography (EMG) and should be performed by someone who is experienced in the examinations of infants and young children, both for the most precise evaluation and the most comfortable experience for the youngster. The following EDX pearls should be noted:

1. Normal electrical sensory response in areas where the child cannot feel indicates a *preganglionic neurotmesis* (avulsion).
2. Motor nerve conduction studies are useful to check for continuity of nerve fibers to muscles that are weak or paralyzed.
3. F waves are useful in evaluating proximally because these responses go from peripheral nerves to the spinal cord and back.
4. Somatosensory evoked potentials are difficult to perform on infants while awake, because of motor artifact obliterating the responses

with movement, and are imprecise because of overlapping responses to peripheral stimulation. These are useful intraoperatively because stimulation can be performed on the nerve roots themselves to determine proximal continuity.

5. EMG can show activation in muscles with paralysis or severe weakness.
6. The absence of biceps motor unit potentials at 1 month of age predicts future lack of clinical biceps recovery, although biceps EMG at 3 months has been reported to overestimate recovery potential.

TREATMENT

Early referral or consultation with a specialty clinic or specialized physician is paramount and should be completed as early as possible or by 1 month of age for close monitoring and consideration of possible microsurgery. Postoperative improvement in hand and arm function has been shown to have a negative correlation with age at time of primary surgery. Infants who do not show satisfactory improvement in muscle strength are candidates for such primary surgeries, which may include nerve transfers, in which branches from an uninvolved nerve are microsurgically transferred to the distal peripheral nerves supplied by the injured nerve roots and/or nerve grafting, in which one or more of the nonavulsed roots is attached distally to the trunk, cord, or peripheral nerve by means of an autogenous graft (commonly the sural nerve of the leg) or synthetic nerve conduits. There is general consensus that primary nerve surgeries should be performed at 3 months of age for Narakas type III and type IV. Those with upper-plexus (Narakas type I and type II) involvement are monitored closely, and there is surgical consideration for primary nerve surgery between 3 and 6 (or even 9) months of age. Classically, observed elbow flexion less than 3/5 at 6 months of age or a positive "cookie test" (child cannot bring cookie to mouth without bending neck forward more than 45 degrees) at 9 months would prompt decision to undergo primary surgery in these populations. The surgical focus for a complete palsy or "flail arm" is reinnervation of the hand, whereas the surgical goals of an upper-plexus reconstruction include, in descending priority, elbow flexion, glenohumeral abduction, shoulder stability, and shoulder external rotation. It should be noted that the goals of surgery are not to regain normal arm function but rather to have a more functional arm.

Regarding primary nerve surgeries, some have reported better outcomes with nerve transfer rather than nerve graft procedures. However, the heterogenous nature of BBPP, variable surgical techniques, and available nerve options often dictate what can be performed. Spinal accessory to suprascapular nerve transfer and radial nerve (long head of triceps branch) to axillary nerve transfer has been reported as the most common dual nerve transfer procedure. Other common nerve transfers include median or ulnar nerve to the musculocutaneous nerve (MCN), medial pectoral nerve to MCN, intercostal nerve to MCN, and contralateral or cross cervical nerve root transfers. Nerve graft procedures typically include harvesting of the sural (purely sensory) nerve or using synthetic nerve grafts. These grafts are typically used to reestablish the conduit of the suprascapular nerve, graft C5-to-posterior division, or graft C3/C4-to-upper trunk.

Regardless of whether primary surgery is pursued, treatment begins on the initial evaluation with instruction to the parents for positioning and early stretching exercises to begin at 2 weeks, or at 3-4 weeks if a humerus or clavicle fracture is present. They are also told of the critical task of maintaining infant awareness of the involved arm, initially by manually mimicking activities with the affected arm that the baby performs with the contralateral arm and by using a wrist rattle on the arm. Lack of awareness of the arm, sometimes called *developmental disregard*, in children can result in less active use of the arm, with functional loss, as a consequence. The parents also are informed of the higher risk of BBPP for future infants, and so the families are encouraged to speak with the obstetrician about optimal management in future deliveries.

The baby will start with occupational or physical therapy at approximately 2 weeks of age with focus on maintaining joint motion, maximizing strength, promoting sensory awareness, and supporting age-appropriate development. Parent education should be reinforced and a home program including daily stretching, positioning, and strengthening techniques should be constructed. Therapeutic taping may be done for supination, wrist extension, or, most commonly, for shoulder positioning to minimize an adducted, internally rotated posture. Neuromuscular electrical stimulation to the muscles minimizes atrophy and promotes increased size, and therefore strength, of muscle fibers. Ideal parameters for its use have not yet been determined, but a 20-30–minute twice-daily program is effective and has been shown to increase bone density.

The therapist or physician may consider a brace or splinting. Splints can be prescribed in conjunction with a physical or occupational therapist's guidance and are often worn the majority of the day (e.g., 22 hours/day). Common splinting strategies include supporting wrist extension with a baby with wrist-drop and/or extending the fingers and abducting the thumb as well, providing straps to assist with supination (Sup) of the forearm and even braces focused on positioning the shoulder in external rotation (ER). Protocols for splinting strategies such as the "Sup-ER orthosis" have been created and studied in small populations; however, there is currently no general consensus on implementation of such protocols. Early, close monitoring is not only important for surgical considerations, but it is also important for monitoring for secondary problems that can increase the negative impact of functional deficits in children with BBPP. Contractures of the elbow, shoulder, forearm, wrist, and fingers may occur. Although muscle imbalance and fibrosis can contribute to contracture, the evidence suggests a physiologic response related to muscle denervation leading to a failure of growth in the sarcomeres of these affected muscles. Early shoulder dislocations have been described in severe presentations. Botulinum toxin injections help balance out muscles that are overpowering weak muscles and such an intervention can minimize contractures and even prevent or help reduce a shoulder dislocation in these severe cases.

For older babies and children, muscle, tendon, and bony procedures are generally performed. These are often called *secondary surgeries*. Monitoring for shoulder deformity and dislocation is an important part of long-term follow-up. Because the shoulder joint develops as the infant and toddler grows, deficits frequently develop. Glenohumeral dysplasia, sometimes with shoulder dislocation, occurs in 60–80% of those with BBPP. Muscular imbalance across the developing shoulder results in deformity of the skeletally immature glenohumeral joint. The weakness of shoulder external rotation, combined with strong internal rotation, leads to this difficulty. The natural history of this deformity is progression if left untreated. This leads to further functional limitations, even with a strong hand. Treatment aims to minimize this progression. Treatment options include botulinum toxin injections, arthroscopic or open anterior capsule release or release of contracture, musculotendinous lengthening, tendon transfers (e.g., latissimus dorsi to increase external rotation and abduction strength), muscle transfers (e.g., gracilis muscle can be transferred to allow for elbow flexion and/or wrist extension), and, for severe deficits, a derotational humeral osteotomy.

Chapter 754

Meningomyelocele (Spina Bifida)

Pamela E. Wilson and Tess S. Simpson

See also Chapter 631.

Meningomyelocele, or spina bifida (SB), is a congenital neural tube defect that results in the malformation of the spine and a potential dysplastic spinal cord. The severity of defect ranges from SB occulta (see Chapter 631.2) upward to anencephaly (see Chapter 631.6). SB without anencephaly is the most prevalent nonchromosomal central nervous system (CNS) defect in the United States. For unknown reasons, Hispanic women have the highest rate of SB (3.80/10,000 live births), followed by non-Hispanic White women (3.09/10,000 live births); the lowest rate is in non-Hispanic Black women (2.73/10,000 live births).

ETIOLOGY

See Chapter 631.1.

PREVENTION

See Chapter 631.1.

PRENATAL SCREENING

Prenatal screening is recommended for all pregnant women to detect neural tube defects. A blood test is done in the second trimester to evaluate alpha-fetal protein (AFP). If a neural tube defect is present, the AFP is often elevated, and further screening using high-resolution ultrasound is indicated. Ultrasound may reveal not only the spinal defect but also abnormal brain development, suggested by the "lemon and banana signs." The lemon sign is a medial indentation and scalloping of the frontal bones in the skull, whereas the banana sign is associated with hindbrain herniation of the cerebellum into the foramen magnum. The importance in early identification allows families to plan for delivery and consider fetal interventions, mainly prenatal surgical closure of the defect. Prenatal closure decreases the need for a ventricular shunt and lowers the incidence of severe Arnold-Chiari malformations, along with improved motor outcomes. However, there is an increased incidence of preterm delivery and a risk for uterine dehiscence; these risks may be reduced with fetoscopic procedures.

CLINICAL IMPLICATIONS

Meningomyelocele is a multisystem condition that includes characteristic abnormalities within the CNS. The neurologic lesion is assessed by the most caudal intact nerve segment with a motor test of grade 3. Lesions associated with SB are often grouped together as thoracic, upper lumbar (L1-L2), midlumbar (L3), lower lumbar (L4-L5), and sacral. Based on this information, a clinician can make inferences on the functional capabilities of the child and answer pertinent questions during the initial encounters (Table 754.1). The most basic question all families ask is: "Will my child walk?"

Initial surgical interventions are related to closure of the open defect. This is generally done the first day of life. Once the back is closed, the child will be monitored to see if hydrocephalus develops. Hydrocephalus is very common and related to hindbrain herniation and obstruction of the fourth ventricle. Hydrocephalus may occur at any time but most frequently within the first few months. Ventricular dilation may precede a change in head circumference or signs of increased intracranial pressure. The occurrence of hydrocephalus is approximately 77–95% and does appear to have an association with level of lesion. Treatment of ventriculomegaly, if mild, may be limited initially to clinical observation. Surgical placement of a ventricular shunt or endoscopic third ventriculostomy is indicated when occipital frontal circumference (OFC) is increasing. The risk for shunt revision in the first 2 years is 30–50%, which then decreases to 10%.

Hindbrain herniation or the **Chiari type II malformation** is seen in 80–90% of individuals with meningomyelocele. The classic manifestations include caudal displacement of the cerebellum, pons, and medulla and elongation of the fourth ventricle. The Chiari II malformation can be symptomatic (from brainstem herniation/compression) in approximately 20% of children. Respiratory symptoms associated with a Chiari malformation include stridor, vocal cord dysfunction, and central or obstructive apnea. Swallowing and feeding problems may require gastrostomy tube placement. If the child has a symptomatic Chiari II malformation, surgical

Table 754.1 Prognosticating in Meningomyelocele

MOTOR LEVEL SPINAL CORD SEGMENT	CRITICAL MOTOR FUNCTION PRESENT	MOBILITY: SCHOOL AGE	RANGE: ADULT	ACTIVITY: ADOLESCENT
T12	Totally paralyzed lower limbs	Standing brace, wheelchair	Wheelchair	Wheelchair, no ambulation
L1-L2	Hip flexor muscles	Crutches, braces, wheelchair	Wheelchair, household ambulation	Wheelchair, nonfunctional ambulation
L3-L4	Quadriceps muscles	Crutches, braces, household ambulation, wheelchair	Crutches, household ambulation, wheelchair	50% Wheelchair, household ambulation with crutches
L5	Medical hamstrings, anterior tibial muscles	Crutches, braces, community ambulation	Crutches, community ambulation	Community ambulation with crutches

S2-S3	Mild loss of intrinsic foot muscles possible	Normal	Normal	Limited endurance because of late foot deformities

From Braddon RL, ed. *Physical Medicine & Rehabilitation*, 4th ed. Philadelphia: Saunders; 2011: Table 54.1.

decompression is indicated. All children with SB are at risk for **tethered cord syndrome** (see Chapter 646.1). After shunt malfunction, this is the second most common cause for neurologic decline. Clinical manifestations of tethered cord syndrome include any change in gait, change in bowel or bladder function, increasing scoliosis, back pain, or orthopedic changes. Surgical detethering procedures are indicated in those with neurologic decline, but the success rate is variable.

The **orthopedic complications** of myelomeningocele are common and have predictable patterns. The spine deformities include scoliosis, lordosis, and kyphosis (see Chapter 720). The development of scoliosis has an association with the neurologic level. Children with thoracic level meningomyeloceles have an 80–100% risk, whereas those with a sacral level are at very low risk. Spine deformities tend to increase more rapidly during growth, especially puberty. Treatment of scoliosis includes both nonsurgical and surgical options. Braces, such as thoracic-lumbar-sacral orthotics (TLSO), therapy, and proper seating options may be beneficial. Surgically implanted growing rods to support the developing spine have been used in younger children. Spine surgery should be considered if the scoliotic spine curvature reaches 45 degrees; the child who is nearing skeletal maturity is a better candidate for spine surgery. Realistic expectations need to be discussed with the child and family. Correction of the spine may improve sitting, posture, and pelvic obliquity but may have a negative impact on function and ambulation.

The **development of the hip** is also influenced by neurologic level (see Chapter 719). The risk for dislocation is highest for those with lesions at the L3 level, followed by L1-L2. Unilateral hip dislocations should be fixed surgically because they may result in pelvic obliquity and problems with sitting, whereas bilateral dislocations generally do not require interventions. Contractures of soft tissues are commonly seen in children with higher lesion levels. Hip flexors and knee flexors are commonly involved.

Abnormalities in the foot occur in approximately 90% of children and adolescents. The goal of treatment is to achieve a plantar grade foot for weight bearing and to allow shoe wear. Clubfoot deformities are common in babies, and treatment includes serial casting and orthotics (see Chapter 715.3). The results are often suboptimal, and surgery may be needed. In addition, congenital vertical talus (rocker-bottom feet) is often encountered and needs to be addressed (see Chapter 715.4).

Osteoporosis (see Chapter 749) begins to develop in childhood and is more severe in higher-level meningomyelocele. Fractures of the lower extremities are most common in the femur, followed by the tibia. Preventive treatment includes nutritional approaches such as the use of supplemental calcium and vitamin D. Those with documented fractures should undergo a diagnostic evaluation (see Table 749.1), including dual-energy x-ray absorptiometry (DEXA). The use of bisphosphonates may be considered if the diagnostic evaluation does not reveal other underlying causes. The utility of early weight bearing has been advocated, but passive standing may have little impact on bone density.

Neurogenic bladder and bowel can be anticipated. The goals of treatment interventions are to protect kidney function and achieve social continence. For continence of urine, clean intermittent catheterization (CIC) is the mainstay of management. It is not atypical for newborn babies to be started on a CIC program. Urodynamics and renal ultrasounds are routinely used to monitor for hydronephrosis and track intravesicular pressures. Medications may be used to reduce bladder contractions and improve volume capacity. Surgical techniques are being used to improve continence, including bladder augmentation, urethral surgeries, and catheterizable channels. Poor CIC technique and/or urinary reflux may lead to urinary tract infection (UTI), which is diagnosed by having two findings: a urinalysis with white cell count of >10 and urinary culture >100,000 cfu/mL. A multicomponent bowel program is generally needed to achieve bowel continence. Nonsurgical interventions include adequate hydration, dietary manipulation, fiber regulation, and use of laxatives and enemas. Surgical interventions, such as the antegrade continence enema (ACE), have improved continence in many children and adolescents with SB.

Latex allergies are common. The etiology is likely multifactorial, but increased early exposure may play a role in the development of severe reactions (see Chapter 190). Care providers need to be keenly aware of products that contain latex or that have a cross reactivity, such as foods mixed with avocado, bananas, or kiwi fruit. Radioallergosorbent testing is used for identification of potential severe allergens.

People with SB show a wide range of **neuropsychologic abilities**. Many show a complex neuropsychologic profile that includes strengths in some areas and weaknesses in other areas. Common areas of strengths include vocabulary, word reading, spelling, and certain types of memory. Common weaknesses include motor skills, attention, organization, math, reading comprehension, and executive functioning skills. Overall cognitive functioning typically falls within the average range for children with SB; however, neurologic factors such as a Chiari II malformation or the presence of hydrocephalus increase the risk for neuropsychologic challenges. Neuropsychologic assessment is recommended to identify any potential gaps in cognition and social or emotional skills. This assessment can provide helpful information related to a child or adolescent's education and employment needs and assist with development of an individualized educational plan (IEP) or vocational rehabilitation plan. Appropriate early intervention and support programs should be initiated through an IEP or 504 plan if indicated (see Chapter 56). Effective interventions both at school and the home should be structured, explicit, and individualized. Parents and teachers can support learning goals by progressing in an orderly fashion from one learning target to the next and by modeling how to approach problems or tasks, often with step-by-step instructions and supervised practice.

ADOLESCENCE AND TRANSITION TO ADULTHOOD

Improved and expanded clinical care has increased the life span of individuals with SB, with the majority of individuals now living well into adulthood. Secondary conditions associated with SB (e.g., UTIs, skin breakdown, learning challenges) and more difficulty accessing healthcare services compared with their age-matched peers make adolescents and young adults with SB less likely to achieve emerging adult milestones such as leaving home, attending college, or finding employment.

The primary care clinician, in conjunction with specialty services, plays a pivotal role in developing future planning. It is important to discuss early on strategies to encourage developmentally appropriate independence and self-management skills. Individualized, comprehensive transition care that includes care coordination, decision-making support, education and employment resources, and independent living support is recommended for providers caring for children and adolescents with SB.

Chapter 755

Upper and Lower Extremity Assistive Devices

Abigail Case and Sarah Helen Evans

Assistive devices, such as orthoses, prostheses, walkers, crutches, and wheelchairs, are key components of intervention for individuals with physical disabilities, and with the continued advancement in technology, robotic forms of these devices are also important to consider. The type of device chosen depends on the underlying diagnosis, functional abilities of the individual, prognosis for functional improvement or decline, tone abnormalities, range of motion, strength, and the overall gait pattern. Physicians, licensed independent practitioners, and physical therapists perform the evaluation of a child requiring an assistive device.

ORTHOSES

An **orthosis** is a device that is applied to the surface of the body to maintain alignment or position, to prevent or assist movement of the body part, or to provide support. Named for the body parts covered, orthoses can be static, made of rigid material, and designed to immobilize joints to inhibit movement, or they can be dynamic, allowing movement of the limb to occur. For example, **AFO** stands for *ankle-foot orthosis*, a brace worn on the foot that extends from the toes to the mid-calf position, supporting the foot and ankle joints (Fig. 755.1). Prefabricated orthoses are available, but many children require custom-made orthoses for optimal fit. Orthoses are modified or replaced during periods of growth or changes in function and can be obtained either directly through the orthotist or through the child's physical therapist. In most of the United States, braces must be prescribed by a physician or licensed independent practitioner to obtain insurance coverage, and it is best practice to have a prescription.

The use of an upper limb orthosis can be more conspicuous than its lower limb counterparts, and physicians should analyze the user's psychosocial well-being and tolerance for such device. In addition to patient goals and outcomes, the therapeutic intent of the upper limb orthosis must be considered. The efficacy of the orthosis may be measured by the reduction of the effects of the three Ps: paralysis, pain, and position.

Fig. 755.1 Hinged ankle-foot orthosis. *(Courtesy Ultraflex Systems, Inc., Pottstown, PA.)*

The type of lower-extremity orthosis prescribed is based on the child's diagnosis, functional status, prognosis, and the goals of treatment, with the prescription frequently modified over time as the child changes. Before writing a prescription, the provider performs an examination, which may include an evaluation of the child's gait, strength, tone, and range of motion. There are many types of braces that have specific functions to improve gait. Table 755.1 lists examples of these orthoses and their potential uses.

The most prescribed braces are solid and articulated AFOs. Solid AFOs are used for children with hypertonicity because they help to biomechanically reduce tone and provide stability with standing and walking. Children who are nonambulatory also benefit from wearing solid AFOs to maintain range of motion of the ankle.

Articulated (hinged) AFOs allow the child to have ankle dorsiflexion by permitting forward movement of the tibia and supporting the foot for heel strike. This design makes ambulating on uneven surfaces and using stairs easier because of the movement allowed at the ankle, while still supporting the foot position and maintaining medial-lateral stability of the ankle. Articulated AFOs should not be used in children with cerebral palsy, spina bifida, or other disorders if they have a crouched gait pattern because the hinge in the ankle joint may allow further crouching. In crouched gait, the hips and knees are held in flexion and ankles in dorsiflexion throughout the gait cycle, leading to an inefficient gait pattern.

PROSTHESES

A prosthesis is a device that replaces a missing body part, such as an arm or a leg. Lower-extremity prostheses are used to improve mobility, but upper-limb prostheses are not always needed to improve function because children can be quite independent with a single upper limb. Children with congenital upper limb amputations or deficiencies need to have prosthetic devices fit at the time they begin to sit for them to use the prosthesis functionally, and because, developmentally, young children are not ready to learn to use complicated devices, teaching them to use a mechanical prothesis requires intensive occupational therapy. Myoelectric protheses are too heavy and too hard to use at this age. Children with acquired upper limb amputations may be more likely to adjust to the use of a prosthetic arm.

Lower-limb prostheses are used in children with acquired amputations as a result of trauma or cancer and also in congenital transverse amputations or for those who have undergone surgical correction, as often occurs with longitudinal fibular deficiency or proximal femoral focal deficiency.

There are multiple components to lower-limb prostheses, which include the socket and foot, but may also include a hip and knee joint, depending on the level of amputation. A prosthetist works with the child and family to fabricate the prosthesis. A physician or licensed independent practitioner with experience in prostheses provides the prescription for this device.

The type of prosthesis depends on the age of the child, the level of the amputation, and the status of the residual limb. In very young children, use of a lower-extremity prosthesis follows developmental milestones, with the first prosthesis prescribed at the time the child should be pulling to stand. Addition of joints to the prosthesis also occurs when developmentally appropriate, such as use of a knee joint around the age of 3 years when the child is learning to use stairs.

Advances in technology are helping children who use prostheses achieve a fluid gait pattern that makes their prosthetic use virtually undetectable to the untrained eye. New components and designs allow amputees to lead active lifestyles that may include running, swimming, biking, and mountain climbing.

ASSISTIVE MOBILITY DEVICES

The function of assistive mobility devices is to provide a wider base of support to improve stability during ambulation, reduce the possibility

Table 755.1 Orthotic Options

ORTHOSIS	FUNCTION	COMMENTS
Neoprene thumb abductor	Places thumb in abduction to promote functional use of hand	Will not overcome severe cortical thumb position
Thumb spica	Immobilizes and protects the thumb and provides a stable post against which the index finger can pinch	Need to allow for full metacarpophalangeal (MCP) flexion of the fingers
Resting hand	Preserves balance between extrinsic and intrinsic musculature and provides joint stability; prevents contracture	Pressure at the MCP joint or proximal phalanx should be avoided because it can injure the MCP joint. This splint is to be used for positioning, not function
Wrist cock-up	Supports, immobilizes, or stabilizes wrist in extension, which allows for mechanical advantage in grasp	Must maintain full MCP flexion and thumb motion
Elbow extension	Increases extensor end range of motion (ROM)	Not for severe flexor tone with contracture or fluctuating tone; in that case, use a drop out cast or splint
Gunslinger	Supports shoulder girdle and prevents subluxation	Make sure the edges of splint are not cutting into hip area; check in standing and supine
Myomo	Sensor-activated, power-driven upper limb orthosis can train the arm and hand while providing assistance with bimanual activities	Heavy Minimal growth with a child
Foot orthosis (FO)	Provides support of foot only to keep ankle in subtalar neutral	Not typically customized but can be with a UCBL*
Supramalleolar orthosis (SMO)	Provides medial-lateral support of foot to prevent excessive pronation, supination, or instability	Appropriate for children with low tone such as in Down syndrome. Also useful for young children with equinovarus posture or mediolateral instability
Ankle-foot orthosis (AFO)	Provides support at the ankle and reduces foot drop or plantarflexion tone by keeping the ankle in a neutral position	Commonly used for ambulatory and nonambulatory children Assists with dorsiflexion and inhibits plantarflexion. Requires rocker bottom shoe for rollover in gait
FES activated AFO	Uses functional electrical stimulation to assist dorsiflexion at the appropriate time in the gait cycle	Cannot inhibit plantarflexion Less restrictive than a solid or hinged AFO Can be used with an SMO to provide mediolateral stability at the ankle
Ground reaction ankle-foot orthosis (GRAFO)	Provides knee extension moment to reduce crouching or collapsing into dorsiflexion during standing or walking	Appropriate for children with spina bifida or who have weakness in the plantar flexors who crouch when walking
Knee-ankle-foot orthosis (KAFO)	Provides support at the knee when there is quadriceps weakness to promote an upright posture with standing or walking	Less commonly used because of large size of brace but may be appropriate for child with spina bifida or spinal cord injury
Walking assistance exoskeleton	Bionic robot for use in paraplegic patients	Heavy. Very expensive. Does not grow with a patient. Cannot be used in patients with spared sensation in the legs

*UCBL – University of California Berkley Laboratories, where this maximum control foot orthosis was developed.

of falls, and improve efficiency of gait. The least supportive device is a traditional single-point cane commonly used after an orthopedic injury. For most children with gait abnormalities secondary to neurologic disorders, this is not a functional option because a cane does not provide enough stability. More supportive gait aids, such as forearm (Lofstrand) crutches, are appropriate in children with neurologic disorders; however, use of these devices requires good coordination and strength. Children with cerebral palsy and spina bifida may benefit from these devices.

Walkers provide more support than crutches and canes; they do not require as much strength and coordination to operate. Children with cerebral palsy, for example, may use a reverse walker, which they pull behind them. This reverse configuration provides a wide base of support and stability, helps maintain an erect posture, and allows the child to engage with the environment without the barrier of the walker in front of them. Having the walker behind them also reduces the risk for more serious injury from a forward fall.

For children who require a significant amount of support because of poor head and trunk control, **gait trainers** are often used. These devices allow the child to work on leg movements while the trunk and pelvis are stabilized (Fig. 755.2). Although gait trainers provide a child with moderate to severe motor impairments upright supportive mobility, "gait trainer" is a misnomer in that it is not intended to train a child to walk independently.

WHEELCHAIR

Wheelchairs should be considered as a means of mobility when ambulation is not possible or is difficult outside of the home setting. Children with spinal cord injuries, spina bifida, neuromuscular diseases, or cerebral palsy may benefit from the use of a wheelchair. The goal is to provide a wheelchair that will allow the child to move independently about the environment, including home, school, and the community. Children as young as age 2 years can self-propel a manual wheelchair and operate a power wheelchair. The type of wheelchair prescribed will depend on the child's underlying diagnosis, cognition, vision, motor skills (such as head and trunk control), strength and endurance of upper limbs, musculoskeletal deformities, if present, and medical comorbidities. One must also consider future growth or

Fig. 755.2 Gait trainer. *(Photo copyright 2013 by Rifton Equipment, http://www.rifton.com.)*

anticipated changes in function over time, as well as the family's ability to transport the chair. An important consideration when ordering a pediatric wheelchair is the adjustability to accommodate growth. A typical wheelchair may last 3-5 years with periodic adjustments to growth by a seating specialist. There are many components that can be added to provide more support in the wheelchair, including head rests, lateral trunk support, hip guides, antitippers that prevent the wheelchair from tipping backward, and specialized tires. The seating system is considered a separate item from the wheelchair itself and is, in fact, a seating orthosis. It should be properly fit for the child's current size and seating needs. The function of a seating system is to promote the upright positioning of the head and trunk as well as control of the position of the legs, especially the hips, in sitting. Children with good trunk control will require a simple seat back, while a child with poor trunk control, such as someone with a high cervical spinal cord injury, will require a system that includes a head rest and lateral thoracic supports. The seat itself must be customized to provide a stable base on which the trunk can align. Restraint at the pelvis, such as a seatbelt or bar, helps maintain proper positioning in the chair. Specialized cushions are needed for those with decreased sensation to prevent pressure-related skin sores.

ROBOTIC DEVICES

Rehabilitation robotics is a subspecialty field that is helping to increase independence for individuals with disabilities. Robots are currently defined as machines programmable by a computer and capable of carrying out a complex series of activities automatically. Although there is a wide range of the types of robots used in rehabilitation, a subset of robots provide assistance in the form of adaptive equipment. Most of these robots are wearable; notable exceptions are fully automated voice-controlled feeding systems and speech generating devices. Lower limb devices are designed to help a child progress toward a typical gait pattern and range in complexity from exoskeletons to programable AFOs that provide electrical stimulation to muscles that control foot position and strength across the ankle joint. Upper limb devices are designed to increase the use of a minimally functional arm and hand. Programmable prostheses, such as myoelectric arms and hands, respond to input from the user's neuromuscular system while bionic limbs respond to sensors implanted in the brain. The use of robotic assistive devices is less common than mechanical devices, in part because of availability and in part because of higher cost. The advantage of most robotic assistive devices compared with their mechanical counterparts is the ability of the device to train the user to need it less while providing the assistance required in the moment.

Chapter 756

Health and Wellness for Children with Disabilities

Meghan A. Klawonn, David M. Kanter, and Margaret A. Turk

DISABILITY

Children with Special Healthcare Needs

The expansion of the *disability* definition to include children with special healthcare needs (CSHCN), chronic conditions, and activity limitations from any cause (e.g., limitations in usual daily activities such as age-appropriate self-care, mobility, communication, and cognition) has made the health issues of the more *traditional* childhood disability types (e.g., cerebral palsy, intellectual disability, spina bifida, congenital musculoskeletal disorders) more difficult to identify. U.S. data note continued increasing prevalence of developmental disabilities and identify developmental, emotional, and behavioral conditions as the leading conditions. Physical health conditions comprise a smaller proportion of disabilities, although mobility and motor control issues may be noted among the aforementioned developmental, behavioral, and emotional conditions. These disabilities contribute to continued economic and health problems into adulthood. Childhood and adolescent health promotion interventions can decrease functional impairment across the life span. Monitoring children with disabilities throughout their development is essential for identifying times when support to children, adolescents, and/or their families is needed to promote positive health outcomes.

Health Promotion Definitions and Background for Disability

The World Health Organization (WHO) defines *health promotion* as "the process of enabling people to increase control over, and to improve, their health." For people with disabilities, this concept is important because they are both underserved and have comparatively large health disparities. The WHO further defines health promotion approaches as including more than health education and consisting of community action, supportive and accessible environments, policy changes, health service modifications, and development of personal skills. Health and wellness programs also include traditional preventive management strategies, such as anticipatory guidance. There is ample evidence that engaging in specific areas of health promotion results in improvement, although the evidence for its influence on adult health is less robust.

Children with disabilities encounter many barriers to healthy behaviors (Table 756.1). Both broad and focused health promotion programs consider severity of condition, barriers and resources, and self-efficacy to achieve health-promoting behaviors. Children with disabilities may also require modeling or assistance to apply healthy behaviors to their particular disability or economic, social, and environmental circumstances.

Individuals with disabilities and their families often view health differently than those without disabilities. Disability may influence health and

Table 756.1 Barriers and Facilitators for Children to Engage in Healthy Behaviors

SELF	FAMILY	INSTITUTION
BARRIERS	BARRIERS	BARRIERS
1. Lack of knowledge and skills 2. Fear of injury or failure 3. Personal choices 4. Fatigue 5. Lack of initiative 6. Limited functional capability	1. Negative attitudes by parents, peers, healthcare providers 2. Limited parental healthy behaviors 3. Stress in the close family network 4. Economic restrictions	1. Inaccessible facilities or resources 2. Needing adult or aide assistance 3. Policies and procedures of facilities or programs 4. Noninclusive providers 5. Transport challenges
FACILITATORS	FACILITATORS	FACILITATORS
1. Education or knowledge about heathy behaviors 2. Engaging child in discussions and decisions 3. Desire to be active 4. Making activities a part of the routine—repetition and consistency promote ongoing activities	1. Promotion of activities by rehabilitation and other healthcare professionals 2. Family support and participation 3. Involvement of friends and peers in activities 4. Models or directions for participation with adaptions 5. Creative and knowledgeable professionals	1. Accessible facilities and opportunities with knowledgeable staff 2. Policies and resources promoting participation 3. Welcoming and inclusive providers: Adaptable approaches

vice versa, but their perception of their own health and wellness does not equate with their level of disability. Experiences as a child with a disability often foreshadow adult behaviors, especially negative attitudes toward therapy, exercise, and activity. Beliefs of parents, families, and healthcare providers also influence the views of health by children with disabilities. Health promotion programs for these children must (1) understand and support the role and well-being of parents, (2) recognize that parents of children with more functional limitations may require more resources and support, (3) involve children with disabilities in the design of programs and decisions about participation, and (4) address barriers to participation, perceived and real (see Table 756.1).

An effective health and wellness program should involve multiple approaches and opportunities for success by considering novel and inclusive approaches, including partnerships with families, school staff, and rehabilitation providers. Effectiveness requires addressing any mismatch between the child's positive sense of health and well-being and that expected by the healthcare providers; recognizing limitations of an education-only model; engaging the child in discussions about the importance of healthy behaviors, ways to engage in healthy behaviors related to the child's disability and circumstances, and decisions about participation; promoting self-efficacy and self-management of health and wellness in preparation for adult healthcare when possible; and parent and family involvement coupled with sensitivity for the high level of support a family may already be providing for a child with a disability.

Anticipatory Guidance, Counseling, and Preventive Care

Preventive healthcare through health education, anticipatory guidance, and participation in screening and immunization schedules is the mainstay of pediatric public health programs (see Chapter 12). *Bright Futures*, developed by the American Academy of Pediatrics and their collaborators and supported by the Maternal and Child Health Bureau, Health Resources, and Services Administration, provides a knowledge base for pediatric healthcare providers and the public about anticipatory guidance, health promotion, and prevention for children and adolescents with a section in the 4th edition titled "Promoting Health for Children and Youth with Special Health Care Needs." For the general population, 25% of parents receive no information, and <50% receive all recommended guidance. Although parents of CSHCNs report similar or better receipt of general preventive information, it is not clear whether those with higher severity of functional limitations receive this guidance or counseling, and whether it is provided in the context of disability and other circumstances.

CSHCNs require typical prevention, as well as more specific counseling or screening related to their disability. Some of this more specific counseling can be managed by specialty care providers, although CSHCNs often have difficulty obtaining appropriate specialty outpatient services. Additional barriers to care, especially with increasing age of the child, are the lack of accessible medical equipment and facilities. Planning for transitions to adult care should begin early, with consideration of environmental access, preparedness for self-management when possible, and knowledge and skills of local healthcare providers. Although discussions of health risks with adolescents about smoking, drinking, and protected sexual activity should be undertaken, the discussions may require a different focus for adolescents with disabilities. Higher violence and abuse rates toward children with disabilities are reported, for which providers must be vigilant. Internet and social media use increases the risk of bullying and other negative experiences. It appears adolescent females with disabilities are more vulnerable than males to this victimization.

The recommendation is to recognize the need for modifications to typical guidance and to be alert for any signs of emotional disturbances. CSHCNs experience family issues with separation/divorce, mental health and substance abuse problems, incarceration, domestic or neighborhood violence, discrimination, parental death, and maltreatment more than those without special needs. Counseling should be broadened to include questions and discussions about conditions associated with the specific disabilities (e.g., epilepsy or cognitive impairments often seen with cerebral palsy, or neurogenic bladder and bowel in spinal cord dysfunction) or secondary conditions, such as pain, osteoporosis/fractures, or the fatigue seen in many CSHCNs. Early recognition of emotional and psychiatric disorders, at early ages and especially during times of transition, can help to address nationally acknowledged unmet mental healthcare needs. There are also signs of comorbidities commonly seen in adulthood, such as cardiovascular and renal conditions, in children with disability.

Physical Activity and Exercise

National health guidelines recommend at least 60 minutes of physical activity daily for children, but any activity increase from sedentary levels to even moderate activity (30-40 minutes of moderate intensity or 20 minutes of more strenuous activity) provides some health benefit. Health professionals should give specific advice about how children with disabilities can increase their level of activity. Exercise and activity increase aerobic capacity, functional ability, and quality of life for children with many kinds of disabilities and chronic diseases. National 24-hour movement guidelines have been established in Canada and Australia, with age-specific recommendations regarding lengths of time to sleep, perform physical activity, and sedentary time. It has been shown that individuals with disabilities meet the 24-hour movement guidelines at lower rates compared to the general population, which in turn may affect mental health. And yet, many healthcare providers and families accept sedentary lifestyles for children and adolescents with disabilities, whatever their functional abilities. Video gaming systems that involve movement can help to overcome this lack of activity because they can provide another way to increase movement. For children with disabilities, school physical education and recess programs can support activities at or greater than the recommendation, and school requirements can reinforce activity expectations; however, there should be monitoring for possible negative affect, poor sense of belonging, and presence of victimization during open recess opportunities. School-based interventions for adolescents with intellectual and developmental disabilities have been shown to increase healthy behaviors, such as engagement in physical activity and increased consumption of fruit and vegetables. Healthy behaviors are in turn associated with improvement in mental health. The need for exercise beyond physical therapy should be clarified to help children understand the benefits and purpose of both. The activities in which youth with disabilities wish to participate can be supported, and shared decision-making should be invoked. Children with disabilities who participate in physical activities report social benefits, such as developing friendships, building a support system, gaining knowledge of self, and acquiring a sense of accomplishment. These factors also contribute to higher adherence to activities. Children with disabilities may also be more likely to participate in physical activities when those activities are supervised and organized, as opposed to free play in an open room. For children with disabilities to engage in physical activity in supported environments, school and public playgrounds must be made sufficiently accessible to support community physical activity. A number of agencies have endorsed the Commit to Inclusion campaign to promote building healthy, inclusive communities for people of all ages with disability (e.g., the President's Council on Fitness, Sports, and Nutrition, along with the National Center on Health, Physical Activity, and Disability; the American Association on Health and Disability; and the Center on Disability at the Public Health Institute).

Physical activity for children and adolescents improves fitness and quality of life for youth with developmental disabilities (Table 756.2). These exercise and fitness programs require 2-3 months of participation, at least twice a week, to achieve any changes, and many of the changes achieved are longer lasting than expected. These programs are not traditional therapy, and participation in therapy is not a substitute. These focused fitness and

Table 756.2 Examples of Effective Exercise Programs for Children with Disabilities

CENTER-BASED FITNESS PROGRAM AND HOME PROGRAM	GROUP AQUATIC AEROBICS	GROUP TRAINING CLASS	ONLINE EXERCISE PRESCRIPTION TOOL
• Children with a variety of disabilities • Group exercise: 2×/wk for 14 wk, warm-up, aerobics, strengthening, cool-down • Home program: 2×/wk for 12 wk using video exercises • *Outcomes:* improved walking efficiency, strength, general function[a]	• Children with a variety of disabilities, 50% able to walk 2×/wk • Recreation to achieve target heart rate; aquatic strengthening program • *Outcomes:* improved walk/run[b]	• Children with cerebral palsy able to walk 2×/wk for 14 wk • Warm-up, circuit training stations (treadmill, balance stairs, closed-chain exercises) • *Outcomes:* improved muscle strength, mobility, function[c]	• Children with a variety of disabilities • 8 wk home exercise program delivered using Physitrack, an online exercise prescription tool • *Outcomes:* equivalent adherence to traditional paper-based method, more easily accessible[d,e]
• Strength • Training	• Walking-jogging program	• Treadmill training program	• Skill-related fitness (SRF)
• Children with cerebral palsy including a majority able to walk with assistive devices 3×/wk for 6 wk • Progressive training program, conducted in the home • *Outcomes:* improved perceptions of strength, walking, stair management, improved psychologic benefits[f]	• Children with down syndrome • 3×/wk for 10 wk, 30 min sessions, achieving 65–70% peak heart rate • *Outcomes:* improved peak exercise time and grade, improved walking capacity[g]	• Children with intellectual disabilities daily for 2 months • Progressive treadmill use with goal of 20-30 min • *Outcomes:* improved heart rate with and without activities[h]	• Adolescents with intellectual disabilities • SRF is a physical fitness component related to sports performance, used to enhance participation with peers in leisure activities • *Outcomes:* positive exercise training effects on agility, power RT, and speed[i]

exercise programs generally require the support and direction of rehabilitation professionals, although programs can be community based in nonmedical surroundings.

Recreation and organized sports are other areas where children and adolescents with disabilities can engage successfully, at times with modifications. Participation improves cardiopulmonary parameters, motor function, social competence, and general sense of well-being. Many children with disabilities require 1-on-1 instruction for development of skills, with a goal of participation in activities with their peers. Perceived barriers to participation in sports differ based on the source: children were concerned about dependency; parents required more information about possible sport participation. Programs through Special Olympics International are an opportunity for children and adolescents to engage in supportive and monitored environments for sport and recreation.

Rehabilitation professionals can assist with problem-solving activity participation, such as by using computerized technologies for "exergaming" (e.g., Wii, Xbox, PlayStation), developing individual or group challenges with mobile devices (e.g., activity trackers), adapting equipment (e.g., modified upper-limb prosthesis to allow baseball glove use or modified bicycle equipment), and knowing of adapted recreation programs in the area (e.g., horseback riding, winter/water sports). Technologies that allow for exercise as part of gaming provide new opportunities for moderate to vigorous exercise in people with disabilities, especially in those with limited use of the lower limbs. Youth with greater functional limitations may not be able to achieve moderate to vigorous exercise, but even light intensity exercise may be enough to give them some health benefits. "Exergaming" programs are viewed as more fun than traditional exercises, which may increase likelihood of participation.

Sleep and Pain

Poor sleep quality or the presence of pain will have an impact on physical activity and general performance in children and youth with disabilities. Regular inquiry about sleep and pain is important because of the higher prevalence of problems in these areas in children with disabilities. Common sleep disturbances include difficulty initiating sleep, frequent sleep disruptions, and reduced sleep duration. Causes are often complex and multifactorial, with some associations with disability type (e.g., obstructive sleep apnea with Down or Prader-Willi syndromes, disrupted sleep patterns with autism, negative bedtime behaviors with attention-deficit/hyperactivity disorder, pain as trigger with cerebral palsy) and comorbidities (e.g., epilepsy, gastroesophageal reflux). Frontline approaches are sleep hygiene and behavioral interventions, and further evaluation may be warranted for targeted interventions (see Chapter 31).

Pain has been described as a cause for behavioral changes, poor sleep, activity interference, and change in school performance in children with a variety of disabilities. Children with cerebral palsy have been most closely studied, with high prevalence of both acute and chronic pain. Routine screening is important for early identification and evaluation for cause, and interventions should be tailored to address the biopsychosocial model of pain management.

Nutrition and Obesity

See also Chapter 65.

Managing the combination of nutrition and physical activity is the key ingredient of weight control. Estimates suggest that children with physical activity limitations were twice as likely as the general population to be overweight, and youth with cognitive impairments are at increased risk. It is unclear if obesity is a cause for the activity limitations or is a result of the limited activity, which may be an important distinction in developing interventions. The concern with obesity contrasts with early life weight gain needs of many children with disabilities, and it may be confusing for parents and families when the focus changes to weight decrease. Confounding factors related to monitoring percent body fat in children with disability include (1) the propensity for some disabilities, often those that are genetically mediated, to be associated with obesity; (2) standards of measurement may not be appropriate for certain diagnoses or disability types (e.g., inaccurate weight [limb deficiencies/amputation, scale inaccessibility], inaccurate height [unable to stand, contractures], no standards related to short stature or muscle wasting); (3) obesity may be a side effect of medication, and this effect must be balanced against the drug benefits (e.g., antipsychotics, steroids); and (4) the social network of family, friends, schools, and healthcare providers may unwittingly negatively influence health habits, including use of food as reward for behavior management. Both children and their parents should be a part of the conversations related to obesity or any weight-related topic. Information must be presented in a direct and understandable way and modified for the child's and parents' needs. Discussion of promoting health through nutrition and physical activity, while problem solving challenges to participation, may be a better approach than explaining body composition and metabolic pathways.

Emotional Health and Leisure Activities

Emotional health is often overlooked in children with disabilities. Youth and adolescents with disabilities appear to be at higher risk for feeling low, stressed, or anxious (especially those with higher levels of limitations), and those with mental health needs may have lower adaptive functioning or a family history of mental illness. While children and young adults diagnosed with autism have received much attention related to emotional support needs, there are increasing reports of this need with most childhood-onset disability conditions, including at ages before teenage years. Sexuality, gender identity, and other sex-related issues can also be reasons for emotional turmoil. Adolescents with physical disabilities participate in fewer social activities, have fewer close or intimate friends, and have fewer plans for ongoing education. There is a risk for continued isolation into adulthood. Passive social media use may exacerbate this problem. Novel programs to improve self-concept and build resilience based on psychoeducational therapy principles, typically developed through interdisciplinary teams, and involving peer groups, parents, and family members, have been shown to successfully promote positive outcomes. Medications may be considered, but effectiveness is not guaranteed, and unwanted side effects may produce more health challenges. Counseling requires insurance support or discretionary funding. There is some early work on using apps to try and help track mental health issues.

Leisure and recreational activities provide social supports, additional stress-coping mechanisms, and ability to develop social skills and a stronger personal identity. Although the negative aspects of social media are often discussed, there are also positive aspects. Adolescents with disabilities may more easily communicate and socialize with peers online, improving their mental well-being. Females with disabilities tend to engage in social or skill-based activities, and males in physical activities, with decreasing participation with increasing age. In general, encouraging socialization through leisure activities, recreation, or sports and physical activity can be a part of counseling in a routine health visit.

Dental Care

Dental care is a frequently unmet healthcare need for children with disabilities, especially for those in low-income families or with more severe impairments. The principal deficits are in receipt of specific dental care (not preventive services). Condition severity may also predict the degree to which parents are interested in oral health–related education and actually engage in oral health efforts. Parents and caregivers play a critical role in oral health support. Challenging behaviors often limit dental care, and the use of behavior management techniques and education programs have been effective in allowing dental care. Dental treatment under anesthesia may be necessary to provide effective oral healthcare.

Role of Healthcare Providers

Primary care and other healthcare providers should be mindful of discussing and promoting health and healthy behaviors with children and adolescents with disabilities and their families (Table 756.3). Initial discussions and preventive screening, including exploration for early signs of cardiovascular or renal diseases and assessing the need for emotional support, are a responsibility of primary care providers individually or in conjunction with specialty care providers. Children with a wide range of impairments should be included in multi-method inclusive research. Innovative strategies for engaging

Table 756.3 Targeting Healthy Behaviors for Children with Disabilities

GENERAL PREVENTION	PHYSICAL ACTIVITY	NUTRITION AND OBESITY
• Recognize risks for less healthy behaviors and facilitators of behavior changes and participation. • Cover typical topics for all children counsel regarding disability or situation context. • Specifically monitor for abuse and violence. • Provide typical age-appropriate adolescent information about smoking, drinking, substance abuse, sexual contacts; refer if unable to provide. • Monitor for disability-specific health conditions; many require referral.	• Promote exercise and activity with an expectation for activity. • Ensure that family and child/adolescent are knowledgeable about benefits and possible adaption. • Review need for possible dietary changes. • Consider referral to community programs and/or rehabilitation professionals	• Recognize obesity can cause limitations and can be the result of poor dietary habits and limited activity. • Follow percent body fat in a consistent way, recognizing the need for accurate measures or limitations of measures (e.g., weight, body mass index [BMI], skinfold thickness, other traditional measures) in many disability conditions. • Ensure that family and child/adolescent are knowledgeable about healthy nutrition. • Consider referral to nutritionist or other professional to engage patient and family in education and behavior change counseling • Review need for increased activity level with dietary intervention.
EMOTIONAL	**HEALTH, RECREATION, AND LEISURE**	**DENTAL**
• Question for sense of anxiety/feeling low, stress management and ability to adapt, and social supports. • Consider medications and counseling based on expected effect, monitor effects/side effects; consider referral, making sure that insurance/payment coverage is available. • Consider recreation and leisure activities to promote social support and ability to develop social skills. • Recommend use of social media in positive ways to enhance connections.	• Question about social activities outside the home: highlight the importance of developing social skills, sense of self, and support networks • Consider referral to community programs or rehabilitation professionals. • Consider recommending online support groups, social groups.	• Discuss more than preventive dental care. • Suggest behavior strategies if there are problems engaging in dental appointments and refer for this service as needed.

children with disabilities have been identified and offer much hope for the future. Parents are more likely to positively engage with a referral to healthcare professionals with expertise in providing a more tailored approach to health promotion after initial advice and support. Strategizing with parents about accessible environments or opportunities can promote inclusive community opportunities for participation. Providers should be willing to discuss intimate relationships and sex-related issues at appropriate times as they do with youth without disabilities—and refer when unable to meet those needs. Family-centered and coordinated care, commonly found in medical homes, can support healthy behaviors and emergency planning for unforeseen events.

Environmental Health

PART XXXII

Chapter 757

Overview of Environmental Health and Children

Ruth A. Etzel

GLOBAL CLIMATE CHANGE

Pediatricians' primary goal is prevention. One dominant prevention challenge of the 21st century is the climate crisis. The Intergovernmental Panel on Climate Change concluded that the Earth is undergoing adverse global climate change and that anthropogenic (human-made) contributions are significant. These climate changes are creating conditions that have already affected public health, with disproportionate impacts on certain life stages, including children. Children are especially vulnerable to the impacts of climate change because their bodies are growing and developing, they have unique behaviors and interactions with their environment, and they must rely on parents or caregivers to provide for their basic needs. Climate change affects children's health as a result of their exposure to elevated temperatures; more frequent, severe, or longer-lasting extreme weather events; transmission rates of food-borne, waterborne, and vector-borne diseases; increases in air pollution from molds, pollens, and the burning of fossil fuels; and mental health stressors (Fig. 757.1). Natural disasters such as floods and hurricanes, damp housing, and mycotoxin-related illnesses are worsening as temperatures and sea levels rise. The impacts are being felt most among young children and those who are living in poverty. The need to reduce carbon dioxide in the environment has compelled many countries to sign the Paris Agreement. This agreement promises to keep the global temperature rise well below 2°C above preindustrial levels, and to try to limit the temperature increase to 1.5°C. Even though the Paris Agreement began in 2016, its promises have not been kept and the temperature is already 1.2°C higher than in the preindustrial era. Individual actions are another necessary step in carbon dioxide reduction. Parents and caregivers can work to reduce their family's burning of fossil fuels. They also can protect children's health by checking the air quality index and pollen counts and considering a limit to children's outdoor play time if levels are high. Parents can watch for signs of dehydration or overheating in their children and can prevent tick and mosquito bites by using insect repellent and protective clothing. Pediatricians and those who care for children can be highly effective advocates for an urgent governmental response to the climate crisis by speaking out at the community, national, and international level.

LOCALIZED ENVIRONMENTAL HAZARDS

Localized exposures to a wide variety of chemical, biologic, and physical agents can also harm children. Numerous epidemics of disease from chemical, biologic, and physical agents (both natural and human-made) over the past 80 years have documented a variety of adverse outcomes among children (Table 757.1). Some epidemics, such as those caused by the nighttime release of methyl isocyanate from a factory in Bhopal, India, the nuclear meltdown in Chernobyl, and the melamine contamination of infant formula in China, received widespread attention and heightened the awareness of parents and pediatricians about hazards in the environment. For many people, the word *epidemic* conjures up images of hospital isolation wards, poor sanitation, and rapidly spreading infectious diseases. Epidemics of environmental origin often have served to elucidate new hazards for children. Many of the routinely used chemicals understood to be toxic to children were initially identified when a cluster of children was exposed and developed symptoms during a relatively short period of time. Unfortunately, the children served as the "canaries in the coal mine" to indicate that specific chemicals (including thallium, mercury, arsenic, and lead) contained in products for children such as diaper rinses, teething powders, and depilatory agents, posed a threat to their health. The comparison of children to canaries is apt: following underground mine explosions, canaries were used by miners throughout recent history to help detect elevated levels of carbon monoxide gas. Canaries were useful "carbon monoxide detectors" because of their rapid breathing rate and high metabolism, making them more sensitive to the effects of gases, including carbon monoxide. Likewise, young children have a rapid breathing rate and a high metabolic rate and may be more sensitive than adults to chemicals in the environment.

Table 757.1 summarizes major incidents of environmental poisoning that affected children. The characteristics of environmental exposure and the age and developmental stage of the child affect the likelihood of developing health problems. After the release of methyl isocyanate (used in the production of some pesticides) at Bhopal in 1984, an estimated 200,000 children living near the Bhopal chemical plant were affected by the gas release (see Table 757.1). Methyl isocyanate gas is 1.4 times heavier than air; thus higher concentrations of the gas were found near the ground or floor. Because of their short stature, children's breathing zones are closer to the ground or floor than adults' breathing zones; therefore children likely inhaled higher concentrations of the toxic gas. Children exposed to the same levels of methyl isocyanate as adults may have received larger doses because they have relatively greater lung surface area to body weight ratios and higher minute volume to weight ratios. Based on each of the poisoning events listed in Table 757.1, additional precautions were taken to avoid children's unnecessary exposure to the specific product or chemical implicated.

Although major poisonings such as those listed in Table 757.1 have caused substantial morbidity and mortality among children, environmental health hazards may also result in more subtle effects that may not manifest until later in life. In addition to the exposures received during large outbreaks, children receive smaller doses of chemicals on an almost daily basis through the water they drink, the food they eat, and the air they breathe. Because of their unique vulnerability, they may exhibit symptoms from these exposures earlier than do adults.

TOXINS VERSUS TOXICANTS

A toxin is a poisonous substance produced naturally by a living organism (e.g., aflatoxin). A toxicant is a poisonous substance made by humans or introduced into the environment by human activity (e.g., dioxins). Synthetic chemicals are referred to as toxicants.

MYCOTOXINS

Children's exposures to mycotoxins, the toxins produced by certain fungi on grains, nuts, and other crops, will likely increase as the

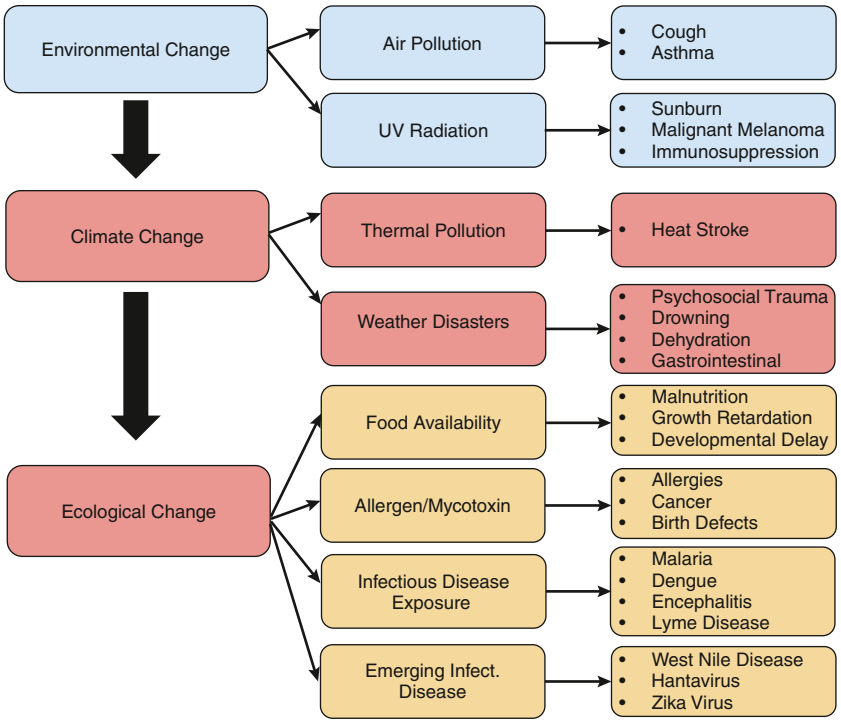

Fig. 757.1 The relationship between environmental change, climate change, ecologic change, and child health. *(Adapted from Bunyavanich S, Landrigan CP, McMichael AJ, et al. The impact of climate change on child health. Ambul Pediatr. 2003;3:44–52. Fig. 2.)*

Table 757.1 Epidemics of Environmental Disease Affecting Children

CONTAMINANT	VEHICLE	DATE	COUNTRY	APPROX. # SICKENED	ILLNESS	APPROX. # WHO DIED
Thallium	Depilatory agents	1930	Grenada	16	Thallotoxicosis	13
Methylmercury	Fish and shellfish	1956	Japan	2,265	Cerebral palsy	1,784
Arsenic	Contaminated milk powder	1955	Japan	11,778	Fever, diarrhea darkened skin, swollen abdomen	113
Hexachlorobenzene	In human milk after pregnant women ate HCB-treated seed grain	1957	Turkey	~200	Pembe yara (pink sore) rash, weakness convulsions	<2 yr ~200
Methyl isocyanate	Leak from chemical plant	1984	India	<15 yr: 200,000	Coughing, eye irritation choking death	All ages 2,500-5,000
Dioxin	Chemical plant explosion	1976	Italy	193 (88%)	Chloracne	0
Radiation	Chernobyl	1986	Ukraine	<18 yr: 4,000	Thyroid cancer	~8
Radiation	Scrapped medical machine stolen from hospital	1987	Goiânia, Brazil	249	Acute radiation syndrome	4 (1 child)
Fungi	Water-damaged homes	1990s	Ohio, US	30	Pulmonary hemorrhage	5
Aflatoxin	Grain	2004	Kenya	317	Aflatoxicosis	125
Melamine	Infant formula	2008	China	290,000	Kidney stones	6
Lead	Small-scale gold mining	2010	Nigeria	>2,000	Seizures, death	200

climate changes because their production is influenced by temperature, humidity, and rainfall. Exposure to mycotoxins results in different health outcomes dependent on the route of exposure. Exposure from eating or drinking may lead to gastrointestinal illness, tremors, and cancer in adulthood; exposure via breathing may result in acute respiratory illness during infancy. There also is emerging evidence linking mycotoxin exposures among children, especially those in developing countries, to stunted growth.

Pediatric Conditions Linked to Mycotoxin Exposures

Exposures to mycotoxins have been linked to at least two conditions that affect children: neural tube defects and acute pulmonary hemorrhage.

Neural Tube Defects

Studies of an epidemic of birth defects in 1990 in south Texas suggested an association between maternal ingestion during pregnancy of high levels of fumonisin, universally present in corn and in corn-based products, and birth defects such as anencephaly and spina bifida. Fumonisins are known to interfere with cellular folate uptake.

Infant Pulmonary Hemorrhage

Several studies of a 1994 epidemic of acute pulmonary hemorrhage in Cleveland, Ohio, documented a novel association between life-threatening pulmonary hemorrhage and the presence of the toxigenic mold *Stachybotrys* in the water-damaged homes in which the infants were living. *Stachybotrys* produces mycotoxins that are lipid soluble and readily absorbed by the airways, as well as a hemolysin and several proteinases that can degrade vascular collagen. In subsequent years, *Stachybotrys* and other toxigenic fungi including *Trichoderma* have been associated with acute pulmonary hemorrhage among infants in other areas of the United States, Canada, and New Zealand. The rapidly growing lungs of infants are especially vulnerable to the effects of the trichothecene mycotoxins produced by *Stachybotrys* and *Trichoderma*.

FOOD-BORNE DISEASES CAUSED BY ENVIRONMENTAL EXPOSURES

Contamination of food with viruses and bacteria is a major cause of childhood food-borne diseases (see Chapter 387), and children are also at risk from a variety of noninfectious food-borne hazards in the environment, which include natural hazards such as mycotoxins and synthetic persistent organic pollutants such as dioxins (see Chapter 759; Table 757.2).

Table 757.2 Food-Borne Illnesses (Noninfectious)

ETIOLOGY	INCUBATION PERIOD	SIGNS AND SYMPTOMS	DURATION OF ILLNESS	ASSOCIATED FOODS	LABORATORY TESTING	TREATMENT
Antimony	5 min to 8 hr usually <1 hr	Vomiting, metallic taste	Usually self-limited	Metallic container	Identification of metal in beverage or food	Supportive care
Arsenic	Few hours	Vomiting, colic, diarrhea	Several days	Contaminated food	Urine; may cause eosinophilia	Gastric lavage BAL (dimercaprol)
Cadmium	5 min to 8 hr usually <1 hr	Nausea, vomiting, myalgia, increase in salivation, stomach pain	Usually self-limited	Seafood, oysters, clams, lobster, grains, peanuts	Identification of metal in food	Supportive care
Ciguatera fish poisoning (ciguatera toxin)	2-6 hr	**GI:** abdominal pain, nausea, vomiting, diarrhea	Days to weeks to months	A variety of large reef fish, grouper, red snapper, amberjack, and barracuda (most common)	Radioassay for toxin in fish or a consistent history	Supportive care, IV mannitol; children more vulnerable
	3 hr	**Neurologic:** paresthesias, reversal of hot and cold, pain, weakness				
	2-5 days	**Cardiovascular:** bradycardia, hypotension, increase in T-wave abnormalities				
Copper	5 min to 8 hr usually <1 hr	Nausea, vomiting, blue or green vomitus	Usually self-limited	Metallic container	Identification of metal in beverage or food	Supportive care
Mercury	1 wk or longer	Numbness, weakness of legs, spastic paralysis, impaired vision, blindness, coma Pregnant women and developing fetuses are especially vulnerable	May be protracted	Fish exposed to organic mercury, grains treated with mercury fungicides	Analysis of blood, hair	Supportive care
Mushroom toxins, short-acting (muscinol, muscarine, psilocybin, coprius artemetaris, ibotenic acid)	<2 hr	Vomiting, diarrhea, confusion, visual disturbance, salivation, diaphoresis, hallucinations, disulfiram-like reaction	Self-limited	Wild mushrooms (cooking may not destroy these toxins)	Typical syndrome and mushroom identified or demonstration of the toxin	Supportive care

Continued

Table 757.2 Food-Borne Illnesses (Noninfectious)—cont'd

ETIOLOGY	INCUBATION PERIOD	SIGNS AND SYMPTOMS	DURATION OF ILLNESS	ASSOCIATED FOODS	LABORATORY TESTING	TREATMENT
Mushroom toxin, long-acting (amanitin)	4-8 hr diarrhea; 24-48 hr liver failure	Diarrhea, abdominal cramps, leading to hepatic and renal failure	Often fatal	Mushrooms	Typical syndrome and mushroom identified and/or demonstration of the toxin	Supportive care, life-threatening, may need life support
Nitrite poisoning	1-2 hr	Nausea, vomiting, cyanosis, headache, dizziness, weakness, loss of consciousness, chocolate brown–colored blood	Usually self-limited	Cured meals, any contaminated foods, spinach exposed to excessive nitrification	Analysis of food, blood	Supportive care, methylene blue
Pesticides (organophosphates or carbamates)	Few minutes to few hours	Nausea, vomiting, abdominal cramps, diarrhea, headache, nervousness, blurred vision, twitching, convulsions, salivation, and meiosis	Usually self-limited	Any contaminated food	Analysis of food, blood	Atropine: 2-PAM (pralidoxime) is used when atropine is not able to control symptoms and is rarely necessary in carbamate poisoning
Puffer fish (tetrodotoxin)	<30 min	Paresthesias, vomiting, diarrhea, abdominal pain, ascending paralysis, respiratory failure	Death usually in 4-6 hr	Puffer fish	Detection of tetrodotoxin in fish	Life-threatening, may need respiratory support
Scombroid (histamine)	1 min to 3 hr	Flushing, rash, burning sensation of skin, mouth, and throat, dizziness, urticaria, paresthesias	3-6 hr	Fish: bluefin, tuna, skipjack, mackerel, marlin, escolar, and mahi mahi	Demonstration of histamine in food or clinical diagnosis	Supportive care, antihistamines
Shellfish toxins (diarrheic, neurotoxic, amnesic)	Diarrheic shellfish poisoning (DSP)—30 min to 2 hr	Nausea, vomiting, diarrhea, and abdominal pain accompanied by chills, headache, and fever	Hours to 2-3 days	A variety of shellfish, primarily mussels, oysters, scallops, and shellfish from the Florida coast and the Gulf of Mexico	Detection of the toxin in shellfish; high-pressure liquid chromatography	Supportive care, generally self-limiting
	Neurotoxic shellfish poisoning (NSP)—few minutes to hours	Tingling and numbness of lips, tongue, and throat, muscular aches, dizziness, reversal of the sensations of hot and cold, diarrhea, and vomiting				
	Amnesic shellfish poisoning (ASP)—24-48 hr	Vomiting, diarrhea, abdominal pain and neurologic problems such as confusion, memory loss, disorientation, seizure, coma				
Shellfish toxins (paralytic shellfish poisoning)	30 min to 3 hr	Diarrhea, nausea, vomiting leading to paresthesias of mouth, lips, weakness, dysphasia, dysphonia, respiratory paralysis	Days	Scallops, mussels, clams, cockles	Detection of toxin in food or water where fish are located; high-pressure liquid chromatography	Life-threatening, may need respiratory support

Table 757.2 Food-Borne Illnesses (Noninfectious)—cont'd

ETIOLOGY	INCUBATION PERIOD	SIGNS AND SYMPTOMS	DURATION OF ILLNESS	ASSOCIATED FOODS	LABORATORY TESTING	TREATMENT
Sodium fluoride	Few minutes to 2 hr	Salty or soapy taste, numbness of mouth, vomiting, diarrhea, dilated pupils, spasms, pallor, shock, collapse	Usually self-limited	Dry foods (e.g., dry milk, flour, baking powder, cake mixes) contaminated with sodium fluoride–containing insecticides and rodenticides	Testing of vomitus or gastric washings, analysis of food	Supportive care
Thallium	Few hours	Nausea, vomiting, diarrhea, painful paresthesias, motor polyneuropathy, hair loss	Several days	Contaminated foods	Urine, hair	Supportive care
Tin	5 min to 8 hr, usually <1 hr	Nausea, vomiting, diarrhea	Usually self-limited	Metallic container	Analysis of food	Supportive care
Vomitoxin	Few minutes to 3 hr	Nausea, headache, abdominal pain, vomiting	Usually self-limited	Grains such as wheat, corn, barley	Analysis of food	Supportive care
Zinc	Few hours	Stomach cramps, nausea, vomiting, diarrhea, myalgias	Usually self-limited	Metallic container	Analysis of food, blood, and feces, saliva, or urine	Supportive care

BAL, Bronchoalveolar lavage; GI, gastrointestinal; IV, intravenous.
Adapted from Centers for Disease Control and Prevention. Diagnosis and management of foodborne illnesses: a primer for physicians and other health care professionals. *MMWR.* 2004;53(No. RR-4):1–33.

Aflatoxins

Aflatoxins are poisonous substances that are formed as a result of mold growth on peanuts, corn, figs, oil-seeds, tobacco, and other products. The International Agency for Research on Cancer (IARC) has classified aflatoxin B1 as a group I carcinogen (known to be carcinogenic to humans). Ingestion of elevated levels of aflatoxin also can result in acute aflatoxicosis, characterized by vomiting, abdominal pain, hepatitis, and sometimes death.

Ochratoxin A

The mycotoxin ochratoxin A, produced by many different species of *Aspergillus* molds, is toxic to the kidneys. Ochratoxin A contaminates many foods, including barley, rye, and other cereals, cereal-derived foods, dry fruits, beans, cocoa, coffee, beer, wine, poultry, eggs, pork, and milk. Ochratoxin A is teratogenic, immunotoxic, genotoxic, and mutagenic. The IARC has indicated that ochratoxin is a possible human carcinogen (category 2B).

Fumonisins

Fumonisins are mycotoxins that may contaminate cornmeal and cereals. The fumonisins are known to interfere with sphingolipid metabolism. Consuming foods contaminated with fumonisins during pregnancy has been linked to an increased risk of having a child with a neural tube defect and an increased risk of esophageal cancer in adulthood.

Deoxynivalenol

This mycotoxin, often called *vomitoxin* because its predominant effect is vomiting, can be present in foods made from wheat and corn. Even after the grain is baked or cooked, vomitoxin retains its toxicity. Multiple epidemics of vomiting illness that occurred in China during 1961 to 1985 were associated with ingesting grain contaminated with vomitoxin. In India in 1987, almost 100 people started vomiting after they ate wheat products that contained vomitoxin and other mycotoxins. For infants, the estimated tolerable daily intake is 1.5 µg/kg body weight. A suspected epidemic of vomitoxin-related illness that affected about 1,700 school children in the United States in 1997-98 was linked to burritos that had measurable levels of vomitoxin of 0.3 parts per million (ppm; the advisory level set by the U.S. Food and Drug Administration for adults is 1 ppm).

Chapter 758

Biologic Effects of Ionizing Radiation on Children

Samuel L. Brady and Donald P. Frush

DIAGNOSTIC IMAGING, RADIATION THERAPY

Ionizing radiation is produced when energy is absorbed within an atom such that a bound electron is liberated, and the atom becomes ionized. Exposure to ionizing radiation is characterized by three

categories: (1) **absorbed dose**, (2) **equivalent dose**, and (3) **effective dose**. In terms of radiation interaction with humans, absorbed dose is defined as the energy imparted (i.e., absorbed) within a mass of tissue from a radiation source. Absorbed dose is calculated based on the attenuation properties of the irradiated tissue (e.g., attenuation is greater in bony tissue due to its higher electron density and mass than water equivalent, soft tissue organs). The units of absorbed dose, as defined by the International Commission of Radiation Units, are the **Gray** (Gy), the preferred unit, and the older radiation absorbed dose **(rad)**. There are different types of radiation including x-ray, γ-ray, α particles (helium nucleus stripped of all electrons), β particles (unbound electrons), neutrons, and protons. Not all radiation has the same effect on biologic tissue for a given absorbed dose; for example, β particles are quite superficial, protons deposit most of their energy deeper within the body, and α particles and neutrons cause significantly more damage than x-rays or γ-rays. Diagnostic imaging uses x-rays and γ-rays. The therapeutic use of radiation for cancer treatment primarily uses x-rays, β particles, and protons depending on their application and location of disease within the body. **Equivalent dose** is a term used to define the relative effectiveness to cause biologic damage. The International Commission on Radiological Protection (ICRP) gives x-rays, γ-rays, and β particles a relative weighting of 1, protons a weighting of 2, neutrons a weighting of 2.5-20 (neutron weighting factor depends on the energy of the neutron), and α particles a weighting of 20. Thus, for the same level of radiation exposure to an organ, the equivalent dose, i.e., the relative level of biologic damage, would be higher for absorbed doses from protons compared with x-rays. **Effective dose** is a term that represents "the sum of the weighted [applying organ and tissue weighting factors] equivalent doses for the radiosensitive tissues and organs of the body" (National Council on Radiation Protection and Measurements). A list of relative organ and tissue weighting factors defined by the ICRP is provided in Table 758.1. Equivalent dose and effective dose are measured in units of **sievert** (Sv), with levels in diagnostic imaging typically in millisieverts (mSv), and the **rem** (older unit) (Table 758.2). Effective dose is not applied as a metric of dose to an individual but is a population average. Effective dose is not adjusted based on real or potential radiation susceptibilities for tissues for either gender or age.

Nuclear medicine and PET imaging examinations are described by the amount of radioactivity given, commonly injected intravenously. Administered radioactivity is referred to as the administered radiopharmaceutical dose, commonly defined in millicuries (mCi) or megabecquerels (MBq). Radiopharmaceutical dose may be converted to effective dose by applying correction factors provided in ICRP reports 53, 80, 106, and 128.

Table 758.1 Tissue Radiosensitive Weighting Factors; ICRP Report 103

TISSUE	TISSUE WEIGHTING FACTOR (W_T)	$\sum w_T$
Red bone marrow, colon, lung, stomach, breast, remainder tissues*	0.12	0.72
Gonads	0.08	0.08
Bladder, esophagus, liver, thyroid	0.04	0.16
Bone surface, brain, salivary glands, skin	0.01	0.04
Total		1.00

*Remainder tissues: Adrenal glands, extrathoracic region, gallbladder, heart, kidneys, lymphatic nodes, muscle, oral mucosa, pancreas, prostate, small intestine, spleen, thymus, uterus/cervix

For the average adult, ionizing radiation exposure occurs from both natural (60%) and medical (40%) sources, and for the average pediatric-age individual, ionizing radiation exposure occurs primarily from natural sources (91%) as compared to medical sources (9%) (National Council on Radiation Protection and Measurements). Radon gas accounts for the majority of natural radiation exposure. For the adult population, the percentage contribution from medical imaging to the total ionizing radiation exposure had been increasing in the late 20th and early 21st century, but is now declining since 2006. As of 2016, for the average adult, CT imaging comprised 63% of the total of ionizing radiation procedures (Fig. 758.1A), but medical imaging accounted for only 42% of the average adult population exposure to ionizing radiation; this has decreased slightly in the past decade due to technologic advances in imaging equipment and how we use the equipment in practice. For the pediatric patient population, CT remains the primary source of medical radiation exposure, accounting for 84% of the total medical exposure (annual per capita exposure) from ionizing radiation (see Fig. 758.1B). Despite efforts to educate the medical community and the public on radiation safety and the guiding principle of keeping radiation dosing "as low as reasonably achievable (ALARA)," understanding of sources, amounts, and potential risks of ionizing radiation can still be limited. Some imaging procedures do not produce ionizing radiation (Table 758.3), and not all ionizing radiation-producing modalities expose a child to the same amount of radiation (Table 758.4). To facilitate choosing the appropriate imaging modality for a patient's clinical indications, American College of Radiology appropriateness criteria have been published (https://www.acr.org/Clinical-Resources/ACR-Appropriateness-Criteria) to assist referring physicians in making the most appropriate imaging or treatment decision for a specific clinical condition.

BIOLOGIC EFFECTS OF RADIATION

Biologic effects of radiation are divided into **tissue reactions** (previously known as **deterministic effects**) and **stochastic effects**. Tissue reactions do not occur below a threshold absorbed dose, and severity is directly related to the magnitude once the threshold is exceeded. No evidence of tissue reactions has been demonstrated from radiation dose levels typical of diagnostic imaging examinations (i.e., <100 mGy), but complicated interventional procedures have on rare occasions led to these effects. Typical tissue reactions can present as temporary hair loss (epilation) and skin reddening (erythema), which occur in regions of peak dose of >2 Gy (Table 758.5). Cataracts have been reported to occur with acute exposure of >0.5 Gy.

The second type of biologic effect is the **stochastic effects** that are of concern because they are assumed to potentially occur at any dose; that is, there is no threshold. Stochastic effects are most commonly discussed as cancer risk but also include heritable effects. The probability of a stochastic effect increases with rising level of absorbed dose, but not the severity. Cancer, if radiation induced, is not more severe with higher doses. It is generally accepted by the scientific and medical community that stochastic effects may be caused by any level of radiation striking vulnerable tissue (most importantly DNA, but cytoplasm also may be at risk) and causing irreversible damage. The most widely accepted model representing stochastic effects is the **linear no (dose) threshold (LNT) model**. This model maintains that any level of radiation dose has a potential risk, although this risk is currently uncertain at effective dose levels below 50-100 mSv. Greater than this range, there is a recognized, although very small, statistically significant risk of a stochastic effect. In the LNT model, no level of radiation exposure is assumed to be safe.

Table 758.2 Radiation Measurements

UNITS	RADIOACTIVITY	ABSORBED DOSE	EFFECTIVE DOSE	EXPOSURE
Common units	Curie (Ci)	rad	rem	Roentgen (R)
SI units*	Becquerel (Bq)	Gray (Gy)	Sievert (Sv)	Coulombs/kg

CONVERSION EQUIVALENTS
1 millicurie (mCi) = 37 megabecquerels (MBq)
100 rad = 1 Gy (1 rad = 1 cGy)
100 rem = 1 Sv (1 rem = 10 mSv)
Background radiation dose is approximately 10 μGy/day (1 millirad/day)

*SI units: International System of Units.

Radiation can cause permanent cell injury leading to carcinogenesis, genetic variants, or cell death. The biologic effects of radiation result primarily from damage to DNA. **Direct effect** reactions occur mainly through interactions of high **linear energy transfer (LET)** particles, such as α particles or neutrons, directly with the DNA structure. A similar mechanism also can occur with x-ray or γ-ray photons by directly liberating an electron from atoms (called a recoil electron) near the DNA structure. The kinetic energy of the recoil electron or high LET particles may directly cleave chemical bonds in the DNA structure.

An **indirect effect** is caused by the formation of free radicals. This is the more common mechanism with x-rays and γ-rays used in medical imaging. Approximately 80% of the cell is water, so most of the energy deposited in a cell results in the production of aqueous free radicals. This occurs when the absorbed x-ray or γ-ray photon energy is converted to recoil electrons that create ion radicals (H_2O^+ and H_2O^-). The ion radicals promptly decay (10^{-18} to 10^{-3} seconds) into free radical species (OH^-, H^+, H_3O^+). Approximately two thirds of DNA damage is believed to be caused by this indirect effect through creation of hydroxyl (OH^-) free radicals, which then primarily reacts with DNA by attaching to the hydrogen bound to the deoxyribose carbon resulting in a base release from the DNA structure and strand break of the DNA helix. The biochemical changes that follow either direct or indirect effects take hours or days to manifest, whereas the physiologic changes leading to the likely complex cascade of a variety of factors for cancer induction may take years to decades to manifest.

The results from DNA injury are variable. The cell containing the damaged DNA almost always repairs itself and continues as a viable cell for miotic division. In some instances, the cell might die; one form of cell death is called **apoptosis**, which is a common pathway to eliminate heavily damaged and potentially mutable cells. Damage to a single base pair from radiation exposure is the most prevalent and least significant effect. Ninety percent of single-strand DNA breaks are repaired within an hour by naturally occurring DNA repair processes; therefore they usually have little biologic significance because each strand is repaired with use of the opposite strand as a template. Though less likely, a pathogenic variant can result from single-strand break repair if inaccurate repairs occur; however, large regions of the DNA genome on somatic cells are not active or do not have genes that are expressed. Inaccurate repair in these regions of the genome lead to minimal biologic effect and are sufficient to produce viable cells.

Breakage of both strands of DNA (i.e., double-strand break) is the least common event, but more problematic. The ultimate outcome for cell viability depends on the proximity of the break in each strand. If widely separated (greater than 10 base pairs), which is essentially two remote single-strand breaks, repairs occur rather seamlessly. If the breaks in the two strands are opposite or near each other (separated by less than 10 base pairs), repair is more difficult as there is no reciprocal base pair to serve as a "memory" template. Radiation-induced double-stranded breaks generally lead to cell death or **chromosomal misrepair,** potentially leading to pathogenic gene variants that may result in carcinogenesis.

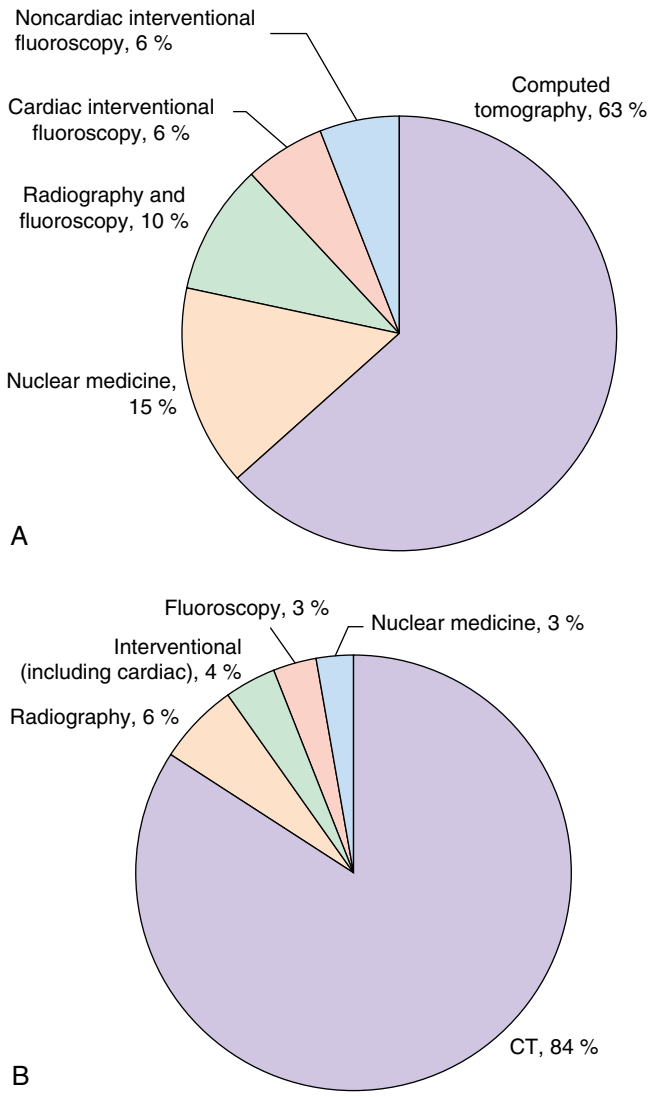

Fig. 758.1 Percentage radiation exposure by diagnostic imaging modality for (A) adult and (B) pediatric populations. *(Adapted with permission of the National Council on Radiation Protection and Measurements, Report 184: Medical Radiation Exposure of Patients in the United States, 2019. Figs. 14.3 and 12.2.)*

When misrepaired DNA damage occurs, aberrations may then be produced in chromosomes, resulting in an *unstable aberration* (usually lethal to dividing cells) or a *stable aberration.* Stable aberrations can result in failure of chromosomes to reunite (leading to deletions) or in abnormal rearrangement of chromosomes, such

as reciprocal translocation or aneuploidy. Although it is logical to think that these abnormalities in chromosomes lead to variants that can activate oncogenes or protooncogenes, or cause variants in tumor-suppressor genes (see Chapter 541), few radiation-induced cancers show specific translocations such as would be associated with activation of specific oncogenes or known tumor-suppressor genes. An exception is the radiation induction of papillary thyroid carcinoma in children, which probably results from activation of the RET oncogene (see Chapter 607).

A longitudinal study of the lifetime risks of excess cancer mortality to irradiation has been evaluated in atomic bomb survivors. More than 120,000 survivors since 1950 have been followed since exposure; additionally, 3,600 in utero survivors and their 77,000 progeny have been followed since 1945. Individual radiation doses were estimated by considering the person's location in relation to distance from the epicenter and individual shielding situations (such as line of sight with respect to buildings and terrain). Radiation types were mixed, and most of the exposure was direct gamma irradiation; neutron exposure was out to approximately 2,000 m. Age at exposure, lifestyle, and other factors were considered in the analytic models when calculating cancer occurrence (Fig. 758.2).

The pediatric population is approximately two to three times more sensitive to radiation-induced carcinogenesis compared with middle-age adults; however, the risk even in this population is indirectly related to age where the neonate is more sensitive than the older child to an identical radiation exposure. Because of the higher risks associated with breast and thyroid cancer, females are also more sensitive than males. It must be understood that cancer rates in this study are mortality figures; the incidence of cancer is approximately twice that of the mortality incidence for all ages. The Centers for Disease Control and Prevention (CDC) reports no scientific evidence demonstrating noncancerous effects (e.g., malformations, growth, intellectual disability, etc.) from in utero exposure <50 mGy, an exposure level that is greater than essentially any single diagnostic examination using ionizing radiation. Additionally, noncancerous effects may only increase slightly with exposure levels between 50 and 500 mGy. In utero radiation exposure is associated with an excess risk of developing (all types) childhood cancer: 1% (<100 mGy), 1–6% (100-500 mGy), and >6% (>500 mGy) as compared to 0.7% naturally. Children are at increased risk of stochastic risks for identical levels of exposure seen in adults because (1) children are growing rapidly, with many

Table 758.3 Imaging Modalities

MODALITY	SOURCE
Radiography (digital plain film x-ray)	Radiation (x-ray)
Fluoroscopy and fluoroscopically guided procedures	Radiation (x-ray)

Philadelphia: Elsevier; 2019: p. 5; and Hall EJ. *Radiobiology for the Radiologist*, 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2006: p. 41.

cells undergoing mitotic activity dependent on undamaged DNA and chromosomes, and (2) radiation-induced tumors (except leukemia) take a relatively long time to develop and children have a longer lifetime. Policies relating to the use of therapeutic abortion have been established by the ICRP and American College of Obstetricians and Gynecologists, which state that fetal doses <100 mGy should not be considered a reason for terminating pregnancy, and that every woman should be counseled that exposure from a single diagnostic procedure does not result in tissue effects to the fetus.

Most childhood tumors occur sporadically, but 10–15% of cases have a strong familial association. Familial tumors have specific chromosomal deletions in common. In some of these tumors (e.g., retinoblastoma), the two-hit hypothesis is apparent (see Chapter 541). Individuals with certain congenital diseases are at higher risk for the development of tumors after irradiation. Table 758.6 lists diseases that are associated with sensitivity to radiation.

RADIATION EXPOSURE IN DIAGNOSTIC IMAGING OF CHILDREN

Imaging modalities utilizing ionizing radiation for diagnostic purposes (e.g., CT, nuclear medicine, PET, radiography, and fluoroscopy or fluoroscopically guided procedures) are commonly utilized; however, increased awareness of the long-term risk for cancer induction and mortality has led to declining pediatric CT use over the past decade. The European EPI-CT study found a significant dose-response relationship between CT-related radiation exposure and brain cancer as well as hematologic malignancies in a large international study cohort, supporting the concept that stochastic effects are a dose-dependent probability, with the probability of an effect increasing with radiation dose. Therefore it is important that we use the lowest dose necessary to get sufficient diagnostic images. Various federal agencies, healthcare accrediting bodies, and national professional organizations support this goal and provide recommendations or requirements for all imaging examinations to have some retrievable radiation dose estimate, and for institutions and clinics that provide ionizing radiation imaging services to track and review patient examination dose levels annually, comparing these dose levels with expected dose ranges and external benchmarks.

Dose reporting and aggregating software provides the ability to collect and analyze individual examination doses and gives healthcare providers a powerful tool to correct outlier examinations (i.e., over exposures), over utilization, and address other systemic errors present in imaging clinics (such as radiation dose creep with time).

DECREASING UNNECESSARY DIAGNOSTIC RADIATION IN CHILDREN WHILE STILL OBTAINING DIAGNOSTIC IMAGES

Ultimately, the lowest radiation dose examination is the imaging examination performed without ionizing radiation. For an increasing number of indications, utilization of nonionizing radiation modalities such as ultrasound or MRI may be the first consideration for diagnosis. Selecting the correct examination is the responsibility of the requesting healthcare provider and may involve consultation with the radiologist, preferably with pediatric expertise. Clinical decision support algorithms are also available to assist with examination appropriateness (e.g., American College of Radiology's Appropriateness Criteria). The risk of using ionizing radiation for imaging should be weighed against other risks during imaging. CT (depending on the indication and region examined) may detect as many abnormalities as MRI, but CT involves ionizing radiation. However, sedation is often required to successfully obtain MRI imaging in young children; in these cases, consideration of the relative risks of cognitive impairment from moderate sedation and anesthetic versus potential radiation risks use should come into play.

Reducing Radiation from the CT Examination

The most common source of medical radiation for all ages is CT. CT offers the ability to acquire high-quality volumetric imaging datasets in seconds. For many years, adult parameters for CT settings were used for children, which led to dosages for children much higher than the dosage for adults. This occurs because lower energy x-rays that would have been absorbed in the near field in an adult pass into the entire child, with relatively greater organ irradiation for the same exposure. When comparing dosages given to newborns and adults during CT scanning of the head, with the same parameters in both groups, the dosage given to newborns can be four times that of the dosage given to adults; with abdominal imaging, the dosage is increased by 60%. It is the role of the radiologist and technologist, with the help of a medical physicist, to develop and monitor protocols that tailor the examination to the individual indication and for the variabilities in sizes found in the pediatric population.

Modern CT scanners have many tools to help administer the appropriate amount of radiation dose to a pediatric patient and acquire the necessary diagnostic image quality from the imaging examination. Radiologists should work in conjunction with medical physicists and vendor supplied application specialists to tailor specific examination protocols to the pediatric patient population by establishing appropriate scan parameters such as the kilovoltage (kV). Scan range should be limited to only the necessary area for diagnosis (e.g., a chest only scan should begin at the lung apices and extend to no more than a little below the lowest lung base). Multiphasic scanning should be only obtained when justified; for example, in pediatric abdominopelvic CT multiple phases should be necessary in no more than approximately 5% of examinations.

Technologic advances for modern CT scanners are using reconstruction algorithms, such as statistical iterative reconstruction (IR), model-based IR, and deep learning reconstruction (DLR), as well as photon counting technology. These algorithms have been shown to allow the reduction of radiation dose for IR algorithms by 15-30% and DLR algorithms by 44-83% in some patient populations while maintaining equivalent diagnostic confidence to the pre-dose reduced image datasets. Other practical steps to reduce pediatric population radiation dose include replacing older CT scanners with technologically advanced scanners; monitoring institution dose values, which can be compared with available benchmarks, such as **diagnostic reference levels (DRLs)**; and performing only examinations that are justified. Advances in technology and attention to proper performance of examinations have contributed to overall reductions in pediatric patient population doses by >50% during the past two decades.

RADIATION THERAPY: ACUTE AND LATE EFFECTS

Radiation therapy uses high doses to kill malignant cells. The sensitivity of normal cells is quite close to that of malignant cells, and to achieve significant cure rates, radiation oncologists must accept a given percentage of serious complications (5–10%). Radiation causes tissue loss plus injury to the underlying vasculature. The vascular change may be progressive, leading to arteriocapillary fibrosis and irreparable injury, in turn leading to further tissue loss.

The acute effects of therapy (occurring less than 3 months after therapy begins) are usually related to the area of the body being irradiated (except fatigue, which can begin during this time period). These acute effects include radiation-induced pneumonitis, dermatitis, mucositis and esophagitis, cerebral edema, and swelling of the organ irradiated. There may be changes in bowel movement patterns. Of these, one of the most severe acute reactions is pneumonitis. It can manifest within

Table 758.7 Late Effects of Radiation Therapy in Children Treated for Cancer

SYSTEM	LATE EFFECT	DOSE (GY)
Musculoskeletal	Muscular hypoplasia	>20
	Scoliosis, kyphosis, lordosis	>20
	Osteocartilaginous exostosis/ osteochondroma	>12
Neuroendocrine (cranial or cranial spinal)	Impaired growth hormone	>15
	Adrenocorticotropic hormone deficiency	>30
	Thyrotropin-releasing deficiency	>40
	Precocious puberty (females mostly)	>18
	Gonadotropin deficiency	>30
Gonad failure	Ovarian failure	>10
	Testicular failure	>3
Central nervous system dysfunction	Structured changes	>18
	Cognitive changes/Processing speed	Variable
Other	Pulmonary fibrosis	>15
	Nephropathy	>20
	Liver disease	>30 (>60% liver volume)
	Cerebral arteriopathy	>50
	Eye impairment (cataracts, legally blind, double vision, dry eyes)	>5
	Hearing loss	>30
	Dental abnormalities	>20
	Cardiac impairment	>30

24 hours of irradiation when there is an exudation of proteinaceous material into the alveoli and interalveolar edema. Most often, however, radiation pneumonitis begins 2-6 months after the beginning of radiation with a clinical presentation of fever, cough, congestion, and pruritic pain. The late effects of therapy (beginning more than 3 months after therapy) are numerous (Table 758.7). The most common are abnormalities of musculoskeletal development, endocrine/reproductive function, pulmonary function, neurocognition, hearing loss, cardiac function, eye impairment, and dental abnormalities.

As of 2020, there are more than 500,000 childhood cancer survivors in the United States. The risk of developing a second cancer among cancer survivors is over fivefold higher than the general population. Second cancers account for 2.3% of all cancers in children; this reflects an overall standard incidence rate (SIR) of 5.5%. Primary malignancies with the highest cumulative incidence of a second neoplasm in the order of frequency are retinoblastoma (10.4%), CNS cancers (7.4%), cancers of bone (7.2%), soft tissue sarcomas (6.5%), hepatic cancer (5.9%), and neuroblastoma (5.9%) [data from the U.S. Surveillance, Epidemiology, and End Results program (SEER)]. Table 758.8 relates second cancers to primary cancer and latency period. Almost 70% of the second neoplasms are in the field of the original irradiation. Radiation therapy increases the risk of second cancers in a dose-dependent manner for nongenetic neoplasms.

The exact complications depend on the location of the treatment field. In children, because of the location of many childhood tumors, the normal brain is commonly in the treatment field. Standard irradiation of the brain in children results in cortical atrophy in more than half of patients who receive 20-60 Gy; 26% are left with white matter changes (leukoencephalopathy) and 8% with calcifications. The younger the child is at the time of irradiation, the greater the atrophy. Some patients also demonstrate mineralizing microangiopathy. Radiation-induced changes of the brain are potentiated by methotrexate administered before, during, or after radiation therapy.

Cerebral necrosis is a serious complication of radiation-induced vascular disease. It is usually diagnosed 1-5 years after irradiation but can occur up to a decade later. Brain necrosis may manifest as headache, increased intracranial pressure, seizures, sensory deficits, and psychotic changes.

Spinal cord irradiation may result in **radiation myelitis,** which may be either transient or permanent. Acute transient myelitis often appears 2-4 months after irradiation. Patients with myelitis usually present with **Lhermitte sign,** a sensation of little electrical shocks radiating down the spine into the arms and legs, occurring with neck flexion or other movements that stretch the spinal cord. Reversal of transient myelopathy usually occurs between 8 and 40 weeks and does not necessarily progress to delayed necrosis.

Delayed myelopathy occurs after a mean latent period of 20 months but can occur earlier if the total dose or the dose per fraction is high. It usually manifests as discontinuous deterioration and is irreversible. In the cervical and thoracic regions, sensory dissociation develops, followed by spastic and then flaccid paresis. In the lumbar cord, flaccid paresis is dominant. The mortality for high thoracic and cervical lesions reaches 70% with death commonly being due to pneumonia and urinary tract infections.

CNS irradiation may affect growth by compromising function of the pituitary-hypothalamic axis and leading to diminishing growth hormone production and release. Non–growth hormone tropins may also be affected by CNS irradiation, leading to gonadotropin deficiency or precocious puberty. Central hypothyroidism can also develop. CNS irradiation also compromises bone mineral deposition both locally (in the radiation field) and systemically.

Irradiation has other effects specific to children. Scoliosis and hypoplasia of bones may occur if fractionated treatment schemes exceed 4,000 rad. Fractionated doses higher than 25 Gy can result in slipped capital femoral epiphyses. An increase in the incidence of benign osteochondromas has been reported after childhood irradiation. Chest wall irradiation in females (besides causing breast cancer) may impair breast development and/or cause fibrosis and atrophy of breast tissue.

WHOLE BODY IRRADIATION

Uncontrolled Large- or Small-Scale Exposure to Radiation

Large-scale exposure to radiation can occur in an event of nuclear accidents, war, or terrorist attacks (Fig. 758.3). Radiation as well as explosive and thermal injury need to be considered.

Clinical Manifestations

A large single exposure of penetrating radiation can result in **acute radiation syndrome** (Table 758.9). The signs and symptoms of this syndrome result from damage to major organ systems that have different levels of radiation sensitivity, modulated by the rate at which the radiation exposure occurred. Delivery of 1 Gy in 1 minute would be symptomatic, but delivery of 1 cGy/day for 100 days would not be symptomatic.

The **hematopoietic syndrome** results from acute whole body doses >0.7-10 Gy; where healthy patients will almost always recover from doses <2 Gy. The dose that kills 50% of a population in 60 days is approximately 3.5-4.5 Gy, where effective blood transfusions and antibiotics may extend the dose range to 5-8 Gy. Doses >8 Gy almost always lead to hematopoietic-induced death. Symptoms of exposure consist of a *prodromal phase* during which the patient will experience nausea/vomiting, diarrhea, and fatigue within the first 12 hours, with symptoms usually lasting up to 48 hours. A *latent period* of 2-3 weeks, during which patients may feel quite well, follows. Although patients are asymptomatic, bone marrow impairment has occurred. The most obvious laboratory finding is lymphocyte depression (Table 758.10). Maximal bone marrow depression occurs approximately 30 days after exposure, when hemorrhage and infection can be major problems. If the bone marrow was not completely eradicated, a *recovery phase* then ensues. This radiation effect is similar to what occurs when whole body irradiation (given as 12 Gy in two treatments) is used

Table 758.8 Second Cancers and Their Relationship with Primary Cancers

SECOND CANCERS	PRIMARY CANCERS	LATENCY (MEDIAN IN YEARS)	RISK FACTORS
Brain tumors	ALL; brain tumors; HD	9-10	Radiation; younger age
Myelodysplastic syndromes/ acute myelogenous leukemia	ALL; HD; bone tumors	3-5	Topoisomerase II inhibitors; alkylating agents
Breast cancer	HD; bone tumors; soft tissue sarcomas; ALL; brain tumors; Wilms tumors; NHL	15-20	Radiation; female gender
Thyroid cancer	ALL: HD; neuroblastoma; soft tissue sarcomas; bone tumors; NHL	13-15	Radiation; younger age; female gender
Bone tumors	Retinoblastoma (heritable); other bone tumors; Ewing sarcoma; soft tissue sarcomas; ALL	9-10	Radiation; alkylating agents; removal of the spleen
Soft tissue sarcomas	Retinoblastoma (heritable); soft tissue sarcomas; HD; Wilms tumors; bone tumors; ALL	10-11	Radiation; younger age; anthracyclines

ALL, Acute lymphocytic leukemia; HD, Hodgkin disease; NHL, non-Hodgkin lymphoma.

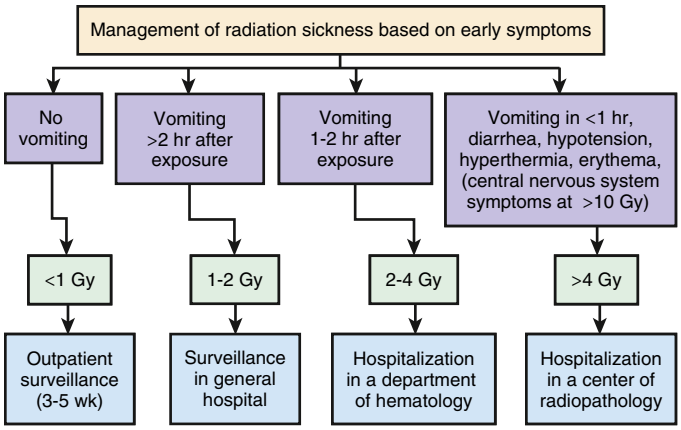

Fig. 758.3 Management algorithm for radiation sickness at different levels of medical care, depending on the appearance of early symptoms and the estimated radiation dose to the whole body. *(From Turai I, Veress K, Günalp B, et al. Medical response to radiation incidents and radionuclear threats. BMJ. 2004;328:568–572.)*

to obliterate the bone marrow in children with leukemia before bone marrow transplantation.

The **gastrointestinal (GI) syndrome** occurs from acute whole body doses >6-10 Gy. Prompt onset of nausea, vomiting, and diarrhea follows. There is a latent period of approximately 1 week if intense medical treatment is administered. Following the latent period, recurrence of GI symptoms, sepsis, and electrolyte imbalance occurs, which results in death at about 2 weeks postexposure from GI tract and bone marrow destruction.

At dose levels exceeding 20-50 Gy, the **cardiovascular/CNS syndrome** predominates. Nausea, vomiting, prostration, hypotension, ataxia, and convulsions are almost immediate. The latent period occurs between 4 and 6 hours postexposure followed by severe manifestation of the initial illness stage leading to eventual coma and death within 2-3 days.

Treatment

For the hematopoietic and GI syndromes, treatment is supportive involving transfusions and Neupogen (filgrastim), Neulasta (pegfilgrastim) and other hematopoietic growth factors, fluids, and, if infected antibiotics and antiviral agents. Stem cell (bone marrow) transplantation may be needed in severe cases.

Localized Irradiation

Clinical Manifestations

Because localized exposure involves a small amount of tissue, systemic manifestations may be less severe, and patients may survive even if locally absorbed doses are very high. The hand is the most common site for accidental localized irradiation injuries, usually as a result of picking up or playing with lost radiation sources. The second most common accidental site is the thigh and buttocks, predominantly from placing unsuspected highly radioactive sources in the pockets.

Table 758.11 lists the skin changes that occur after a single acute, localized irradiation. As opposed to other forms of thermal burns, signs of irradiation appear a period of days *after* the exposure. Vascular insufficiency may appear months to years later and cause ulcerations or necrosis in formerly healed areas. The penetrability of the radiation is an important factor in the outcome of local radiation injury. Beta particles from heavy radiation fallout can cause superficial skin burns because they have low penetrability.

Some tissues that may receive localized radiation exposure are relatively radiosensitive. **Cataract formation** (see Chapter 668) may occur with single γ-ray exposures in the range of <1 Gy. Such cataracts usually take from 2 months to several years to develop. **Oligospermia** may take up to 2 months to develop. Transient infertility in men may result from doses as low as 0.15 Gy, and permanent sterility may occur in males at dose levels between 3 and 6 Gy.

Treatment

Skin therapy is directed at prevention of infections. Treatment of localized injuries usually involves class II to III topical steroids and plastic surgery and grafting, if the radiation exposure was not deeply penetrating (see Chapter 89). The nature of the surgery depends on the dose at various depths in tissue and the location of the lesion. The full expression of radiation injury often is not apparent for 1-2 years due to slow arteriolar narrowing that can cause delayed necrosis. After relatively penetrating radiation, amputation may be necessary because of obliterative changes in small vessels.

INTERNAL CONTAMINATION

Epidemiology

Accidents involving internal contamination are rare and are usually the result of misadministration in hospital settings or voluntary ingestion of unsuspected contaminated radioactive materials. Other possible causes of internal contamination of children include ingestion of breast milk from mothers who have had diagnostic nuclear medicine scans and radiation exposure when a parent or sibling receives a therapeutic dose of iodine-131.

Table 758.9 Acute Radiation Syndrome

SYNDROME	DOSE*	PRODROMAL STAGE	LATENT STAGE	MANIFEST ILLNESS STAGE	RECOVERY
Hematopoietic (bone marrow)	>0.7 Gy (>70 rads) *(mild symptoms may occur as low as 0.3 Gy or 30 rads)*	• Symptoms are anorexia, nausea and vomiting • Onset occurs 1 hr to 2 days after exposure • Stage lasts for minutes to days	• Stem cells in bone marrow are dying, although patient may appear and feel well • Stage lasts 1-6 wk	• Symptoms are anorexia, fever, and malaise • Drop in all blood cell counts occurs for several weeks • Primary cause of death is infection and hemorrhage • Survival decreases with increasing dose • Most deaths occur within a few months after exposure	• In most cases, bone marrow cells will begin to repopulate the marrow • There should be full recovery for a large percentage of individuals from a few weeks up to 2 yr after exposure • Death may occur in some individuals at 1.2 Gy (120 rads) • The $LD_{50}/60$† is about 2.5-5 Gy (250-500 rads)
Gastrointestinal (GI)	>10 Gy (>1,000 rads) *(some symptoms may occur as low as 6 Gy or 600 rads)*	• Symptoms are anorexia, severe nausea, vomiting, cramps, and diarrhea • Onset occurs within a few hours after exposure • Stage lasts about 2 days	• Stem cells in bone marrow and cells lining GI tract are dying, although patient may appear and feel well • Stage lasts <1 wk	• Symptoms are malaise, anorexia, severe diarrhea, fever, dehydration, and electrolyte imbalance • Death is due to infection, dehydration, and electrolyte imbalance • Death occurs within 2 wk of exposure	• The LD_{100}‡ is about 10 Gy (1,000 rads)
Cardiovascular (CV)/ central nervous system (CNS)	>50 Gy (5,000 rads) *(some symptoms may occur as low as 20 Gy or 2,000 rads)*	• Symptoms are extreme nervousness and confusion; severe nausea, vomiting, and watery diarrhea; loss of consciousness; and burning sensations of the skin • Onset occurs within minutes of exposure • Stage lasts for minutes to hours	• Patient may return to partial functionality • Stage may last for hours but often is less	• Symptoms are return of watery diarrhea, convulsions, and coma • Onset occurs 5-6 hr after exposure • Death occurs within 3 days of exposure	• No recovery is expected

*The absorbed doses quoted here are "gamma equivalent" values. Neutrons or protons generally produce the same effects as γ-, β-, or x-rays but at lower doses. If the patient has been exposed to neutrons or protons, consult radiation experts on how to interpret the dose.
†The $LD_{50}/60$ is the dose necessary to kill 50% of the exposed population in 60 days.
‡The LD_{100} is the dose necessary to kill 100% of the exposed population.
From Centers for Disease Control and Prevention. Acute radiation syndrome: a fact sheet for clinicians. Table 1. https://www.cdc.gov/nceh/radiation/emergencies/arsphysicianfactsheet.htm.

Table 758.10 Expected Outcome Based on Absolute Lymphocyte Count After Acute Penetrating Whole Body Irradiation

MINIMAL LYMPHOCYTE COUNT WITHIN FIRST 48 HR AFTER EXPOSURE	PROGNOSIS
1,000-3,000 (normal range)	No significant injury
1,000-1,500	Significant but probably nonlethal injury, good prognosis
500-1,000	Severe injury, fair prognosis
100-500	Very severe injury, poor prognosis
<100	Lethal without compatible bone marrow donor

Clinical Manifestations

The hazards from internal contamination depend on the nature of both the radionuclide (particularly in terms of its solubility in water, half-life, biologic half-life, and radioactive emission) and the chemical compound.

Treatment

The most effective treatment requires knowledge of both the radionuclide and the chemical form. Treatment must be instituted quickly to be effective (Table 758.12). **Removal treatment** involves cleaning a contaminated wound and performing gastric lavage or administration of cathartics in the case of ingestion. Administration of alginate-containing antacids (e.g., Gaviscon) also usually helps in removal by decreasing absorption in the GI tract. An example of **blocking therapy** is the administration of potassium iodine or other stable iodine-containing compounds to patients with known internal contamination with radioactive iodine. The stable iodine effectively blocks the thyroid, although its effectiveness decreases rapidly as time elapses after the contamination. The recommended dose of potassium iodine is 16 mg

for neonates (up to 1 month of age); 32 mg for children ages 1 month to 3 years; 65 mg for children ages 3-18 years (if less than 70 kg), and 130 mg for adults and adolescents >70 kg. Each dose protects for only 1 day. **Dilution therapy** is used in cases of tritium (radioactive hydrogen as water) contamination. Forcing fluids promotes excretion. Cases of internal contamination with transuranic elements (americium and plutonium) may require **chelation therapy** with calcium diethylenetriamine pentaacetate.

Prussian blue is a drug approved by the FDA for patients with internal contamination with cesium or thallium. It can speed fecal elimination of radioactive cesium from the body. It acts by intercepting the cesium coming into the gut from the bile. Prussian blue prevents

Table 758.11 Skin Changes After a Single, Acute, Localized Radiation Exposure

APPROXIMATE THRESHOLD (GY)	CHANGE
2-4	Primary erythema within hours of exposure (appears more quickly after larger doses)
3	Second phase erythema (develops during the manifestation phase of local radiation injury); appears 14-21 days after exposure
3	Temporary epilation (14-18 days after exposure)
7	Definitive epilation (25-30 days after exposure)
10	Dry desquamation (20-28 days after exposure)
15	Moist desquamation, possible ulceration (15-25 days after exposure)
25	Desquamation with blistering, ulceration, and necrosis (>21 days after exposure)

Table 758.13 Nuclear Regulatory Commission Guidelines on Breastfeeding During the Period During a Nuclear Medicine Examination

RADIOPHARMACEUTICAL	BREASTFEEDING CESSATION
^{11}C, ^{13}N, ^{15}O, ^{82}Rb	None
^{18}F-labeled	12 hr
^{68}Ga-labeled	12 hr
^{99m}Tc-labeled	24 hr
^{123}-I Sodium iodide	7 days
^{111}In-leukocytes	7 days
^{99m}-Tc labeled	No interruption*
^{201}Tl chloride	14 days
^{67}Ga and ^{89}Zr	28 days
^{177}Lu, diagnostic	35 days
^{131}I-NaI	Stop breastfeeding
^{177}Lu, therapeutic	Stop breastfeeding
^{223}Ra and all alpha emitters	Stop breastfeeding

*The guideline for ^{99m}Tc compounds is a 24-hr interruption for >1110 MBq administered, 12 hr for 444-1110 MBq, and no interruption for <444 MBq administered. The normally administered activity is below activities that require any interruption.

From Dilsizian V, Metter D, Palestro C, Zanaonico P. The Advisory Committee on Medical Uses of Isotomes (ACMUI) Sub-Committee on Nursing Mother Guidelines for the Medical Administration of Radioactive Materials, 2018, p. 12. https://www.nrc.gov/docs/ML1803/ML18033B034.pdf

cesium from being absorbed again from the gut. Prussian blue can be given days after ingestion, unlike potassium iodine, which must be given initially in the first 12-24 hours after exposure.

In the case of breastfeeding after a nuclear medicine procedure, two primary concerns are considered: (1) the internal dose to the infant passed through the excreted milk and (2) the dose from the radiopharmaceutical absorption in the female breast that exposes the infant to external γ-rays while undergoing decay. Most imaging radiopharmaceuticals are below the activity calculated to expose the infant to a dose of 1 mSv via either internal or external mode of exposure. Table 758.13 provides a comprehensive list of radiopharmaceuticals and the recommended period for breastfeeding cessation by the U.S. Nuclear Regulatory Commission. In the case of delaying breastfeeding, pumped milk may be stored for the times indicated in Table 758.13, after which they will be safe to feed the infant.

EXTERNAL CONTAMINATION

The presence of external radioactive contamination on a patient's skin is not an immediate medical emergency. Management involves removing and controlling the spread of radioactive materials. If a patient has suspected surface contamination and no physical injuries, decontamination can be performed relatively easily. If substantial physical trauma or other life-threatening injuries are combined with external contamination, surface decontamination should proceed only after the patient has been stabilized physiologically. In many accident situations, essential medical care may be delayed inappropriately by hospital emergency staff because of fear of radiation or spread of contamination in the hospital. After a radiation accident, triaging of patients is critical and is based on exposure and symptoms (see Fig. 758.3).

Chapter 759

Chemical Pollutants

Joel A. Forman and Lauren M. Zajac

More than 85,000 new synthetic chemicals have been developed in the past 75 years. These chemicals are used in millions of products, ranging from food packaging to clothing, building materials, motor fuels, cleaning products, cosmetics, medical products, toys, and baby bottles.

Synthetic chemicals are widely disseminated in the environment. The Toxic Release Inventory of the U.S. Environmental Protection Agency (EPA) reports that in 2021, of 29.3 billion pounds of production-related chemical waste managed, nearly 3.3 billion pounds (11%) were discharged into air, water, and land in the United States. These chemicals are detected today in even the most remote corners of the planet, such as the polar icecaps and in the ocean depths.

All people are at daily risk of exposure to synthetic chemicals, and children are especially likely to be exposed to the nearly 3,000 chemicals that are produced in amounts of 1 million pounds or more per year, designated by the EPA as high-production-volume chemicals. Biomonitoring data on blood and urine levels of more than 400 high-production-volume chemicals are obtained annually by the Centers for Disease Control and Prevention in a sample of the U.S. population through the National Health and Nutrition Examination Survey (NHANES). These data document that most Americans, including children, are routinely exposed to scores of synthetic chemicals; exposure often falls disproportionately on poor children and children of color. Examples are wide ranging and include lead, air pollutants, endocrine disrupting chemicals like phthalates, and many others.

Toxic chemicals are exported in ever-increasing quantities to the world's poorer countries as these countries undergo industrial development. Environmental safeguards in those countries are typically not as stringent as in high-income countries, and the potential for serious exposure is therefore high. Examples of tragedies that have resulted from the movement of toxic chemicals to low- and middle-income countries include the Bhopal disaster in India, in which hundreds were killed and thousands injured by methylisocyanate gas released by an explosion in a pesticide production facility, and the ongoing export each year of more than 2 million tons of newly produced asbestos to the world's poorest countries, where this asbestos is responsible for nearly 200,000 deaths annually from asbestosis, lung cancer, and malignant mesothelioma.

SYNTHETIC CHEMICALS AND HUMAN HEALTH

A recurrent pattern is that chemicals are brought to market with great enthusiasm, presumed harmless, and undergo little or no premarket safety testing. Then years or decades later, after they had come into wide use, the chemicals were found to be harmful to children's health.

Often the first cases of disease caused by these chemicals are clinically severe, but as time passes, evidence of widespread subclinical toxicity comes to light.

Classic historical examples of epidemics caused by inadequately tested toxic chemicals include the following:

- *Tetraethyl lead:* This was added to gasoline in the United States from the early 1920s until 1980. It was responsible for widespread lead poisoning, initially evident as an epidemic of acute toxicity manifesting as encephalopathy, seizures, and even death, but later demonstrated to have caused subclinical neurotoxicity and reduction in IQ across two generations of U.S. children (see Chapter 761).
- *Dichlorodiphenyltrichloroethane (DDT):* This pesticide very nearly led to extinction of the osprey and the American bald eagle and more recently has been linked to increased risk for breast cancer among women exposed decades ago in utero.

- *Polychlorinated biphenyls (PCBs)*: These are highly persistent pollutants banned from production in the United States in 1977, which continue today to contaminate major lakes and rivers and have been found also to be responsible for loss of IQ and disruption of behavior in children.
- *Chlorofluorocarbons:* These destroy the ozone.

Other examples of synthetic chemicals that came into wide use with little assessment of their safety and are now recognized as causing harm to children's health include the following:

- *Phthalates:* These chemicals are added to plastics, cosmetics, medical equipment like intravenous tubing, and common household products that are now linked to increased risk for reproductive abnormalities in male infants and heightened risk of behavioral abnormalities such as attention-deficit/hyperactivity disorder (see Chapter 50).
- *Polybrominated diphenyl ethers:* These are used as flame retardants in carpets, furniture, and electronic equipment and are now linked to persistent loss of intelligence and disruption of behavior in children.
- *Bisphenol A:* A plastics chemical linked to neurodevelopmental disorders.

These chemicals are all produced in volumes of millions of tons per year, are widely disseminated in the environment, and are detectable in the bodies of nearly all Americans. Only decades after their introduction are these chemicals' risks to children beginning to be recognized.

CHILDREN'S UNIQUE SUSCEPTIBILITY TO SYNTHETIC CHEMICALS

The health effects of synthetic chemicals are especially serious when exposure occurs during windows of vulnerability in early life such as during pregnancy, infancy, and early childhood. Children are highly vulnerable to chemical pollutants for several reasons:

1. Children have proportionally greater exposure to environmental pollutants than adults. Because they drink more water, eat more food, and breathe more air per kilogram of body weight, children are more heavily exposed to pollutants in water, food, and air. Children's hand-to-mouth behavior and their play close to the ground further magnify their exposures.
2. Children's metabolic pathways, especially in the first few months after birth, are immature. Although in some instances children are better able than adults to cope with environmental toxicants because they cannot metabolize these chemicals to their active forms, more commonly children are not as able as adults to detoxify and excrete chemical pollutants.
3. Infants and children are growing and developing, and their complex, fast-moving, and highly choreographed developmental processes are exquisitely sensitive to disruption by chemical pollutants. Exposures to even minute doses of toxic chemicals during windows of vulnerability in early development have been shown to cause a wide array of diseases in childhood and to increase risk for chronic disease and disability lifelong (Table 759.1).
4. Because children have many future years of life, they have time for the development of multistage chronic diseases that may be triggered by early exposures.

Table 759.1 Effects of Selected Chemical Pollutants on Infants and Children

CHEMICAL POLLUTANT	EFFECT(S)
Air pollution	Asthma, other respiratory diseases, sudden infant death syndrome
Asbestos	Mesothelioma and lung cancer
Benzene, nitrosamine, vinyl chloride, ionizing radiation	Cancer
Environmental tobacco smoke	Increased risk of sudden infant death syndrome and asthma
Ethyl alcohol	Fetal alcohol syndrome after intrauterine exposure
Lead	Neurobehavioral toxicity from low-dose exposure
Methyl mercury	Developmental neurotoxicity
Organophosphate insecticides	Developmental neurotoxicity
Per- and poly-fluoroalkyl substances (PFAS)	Increased cholesterol levels, altered liver function tests, decreased antibody response to childhood vaccines
Polychlorinated biphenyls	Developmental neurotoxicity
Polybrominated diphenyl ethers	Developmental neurotoxicity
Phthalates	Developmental neurotoxicity and reproductive impairment
Trichloroethylene	Elevated risk of leukemia after intrauterine exposure

SAFETY TESTING OF SYNTHETIC CHEMICALS

Legally mandated testing of chemicals for safety and toxicity coupled with strict controls on dangerous chemicals are the linchpins of chemical safety. Strong chemical safety policies are needed to protect children against disease and death caused by chemicals. A fundamental problem in environmental pediatrics today is that chemical safety policies in many countries are weak. Only approximately 65% of high-production-volume chemicals have been tested for their safety or potential hazard to human health, and fewer than 30% have been assessed for their pediatric or developmental toxicity.

Failure to test chemicals for safety and toxicity reflects the chemical industry's unwillingness to take responsibility for the products they produce coupled with long-standing failure of the previous U.S. federal law on chemical safety, the Toxic Substances Control Act (TSCA). Only five chemicals were banned or controlled under the original TSCA law: PCBs, the ozone-destroying chlorofluorocarbons, and three known human carcinogens—dioxin, asbestos, and hexavalent chromium.

To address the problem of exposure to untested chemicals, countries have enacted stronger chemical safety legislation. In 2007, the European Union enacted the Registration, Evaluation, Authorization, and Restriction of Chemical Substances (REACH) legislation. This law places responsibility on industry to generate data on potential risks of commercial chemicals and to register this information with the European Chemical Agency in Helsinki. The European Union is using this information to craft regulations to protect children's health. Since 2009 REACH has restricted more than 1,000 toxic substances.

In June 2016, the United States passed legislation to revamp TSCA. This law—the Frank R. Lautenberg Chemical Safety for the 21st Century Act—requires the EPA to assess the safety of any new chemical before it is allowed to enter the market, to prioritize safety testing of existing chemicals, and to use a risk-based standard to evaluate chemical safety that considers only hazards to health and is blind to the costs of protective action. This law holds much promise for improving the protection of children's health against toxic chemicals, but it also includes a federal preemption clause that could inhibit state-based protective regulations. Transparency, oversight, and advocacy is critical to ensuring that the law is implemented in a timely manner that is true to the intent to prioritize children's health.

The UN Environment Programme (UNEP) is the United Nations agency responsible for chemical safety. UNEP has called for "a global commitment to the sound management of chemicals. The agency supports and tracks the progress of international agreements and treaties limiting the manufacture, environmental release and global transport of persistent pollutants, pesticides, hazardous waste, and mercury." The Strategic Approach to International Chemicals Management, a program supported by UNEP, provides a platform for coordinating international control of toxic chemicals and hazardous waste across a broad

range of stakeholders. UNEP has worked closely with the World Health Organization (WHO) to coordinate the removal of lead from gasoline in countries around the world.

SYNTHETIC CHEMICALS AND DISEASE IN CHILDREN

A large and growing body of evidence documents that toxic chemicals can cause disease, disability, and death in children. High-dose exposures can cause acute, clinically evident disease. Lower-dose exposures can cause subclinical injury (injury that is very real but detectable only through special testing), such as decreases in intelligence, shortening of attention span, reductions in fertility, and slowing of lung growth. When exposure to a neurotoxic pollutant is widespread, the resulting widespread subclinical neurotoxicity can reduce the intelligence, creativity, and economic productivity of entire societies.

Exposures to toxic chemicals in early life are linked not only to increased risks of disease in childhood, but also to increased risks of disease in later life. This recognition, termed the *developmental origins of health and disease concept*, derives from studies conducted by Barker and colleagues who found that undernutrition in utero is associated decades later with increased risks for hypertension, obesity, diabetes, and cardiovascular disease. Epigenetic programming of gene expression during windows of vulnerability in early development appears to be the underlying mechanism. Increased risks for disease in adult life have now been associated also with early-life exposures to toxic chemicals and appear to be mediated through epigenetic changes in gene expression. Among the health problems linked to toxic chemical exposures in early life are decreased cognition in adults who were exposed as children to lead, neurobehavioral disorders in children exposed to a range of developmental neurotoxicants, and cancer.

CHEMICAL POLLUTANTS OF MAJOR CONCERN

Air Pollutants

Air pollution—ambient air pollution and household air pollution—is the world's largest environmental threat to health and, according to the WHO, is responsible for an estimated 6.7 million deaths each year. The air pollutants of greatest concern for children's health are particulate matter (especially fine particulates less than 2.5 microns in aerodynamic diameter), photochemical oxidants (especially ozone), oxides of nitrogen, sulfur oxides, and carbon monoxide; these are the "criteria air pollutants" regulated by the U.S. EPA in the Clean Air Act. In the United States, approximately 60% of children live in areas that do not meet national ambient air quality standards (NAAQS), most commonly particulate matter and ozone. Globally, ambient levels of air pollutants can be magnitudes higher than the United States.

Fuel combustion is the principal source of air pollution. In high- and middle-income countries, combustion of fossil fuels—coal, oil, and gas—accounts for most air pollution. In low-income and lower middle-income countries, the major source is burning of biomass, such as wood, dung, straw, and charcoal. Coal is the single most highly polluting fossil fuel and the most important source of the greenhouse gas emissions that drive global climate change, but fixed and mobile oil and gas combustion are also major contributors. As the climate changes, wildfires are becoming more common and are further contributing to air pollution and climate change.

Elevated levels of ambient air pollutants are associated with respiratory problems in children, including decreased expiratory volume, wheezing, exacerbations of asthma, and slowed lung growth. Slowed lung growth leads to decreased lung volume and increases risk for respiratory disease in childhood, adolescence, and adult life. Long-term improvements in ambient air quality, especially reductions in levels of particulates and oxides of nitrogen, are associated with statistically and clinically significant improvements in lung growth in children, effects that appear likely to persist into adulthood and to reduce lifetime risk of pulmonary and cardiovascular disease.

Aside from the criteria air pollutants, other pollutants emitted from mobile, stationary, and area sources are considered *hazardous air pollutants* (HAPs), which are known or suspected to cause cancer, reproductive effects, or birth defects. Some common examples are metals such as mercury (neurotoxin), asbestos (mesothelioma, lung cancer), and volatile organic compounds such as polychloroethylene (reproductive effects, cancer). Diesel exhaust is a particularly concerning source of air pollution as it contains fine and ultrafine particulates (capable of reaching alveoli and getting absorbed into bloodstream) and multiple HAPs (e.g., formaldehyde), and has been classified by the International Agency for Research on Cancer as a known human carcinogen.

The effects of household air pollution on children's health are magnified by the fact that many children spend 80–90% of their time indoors, and pollutant levels can be 2-5 times higher indoors especially in poorly ventilated spaces. In 2020, the WHO estimated that 237,000 children <5 years old died from illnesses attributable to household air pollution. Secondhand tobacco smoke (SHS) is an especially hazardous constituent of indoor air pollution and a powerful trigger for asthma (see Chapter 759.1). Household products, particularly some disinfectants, cleaners, paints, and floor finishes, have also been connected to respiratory tract irritation and increased asthma morbidity. Allergens in indoor air can contribute to respiratory problems and include cockroach, mite, mold, and cat and dog allergens.

HEALTH HAZARDS OF UNCONVENTIONAL NATURAL GAS DEVELOPMENT (FRACKING)

Unconventional natural gas development (UNGD) using high-volume horizontal hydraulic fracturing (fracking) has made possible the cost-effective extraction of natural gas from previously inaccessible underground shale deposits and has catalyzed a 16-fold increase in fracking wells in the United States between 2000 and 2020. Natural gas has surpassed coal to become the major source of electricity generation in North America.

In fracking, large volumes of water containing a mix of chemicals (whose composition is a closely guarded secret) are injected at very high pressure through deep wells into shale deposits to break apart the rock and allow release of gas. The gas is brought up to the wellhead through return pipes, collected, and sent to market. In some areas, gas and oil occur together, and the gas may be burned off (flared) at the wellhead while the more valuable oil is piped to market.

The hazards of fracking to children's health include:

- *Toxic air pollution by volatile organic compounds released from fracking wells such as benzene, ethyl-benzene, hydrogen sulfide (H_2S), n-hexane, and methane:* Benzene and ethyl-benzene are known human carcinogens, H_2S and n-hexane are neurotoxicants, and methane is a climate pollutant that contributes to greenhouse gas emissions.
- *Traffic-related air pollution resulting from the large volumes of diesel truck traffic required to bring piping, chemicals, and water to drilling operations:* Diesel exhaust contains coarse and fine particulates, polycyclic aromatic hydrocarbons (PAHs), and formaldehyde, and has been classified by the International Agency for Research on Cancer as a known human carcinogen.
- *Water pollution by toxic chemicals:* Leaks of toxic materials into waterways occur commonly during fracking operations; in addition, much of the water injected into the wells returns to the surface containing proprietary injected chemicals, along with high concentrations of salt dissolved from underground deposits and naturally occurring radioactive materials. These chemicals have been shown to contaminate both ground and surface waters. Water pollution is a particularly severe problem in arid regions with limited water supplies.
- *Radon released from underground deposits:* Radon has been shown to contaminate air near wellheads, and high concentrations of radon have been identified in shipped gas. Additional, nonchemical hazards of fracking include incessant noise, high risk of vehicular injury to children from fast-moving heavy trucks on poorly maintained rural roads, societal disruption in rural communities, and extensive degradation of the environment.

Lead

See Chapter 761.

Mercury

See Chapter 760.

Asbestos

Between 1947 and 1973, asbestos was sprayed as insulation on classroom walls and ceilings in approximately 10,000 schools in the United States. It was also widely utilized in homes as pipe insulation and in floor tiles. Subsequent deterioration or unsafe removal of this asbestos can release asbestos fibers into the air. Asbestos is not a health hazard so long as it is intact, but once it becomes airborne, it can be inhaled by children to produce adverse health effects. Asbestos is a human carcinogen, and the two principal cancers caused by asbestos are lung cancer and mesothelioma. U.S. federal law requires that all schools be inspected periodically for asbestos and that the results be made public. Removal by an EPA-certified contractor is required only when asbestos is visibly deteriorating or is within the reach of children. In most cases, placement of barriers (drywall walls or drop ceilings) provides appropriate protection.

Pesticides

Pesticides are a diverse group of chemicals used to control insects, weeds, fungi, and rodents, and are used in large quantities in agriculture, homes, schools, parks, gardens, and recreational areas. Children are at risk of exposure when pesticides are used inside or outside in places where children live, learn, and play, and in rural areas they can be exposed to pesticide drift from fields that have been sprayed. Children employed in agriculture or living in migrant farm camps are at risk of direct exposure to pesticides. Diet is another major route of exposure because children are exposed to residual levels of multiple pesticides on fruit and vegetables, especially fruits and vegetables imported from countries where pesticide use is heavier than in the United States. Children can be acutely overexposed to pesticides and clinically evident poisoning results. High-dose exposure to neurotoxic insecticides such as the organophosphate and carbamate pesticides can cause acute neurotoxicity. Both classes of pesticides act through inhibition of acetylcholinesterase and are responsible for the largest number of acute poisoning cases. Symptoms include meiosis, excess salivation, abdominal cramping, vomiting, diarrhea, and muscle fasciculation. In severe cases, the child may experience loss of consciousness, cardiac arrhythmias, and death by respiratory arrest. The war gas sarin is an organophosphate. See Chapter 94 for treatment of poisoning from drugs, chemicals, and plants.

Pesticides can also cause a range of chronic toxic effects that include polyneuropathy and central nervous system (CNS) dysfunction (organophosphates), hormonal disruption and reproductive impairment (DDT, kepone, dibromochloropropane), cancer (aldrin, dieldrin, chlorophenoxy herbicides [2,4,5-T]), and pulmonary fibrosis (paraquat).

Prenatal exposure to the organophosphate pesticide **chlorpyrifos** at levels that produce no evident toxicity in pregnant women has been associated with neurodevelopmental disability in children with reduced cognitive function (lowered IQ), disordered executive function, and functional and anatomic changes in the brain discernible by functional magnetic resonance imaging (fMRI).

Two classes of pesticides of concern are synthetic herbicides and the neonicotinoid insecticides. Herbicides account for about 48% of total pesticide use, and their application is increasing. A major use of herbicides is in production of *genetically modified (GM) food crops*, mainly corn and soybeans that are engineered to be tolerant to **glyphosate (Roundup)**, the most used herbicide worldwide. Herbicides can be sprayed on herbicide-resistant crops throughout the growing season, and glyphosate-resistant, "Roundup-Ready," GM crops account for more than 90% of all corn and soybeans planted in the United States.

Studies of agricultural workers exposed occupationally to glyphosate and other herbicides have found evidence for increased incidence of non-Hodgkin lymphoma. On the basis of these studies and convergent results from toxicologic studies, the International Agency for Research on Cancer has determined that glyphosate is a "probable human carcinogen." Measurable levels of glyphosate metabolites are commonly detected in the urine of Americans.

The **neonicotinoids** are a class of neurotoxic pesticides developed in the 1980s to replace the organophosphates and carbamates. Use of neonicotinoids rose dramatically in the early 2000s, and the neonicotinoid insecticide, imidacloprid, is one of the most widely used insecticides in the world. A growing body of evidence indicates that neonicotinoids are toxic to bees and other pollinators at concentrations found currently in agricultural areas, and neonicotinoids are suspected of contributing to bee colony collapse disorder. In 2020, the EPA proposed a number of restrictions and precautions for neonicotinoid use. More than a dozen states have also introduced legislation limiting neonicotinoids, and several European countries have banned or severely restricted their use. Almost no information is available on the possible developmental or pediatric toxicity of the neonicotinoids. This is another example of a new pesticide in widespread use without prior testing for health impacts on children.

Children's exposures to pesticides can be reduced by minimizing applications to lawns, gardens, schools, and playgrounds; adapting techniques of integrated pest management; and reducing pesticide applications to food crops. Pediatricians and parents can look to resources including the National Pesticide Information Center (NPIC) and the EPA for guidance on integrated pest management and safer use of pesticides in and around the home. Consumption of organic produce has been shown to dramatically reduce pesticide exposure in school-age children. Families can choose organic produce when available and cost-competitive but should not avoid a diet rich in fruits and vegetables if organic options are not feasible.

Persistent Organic Pollutants: Per- and Poly-fluoroalkyl Substances and Chlorinated Hydrocarbons

Per- and Poly-fluoroalkyl Substances. Per- and poly-fluoroalkyl substances (PFAS) are a group of synthetic chemicals that have been used in industrial processes and consumer products because they are resistant to water and heat, and do not break down in the environment. In addition, they can move through soil into drinking water sources and can build up in fish and wildlife (bioaccumulate). They may make clothing stain resistant and also reduce friction. PFAS are also known as "forever chemicals" due to their persistence in the environment, as their strong carbon-fluorine chain is resistant to degradation. NHANES has documented universal exposure to some PFAS due to their ubiquity in consumer products (e.g., nonstick pans, take-out food containers, water-resistant textiles) and the food chain. PFAS have also been detected in drinking water sources (both municipal systems and private wells) across the United States. In March 2023, the EPA proposed a draft of enforceable maximum contaminant levels (MCLs) for six different PFAS chemicals in public drinking water systems; the final regulations are expected by the end of 2023. Several states have enacted their own MCLs for various PFAS compounds; these state MCLs will have to become at least as stringent as the federal MCLs (once finalized).

Ingestion of contaminated food, water, or household dust is the major route of exposure to these chemicals. PFAS can cross the placenta and enter breastmilk. The half-life in the body can be days to decades, depending on the specific PFAS compound. Epidemiologic studies suggest a link between PFAS exposure and increased cholesterol levels, altered liver function tests, decreased antibody response to childhood vaccines, increased risk of preeclampsia/high blood pressure during pregnancy, and cancer (kidney and testicular). Health outcome studies in highly exposed communities are ongoing.

Chlorinated Hydrocarbons. The chlorinated hydrocarbons are a large and diverse class of chemicals that include insecticides (DDT), plastics (polyvinyl chloride), electrical insulators (PCBs), and solvents (trichloroethylene). Highly toxic chlorinated dioxins and furans are formed during synthesis of chlorinated herbicides or as by-products of plastic combustion. These materials are widely dispersed and highly persistent in the environment. Dioxins and furans are known human carcinogens. Brominated flame retardants are used in carpets, furniture, and computers and are environmentally persistent.

The embryo, fetus, and young child are at particularly high risk of injury from halogenated hydrocarbons. All of these compounds are lipid soluble. They readily cross the placenta, and they accumulate in breast milk. Intrauterine exposure to PCBs and brominated flame retardants has been linked to persistent neurobehavioral dysfunction

in children manifested by cognitive impairment (reduced IQ), shortening of attention span, and behavioral disorders.

Consumption of fish from contaminated waters is a major source of children's exposure to PCBs. Children can be exposed in utero or through breast milk. To protect children and pregnant women against PCBs in fish, government agencies have issued advisories concerning fish consumption for certain lakes and rivers. Combustion of medical wastes containing polyvinyl chloride and the use of chlorine to bleach paper products are major preventable sources of environmental dioxin emissions and should be discouraged. Older fluorescent light ballasts that were installed decades ago in schools in the United States are another source of PCB exposure. PCB-containing ballasts should be removed from schools as soon as possible to prevent environmental contamination. Removal must be performed by trained workers.

Endocrine Disruptors

Endocrine disruptors are synthetic chemicals that mimic, block, or alter the actions of normal hormones such as estrogen, testosterone, growth hormone, insulin, and thyroid hormone. Synthetic endocrine disruptors are manufactured in volumes of millions of pounds per year. They include phthalates, bisphenol A, perchlorate, certain pesticides, brominated flame retardants, certain metals, and dioxins. These chemicals are widespread today in consumer products such as soaps, shampoos, perfumes, and plastics. They are widely disseminated in the environment and encountered in air, food, and drinking water.

Exposures to endocrine disruptors in early human development are especially hazardous. Even extremely low-dose exposures during critical early periods can lead to lasting impairments in organ function and to increased risk of disease. Reproductive effects are one consequence of early life exposures to endocrine disruptors. Endocrine disruption is implicated in the epidemiologic observations of a trend toward earlier thelarche and menarche in females, with rising rates of testicular cancer and hypospadias, and with diminishing sperm counts. Among the most clearly documented reproductive effects of early life exposures to endocrine disruptors are adenocarcinoma of the vagina in women and cryptorchidism in men whose mothers took diethylstilbestrol (DES). Another well-documented effect is shortening of the anogenital distance, a measure of in utero feminization, in infant males whose mothers had elevated exposures to phthalates during pregnancy.

Early life exposures to endocrine disruptors can have adverse effects on brain development. Prenatal exposure to low molecular weight phthalates is associated with shortening of attention span in children 4-9 years old, as well as with increased risk for autistic behaviors. Prenatal exposure to bisphenol A has also been linked to behavioral anomalies.

Endocrine disruptors have been reported to have adverse impacts on lipid metabolism and to increase the risk for obesity. Higher urinary levels of bisphenol A are associated with obesity-related outcomes, such as cardiovascular disease, in a cross-sectional analysis of NHANES 2003-2004 data in adults.

Early life exposures to endocrine disruptors, most notably DDT, are linked with increased risk for cancer. A long-term epidemiologic study of women in California found that those who were exposed in utero to high levels of DDT have increased risk for breast cancer in adult life 40-50 years later.

Environmental Carcinogens

Leukemia and brain cancer, the two most common forms of pediatric malignancy in the United States, both increased in incidence from 1972 to 2018, despite declining mortality. The cumulative increase in incidence for childhood leukemia was more than 20%, and for brain and CNS cancer more than 40%. In the same time period, testicular cancer in young men, ages 15-30 years, more than doubled in incidence and is occurring at younger ages. These increases are too rapid to be of genetic origin and are not likely due to better diagnostic capabilities. They are most probably the result of still undefined exposures in the environment. Cancer is now the second-leading cause of death in American children, surpassed only by injuries.

Children may be exposed to carcinogenic pollutants in utero or after birth. Children appear more sensitive than adults to certain chemical carcinogens and also to ionizing radiation (see Chapter 758). The potential for chemical carcinogenesis in utero was initially recognized with the discovery that clear cell adenocarcinoma of the vagina could develop in young women who were exposed in utero to DES.

Carcinogenesis may be associated with exposures in the home and community. Children of asbestos workers and children who have grown up near asbestos plants have been found to have an elevated incidence of mesothelioma. Children who attended elementary school in communities containing synthetic rubber plants have been shown to be at increased risk of leukemia as a result of their exposure to 1,3-butadiene, a known human carcinogen and a major component of synthetic rubber. Children who grow up on farms have elevated rates of leukemia; pesticides are suspected of playing an etiologic role. Intrauterine exposure to trichloroethylene via contaminated drinking water has been associated with an increased incidence of leukemia among females living near an industrial facility and industrial waste site.

Routes of Exposure

Transplacental. Heavy metals such as lead and mercury, fat-soluble compounds such as PCBs and DDT, and endocrine disruptors such as phthalates, readily cross the placenta. They may have serious and irreversible toxic effects on the developing nervous, endocrine, and reproductive organs, even at very low levels. The American College of Obstetricians and Gynecologists have recognized the hazards of environmental exposures during pregnancy and provide detailed guidance for counseling to reduce these exposures in their 2021 statement Reducing Prenatal Exposure to Toxic Environmental Agents (Table 259.2).

Water. Approximately 200 chemicals have been detected at various levels in water supplies including contaminants like lead, solvents, pesticides, and emerging chemicals like PFAS. Lead is an especially common contaminant. Water supplies are generally lead-free at the source but can become contaminated by lead that dissolves from lead pipes and from lead-containing plumbing fixtures. Lead is especially likely to dissolve from pipes and plumbing when the water is acidic, as happened in Flint,

Table 759.2 Toxic Chemicals or Pollutants and Reported Association with Adverse Reproductive Health Outcomes*

CHEMICAL OR POLLUTANT WITH REPORTED ADVERSE ASSOCIATION	POTENTIAL HEALTH EFFECT
Antineoplastic drugs, bisphenol A (BPA), cigarette smoke, ethylene oxide, formaldehyde, polybrominated diphenyl ether (PBDE) flame retardants, solvents	Infertility and miscarriage
Air pollutants from fracking, ambient air pollutants, antineoplastic drugs, cigarette smoke, ethylene oxide, formaldehyde, perfluorochemicals (PFAS),* pesticides, phthalates, PBDEs, toluene	Preterm birth and low birthweight
Ambient air pollutants, BPA, lead, mercury, pesticides, phthalates, PBDE flame retardants, polychlorinated biphenyls (PCBs)	Neurodevelopmental impairment

*Associations noted are from reports of animal and limited human studies. Although there are reported associations between exposures and adverse obstetric outcomes, an association does not necessarily mean that the exposure is a cause of the outcome. More research is needed to understand if there is causality and, if so, at what level of exposure or use of a specific product.

Modified from American College of Obstetricians and Gynecologists' Committee on Obstetric Practice. Reducing prenatal exposure to toxic environmental agents: ACOG Committee Opinion, Number 832. *Obstet Gynecol.* 2021;138(1):e40–e54. Table 1.

Michigan, in 2014. The highest levels of lead occur in water that has been standing in lead pipes overnight. It is wise therefore to run water for 2-3 minutes each morning before making up infant formula. Solvents and components of gasoline such as methyl tertiary-butyl ether and benzene are commonly encountered in groundwater. Chemical contaminants from gas drilling can contaminate water in areas where fracking is taking place. Herbicides, such as glyphosate and atrazine, are commonly found contaminants in drinking water in agricultural areas.

In the United States, the EPA regulates approximately 90 drinking water contaminants including organic chemicals, inorganic chemicals, radionuclides, and infectious agents in public water systems. The municipal water systems are responsible for ensuring that the regulated contaminants are below MCLs and will notify customers of any exceedance and steps to address the issue. Those families using private wells, however, are responsible for testing their water on a regular basis. Families with well water can be directed to the EPA private well website or their local health department for guidance on the recommended tests.

Air. Vehicular emissions are the major source of urban air pollution, notably ground-level ozone and particulate matter. Diesel exhaust is a human carcinogen. Coal-fired power plants are another major source of outdoor air pollution. In rural areas, wood smoke can contribute to air pollution. Pediatricians and parents can follow local air quality alerts that include recommendations to reduce risk especially for sensitive groups (airnow.gov). Children living in the vicinity of smelters and chemical production plants can be exposed to toxic industrial emissions such as lead, benzene, and 1,3-butadiene. Specific information about toxic air pollution release in a community can be obtained via the Toxics Release Inventory (www.epa.gov/toxics-release-inventory-tri-program).

Food. Many chemicals are intentionally added to food to improve appearance, taste, texture, or preservation, but many such chemicals have been poorly tested for potential toxicity. Residues of many pesticides are found in both raw and processed foods. Levels of pesticides are lower in organic produce than in conventionally grown fruits and vegetables. Children who consume organic produce have substantially lower urinary pesticide levels than children who eat conventional produce. Elevated levels of methylmercury can be found in large predator fish such as swordfish, shark, king mackerel, and tuna sushi; families should be encouraged to follow fish advisories. Baby foods can contain trace amounts of metals, and rice and rice-based products (especially those made of brown rice) can have inorganic arsenic.

Breast Milk. Breast milk provides many benefits to infants including protection from illness, reduction in allergic diseases like asthma, and reduced risk of obesity, among many others. Breast milk can also be a route of exposure to environmental chemicals including fat-soluble persistent organic pollutants, pesticides, and metals. In almost all situations, the benefits of breastfeeding outweigh the risks of these exposures, and numerous professional organizations support breast milk as the first choice for infant feeding. In addition, chemical regulation can further reduce unnecessary exposure through this route.

Work Clothes. Illnesses in children sometimes may be traced to contaminated dust from parents' work clothes; toxicity from lead, beryllium, dioxin, organophosphate pesticides, and asbestos has occurred. Such exposure (termed *fouling the nest*) can be prevented by providing facilities at work for changing and showering. If facilities are not available, caregivers can be advised to change clothes and shoes before returning home and wash work clothes separately from household laundry. Some work activities and hobbies that occur at home can also expose children to toxins including metals like lead and solvents.

School. Children may be exposed in schools, kindergartens, and nurseries to lead paint, molds, asbestos, tobacco smoke, pesticides, and hazardous arts and crafts materials. Substantial opportunities for prevention exist in the school environment, and pediatricians are often consulted for advice. The EPA has school related environmental health materials (www.epa.gov/schools) that can be shared with stakeholders.

Child Labor. Four to five million children and adolescents in the United States work for pay, and child labor is widespread around the world. Working children are at high risk of physical trauma and injury. They also may be exposed to a wide range of toxic chemicals, including pesticides in agriculture and lawn work, asbestos in construction and building demolition, and benzene in pumping gasoline.

THE PHYSICIAN'S ROLE

Pediatricians have time and again played key roles in the initial recognition of diseases caused by toxic chemicals. Every pediatrician needs to be an "alert clinician" open to the possibility of discovering new diseases in children caused by hazardous exposures in the environment. In considering the origins of noninfectious disease, pediatricians should ask about the home environment, parental occupation, unusual exposures, and neighborhood factories. An environmental cause is particularly likely when several unusual cases of disease or constellations of findings occur together. Any adolescent with a traumatic injury may have been injured at work.

The history is the single most important instrument for obtaining information on environmental exposures (Table 759.3). Information about current and past exposures (including questions about work and travel to or residence in developing countries) should be sought routinely for every new patient. The age of the patient can help focus questions and provide anticipatory guidance on key exposures of concern, such as screening for common sources of lead exposure in young children. Patients with asthma should be evaluated for exposure to common allergens (mold, cockroaches, dust mites) and irritants (tobacco smoke, strong odors). Children with neurodevelopmental disorders should be assessed for pica and other behaviors that increase their risk of toxic exposures. Consider targeted environmental health history questions in patients with illness of unclear causation. Changes in patterns of exposure or new exposures may be especially important. If suspicious information is elicited, more detailed follow-up should be pursued. Referral to a state or local health department or to a Pediatric Environmental Health Specialty Unit may be indicated (https://www.pehsu.net/). Accurate diagnosis of an environmental cause of disease can lead to better care of sick children and prevention of disease in other children.

759.1 Tobacco

Judith A. Groner

Cigarette smoking is the single most preventable cause of morbidity and mortality, contributing to over 480,000 annual deaths in the United States. The most common reason that people smoke is nicotine addiction, and people who start smoking at an earlier age are more likely to develop a severe addiction than those who start when they are older. In 2022, 4.5% of middle school students and 16.5% of high school students reported current tobacco use (see Chapter 157.2). While youth use a variety of tobacco products, e-cigarettes are the most common. E-cigarettes work by heating liquid to produce an aerosol that is then inhaled into the lungs; this process is called **vaping**. While the long-term health effects of vaping are still being evaluated, the 2019 E-cigarette or Vaping Use-Associated Lung Injury (EVALI) epidemic drew attention to the dangers associated with e-cigarette use (see Chapter 450).

COMPOSITION OF SECONDHAND SMOKE AND TOXICITIES

Along with active tobacco use, secondhand tobacco smoke (SHS) exposure is a very serious health hazard for both children and adults. SHS is a mixture of approximately 7,000 chemicals and is made up of the mainstream smoke exhaled by the smoker and side-stream smoke expelled from the end of a lit tobacco product. At least 70 carcinogens have been identified in SHS, along with 250 chemicals that are toxic to the CNS, immune system, heart, and liver.

SHS also contains particulate matter, which is an independent health hazard. Particulate matter is microscopic solid and liquid matter suspended in air, which can be inhaled and enter the circulation. The most studied of these include polycyclic aromatic hydrocarbons (PAHs) and the tobacco-specific nitrosamines, which are both carcinogenic. Most particulate matter in side-stream smoke is unfiltered by the smoker

Table 759.3 Clinical Tools for Incorporating Environmental Health into Patient Care

Tips for implementing a focused environmental health history:

1. *Age:* Patient age can help direct screening questions and anticipatory guidance on key exposures of concern, such as lead screening questions for young children. Refer to American Academy of Pediatrics (AAP) Bright Futures or the Pediatric Environmental Health Toolkit for age-specific information.
2. *Location*: Local environmental conditions can help direct environmental guidance. For example, in rural communities with high prevalence of private wells for drinking water, families can be counseled on the importance of routine well water testing.
3. *Symptoms*: Consider environmental exposures in the differential diagnosis. For example, carbon monoxide exposure should be on the differential for families presenting with headaches and flulike symptoms (afebrile, no cough).
4. *Asthma*: assess for common environmental asthma triggers in the home such as mold, cockroaches, mice, environmental tobacco smoke, furry pets, cleaning chemicals, strong odors/fragrances
5. *Neurodevelopmental disorders*: assess for pica behavior and other risk factors that may increase the likelihood of exposures (e.g., lead); assess for use of alternative medications

Components of environmental health history (can be adapted based on patient scenario):

General home health and safety:
- Age and condition of home (lead paint in pre-1978 home)
- Carbon monoxide and fire alarms
- Heat and cooking sources (stove ventilation, safe space heater use)
- Tobacco smoke
- Radon (test basement and first/second floors)
- Cleaning products-safe storage and use (e.g., bleach)

Common indoor allergens:
- Water leaks/mold
- Pests (cockroaches, mice) and pesticide use

Water and food:
- Drinking water source (well water requires routine testing)
- Fish advisories (methylmercury) for pregnant persons and children
- Fresh produce (rinse well before eating)
- Rice-based products (vary grains to reduce arsenic exposure)

Jobs and hobbies:
- Caregiver jobs (contaminant transfer from clothing, shoes)
- Adolescent jobs (safety)
- Hobbies in the home (paints, chemicals)
- Sun protection outdoors
- Noise from headphones, toys

Resources and tools for clinical practice:

Environmental history forms:
- National Environmental Education Foundation (NEEF) has a general environmental history and an asthma-focused environmental history (English and Spanish): www.neefusa.org/resource/pediatric-environmental-history
- World Health Organization (WHO) Paediatric Environmental Health History (Green Page) provides a series of concise questions to assess potential exposures: https://www.who.int/publications/m/item/children-s-environmental-record--green-page

Evidence-based clinical resources:
- The Green Book: American Academy of Pediatrics. *Pediatric Environmental Health*. 4th ed. Etzel RA, Balk SJ, eds. Elk Grove Village, IL: American Academy of Pediatrics; 2019.
- Pediatric Environmental Health Specialty Unit (PEHSU). One PEHSU is located in each of the 10 federal regions in the United States. The PEHSUs provide online classroom materials, resources, and access to network of experts in pediatric and reproductive environmental health: www.pehsu.net
- The Pediatric Environmental Health Toolkit is an online clinical tool that providers can use to access information on common exposures, including identification of sources of exposure and provision of targeted anticipatory guidance: https://peht.ucsf.edu.
- Bright Futures provides guidance for well child care for children and adolescents (includes key environmental anticipatory guidance): https://brightfutures.aap.org/.
- American College of Obstetricians and Gynecologists (ACOG). Reducing Prenatal Exposure to Toxic Environmental Agents: https://pubmed.ncbi.nlm.nih.gov/34259492/

Resources for patients:
- Prescriptions for Prevention are tools that link patients to evidence-based simple steps to reduce or prevent common environmental exposures (English and Spanish): https://nyscheck.org/rx
- National Institute of Environmental Health Sciences (NIEHS). Environmental health topics: https://www.niehs.nih.gov/health/topics/index.cfm

and is in the submicron (<1 μm diameter) range, meaning that it is classified as fine particulate matter. These are smaller than the particles in mainstream smoke and can penetrate deeper into the lungs, resulting in higher toxicity through oxidative stress and inflammation. Short- and long-term exposure to fine particulate matter contributes to the aggravation of asthma and other respiratory diseases, lung and other cancers, cardiovascular disease, and death.

SHS concentration in the indoor environment depends on the number of cigarettes smoked in a period, the volume of the room, the ventilation rate, and other processes that eliminate pollutants from the air. There are multiple mechanisms by which SHS causes injury to the respiratory tract, and injury to the cardiovascular system is due to endothelial cell dysfunction due to smoke exposure and its prothrombotic effects.

THIRDHAND SMOKE

Thirdhand smoke (THS) was defined in 2011 as consisting of the residual tobacco smoke pollutants that remain on surfaces and in dust after tobacco has been smoked. These toxins are reemitted into the gas phase or react with oxidants and other compounds in the environment to yield secondary pollutants. These residual pollutants can be detected in the indoor environment well after being generated. About half the particulate matter from SHS is still airborne after 5-6 hours. Many chemicals, such as nicotine and some PAHs, exist in both the gaseous and the particulate phase of SHS. Classified as "semi-volatile," their ability to change form according to environmental conditions means that they remain detectable in the indoor environment for longer periods after active smoking has ceased. These components in dust and on surfaces can be ingested, inhaled, or even absorbed through the skin. The health implications of THS are not well understood, but there is growing evidence both in vitro and in vivo of health harms of THS exposure, particularly respiratory symptoms. Young children are at higher risk of health issues due to THS absorption because of their hand to mouth behaviors, crawling near surfaces, time spent in the home, and increased respiratory rate.

TOBACCO USE AND EXPOSURE IS A HEALTH RISK DISPARITY

Tobacco use, and hence childhood exposure, is found disproportionately among socially disadvantaged low-income populations, who can least afford tobacco and SHS-related illness and evidenced-based treatment for nicotine addiction. There has been a profound decrease in smoking rates among the middle and upper classes within the United States since the 1960s (83% decrease), but the rate of decrease is much less (39%) among lower income groups. The smoking rate for the overall U.S. population is approximately 12.5%, but it is as high as 32% among adults with a high school equivalency degree. Because of these disparities in smoking rates among adults, children born into low-income homes are more likely to be exposed to SHS. More than 38% of U.S. children age 3-11 years were exposed to tobacco smoke from 2017 to 2018, based on a biologic marker of exposure, serum cotinine levels. Children from low-income homes have the highest rates of biologically measured SHS exposure; for every decrease in family income ratio, serum cotinine levels increase by 1.18 ng/L among children. Having a parent who smokes has also been shown to be an independent risk factor for food insecurity in children.

MATERNAL SMOKING DURING PREGNANCY AND TOBACCO SMOKE EXPOSURE DURING PREGNANCY

The effects of maternal smoking on the fetus are profound and can be divided into pregnancy-related and long-term effects. Fetal exposure is one of the most important modifiable risk behaviors for childhood and long-term health.

Pregnancy-Related Effects

Maternal smoking increases the risk of placenta-associated complications of pregnancy, with an increased rate of placental abruption and placenta previa among maternal smokers. Both active maternal smoking and secondhand maternal tobacco smoke exposure have been shown to reduce birthweight and to increase the risk of preterm birth. In utero tobacco exposure from either maternal active tobacco product use or maternal SHS exposure increases the rate of stillbirth. Smoking both during and after pregnancy is a risk factor for **sudden infant death syndrome (SIDS)**; one study found that any smoking during pregnancy was associated in a doubling of SIDS risk and that there was a linear correlation between the average number of cigarettes smoked daily and an increased risk for SIDS. These associations are modifiable by public policy. Several countries in Europe have shown decreased perinatal complications after comprehensive smoke-free laws; within the United States, pregnancy complications and SIDS are inversely related to tobacco taxation levels.

Long-Term Effects

Maternal smoking in early pregnancy is considered causal for orofacial clefts (Surgeon General Report 2014).

Both active smoking during pregnancy and SHS exposure of the mother increases the *child's* later risk of being overweight or obese. This finding may appear surprising due to the long-known relationship between smoking during pregnancy and low birthweight. This relationship has been shown in multiple epidemiologic studies and is robust to adjustment for potential confounders, such as parental body mass index (BMI), breastfeeding, family diet, and lifestyle.

Maternal smoking during pregnancy has been associated with both an increased risk of learning problems and neurobehavioral issues during childhood. The adverse effects of prenatal smoking on child neurodevelopment include poor language development and reduction in cognitive functioning. Prenatal exposure to smoking may also reduce the child's motor performance, mental development (measured by the Bayley Scales of Infant Development), IQ scores, and language development through age 3 years. This exposure may also increase the risks of several child behavioral problems, including externalization of aggressive and hyperactive behavior, prolonged periods of verbal or physical aggression and socially undesirable behavior (conduct disorder) throughout childhood, and delinquency in later childhood. In one study, a dose-response relationship with increasing severity of poor school performance was related to the number of cigarettes the mother smoked during pregnancy.

Maternal Smoking During Pregnancy and Lung Development

Smoking during pregnancy is associated with poor lung growth and function in the offspring and with a greater risk for wheezing between age 2-4 years. According to the Surgeon General Report (2014), there is sufficient evidence to consider this relationship to be causal.

POSTNATAL SECONDHAND SMOKE EXPOSURE—EFFECTS ON THE CHILD

Respiratory

Children exposed to SHS have a higher rate of asthma prevalence and greater asthma severity. The Surgeon General Report (2006) concluded that there is a causal relationship between parental smoking and cough, phlegm, wheezing, and breathlessness, along with asthma, among school-age children. Children with SHS exposure have a weakened response to inhaled corticosteroids. Children with asthma who are SHS-exposed are more likely to have an acute care visit, an overnight hospital stay, and a higher number of hospital admissions than children with asthma and no SHS exposure. The rate of hospital readmissions for asthma has been associated with the level of the child's saliva cotinine, a biomarker of smoke exposure, and this is true even at very low levels of exposure.

Tobacco smoke exposure is a cause of lower respiratory tract infection in children. Findings of the Surgeon General in 2006 were updated by a systemic review of parental and household smoking and risk of lower respiratory tract infections in infancy in 2011. The strongest relationship was for bronchiolitis, where the risk of any household smoke exposure was increased in the first two years of life.

SHS exposure during childhood increases the rate of middle ear disease, including acute, recurrent otitis media and chronic middle ear effusion. The Surgeon General Report (2006) rated this evidence as sufficient to infer a causal relationship between parental smoking and middle ear disease in children.

Cardiovascular Effects

Tobacco smoke exposure during adulthood has been linked to an increased risk of cardiovascular disease. Evidence links childhood exposure to findings of preclinical atherosclerosis. These include increased carotid intima-media thickness and decreased flow-mediated dilation, both indirect tests for preclinical changes leading to atherosclerosis during adulthood. Other findings have included increased inflammation as measured by C-reactive protein, abnormal lipid profiles, higher blood pressure, and increased rates of metabolic syndrome among SHS-exposed children and youth.

Infection

Childhood exposure to SHS is related to increased rates of invasive meningococcal disease in children less than 5 years old. SHS in the home doubled the risk of invasive meningococcal disease with some evidence of a dose-response relationship. The strongest effect was seen in children under 5 years, with SHS exposure more than doubling the rate of meningococcal disease. This relationship was seen both with prenatal smoking and postnatal exposure.

SHS exposure has also been shown to increase the severity of influenza among children hospitalized for the disease. Children with SHS exposure were 4.7 times more likely to be admitted to intensive care and had a 70% longer length of stay than nonexposed children, after controlling for multiple potential confounding factors.

Healthcare Utilization

Children and teens age 3-19 years who are SHS-exposed had higher healthcare utilization compared with nonexposed peers based on an analysis of NHANES data from 2009–2012. Children with high SHS exposure based on serum cotinine were almost three times more likely to have an overnight hospital stay and two times as likely to have a higher number of total hospital admissions as children with no exposure.

Special Vulnerable Pediatric Populations

There is evidence that SHS exposure exacerbates disease processes among children with significant chronic health conditions. Children with sickle cell disease who are exposed to SHS have increased morbidity, specifically increased rates of emergency department visits, and hospitalizations for vasoocclusive crisis and acute chest syndrome (see Chapter 511.1). In addition, tobacco smoke exposure is also associated with pulmonary function abnormalities among children with sickle cell disease, independent of their baseline disease.

Children with cystic fibrosis (CF) are another vulnerable population in which SHS exposure presents an additive threat to overall health. Core health issues for this group of children include problems with growth, lung function, and pulmonary infections (see Chapter 454). SHS-exposed children with CF had decreased growth between 4 and 12 months compared with non–SHS exposed infants. Furthermore, tobacco smoke exposure was associated with increased bronchodilator responsiveness and air trapping, and with increased methicillin-resistant *Staphylococcus aureus* and anaerobic growth on respiratory culture. Tobacco smoke exposure can be considered a modifiable risk factor for children with sickle cell disease and CF.

TREATMENT FOR TOBACCO USE AND SECONDHAND TOBACCO SMOKE EXPOSURE

There is no risk-free level of youth tobacco use or SHS exposure. Thus the best method to treat tobacco use and SHS exposure is to eliminate this exposure by helping adolescents and their caregivers quit smoking. Methods to reduce exposure such as "smoking outside" or wearing a "smoking jacket" have not been shown to eliminate biochemically confirmed SHS exposure. A meta-analysis of six controlled trials aimed specifically at SHS exposure reduction for children (not parental smoking cessation) showed some reduction in tobacco smoke pollution post intervention. However, all homes had significant tobacco-related air pollution at the end of the study period.

The pediatric office has long been considered an excellent venue for pediatricians to screen for youth tobacco use as well as children's SHS exposure and to intervene with youth and their caregivers. The American Academy of Pediatrics (AAP) recommends that providers:

1. Inquire about tobacco use and tobacco smoke exposure as part of health supervision visits and visits for diseases that may be caused or exacerbated by tobacco smoke exposure.
2. Include tobacco use prevention as part of anticipatory guidance.
3. Address parent/caregiver tobacco dependence as part of pediatric healthcare.
4. Offer tobacco dependence treatment and/or referral to adolescents who want to stop smoking.

The United States Preventative Services Task Force also recommends that primary care clinicians provide school-age children and adolescents who have not started to use tobacco with interventions (including education or brief counseling) to prevent initiation of tobacco use. The "Ask-Counsel-Treat" (ACT) model developed by the AAP provides tips on addressing youth tobacco use in the office (available at https://www.aap.org/en/patient-care/tobacco-control-and-prevention/youth-tobacco-cessation/tobacco-use-considerations-for-clinicians/); it is recommended that screening begin at age 11. The Clinical Effort Against Secondhand Smoke Exposure (CEASE) is a program that trains pediatricians and their office staff to systematically provide cessation counseling and interventions to caregivers who smoke. The CEASE model is (1) **ask** if anyone in the home or who cares for the child smokes; (2) **assist** the patient or caregiver with quitting by providing brief counseling, pharmacotherapy, or appropriate referrals; and (3) **refer** the smoker to evidence based cessation treatments, including telephone-based Quitlines or Text to Quit services. The CEASE model (found at https://www.massgeneral.org/children/cease-tobacco) involves training pediatricians to provide smoking cessation pharmacotherapy to caregivers who wish to quit smoking; it includes tools to both identify caregivers who smoke and facilitate pediatric healthcare providers' delivery of counseling, medications, and referral for tobacco treatment.

Despite the AAP recommendations for pediatricians to incorporate these methods into practice, a meta-analysis in 2016 of controlled trials in routine healthcare settings of child SHS exposure reduction did not show an intervention effect. However, three controlled trials of maternal postpartum smoking relapse prevention did demonstrate beneficial outcomes of the intervention.

Decreasing smoking initiation among youth will prevent the children of the future from SHS exposure. Ninety percent of smokers initiate use before 19 years of age, and 80% of youth who are smokers persist in smoking in adulthood. Of those, half will die earlier than their nonsmoking peers. After many years of individual states working to enact stricter tobacco laws, new federal legislation known as Tobacco 21 was signed in 2019 that raised the minimum age for sale of tobacco products from 18 to 21 years nationwide. By increasing the age of tobacco purchase to 21 years, there is hope that a whole generation of smoking can be prevented.

759.2 Marijuana Smoke Exposure

Karen M. Wilson

Unlike tobacco smoke exposure, which has long been recognized as a cause of morbidity and mortality among nonsmokers, marijuana smoke exposure is far less well studied. In 2021, 13.2 million persons age 12 years or older used marijuana on a daily or almost daily basis in the past 12 months, an increase from the 5.7 million daily or almost daily users in 2013 (see Chapter 157.3). The use of marijuana has been increasing in both acceptability and legality in the past 20 years. Current use of marijuana is more common among males and younger adults (18-34 years vs 35 years or older), and those with less than a high school degree. As of 2023, 38 states allow the legal use of marijuana for medical reasons, and 24 states plus Washington DC and Guam have legalized its recreational use. Analysis of poison control center calls for exposure to marijuana for children under 6 years of age showed an increase of 148% from 2006 to 2013; from 4.2/1 million children to 10.4/1 million. Tobacco-smoking parents with young children residing in the home are four times more likely to use marijuana as compared with nontobacco smoking parents. About 38% of young children in the United States are exposed to tobacco smoke, compared to an estimate of 15% of children exposed to marijuana smoke. Studies examining the presence of biomarkers of marijuana smoke exposure have found an exposure prevalence of 16% in young children hospitalized for bronchiolitis in Colorado, and 21% in children 0-3 years being seen at a clinic in New York City.

COMPONENTS OF MARIJUANA SMOKE

While marijuana can also be aerosolized or ingested as hash oil or leaf, combusted marijuana is still the most common form. A recent analysis of data from the U.S. National Health and Nutrition Examination Survey (NHANES) finds that daily marijuana users have higher levels of combustion biomarkers (e.g., volatile organic compounds and polycyclic aromatic hydrocarbons (PAHs) than nonusers. In addition to the particulates and other chemicals of combustion, marijuana comprises two primary active chemicals: Δ9-tetrahydrocannabinol (THC) and cannabidiol (CBD). Exposure to combustion products likely extends to adjacent nonusers, as has been shown for tobacco smoke. Most states with legal marijuana use do not have any restrictions on combustible marijuana use in the presence of children.

IMPACT OF MARIJUANA SMOKE EXPOSURE

While there is clear research on the dangers of secondhand tobacco smoke (SHS), there have been very few studies examining the impact of marijuana smoke exposure. Secondhand marijuana smoke contains particulate matter that is known to be harmful when inhaled, in addition to other toxic and carcinogenic chemicals such as volatile organic compounds, PAHs, and aromatic amines. Studies in adults have demonstrated that it is possible to get a "contact high" from intense exposure. Even brief exposures have been found to impair vascular endothelial function in animal models. Children can be exposed to secondhand and thirdhand marijuana smoke when parents or other household contacts smoke indoors, similar to children living with tobacco smokers. Also similar to tobacco, children could be exposed to marijuana smoke through incursions from neighboring apartments; in a New York City sample, 31% of parents reported marijuana incursions, whereas 34% reported tobacco incursions. Neonates can be exposed to marijuana prenatally or through breast milk. Prenatal exposure has been linked to growth restriction and neonatal intensive care admissions, as well as behavioral issues such as impulsivity. Prenatal exposure has also been linked to impaired executive functioning in young adulthood. One study examined the role of indoor cannabis smoke and health; although they found increased particulates in homes with cannabis use, there was no statistically significant difference in health outcomes.

TREATMENT

In the absence of convincing data showing that marijuana is not harmful, parents should be counseled to avoid exposing their children to marijuana smoke, to lock marijuana in a safe place out of reach of any children, to avoid edibles in appealing or non–child proof packaging, and to be cautious about their own level of impairment if they do choose to use legal marijuana.

Chapter 760

Heavy Metal Intoxication

Prashant V. Mahajan

Lead, mercury, arsenic, and cadmium, four of the World Health Organization's (WHO) "Ten chemicals of greatest public health concern," are the heavy metals posing the greatest threats to humans. The most prevalent of these exposures is lead (see Chapter 761).

Heavy metal intoxication results in multiorgan toxicity through widespread disruption of vital cellular functions. A meticulous history of environmental exposure may be necessary to correctly identify heavy metals as the source of the protean manifestations associated with such exposure. Arsenic exposure can occur from contaminated food or water; globally, more than 140 million people are estimated to be chronically exposed to drinking water containing high arsenic levels. Mercury exposure occurs primarily through food; fish is a major source of methyl mercury exposure.

ARSENIC

Arsenic is a metalloid that exists in four forms: elemental arsenic, arsine gas, inorganic arsenic salts (pentavalent arsenate form or trivalent arsenite form), and organic arsenic compounds. Toxic manifestations are higher in the more soluble and higher-valence compounds. **Arsine gas** is the most toxic form of arsenic. Mass poisonings from exposure to arsenic have occurred throughout history, including one in 1998 in Wakayama, Japan, in which 70 people were poisoned. Children may be poisoned after exposure to inorganic arsenic found in pesticides, herbicides, dyes, homeopathic medicines, and certain contaminated folk remedies from China, India, and Southeast Asia (see Chapter 94). Soil deposits contaminate artesian well water. Groundwater contamination with arsenic is a common problem in developing countries and has been reported to be a common well contaminant in many areas of the United States as well (Fig. 760.1). The Southwest has the highest arsenic concentrations in the country with more than 16% of sampled wells exceeding the maximum contaminant level. Food products (e.g., rice, organic brown rice syrup, fruit juices) cooked in contaminated water may absorb arsenic, thus concentrating it in the food (Fig. 760.2). The WHO and United States Environmental Protection Agency (EPA) have set 10 μg/L as the upper limit of safety. In many parts of Asia and South America, this limit is frequently exceeded. Arsenic concentrations in a quarter of the wells in Bangladesh exceed 50 μg/L, and 35-77 million of the 125 million inhabitants of Bangladesh regularly consume arsenic-contaminated water. Occupational exposure may occur in industries involved in the manufacturing, mining, smelting, or refining of glass, pottery, electronic and semiconductor components, and lasers. Although arsenic is no longer produced in the United States, it is produced in many countries and is imported into the United States for industrial use. Organic arsenic compounds may be found in seafood, pesticides, and some veterinary pharmaceuticals. In contrast to mercury, the organic forms of arsenic found in seafood are nontoxic.

Pharmacokinetics

Elemental arsenic is insoluble in water and bodily fluids, and thus is insignificantly absorbed and nontoxic. Inhaled arsine gas is rapidly absorbed through the lungs. The inorganic arsenic salts are well absorbed through the gastrointestinal tract, lungs, and skin. The organic arsenic compounds are well absorbed through the gastrointestinal tract. After acute exposure, arsenic initially is bound to the protein portion of hemoglobin in the red blood cells (RBCs) and rapidly distributed to all tissues. Inorganic arsenic is methylated and is eliminated predominantly by the kidneys, with approximately 95% excreted in the urine and 5% excreted in the bile. Most of the arsenic is eliminated in the first few days, with the remainder slowly excreted over a period of several weeks. Arsenic concentrates in hair, nails, and skin. Arsenic can also accumulate in the fetus, as it can cross the placenta. Measurement of the distance of **Mees lines** (transverse white striae on the nail) from the nailbed can provide an estimate of time of exposure (nails grow at the rate of 0.4 mm/day) (Fig. 760.3).

Pathophysiology

After exposure to arsine gas, absorbed arsine enters RBCs and is oxidized to arsenic dihydride and elemental arsenic. Complexing of these derivatives with red cell sulfhydryl groups results in cell membrane instability and massive hemolysis. The inorganic arsenic salts poison enzymatic processes vital to cellular metabolism. Trivalent arsenic binds to sulfhydryl groups, resulting in decreased production of

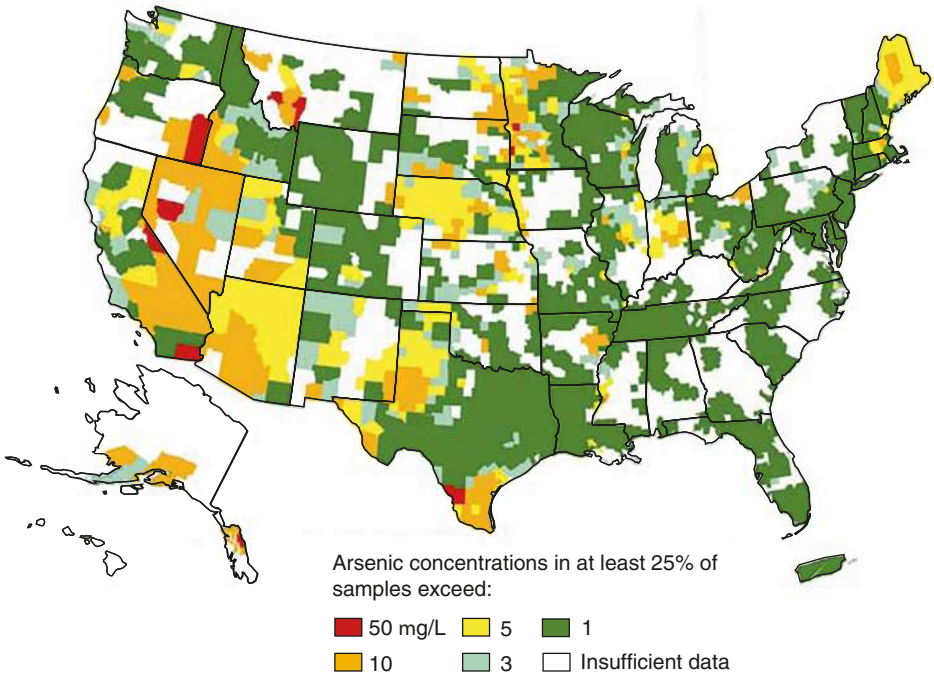

Fig. 760.1 U.S. Geological Survey map of arsenic in groundwater. Groundwater may also contain elevated concentrations of arsenic from agricultural runoff, contamination from runoff from wood preservatives containing arsenic, improperly disposed arsenical chemicals, or mining. adenosine triphosphate through the inhibition of enzyme systems such as the pyruvate dehydrogenase and α-ketoglutarate complexes. Pentavalent arsenic may be biotransformed to trivalent arsenic or substituted for phosphate in the glycolytic pathway, resulting in uncoupling of oxidative phosphorylation.

Clinical Manifestations

Arsine gas is colorless, odorless, nonirritating, and highly toxic. Inhalation causes no immediate symptoms. After a latent period of 2-24 hours, exposed individuals experience massive hemolysis, malaise, headache, weakness, dyspnea, nausea, vomiting, abdominal pain, hepatomegaly, pallor, jaundice, hemoglobinuria, and renal failure (Table 760.1). Acute ingestion of arsenic produces gastrointestinal toxicity within minutes to hours and is manifested as nausea, vomiting, abdominal pain, and diarrhea. Hemorrhagic gastroenteritis with extensive fluid loss and third spacing may result in hypovolemic shock. Cardiovascular toxicity includes QT interval prolongation, polymorphous ventricular tachycardia, congestive cardiomyopathy, pulmonary edema, and cardiogenic shock. Acute neurologic toxicity includes delirium, seizures, cerebral edema, encephalopathy, and coma. Lethal doses of arsenates are 5-50 mg/kg; lethal doses of arsenites are <5 mg/kg.

Table 760.1 Effects of Arsenic on Organ Systems

ORGAN SYSTEM	EFFECTS OF ARSENIC
Gastrointestinal system	Submucosal vesicles, watery or bloody diarrhea, severe hematemesis, pancreatitis, jaundice, toxic hepatitis
Cardiovascular system	Reduced myocardial contractility, prolonged QT intervals, tachyarrhythmias, torsades de pointes, pericarditis Vasodilation, hypotension, shock
Kidneys	Hematuria, proteinuria, oliguria, renal failure
Nervous system	Toxic encephalopathy with seizures, headache, cerebral edema, and coma Chronic exposure: peripheral painful sensorimotor neuropathy, paresthesias
Hematologic and lymphatic system	Anemia, leukopenia, and thrombocytopenia; acute hemolysis with arsine gas, basophilic stippling
Liver	Fatty degeneration with central necrosis
Skin	Desquamation, alopecia, hyperkeratosis, nail changes (Mees lines), brown pigmentation Chronic exposure: hyperkeratosis, hyperpigmentation
Teratogenic	Neural tube defects in the fetus
Oncologic	Urologic cancer, other malignancies

Late sequelae include hematuria, proteinuria, and acute kidney injury. A delayed sensorimotor peripheral neuropathy may appear days to weeks after acute exposure, secondary to axonal degeneration. Neuropathy manifests as painful dysesthesias followed by diminished vibratory, pain, touch, and temperature sensation; decreased deep tendon reflexes; and in the most severe cases, an ascending paralysis with respiratory failure mimicking Guillain-Barré syndrome (see Chapter 656). Adult survivors of infant arsenic poisoning experience higher mortality from disorders of the nervous system compared with adults without such exposure.

Subacute toxicity is characterized by prolonged fatigue, malaise, weight loss, headache, chronic encephalopathy, peripheral sensorimotor neuropathy, leukopenia, anemia, thrombocytopenia, chronic cough, and gastroenteritis. Mees lines in the nails become apparent 1-2 months after exposure in approximately 5% of patients. Dermatologic findings include alopecia, oral ulceration, peripheral edema, a pruritic macular rash, and desquamation.

Chronic arsenic toxicity causes significant morbidity in children resulting in skin lesions, lung disease, and deficits in intellectual function. **Chronic exposure** to low levels of arsenic is usually from environmental or occupational sources. Over the course of years, dermatologic lesions develop, including hyperpigmentation, hypopigmentation, hyperkeratoses (especially on the palms and soles), squamous and basal cell carcinomas, and **Bowen disease** (cutaneous squamous cell carcinoma in situ). Encephalopathy and peripheral neuropathy may be present. Hepatomegaly, hypersplenism, noncirrhotic portal fibrosis, and portal hypertension occur. **Blackfoot disease** is an obliterative arterial disease of the lower extremities associated with chronic arsenic exposure that has been described in Taiwan. Carcinogenicity of chronic arsenic exposure is reflected in increased rates of cancers of the skin, lung, liver, bladder, and kidney as well as of angiosarcomas. Arsenic is carcinogenic, possibly through epigenetic dysregulation. The effects of prenatal exposure to arsenic are uncertain but may include low birthweight.

Laboratory Findings

The diagnosis of arsenic intoxication is based on characteristic clinical findings, a history of exposure, and elevated urinary arsenic values, the last of which confirm the exposure. A spot urine arsenic level should be determined for symptomatic patients before chelation, although initially the result may be negative. Because urinary excretion of arsenic is intermittent, definitive diagnosis depends on a 24-hour urine collection. Concentrations greater than 50 µg/L in a 24-hour urine specimen are consistent with arsenic intoxication (Table 760.2). Urine specimens must be collected in metal-free containers. Ingestion of seafood containing nontoxic arsenobetaine and arsenocholine can cause elevations of urinary arsenic. Blood arsenic levels rarely are helpful because of their high variability and the rapid clearance of arsenic from the blood in acute poisonings. Elevated arsenic values in the hair or nails must be interpreted cautiously because of the possibility of external contamination. Abdominal radiographs may demonstrate ingested radiopaque arsenic.

Later in the course of illness, a complete blood cell count may show anemia, thrombocytopenia, and leukocytosis, followed by leukopenia, karyorrhexis, and basophilic stippling of RBCs. The serum concentrations of creatinine, bilirubin, and transaminases may be elevated; urinalysis may show proteinuria, pyuria, and hematuria; and examination of the cerebrospinal fluid may show protein elevations.

MERCURY

Mercury exists in three forms: elemental mercury, inorganic mercury salts, and organic mercury (Table 760.3). **Elemental mercury** is present in thermometers, sphygmomanometers, barometers, batteries, gold or silver smelting processes, and some latex paints produced before 1991. Workers in industries producing these products may expose their children to the toxin when mercury is brought home on contaminated clothing. Vacuuming of carpets contaminated with mercury and breaking of mercury fluorescent light bulbs may result in elemental mercury vapor exposure. Severe inhalation poisonings have resulted from attempts to separate gold from gold ore by heating mercury and forming a gold-mercury amalgam. Elemental mercury has been used in folk remedies by Asian and Mexican populations for chronic stomach pain, by Latin Americans and Caribbean natives in occult practices, and as a skin-lightening agent. Dental amalgams containing elemental mercury release trace amounts of mercury. An expert panel for the National Institutes of Health concluded that existing scientific evidence does not indicate that dental amalgams pose a health risk and should not be replaced merely to decrease mercury exposure. A 2009 WHO expert panel concluded that a global near-term ban on amalgam would be problematic for public and dental health. However, this committee recommended that alternatives to amalgam should be sought as part of a phase-out of the use of mercury-containing amalgams.

Inorganic mercury salts are found in pesticides, disinfectants, antiseptics, pigments, dry batteries, and explosives and as preservatives in some medicinal preparations. **Organic mercury** in the diet, especially fish containing methyl mercury, is a major source of mercury exposure among the general population. Industries that may produce mercury-containing effluents include chlorine and caustic soda production, mining and metallurgy, electroplating, chemical and textile manufacturing, paper and pharmaceutical manufacturing, and leather tanning. Mercury compounds in the environment are methylated to methyl mercury by soil and water microorganisms. Methyl mercury in the water rapidly accumulates in fish (swordfish, king mackerel, fresh tuna, tile fish, shark) and other aquatic organisms, which are in turn consumed by humans. To address concerns that maternal consumption of large quantities of fish during pregnancy may expose the fetus to concentrations of mercury with adverse consequences, the longitudinal Seychelles Child Development Study has been ongoing since the late 1980s. The first cohort of the study involved nearly 800 mother–child pairs, with subsequent cohorts enrolled. Despite a high maternal fish intake (mean of 12 fish meals per week), follow-up of children at least through 9 years of age has revealed no consistent adverse developmental effects. Well-known large outbreaks of methyl mercury intoxication include the incidents in Japan in the 1950s (**Minamata disease,** from consumption of contaminated seafood) and in Iraq in 1971 (from consumption of grain treated with a methyl mercury fungicide).

Thimerosal is a mercury-containing preservative used in some vaccines. Thimerosal contains 49.6% mercury by weight and is metabolized to ethyl mercury and thiosalicylate. During an ongoing review of biologic products in response to the U.S. Food and Drug Administration (FDA) Modernization Act of 1997, the FDA determined that infants who received thimerosal-containing vaccines at multiple visits might have been exposed to more mercury than recommended by federal guidelines. As a precautionary measure, the American Academy of Pediatrics, American Academy of Family Physicians, Advisory Committee on Immunization Practices, and U.S. Public Health Service issued a joint recommendation in 1999 that thimerosal be removed from vaccines as quickly as possible. *In the United States, thimerosal has been removed from all vaccines in the recommended childhood immunization schedule.* Infants and children who have received thimerosal-containing vaccines do not need to undergo blood, urine, or hair testing for mercury because the concentrations of mercury would be quite low and would not require treatment. The larger risks of not vaccinating children far outweigh any known risk of exposure to thimerosal-containing vaccines. Studies do *not* demonstrate a link between thimerosal-containing vaccines and autism spectrum disorders (see Chapter 58), and no evidence supports a change in the standard of practice regarding administration of thimerosal-containing vaccines in areas of the world where they are used. A rise in blood mercury levels following a single dose of hepatitis vaccine was seen in preterm infants, but the clinical significance is unknown.

Pharmacokinetics

Inhaled elemental mercury vapor is 80% absorbed by the lungs and is distributed rapidly to the central nervous system because of its high lipid solubility. The elemental mercury is oxidized by catalase to the mercuric ion, which is the reactive form that causes cellular toxicity. Elemental mercury liquid is poorly absorbed from the gastrointestinal tract, with less than 0.1% being absorbed. The half-life of elemental mercury in the tissues is approximately 60 days, with most of the excretion occurring in the urine.

Inorganic mercury salts are approximately 10% absorbed from the gastrointestinal tract and cross the blood-brain barrier to a lesser extent than elemental mercury. Mercuric salts are more soluble than mercurous salts and therefore produce greater toxicity. Elimination occurs primarily in the urine, with a half-life of approximately 40 days.

Table 760.2 Acceptable and Toxic Levels of Arsenic and Mercury

	ARSENIC	MERCURY
Molecular weight	74.9 Da	200.59 Da
Acceptable blood level	<5 µg/L (<0.665 nmol/L)	<10 µg/L (<50 nmol/L)
Acceptable urine level	<50 µg/L (<6.65 nmol/L) 24-hr urine sample	<20 µg/L (<100 nmol/L)
Intervene at blood level		>35 µg/L (>175 nmol/L)
Intervene at urine level	>100 µg/L (>13.3 nmol/L) 24-hr urine sample	>150 µg/L (>750 nmol/L)

Table 760.3 Differential Characteristics of Mercury Exposure

	ELEMENTAL	INORGANIC (SALT)	ORGANIC (ALKYL)
Primary route of exposure	Inhalation	Oral	Oral
Primary tissue distribution	CNS, kidney	Blood (transient, acute), kidney, CNS (delayed)	CNS, kidney, liver, blood, hair
Clearance	Kidney, GI	Kidney, GI	Methyl: GI Aryl: kidney, GI
CLINICAL EFFECTS CNS	Tremor	Tremor, erethism (irritability)	Paresthesias, ataxia, tremor, tunnel vision, dysarthria
Pulmonary	+++	—	—
Gastrointestinal	+	+++ (caustic)	+
Renal	+	+++ (acute tubular necrosis)	+
Acrodynia	+	++	—
Therapy	BAL, succimer	BAL, succimer	Succimer (early)

+, mild; ++, moderate; +++, severe; BAL, British antilewisite (also known as dimercaprol); CNS, central nervous system; GI, gastrointestinal.
From Sue YJ. Mercury (heavy metals). In: Nelson LS, Howland MA, Lewin NA, et al., eds. *Goldfrank's Toxicologic Emergencies,* 11th ed. New York: McGraw-Hill; 2019: Table 95.3.

Methyl mercury is the most avidly absorbed of the organic mercury compounds, with approximately 90% absorbed from the gastrointestinal tract. The lipophilic, short-chain alkyl structure of methyl mercury allows it to distribute rapidly across the blood-brain barrier and placenta. Methyl mercury is approximately 90% excreted in the bile, with the remainder being excreted in the urine. The half-life is 70 days.

Pathophysiology

After absorption, mercury is distributed to all tissues, particularly the central nervous system and kidneys. Mercury reacts with sulfhydryl, phosphoryl, carboxyl, and amide groups, resulting in disruption of enzymes, transport mechanisms, membranes, and structural proteins. Widespread cellular dysfunction or necrosis results in the multiorgan toxicity characteristic of mercury poisoning.

Clinical Manifestations

Five syndromes describe the clinical presentation of mercury poisoning. **Acute inhalation of elemental mercury vapor** results in rapid onset of cough, dyspnea, chest pain, fever, chills, headaches, and visual disturbances. Gastrointestinal findings include metallic taste, salivation, nausea, vomiting, and diarrhea. Depending on the severity of the exposure, the illness may be self-limited or may progress to necrotizing bronchiolitis, interstitial pneumonitis, pulmonary edema, and death from respiratory failure. Younger children are more susceptible to pulmonary toxicity. Survivors may demonstrate restrictive lung disease. Renal dysfunction and neurologic disturbances (ataxia, persistent weakness, emotional lability) may develop subacutely. Chronic exposure to volatilized elemental mercury in dental amalgams has not been found to be of any clinical significance.

Acute ingestion of inorganic mercury salts (typically secondary to ingestion of a button battery) can manifest in a few hours as corrosive gastroenteritis, signified by metallic taste, oropharyngeal burns, nausea, hematemesis, severe abdominal pain, hematochezia, acute tubular necrosis, cardiovascular collapse, and death.

Chronic inorganic mercury intoxication produces the classic triad consisting of tremor, neuropsychiatric disturbances, and gingivostomatitis. The syndrome may result from long-term exposure to elemental mercury, inorganic mercury salts, or certain organic mercury compounds, all of which may be metabolized to mercuric ions. The tremor starts as a fine intention tremor of the fingers that is abolished during sleep but that may later involve the face and progress to choreoathetosis and spasmodic ballismus. Mixed sensorimotor neuropathy and visual disturbances may also be present. The neuropsychiatric disturbances include emotional lability, delirium, headaches, memory loss, insomnia, anorexia, and fatigue. Renal dysfunction ranges from asymptomatic proteinuria to nephrotic syndrome.

Acrodynia, or **pink disease**, is a rare idiosyncratic hypersensitivity reaction to mercury that occurs predominantly in children exposed to mercurous powders. The symptom complex includes generalized pain, paresthesias, and an acral (hands, feet) rash that may spread to involve the face. The rash typically is red-pink, papular, pruritic, and painful; it may progress to desquamation and ulceration. Morbilliform, vesicular, and hemorrhagic variants have been described. Other important features include anorexia, apathy, photophobia, and hypotonia, especially of the pectoral and pelvic girdles. Irritability, tremors, diaphoresis, insomnia, hypertension, and tachycardia may be present. Some cases initially were diagnosed as pheochromocytoma. The outcome is good after removal of the source of mercury exposure.

Methyl mercury intoxication (also known as **Minamata disease** after the widespread mercury poisoning that occurred at Minamata Bay in Japan in people who had ingested contaminated fish) manifests as delayed neurotoxicity that appears after a latent period of weeks to months. It is characterized by ataxia; dysarthria; paresthesias; tremors; movement disorders; impairment of vision, hearing, smell, and taste; memory loss; progressive dementia; and death. Infants exposed in utero are the most severely affected, with low birthweight, microcephaly, profound developmental delay, cerebral palsy, deafness, blindness, and seizures. Although there is significant residual morbidity from methyl mercury neurotoxicity, observations on long-term follow-up of children exposed in Iraq reveal complete or partial resolution in most cases.

Laboratory Findings

The diagnosis of mercury intoxication is based on characteristic clinical findings, a history of exposure, and elevation of whole blood or urine mercury values, the last of which confirms the exposure. Thin-layer and gas chromatographic techniques can be used to distinguish organic from inorganic mercury. Blood should be collected in special tubes for trace elements from laboratories that capably perform those tests. Levels <10 μg/L in whole blood and <20 μg/L in a 24-hour urine specimen are considered normal (see Table 760.2). Although blood mercury levels may reflect acute exposure, they decrease as mercury redistributes into the tissues. Urine mercury levels are most useful for identifying long-term exposures, except in the case of methyl mercury, which undergoes minimal urinary excretion. Urinary mercury levels are used in monitoring efficacy of chelation therapy, whereas blood levels are used primarily in monitoring organic mercury poisonings. Hair analysis for mercury is not reliable because hair reflects

both endogenous and exogenous mercury exposure (hair avidly binds mercury from the environment). Abdominal radiographs may demonstrate ingested radiopaque mercury.

Urinary markers of early nephrotoxicity include microalbuminuria, retinol-binding protein, β_2-microglobulin, and *N*-acetyl-β-D-glucosaminidase. Early neurotoxicity may be detected with neuropsychiatric testing and nerve conduction studies, whereas severe central nervous system toxicity is apparent on CT or MRI.

TREATMENT OF ARSENIC AND MERCURY INTOXICATION

The principles of management for arsenic and mercury intoxication include prompt removal from the source of poisoning, aggressive stabilization and supportive care, decontamination, and chelation therapy when appropriate. Once the diagnosis is suspected, the local poison control facility should be contacted, and care coordinated with physicians who are familiar with the management of heavy metal poisoning.

Supportive care for patients exposed to arsine gas requires close monitoring for signs of hemolysis, including evaluation of the peripheral blood smear and urinalysis. Transfusion of packed RBCs may be necessary, as may administration of intravenous fluids, sodium bicarbonate, and mannitol to prevent renal failure secondary to the deposition of hemoglobin in the kidneys. After inhalation of elemental mercury vapor, patients require careful monitoring of respiratory status, which may include pulse oximetry, arterial blood gas analysis, and chest radiography. Supportive care involves administration of supplemental oxygen and, in severe cases, intubation and mechanical ventilation.

Acute ingestion of inorganic arsenic and mercury salts results in hemorrhagic gastroenteritis, cardiovascular collapse, and multiorgan dysfunction. Fluid resuscitation, pressor agents, and transfusion of blood products may be required for management of cardiovascular instability. Severe respiratory distress, coma with loss of airway reflexes, intractable seizures, and respiratory paralysis are indications for intubation and mechanical ventilation. Renal function must be monitored carefully for signs of renal failure and the need for hemodialysis.

Gastrointestinal decontamination after ingestion of inorganic arsenic and mercury salts has not been well studied. Because of the corrosive effects of these compounds, induced emesis is not recommended, and endoscopy may be considered before gastric lavage. Arsenic and mercury are not well adsorbed to activated charcoal, but its use may be helpful if coingestants are suspected. Whole bowel irrigation is used to remove any radiopaque material remaining in the gastrointestinal tract.

Chelation for acute arsenic and mercury poisoning is most effective when administered as soon as possible after exposure. Chelation should be continued until 24-hour urinary arsenic or mercury levels return to normal (<50 μg/L for arsenic and <20 μg/L for mercury), the patient is symptom-free, or the remaining toxic effects are believed to be irreversible. The efficacy of chelation in long-term exposures is reduced because heavy metal in the tissue compartment is relatively nonexchangeable and some degree of irreversible toxicity has already occurred.

Dimercaprol, also known as *2,3-dimercaptopropanol* or *British antilewisite (BAL)*, is the chelator of choice for a patient who cannot tolerate oral therapy, as often is true for critically ill patients and after ingestion of the corrosive inorganic arsenic and mercury salts. Dimercaprol is available in 3-mL ampules at a concentration of 100 mg/mL for deep intramuscular (IM) injection. It is formulated in a peanut oil and benzyl benzoate suspension; as such, it is not suitable for patients with peanut allergy. For **arsenic poisoning**, the recommended regimen of dimercaprol is 2.5 mg/kg IM q4 hours for six doses, then every 6 hours for four doses, then every 8 hours for three doses, then every 12 hours for two doses, followed by once daily for 10 days. For severe arsenic poisoning, the dose of dimercaprol is increased to 3.5-5 mg/kg; the same dosing interval is followed. The dose of dimercaprol for **inorganic mercury poisoning** is 5 mg/kg every 4 hours IM for 24-48 hours, and then 2.5 mg/kg IM q12 hours for 10 days. The dimercaprol–heavy metal complex is excreted in the urine and bile. A period of 5 days between courses of chelation is recommended. Adverse effects of dimercaprol include pain at the injection site, hypertension, tachycardia, diaphoresis, nausea, vomiting, abdominal pain, a burning sensation in the oropharynx, and a feeling of constriction in the chest. Dimercaprol may cause hemolysis in glucose-6-phosphate dehydrogenase–deficient individuals. It is important to note that dimercaprol is contraindicated for chelation of methyl mercury because dimercaprol redistributes methyl mercury to the brain from other tissue sites, resulting in increased neurotoxicity.

Oral chelating agents are used to replace the painful dimercaprol injections when the patient is stable enough to tolerate oral therapy and prolonged chelation is necessary. **Succimer**, also known as *2,3-dimercaptosuccinic acid* (DMSA), is an orally administered water-soluble derivative of dimercaprol. DMSA is available in 100 mg capsules. The recommended regimen of DMSA for both arsenic and mercury poisoning is 10 mg/kg orally every 8 hours for 5 days followed by 10 mg/kg orally every 12 hours for 14 days. The DMSA–heavy metal complex is excreted in the urine and bile. A period of 2 weeks between courses of chelation is recommended. Mild adverse effects include nausea, vomiting, diarrhea, loss of appetite, and transient elevations in liver enzyme levels. DMSA also may cause hemolysis in glucose-6-phosphate dehydrogenase–deficient patients.

D-**Penicillamine** is an orally administered chelator that has been used in the past for less-severe mercury poisoning or as an adjunct to dimercaprol therapy in arsenic poisoning. Its use is largely restricted because of the potential for significant leukopenia, thrombocytopenia, and proteinuria along with the improved tolerability of succimer.

Patients with ingestion of elemental mercury require no follow-up unless there is an underlying disease that decreases the gastrointestinal transit time. Serial abdominal radiographs to document the progression of the metal are recommended. Acute inhalation of mercury fumes and ingestion of inorganic mercury require hospitalization to monitor the respiratory and gastrointestinal status, respectively. Therapeutic abortion may be considered in pregnant patients because of the teratogenic effect of mercury.

Strategies to reduce arsenic exposure in rice are noted in Table 760.4.

Table 760.4 Potential Strategies for Reducing Exposure of Arsenic in Rice

1. Diversify the diet
   - Eat a well-balanced diet and a variety of grains[†,‡,§]
   - Identify children at risk for high consumption of rice and rice products (e.g., gluten-free diets, highly allergic)
2. Consider alternatives to rice for first food
   - Start infants on barley, oats, or other grains[†,‡]
   - If rice cereal must be used for infants, limit to one serving per day[§]
3. Adopt strategies that help minimize exposure
   - Rinse rice in a colander before cooking[§]
   - Cook rice like pasta, with plenty of extra water[§]
   - Choose lower-arsenic varieties of rice (e.g., basmati)[§]
   - Avoid or limit use of rice milk or other rice beverages for infants[‡] and children under 5 yr old[§,¶]
   - Read labels of processed foods: choose alternatives to foods sweetened with brown rice syrup or thickened with rice products
4. Regulatory action
   - Federal agencies should establish regulatory limits for arsenic content in rice and rice products[§]

Chapter 761

Lead Poisoning

Morri Markowitz

Lead is a metal that exists in four isotopic forms. Clinically it is purely a toxicant; no organism has an essential function that is lead dependent. Chemically its low melting point and ability to form stable compounds have made it useful in the manufacture of hundreds of products; this commercial attractiveness has resulted in the processing of millions of tons of lead ore, leading to widespread dissemination of lead in the human environment.

The **blood lead level (BLL)** is the gold standard for determining risk of health effects. The threshold level at which lead begins to cause biochemical, subclinical, or clinical disturbance remains to be determined. In 2021, the Centers for Disease Control and Prevention (CDC) designated 3.5 μg/dL as the *"reference value based on the 97.5th percentile of the population of US children aged 1-5 years."* It is the BLL that identifies the 2.5% of children with the highest BLLs. As a measure of the distribution of BLLs in young American children rather than a toxicity threshold, this number will change in a manner dependent on the epidemiology of BLLs. Surveillance by the CDC has shown that the prevalence of elevated BLLs has declined markedly. Approximately 500,000 U.S. children ages 1-5 years currently have BLLs ≥3.5 μg/dL. Fortunately, children with levels high enough to be life-threatening (>100 μg/dL) are rarely seen in the United States, though deaths continue to occur in other areas of the world. Although BLL ≥3.5 μg/dL is stated as a reference value, it is likely that clinicians and departments of health will consider this a threshold for action.

PUBLIC HEALTH HISTORY

In the late 1970s, nearly all preschool-age children in the United States had BLLs above the current reference value of 3.5 μg/dL. Over the next 25 years, government regulations resulted in the significant reduction of three main contributors to lead exposure by means of (1) the elimination of the use of tetraethyl lead as a gasoline additive, (2) the banning of lead-containing solder to seal food- and beverage-containing cans, and (3) the application of a federal rule that limited the amount of lead allowed in paint intended for household use to less than 0.06% by weight (further reduced by the Consumer Product Safety Commission to 0.009% in 2008). Factors identified by the CDC in the late 1970s that indicate increased risk of lead poisoning, in addition to preschool age, include low socioeconomic status; living in older housing, built primarily before 1960; urban location; and Black race. Another high-risk group that has been identified consists of recent immigrants from less wealthy countries, including adoptees. These risk factors largely persist currently, as indicated by an analysis of over 1 million BLLs obtained from U.S. children between October 2018 and February 2020 and analyzed in a commercial lab. In addition, these data indicated that over half of the children still have measurable BLLs, i.e., ≥1 μg/dL.

Progress is also being made globally. In Mexico, the introduction of unleaded gasoline in 1990 was associated with a decline in BLLs among first-grade students, from 17 μg/dL in 1990 to 6.2 μg/dL in 1997. Algeria, the last country to use leaded gasoline for cars and trucks, phased out its use in 2021. In Malta, after the import of red lead paint was banned and the use of lead-treated wood for fuel in bakeries was prohibited, mean BLLs of pregnant women and newborns decreased by 45%. After it was documented that children living in the neighborhood of a battery factory in Nicaragua had a mean BLL of 17.2 μg/dL, but children in the control community had a mean BLL of 7.4 μg/dL, the factory was closed. Despite these advances, in 2021 the World Health Organization (WHO), citing research for UNICEF by the Institute for Health Metrics and Evaluation, estimated that 815 million children globally may have elevated BLLs above 5 mg/dL. The majority live in developing countries, where in some regions BLLs may be 10- to 20-fold higher than in developed countries.

Unfortunately, local lead-related harms continue to occur. When the water source for Flint, Michigan, was changed (2014) to the Flint River and utilized a water treatment plant with poor corrosion control, the lead level of Flint tap water increased, as did the BLLs of children <5 years of age. Flint is not unique; many other cities have lead pipes that can result in water contamination. In 2021 the US government allocated $15 billion for lead pipe removal.

In 2010, the CDC and WHO identified numerous lead-contaminated villages in northern Nigeria. The grinding of ore to extract gold caused widespread leaded dust dissemination. It is likely that hundreds of children died because of this activity, and all remaining children in some of the villages assessed were lead poisoned, with 97% having a BLL ≥45 μg/dL, the threshold for chelation therapy in the United States. Unfortunately, such disasters continue to occur in Nigeria and neighboring countries from similar metal extraction activities.

SOURCES OF EXPOSURE

Lead poisoning may occur in utero because lead readily crosses the placenta from maternal blood. The spectrum of toxicity is similar to that experienced by children after birth. The source of maternal blood lead content is either redistribution from endogenous stores (i.e., the mother's skeleton) or lead newly acquired from ongoing environmental exposure.

Several hundred products contain lead, including paint, batteries, cable sheathing, cosmetics, mineral supplements, plastics, toys (Table 761.1), and traditional medicines (Table 761.2). Major sources of exposure vary among and within countries; the major source of exposure in the United States remains old lead-based paint. Approximately 34.6 million homes, mainly built before 1950, have lead-based paint (2021 estimate), of which the CDC has estimated that 22.3 million are in a hazardous state. As paint deteriorates, it chalks, flakes, and turns to dust. Improper rehabilitation work of painted surfaces (e.g., sanding) can result in dissemination of lead-containing dust throughout a home. The dust can coat all surfaces, including children's hands. All of these forms of lead can be ingested. If heat is used to strip paint, then lead vapor concentrations in the room can reach levels sufficient to cause lead poisoning via inhalation. There is an increased awareness that tap water in both homes and schools may have substantial amounts of lead. The latter arose from the discovery of contaminated water in most New York City public schools. Moreover, this occurrence raised questions about the safety of the US Environmental Protection Agency (EPA) lead-in-water-standard of 15 parts per billion (ppb; μg of Pb/L of water) that water distribution companies must meet in at least 90% of homes in their service areas. This standard was not based on achieving health safety but rather on what the water companies felt was financially feasible. After review, in 2021 the EPA recommended lowering the "trigger" level to 10 ppb. Breaching this value requires water companies to prepare an intervention plan should the level subsequently go over 15 ppb. It does not require action to reduce the amount of lead in that water supply. Even 10 ppb is still much greater than the 1 ppb recommended by the American Academy of Pediatrics as the limit for allowable lead in drinking water. It should be noted that the EPA lead in water standard does not apply to schools, although many states have set their own standards.

In other parts of the world, especially in poorer countries, additional sources can be found. These include contaminated neighborhoods as the result of car/truck battery lead recycling, aluminum cookware made with recycled metals, spices, and traditional medicines.

METABOLISM

The nonnutritive hand-to-mouth activity of young children is the most common pathway for lead to enter the body. In most cases, lead is ingested either as a component of dust licked off of surfaces or in swallowed paint chips, through water contaminated by its flow through lead pipes or brass fixtures, or from otherwise contaminated foods or liquids. Cutaneous contamination with inorganic lead compounds, such as those found in pigments, does not result in a substantial amount of absorption. Organic lead compounds, such as tetraethyl lead, may penetrate through skin; however, these are rarely encountered.

The percentage of lead absorbed from the gut depends on several factors: particle size, pH, other material in the gut, and nutritional status of

Table 761.1 Sources of Lead

Paint chips
Dust
Soil
Parent's or household contact's occupational exposure (auto repair, smelting, construction, remodeling, plumbing, gun/bullet (firing range) exposure, painting, e-scrap)
Glazed ceramics
Herbal remedies (e.g., Ayurvedic medications)
Home remedies, including antiperspirants, deodorants (litargirio)
Jewelry (toys or parents')
Stored battery casings or recycling (or living near a battery smelter)
Lead-based gasoline (in aviation fuel for propeller planes)
Moonshine alcohol
Mexican candies; Ecuadorian chocolates
Ceremonial spices
Indoor firing ranges
Retained bullet fragments
Imported spices (svanuri marili, zafron, kuzhambu)
Lead-based cosmetics (kohl, surma, kajal)
Lead plumbing (water)
Imported foods in lead-containing cans
Domestic foods (applesauce pouches, others)
Imported toys
Home renovations
Antique toys or furniture
Kratom

Table 761.2 Cases of Lead Encephalopathy Associated with Traditional Medicines by Type of Medication

TRADITIONAL MEDICAL SYSTEM	NO. (%) CASES OF LEAD ENCEPHALOPATHY	NO. (%) PEDIATRIC CASES WITHIN CAM SYSTEM OR MEDICATION
Ayurveda	5 (7)	1 (20)
Ghasard	1 (1)	1 (100)
Traditional Middle Eastern practices	66 (87)	66 (100)

essential elements. Large paint chips are difficult to digest and are mainly excreted; this chemical characteristic of lead compounds is fortunate, as a single chip may contain a potentially lethal dose of lead. Fine dust can be dissolved more readily, especially in an acid medium. Lead eaten on an empty stomach is better absorbed than that taken with a meal. The presence of **calcium** and **iron** may decrease lead absorption by direct competition for binding sites; iron (and probably calcium) deficiency results in enhanced lead absorption, retention, and toxicity.

After absorption, lead is disseminated throughout the body via blood. It circulates bound to erythrocytes; approximately 97–99% of lead in blood is bound on or in the red blood cells. The plasma fraction is too small to be measured by conventional techniques employing atomic absorption spectroscopy or anodic stripping voltammetry; it is presumably the plasma portion that may leave the blood compartment to enter cells and induce toxicity. Thus clinical laboratories report the BLL, not the serum or plasma lead level. The increasing availability and decreasing cost of inductively coupled plasma mass spectrometry, which is capable of measuring lead in ng/dL quantities, may eventually result in clinical availability of tools to measure plasma lead, a more proximal measure to where toxicity is actually occurring.

Most retained lead accumulates in bone, where it resides for years. But in all cells, lead has multiple effects. It binds to enzymes, particularly those with available sulfhydryl groups, changing the contour and diminishing function. For example, three of eight enzymes in the ubiquitously distributed heme pathway are susceptible to lead inhibitory effects. The accumulation of excess amounts of heme precursors is also toxic. The last enzyme in this pathway, ferrochelatase, enables protoporphyrin to chelate iron, thus forming heme. **Erythrocyte protoporphyrin (EP)** levels higher than 35 μg/dL (laboratory dependent) are abnormal and are consistent with lead poisoning, iron deficiency, or recent inflammatory disease. Measurement of the EP level is thus a useful tool for monitoring biochemical lead toxicity. EP levels begin to rise several weeks after BLLs have reached 20 μg/dL in a susceptible portion of the population and are elevated in nearly all children with BLLs higher than 50 μg/dL. A drop in EP levels also lags behind a decline in BLLs by several weeks because it depends on both cell turnover and cessation of further overproduction by marrow red blood cell precursors. The test can be ordered either as the free EP or the zinc protoporphyrin. Results are reported in μg/dL. When reported in μmol/mmol this likely indicates that the analysis has been standardized to a hematocrit of 45, an unwarranted assumption in young children.

A second mechanism of lead toxicity works via its competition with calcium. Many calcium-binding proteins have a higher affinity for lead than for calcium. Lead bound to these proteins may alter function, resulting in abnormal intracellular and intercellular signaling. Neurotransmitter release is, in part, a calcium-dependent process that is adversely affected by lead.

Although these two mechanisms of toxicity may be reversible, a third mechanism prevents the development of the normal tertiary brain structure. In immature mammals the normal neuronal pruning process that results in elimination of multiple intercellular brain connections is affected by lead. Failure to construct the appropriate tertiary brain structure during infancy and childhood may result in a permanent abnormality. In a longitudinal study of childhood lead poisoning, MRI examinations of the participants when in their 20s found smaller areas of brain in the prefrontal cortex and hippocampus regions, areas involved in decision-making and memory formation.

CLINICAL EFFECTS

The BLL is the best-studied measure of the lead burden in children. Although subclinical and clinical findings correlate with BLLs in populations, there is considerable interindividual variability in this relationship. **Lead encephalopathy** is more likely to be observed in children with BLLs higher than 100 μg/dL; however, one child with a BLL of 300 μg/dL may have no symptoms, whereas another with the same level may be comatose. Susceptibility may be associated with polymorphisms in genes coding for lead-binding proteins, such as Δ-aminolevulinic acid dehydratase, an enzyme in the heme pathway.

Several **subclinical effects** of lead have been demonstrated in cross-sectional epidemiologic studies. Hearing and height are inversely related to BLLs in children; in neither case, however, does the lead effect reach a level that would bring an individual child to medical attention. As BLLs increase in the study populations, more sound (at all frequencies) is needed to reach the hearing threshold. Children with higher BLLs are shorter than those with lower levels; for every 10 μg increase in the BLL, the children are 1 cm shorter. Chronic lead exposure also may delay puberty.

Several longitudinal studies have followed cohorts of children for decades after birth and examined the relationship between BLLs and cognitive test scores over time. In general, there is agreement that BLLs, expressed either as levels obtained concurrently with cognitive testing or as a measure that integrates multiple BLLs drawn from subjects over time, are inversely related to cognitive test scores. From these studies, no BLL above 0 μg/dL appears safe. On average, for each 1 μg/dL elevation in BLL, the cognitive score is approximately 0.25-0.50 points lower, though the relationship is not linear across the BLL spectrum.

Because the BLLs from early childhood are predictors of the cognitive test results performed years later, this finding implies that the effects of lead can be permanent.

The effect of in utero lead exposure is less clear. Scores on the Bayley Scale of Mental Development were obtained repeatedly every 6 months for the first 2 years of life in a cohort of infants born to middle-class families. Results correlated inversely with cord BLLs, a measure of in utero exposure. However, after 2 years of age, all other cognitive tests performed on the cohort over the next 10 years correlated with the BLLs at age 2 years but not with cord BLLs, indicating that the effects of prenatal lead exposure on brain function were superseded by early childhood events and later BLLs. Later studies, performed in cohorts of Mexican children monitored from the prenatal period, confirm the association between in utero lead exposure and later cognitive outcomes. In these studies, maternal plasma lead levels, obtained especially during the first trimester, were more strongly associated with cognitive scores in the offspring than with the traditionally measured maternal whole BLLs.

Behavior also is adversely affected by lead exposure. Hyperactivity is noted in young school-age children with histories of lead poisoning or with concurrent elevations in BLL. Older children with higher bone lead content are more likely to be aggressive and to have behaviors that are predictive of later juvenile delinquency. One report supports the concept of long-term effects of early lead exposure. In this longitudinal study, the mothers of a cohort were enrolled during their pregnancies. BLLs were obtained early in pregnancy, at birth, and then multiple times in the offspring during the first 6 years. The investigators report that the later relative rate of arrests, especially for violent crimes, increased significantly in relationship to the presence of these BLLs early in life. For every 5 μg/dL increase in BLL, the adjusted arrest rate was 1.40 for prenatal BLLs and 1.27 for 6-year BLLs. Epidemiologic data support the findings in this observational study. In an analysis that combined two national datasets, total annual leaded gasoline use (U.S. Geological Survey) and total reported violent criminal acts (U.S. Department of Justice), the amount of leaded gasoline used yearly was found to be strongly associated with violent criminal behavior with a lag time of 23 years; that is, early childhood exposure was followed two decades later by violent behavior rising and falling in close tandem. A similar association was found, this time between urban air lead levels and later violent crime, with a similar best-fit model employing a lag of approximately 22 years.

An intervention study, in which children with moderate lead poisoning and initial BLLs of 20-55 μg/dL were aggressively managed over 6 months, addressed the issue of the effects of treatment on cognitive development. Components of treatment included education regarding sources of lead and its abatement, nutritional guidance, multiple home and clinic visits, and for a subset, chelation therapy. Average BLLs declined, and cognitive scores were inversely related to the change in BLLs. For every 1 μg/dL fall in BLLs, cognitive scores were 0.25 point higher. A randomized placebo-controlled treatment study of 2-year-old children with initial BLLs of 20-44 μg/dL that employed the chelating agent succimer administered over 6 months found no difference in mean cognitive scores at age 4 years. However, as in the earlier treatment study, regression analysis did find an inverse relation between *change* scores; that is, a change in BLLs was associated with an inverse change in cognitive scores.

Whether the behavioral effects of lead are reversible is unclear. In one small, short-term study, 7-year-old hyperactive children with BLLs in the 20s were randomly allocated to receive a chelating agent (penicillamine), methylphenidate, or placebo. Teacher and parent ratings of behavior improved for the first two groups but not the placebo group. BLLs declined only in the chelated group. Two-year-old lead-poisoned children enrolled in a placebo-controlled trial of the chelating agent succimer showed no mean difference in behavior at 4 or 7 years of age. However, mean BLLs were also not different in the two groups at those ages.

These studies support the concept that early exposure to lead can result in long-term deficits in cognition and behavior; they also hold out the possibility that reductions in lead burden may be associated with improvement in cognitive test scores.

CLINICAL SYMPTOMS

Gastrointestinal symptoms of lead poisoning include anorexia, abdominal pain, vomiting, and constipation, often occurring and recurring over a period of weeks. Children with BLLs higher than 20 μg/dL are twice as likely to have gastrointestinal complaints as those with lower BLLs. **Central nervous system** symptoms are related to worsening cerebral edema and increased intracranial pressure. Headaches, change in mentation, lethargy, papilledema, seizures, and coma leading to death are rarely seen at levels lower than 100 μg/dL but have been reported in children with a BLL as low as 70 μg/dL. The last-reported death directly attributable to lead toxicity in the United States was in 2006 in a child with a BLL of 180 μg/dL. There is no clear cutoff BLL value for the appearance of hyperactivity, but it is more likely to be observed in children who have levels higher than 20 μg/dL.

Other organs also may be affected by lead toxicity, but symptoms usually are not apparent in children. At high levels (>100 μg/dL), renal tubular dysfunction is observed. Lead may induce reversible Fanconi syndrome. In addition, at high BLLs, red blood cell survival is shortened, possibly contributing to a hemolytic anemia, although most cases of anemia in lead-poisoned children are a result of other factors, such as iron deficiency and hemoglobinopathies. Older patients may develop peripheral neuropathy leading to wrist drop and foot drop, as well as hypertension.

DIAGNOSIS

Screening

It is estimated that 99% of lead-poisoned children are identified by screening procedures rather than through clinical recognition of lead-related symptoms. Until 1997, universal screening by blood lead testing of all children at ages 12 and 24 months was the standard in the United States. Given the national decline in the prevalence of lead poisoning, the recommendations have been revised to target blood lead testing of high-risk populations. High risk is based on an evaluation of the likelihood of lead exposure. Departments of health are responsible for determining the local prevalence of lead poisoning, as well as the percentage of housing built before 1950, the period of peak leaded paint use. When this information is available, informed screening guidelines for practitioners can be issued. For instance, in New York State, where a large percentage of housing was built before 1950, the Department of Health mandates that all children be tested for lead poisoning via blood analyses. *In the absence of such data, the practitioner should continue to test all children at both 12 and 24 months*. In areas where the prevalence of lead poisoning and old housing is low, targeted screening may be performed on the basis of a risk assessment. Three questions form the basis of most published questionnaires (Table 761.3), and items that are pertinent to the locale or individual may be added. If there is a lead-based industry in the child's neighborhood, the child is a recent immigrant from a country that until recently still permitted the use of leaded gasoline, or the child has **pica** (pattern of eating non-food materials) or developmental delay, blood lead testing would be appropriate. All Medicaid-eligible children should be screened by blood lead testing. Venous sampling is preferred to capillary sampling because the chances of false-positive and false-negative results are less with the former. However, capillary screening can be performed rapidly in the office with a point of care (POC) instrument; use of such instruments in primary care offices substantially increases screening rates. Other screening guidelines vary by federal, state, and even local governmental agencies. Contacting your local Department of Health is one way to determine local primary care obligations.

The threshold for lead effects and the reference level for risk management purposes are not the same. Laboratory issues make the interpretation of values more difficult at low levels. Most labs achieve quality control of ±2 μg/dL for reports of BLL, but federal regulations allow laboratories that perform BLL testing to operate with an allowable error of ±4 μg/dL. A capillary screening value ≥3.5 μg/dL requires a venous sample for confirmation (Table 761.4). If the diagnostic (venous) test

Table 761.3 Minimum Personal Risk Questionnaire

1. Does the child live in or regularly visit a house that was built before 1950? (Include settings such as daycare, babysitter's, or relative's home.)
2. Does the child live in or regularly visit a house built before 1978 with recent (past 6 months) or ongoing renovations or remodeling?
3. Does the child have a sibling or playmate who has or did have lead poisoning?

From Screening young children for lead poisoning. Guidance for state and local public health officials. Atlanta: Centers for Disease Control and Prevention, 1997.

Table 761.4 Recommended Schedule for Obtaining a Confirmatory Venous Sample

BLOOD LEAD LEVEL (µg/dL)	TIME TO CONFIRMATION TESTING*
≥3.5-9	Within 3 mo
10-19	Within 1 mo
20-44	Within 2 wk
≥45	Within 48 hr

*The higher the blood lead level is on the initial screening capillary test, the more urgent it is to get a venous sample for confirmatory testing.
Courtesy Centers for Disease Control and Prevention, 2022. https://www.cdc.gov/nceh/lead/advisory/acclpp/actions-blls.htm#anchor_86654

confirms that the BLL is elevated, then further testing is required by the recommended schedule (Table 761.5). A confirmed venous BLL of 45 µg/dL or higher requires prompt chelation therapy.

Other Tools for Assessment

BLL determinations remain the gold standard for evaluating children because of ready availability and its correlation with health outcomes in populations. Techniques are available to measure lead in other tissues and body fluids. Experimentally, the method of x-ray fluorescence (XRF) allows direct and noninvasive assessment of bone lead stores. XRF methodology was used to evaluate a population that had long-term exposure to lead from a polluting battery-recycling factory. The study found that the school-age children had elevated lead levels in bone but not in venous blood, a finding that is consistent with our understanding of the slow turnover of lead in bone, which is measurable in years, in contrast to that in blood, which is measurable in weeks. It also indicates that children may have substantial lead in their bodies that is not detected by routine blood lead testing. This stored lead may be released to toxic levels if bone resorption rates suddenly increase, as occurs with prolonged immobilization of longer than a week and during pregnancy. Thus children with histories of elevated BLLs are potentially at risk for recrudescence of lead toxicity long after ingestion has stopped and may pass this lead to the next generation. XRF methodology is not available for clinical use in children.

Lead also can be measured in urine. Spontaneous excretion, even in children with high BLLs, is usually low. Lead excretion may be stimulated by treatment with chelating agents, and this property of these drugs forms the basis of their use as a component of lead treatment. It also has been used to develop a test that differentiates children with lead burdens responsive to chelation therapy, the **lead mobilization test**. In this test, a timed urine collection follows one or two doses of chelating agent, and the lead content is determined. However, this test is no longer recommended.

Lead in hair, nails, and saliva also is measurable but has problems of contamination and interpretability; thus these have no clinical utility. Radiographs of long bones may show dense bands at the metaphyses ("**lead lines**"), which may be difficult to distinguish from growth arrest

Table 761.5 Schedule for Follow-Up Blood Lead Testing

VENOUS BLOOD LEAD CONCENTRATIONS (µg/dL)	EARLY FOLLOW-UP TESTING (2-4 TESTS AFTER INITIAL TEST ABOVE SPECIFIC VENOUS BLLs)	LATER FOLLOW-UP TESTING AFTER BLL DECLINING
≥3.5-9	3 mo*	6-9 mo
10-19	1-3 mo*	3-6 mo
20-44	2 wk to 1 mo	1-3 mo
≥45	As soon as possible	As soon as possible

BLL, Blood lead level.

Fig. 761.1 Anteroposterior radiograph of the abdomen demonstrates retention of radiopaque lead-based paint chips within bowel, predominantly clustered in the ascending colon. Other etiologies resembling "paint chips" include certain medications, eggshells, other heavy metals including iron- and calcium-containing supplements. Dense "lead lines" are noted in the proximal femoral metaphyses. *(From Swenson DW, Walters MM. Musculoskeletal imaging. In: Walters MM, Robertson RL, eds. Pediatric Radiology: The Requisites, 4th ed. Philadelphia: Elsevier; 2017: Fig. 7.50, p. 214.)*

lines but, if caused by lead, are indicative of months to years of exposure (Fig. 761.1). For children with acute symptoms, when a BLL result is not immediately available, a **kidneys-ureters-bladder (KUB) radiograph** may reveal **radiopaque flecks** in the intestinal tract, a finding that is consistent with recent ingestion of lead-containing plaster or paint chips (see Fig. 761.1). However, the absence of radiographic findings does not rule out lead poisoning.

Because BLLs reflect recent ingestion or redistribution from other tissues but do not necessarily correlate with the body burden of lead or lead toxicity in an individual child, tests of lead effects also may be useful. After several weeks of lead accumulation and a BLL higher than 20 µg/dL, increases in EP values to more than 35 µg/dL may occur. An elevated EP value that cannot be attributed to iron deficiency or recent inflammatory illness is both an indicator of lead effect and a useful means of assessing the success of the treatment; the EP level will begin to fall a few weeks after successful interventions that reduce lead ingestion and increase lead excretion. Because EP is light sensitive, whole blood samples should be covered in aluminum foil (or equivalent) until analyzed.

TREATMENT

All BLLs ≥3 μg/dL should be reported to state or local health departments. Once lead is in bone, it is released slowly and is difficult to remove even with chelating agents. Because the cognitive/behavioral effects of lead may be irreversible, the main effort in treating lead poisoning is to prevent it from occurring and to prevent further ingestion by already-poisoned children. The main components in the effort to eliminate lead poisoning are universally applicable to all children (and adults) and are as follows: (1) identification and elimination of environmental sources of lead exposure, (2) behavioral modification to reduce nonnutritive hand-to-mouth activity, and (3) dietary counseling to ensure sufficient intake of the essential elements calcium and iron and their supporting vitamins, D and C. For the small minority of children with more severe lead poisoning, drug treatment is available that enhances lead excretion. How effective these interventions may be at reducing BLLs or improving cognitive function remains unclear at the lower BLLs commonly observed currently in young children in the United States.

During health maintenance visits a limited risk assessment is warranted, which includes questions pertaining to the most common sources of lead exposure: the condition of old paint, secondary occupational exposure via an adult living in the home, and/or proximity to an industrial source of pollution. If such a source is identified, its elimination usually requires the assistance of public health and housing agencies as well as education for the parents. It would be safest for the family to move out of a lead-contaminated apartment until repairs are completed. During repairs, repeated washes of surfaces and the use of high-efficiency particle accumulator (HEPA) vacuum cleaners help reduce exposure to lead-containing dust. Careful selection of a contractor who is certified to perform lead abatement work is necessary. Sloppy work can cause dissemination of lead-containing dust and chips throughout a home or building and result in further elevation of a child's BLL. After the work is completed, dust wipe samples should be collected from floors and windowsills or wells to verify that the risk from lead has abated. The standards for what are considered acceptable lead dust levels have recently been modified by the EPA to lower limits that are more protective.

A single case of lead poisoning is often discovered in a household with multiple family members, including other young children, and even in a household with a common source of exposure such as peeling lead-based paint. The mere presence of lead in an environment does not produce lead poisoning. Parental efforts at reducing the hand-to-mouth activity of the affected child are necessary to reduce the risk of lead ingestion. Handwashing with soap and water effectively removes lead, but in a home with lead-containing dust, lead rapidly begins to reaccumulate on the child's hands after washing. Therefore handwashing is best limited to the period immediately before nutritive hand-to-mouth activity occurs.

Because there is competition between lead and essential metals, it is reasonable to promote a healthy diet that is sufficient in calcium and iron. The recommended daily intakes of these metals vary somewhat with age. In general, for children 1 year of age and up, a calcium intake of about 1 g/day is sufficient and convenient to remember (roughly the calcium content of a quart of milk [~1,200 mg/qt] or calcium-fortified orange juice). Calcium absorption is vitamin D dependent; milk is fortified with vitamin D, but other nutritional sources of calcium often are not. A multivitamin containing vitamin D may be prescribed for children who do not drink sufficient milk or who have inadequate sunlight exposure. Iron requirements also vary with age, ranging from 6 mg/day for infants to 12 mg/day for adolescents. For children identified biochemically as being iron deficient, therapeutic iron at a daily dose of up to 5-6 mg/kg/day for 3 months is appropriate. Iron absorption from vegetables is enhanced when iron is ingested with vitamin C (ascorbic acid), which is found in citrus juices. Giving additional calcium or iron above the recommended daily intake to mineral-sufficient children has not been shown to be of therapeutic benefit in the treatment of lead poisoning.

For children with BLLs of ≥20 μg/dL, an abdominal x-ray should be considered to check for lead-based paint chips or leaded foreign bodies, if not already obtained. If radiopaque fragments are visualized on imaging, bowel decontamination (typically with whole bowel irrigation) should be initiated (see Chapter 94).

Drug treatment to remove lead is lifesaving for children with lead encephalopathy. In nonencephalopathic children, it prevents symptom progression and further toxicity. Guidelines for **chelation** are based on the BLL. *A child with a venous BLL of 45 μg/dL or higher should be treated.* Four drugs have been used in the United States: 2,3-dimercaptosuccinic acid (DMSA [**succimer**]), $CaNa_2EDTA$ (versenate), British anti-lewisite (BAL [dimercaprol]), and penicillamine. DMSA and penicillamine can be given orally, whereas $CaNa_2EDTA$ and BAL can be administered only parenterally. The choice of agent is guided by the severity of the lead poisoning, the effectiveness of the drug, and the ease of administration (Table 761.6). Children with BLLs of 44-70 μg/dL may be treated with a single drug, preferably DMSA. Those with BLLs of 70 μg/dL or greater require two-drug treatment: $CaNa_2EDTA$ in combination with either DMSA or BAL for those without evidence of encephalopathy, or $CaNa_2EDTA$ and BAL for those with encephalopathy. Published data on the combined treatment with $CaNa_2EDTA$ and DMSA for children with BLLs higher than 100 μg/dL are very limited. However, anecdotal information derived from the treatment of hundreds of severely lead-poisoned children in northern Nigeria indicates that single-drug treatment with DMSA is lifesaving, although the degree of long-term residual damage in survivors has not been reported.

Drug-related toxicities are minor and reversible. These include gastrointestinal distress, transient elevations in transaminases, active urinary sediment, and neutropenia. These types of events are least common for $CaNa_2EDTA$ and DMSA, and more common for BAL and penicillamine. All of the drugs are effective in reducing BLLs when given in sufficient doses and for the prescribed time. These drugs also may increase lead absorption from the gut and should be administered to children in lead-free environments. Some authorities also recommend the administration of a cathartic immediately before or concomitant with the initiation of chelation to eliminate any lead already in the gut.

None of these agents removes all lead from the body. Within days to weeks after completion of a course of therapy, the BLL rises, even in the absence of new lead ingestion. The source of this rebound in the BLL is believed to be release from bone. Serial examinations of bone lead content have shown that chelation with $CaNa_2EDTA$ is associated with a decline in bone lead levels, but that residual bone lead remains detectable even after multiple courses of treatment.

Repeat chelation is indicated if the BLL rebounds to 45 μg/dL or higher. Children with initial BLLs higher than 70 μg/dL are likely to require more than one course. A minimum of 3 days between courses is recommended to prevent treatment-related toxicities, especially in the kidney.

The indication for chelation therapy for children with BLLs <45 μg/dL is less clear. Although use of these drugs in children with BLLs from 20-45 μg/dL will result in transiently lowered BLLs, and in some cases reversal of lead-induced enzyme inhibition, few such children increase their excretion of lead significantly during chelation, raising the question of whether any long-term benefit is achieved. A study of 2-year-old children with BLLs of 20-44 μg/dL who were randomized to receive either DMSA or placebo found that the drop in BLLs was greater in the first 6 months after enrollment in the DMSA-treated group, but the levels converged by 1 year of follow-up. Mean cognitive test scores obtained at 4 and 7 years of age were not statistically different between the groups. Chelation with DMSA (and $CaNa_2EDTA$) is not recommended for all children with BLLs <45 μg/dL. Further work needs to be done to determine whether there are subgroups of children with BLLs <45 μg/dL who might benefit from chelation. It also remains to be demonstrated whether other chelating agents available in the United States or elsewhere are effective at either substantially reducing body stores (bone) of lead or reversing the cognitive deficits attributable to lead at these BLLs.

Table 761.6 Chelators Used for Lead Poisoning

CHELATOR	DOSAGE	INDICATIONS	CONTRAINDICATIONS	ADVERSE EFFECTS
Succimer (DMSA)	1050 mg/m^2/day divided into 3 doses for 5 days, then 700 mg/m^2/day divided into 2 doses for 14 days (maximum 500 mg per dose for children)	BLL >45 µg/dL	None	Nausea, vomiting Diarrhea Metallic taste Transient increase in AST/ALT
$CaNa_2EDTA$	1,500 mg/mm^2/day continuous intravenous (IV) infusion for encephalopathy *Otherwise:* 1,000 mg/m^2/day divided in 2 to 4 doses for up to 5 days, IV or IM	BLL >70 µg/dL (starting after first dose of BAL or succimer) May substitute for succimer if that drug is not tolerated	Severe renal disease Hepatitis	Nephrotoxicity Transient increase in AST/ALT Arrythmia (bradycardia)
Dimercaprol (BAL)	4 mg/kg deep IM injection every 4 hours for 5 days in children and adults	BLL >70 µg/dL and encephalopathy Consider succimer as alternative	Peanut allergy Organic mercury poisoning Hepatic insufficiency	Pain at injection site Hypertension and tachycardia Nausea, vomiting Headache Fever (especially in children) Nephrotoxicity in the setting of an acidic urine
D-Penicillamine	1-1.5 g/day (children: 20-30 mg/kg/day), in 3 or 4 divided doses for 1-6 months To minimize adverse reactions, start at 250 mg/day (children: 10 mg/kg/day) and increase to 50% during week 2 and to a full dose by week 3 Maximum adult daily dose is 2 g	BLL of 45 to 69 µg/dL AND succimer not tolerated	Penicillin allergy	Leukopenia Thrombocytopenia Enuresis Abdominal pain Rashes

Note: Indications for chelation and dosing regimens may change. Consult with a medical toxicologist or regional poison center for the most up-to-date recommendations.
BAL, British antilewisite; BLL, blood lead level; $CaNa_2EDTA$, calcium disodium ethylenediaminetetraacetic acid; DMSA, 2,3-dimercaptosuccinic acid; IM, intramuscular; AST, alanine transaminase; ALT, aspartate transaminase.
Modified from Theobald JL, Mycyk MB. Iron and heavy metals. In: Walls RM, ed. *Rosen's Emergency Medicine*, 10th ed. Philadelphia: Elsevier; 2023: Table 146.5.

With successful intervention, BLLs decline, with the greatest fall in BLL occurring in the first 2 months after therapy is initiated. Subsequently, the rate of change in BLL declines slowly, so that by 6-12 months after identification, the BLL of the average child with moderate lead poisoning (BLL >20 µg/dL) will be 50% lower. Children with more markedly elevated BLLs may take years to reach the current CDC reference level, 3.5 µg/dL, even if all sources of lead exposure have been eliminated, behavior has been modified, and nutrition has been maximized. Early screening remains the best way of avoiding and therefore obviating the need for the treatment of lead poisoning.

Chapter 762 Nonbacterial Food Poisoning

762.1 Mushroom Poisoning

Diane P. Calello and Katherine Baranowski

Mushrooms are an ideal food. They are low in calories, fat free, and high in protein, making them a great source of nutrition. Unfortunately, some are highly toxic if ingested. Picking (foraging) and consumption of wild mushrooms are increasingly popular in the United States. This rise in popularity has led to increased reports of severe and fatal mushroom poisonings.

The clinical syndromes produced by mushroom poisoning are divided according to the rapidity of onset of symptoms and the predominant system involved (Table 762.1). The symptoms are caused by the principal toxin present in the ingested mushrooms. The eight major toxins produced by mushrooms are categorized as cyclopeptide *(amatoxin and phallotoxin),* gyromitrin, muscarine, coprine, ibotenic acid and muscimol, psilocybin, orellanine, and gastrointestinal tract–specific irritants. The edible wild mushroom *Tricholoma equestre* is associated with delayed rhabdomyolysis, and *Clitocybe amoenolens* and *Clitocybe acromelalga* have been reported to cause erythromelalgia, although toxins responsible for these effects are unknown.

Symptoms after eating mushrooms may not be the direct effect of a toxin but may be an allergic reaction or a toxic effect of pesticides or other contaminants. In addition, all who ate the same mushroom may not become sick, or if they do, they may become sick at different intervals. Table 762.2 lists general principles of management. Wherever possible, identification of the implicated mushroom is encouraged via mycologist or regional Poison Control Center.

GASTROINTESTINAL

Rapid Onset

Many mushrooms from various genera (such as *Chlorophyllum* species) produce local gastrointestinal manifestations. The causative toxins are diverse and largely unknown. Within 1 hour of ingestion, patients experience acute abdominal pain, nausea, vomiting, and diarrhea. Symptoms may last hours to days, depending on the species of mushroom.

Treatment is mainly supportive. Children with large fluid losses may require parenteral fluid therapy. It is imperative to differentiate ingestion of mushrooms of this class from ingestion of *Amanita* and

Table 762.1 Summary of Common Mushroom-Associated Syndromes

TOXIN	SYNDROME	CLINICAL COURSE	TYPICAL CAUSATIVE MUSHROOM(S)
Cyclopeptides, principally amatoxins	Delayed gastroenteritis followed by hepatic failure	*Stage 1:* 6-24 hr after ingestion: onset of nausea, vomiting, profuse cholera-like diarrhea, abdominal pain, hematuria *Stage 2:* 12-48 hr after ingestion: apparent recovery; levels of hepatic enzymes are rising during this stage *Stage 3:* 24-72 hr after ingestion: progressive hepatic and renal failure, coagulopathy, cardiomyopathy, encephalopathy, convulsions, coma, death	"Deadly *Amanitas*," *(A. phalloides, A. bisporigera)* *Galerina* species
General gastrointestinal irritants	Early gastroenteritis, may be severe	30 min to 2 hr after ingestion: nausea, vomiting, abdominal cramping, diarrhea; may recover without treatment	*Chlorophyllum molybdites*, backyard mushrooms ("little brown mushrooms"), many others
Gyromitrin	Delayed gastroenteritis with central nervous system toxicity, seizures	6-24 hr after ingestion: nausea, vomiting, diarrhea, abdominal pain, muscle cramps, delirium, convulsions, coma; hemolysis, and methemoglobinemia may occur	*Gyromitra esculenta* ("false morel")
Orellanine	Delayed onset gastroenteritis and renal failure	Abdominal pain, anorexia, vomiting starting over 30 hr after ingestion, followed by progressive renal failure 3-14 days later	*Cortinarius* species
Muscarine	Cholinergic syndrome	30 min to 2 hr after ingestion: bradycardia, bronchorrhea, bronchospasm, salivation, perspiration, lacrimation, convulsions, coma	*Clitocybe* species, *Inocybe* species, *Boletus* species, some *Amanita* species
Coprine	Disulfiram-like reaction with ethanol	30 min after drinking ethanol (may occur up to 1 week after eating coprine-containing mushrooms): flushing of skin of face and trunk, hypotension, tachycardia, chest pain, dyspnea, nausea, vomiting, extreme apprehension	*Coprinus atramentarius*
Ibotenic acid and muscimol	Hyperactivity, delirium, coma	30 min to 2 hours after ingestion: delirium, hallucinations, and coma	*Amanita muscaria, Amanita pantherina*
Psilocybin	Hallucinations	30 min to 3 hr after ingestion: hallucinations, euphoria, drowsiness, compulsive behavior, agitation	*Psilocybe* species

Modified from Brent J, Palmer RB: Mushrooms. In: Shannon MW, Borron SW, Burns MJ, eds. *Haddad and Winchester's Clinical Management of Poisoning and Drug Overdose*, 4th ed. Philadelphia: WB Saunders; 2007: Table 23-1.

Table 762.2 General Management of Mushroom Ingestion

1. Determine history of ingestion: how many types of mushrooms ingested, what time, if anyone else ate them, and what symptoms are present.
2. Attempt to determine which of the possible syndromes (see Table 762.1) the patient may have. For example, gastrointestinal symptoms occurring more than 6 hr after ingestion strongly suggest cyclopeptide, gyromitrin, or *Cortinarius* poisoning.
3. Administer activated charcoal. If the patient has diarrhea, do not give a cathartic. If a cathartic is used, give it only with the first dose of activated charcoal. Use repeated doses of activated charcoal for suspected amatoxin poisonings.
4. If feasible and when indicated, send gastric aspirate or emesis, along with any remaining mushrooms, to a mycologist for identification.
5. Try to perform a preliminary identification of mushroom and spores. Start to develop a spore print as soon as possible.
6. Maintain supportive measures, including airway support, intravenous fluids, and vasopressors (if needed). Monitor volume status.
7. Avoid antispasmodics for gastrointestinal symptoms.
8. Anticipate the clinical course.

From Brent J, Palmer RB: Mushrooms. In: Shannon MW, Borron SW, Burns MJ, eds. *Haddad and Winchester's Clinical Management of Poisoning and Drug Overdose*, 4th ed. Philadelphia: WB Saunders; 2007: Box 23.1.

Galerina species containing cyclopeptide toxins, which present with symptoms after 6 hours of ingestion.

Delayed Onset

Cyclopeptide (Amatoxin) Poisoning

Poisonings by species of *Amanita* (death cap mushroom) and *Galerina* account for 95% of the fatalities from mushroom intoxication; the mortality rate for this group is 5–10%. Most species produce two classes of **cyclopeptide toxins:** (1) **phallotoxins,** which are heptapeptides believed to be responsible for the early symptoms of *Amanita* poisoning, and (2) **amatoxins,** octapeptides that inhibit nuclear RNA polymerase II and subsequent production of messenger RNA leading to impaired protein synthesis and cell death. Cells with high turnover rates, such as those in the gastrointestinal mucosa, kidneys, and liver, are the most severely affected. Other suggested toxin effects are induction of apoptosis, glutathione depletion in the liver, and oxygen free radical formation. Acute yellow atrophy of the liver and necrosis of the proximal renal tubules are found in lethal cases.

The clinical course of poisoning with *Amanita* or *Galerina* species is biphasic. Nausea, vomiting, and severe abdominal pain ensue 6-24 hours after ingestion. Profuse watery diarrhea follows shortly thereafter and may last for 12-24 hours or longer. During this time, patients become severely dehydrated. From 24 to 48 hours

after poisoning, jaundice, hypertransaminasemia (peaking at 72-96 hours), renal failure, and coma occur. Death occurs 4-7 days after the ingestion. A prothrombin time less than 10% of control is a poor prognostic factor. Of note, there are species of Amanita mushrooms that may present with earlier onset of symptoms and confound diagnosis, such as *Amanita smithiana,* which grows in the Pacific Northwest.

Treatment

Treatment for *Amanita* poisoning is both supportive and specific. Fluid loss from severe diarrhea during the early course of the illness is profound, requiring aggressive correction of fluid loss, electrolytes, and acid-base disturbances. In the late phase of the disease, management of renal and hepatic failure is also necessary.

Specific therapy for *Amanita* poisoning is designed to remove the toxin rapidly and to block binding at its target site. Oral activated charcoal is recommended as part of the initial treatment for children with *Amanita* poisoning. For significant ingestions, intravenous silibinin or intravenous penicillin G may be considered after discussion with a toxicologist or Poison Control Center. Silibinin and penicillin G inhibit binding of both toxins, interrupt enterohepatic recirculation of amatoxin, and protect the liver from further injury, although their effectiveness is controversial. *N*-acetylcysteine should be given for hepatoprotective effect. Hemodialysis or hemoperfusion may be beneficial in removing toxin. Orthotopic liver transplantation may be required for children with severe hepatic failure.

Gyromitrin Poisoning

Species of *Gyromitra* contain **gyromitrin,** which decomposes in the stomach to form **monomethylhydrazine** (CH_3NHNH_2) and inhibits central nervous system (CNS) enzymatic production of γ-aminobutyric acid (GABA). Monomethylhydrazine also oxidizes iron in hemoglobin, resulting in methemoglobinemia. Children with *Gyromitra* poisoning often experience vomiting, diarrhea, and abdominal pain within 6-24 hours of ingestion of the toxin. CNS symptoms such as vertigo, diplopia, headache, ataxia, and seizures develop later in the clinical course. Hemolysis and methemoglobinemia (see Chapter 511.6) are rare but potential life-threatening complications of gyromitrin poisoning.

Treatment

Hypovolemia from gastrointestinal fluid losses and seizures require supportive intervention. **Pyridoxal phosphate,** the coenzyme that catalyzes the production of GABA, can reverse the effects of monomethylhydrazine when administered in high doses. Pyridoxine hydrochloride (25 mg/kg infused over 30 minutes) is given at a frequency that is dependent on clinical improvement. Diazepam is given for persistent seizures. Parenteral administration of methylene blue is indicated if the methemoglobin concentration exceeds 30%. Blood transfusions may be required for significant hemolysis.

RENAL

Orellanine Poisoning

Species of *Cortinarius* mushrooms contain the heat-stable toxin bipyridyl **orellanine,** which causes severe nonglomerular renal injury characterized by interstitial fibrosis and acute tubular necrosis. Although the exact mechanism of injury is not fully understood, a metabolite of orellanine is thought to inhibit renal protein synthesis. *Cortinarius* poisoning is characterized by delayed onset of nausea, vomiting, and diarrhea that manifest 36-48 hours after ingestion. Although the initial symptoms may be trivial, more serious renal toxicity occurs in several days. Acute renal failure occurs in 30–50% of those affected, beginning with polyuria and progressing to renal failure (see Chapter 572).

Treatment

Treatment for orellanine poisoning is supportive. Early presentation, within 4-6 hours after ingestion, can be treated with activated charcoal and gastric lavage. Hemodialysis may be needed in patients suffering from renal failure. Most patients recover within 1 month, but chronic renal insufficiency develops in one third to one half of patients who subsequently require renal transplantation.

AUTONOMIC NERVOUS SYSTEM

Muscarine Poisoning

Mushrooms of the genera *Inocybe* and, to a lesser degree, *Clitocybe* contain **muscarine** or muscarine-related compounds. These quaternary ammonium derivatives bind to postsynaptic receptors, producing an exaggerated cholinergic response.

The onset of symptoms is rapid (30 minutes to 2 hours after consumption), and intoxication is characterized by symptoms of cholinergic excess: diaphoresis, excessive lacrimation, salivation, miosis, bradycardia, hypotension, urinary and fecal incontinence, and vomiting. Respiratory distress caused by bronchospasm and increased bronchopulmonary secretions is the most serious complication. The symptoms subside spontaneously within 6-24 hours.

Treatment

Atropine sulfate, the specific antidote, is administered intravenously (0.01 mg/kg; maximum: 2 mg). This is repeated until the pulmonary symptoms resolve or the patient becomes overtly tachycardic.

Coprine Poisoning

Coprinus atramentarius and *Clitocybe clavipes* contain **coprine.** Like disulfiram (Antabuse; Odyssey Pharmaceuticals, Inc.), coprine inhibits the metabolism of acetaldehyde after ethanol ingestion. The clinical manifestations result from accumulation of acetaldehyde.

Coprine intoxication becomes apparent after ethanol ingestion and may be delayed up to 5 days after consumption of the mushroom. Hyperemia of the face and trunk, tingling of the hands, metallic taste, tachycardia, and vomiting occur acutely. Hypotension may result from intense peripheral vasodilation.

The syndrome typically is self-limited and lasts only several hours. No specific antidote is available. If hypotension is severe, vascular reexpansion with isotonic parenteral solutions may be required.

CENTRAL NERVOUS SYSTEM

Ibotenic acid and Muscimol Poisoning

Although *Amanita muscaria* and *Amanita pantherina* may contain muscarine, the toxins responsible for the CNS symptoms after ingestion of these mushrooms are primarily **muscimol** and **ibotenic acid,** the heat-stable derivatives of the isoxazoles. Muscimol, a hallucinogen, and ibotenic acid, an insecticide, act as GABA agonists. From 30 minutes to 3 hours after ingestion, CNS symptoms appear: obtundation, alternating lethargy and agitation, and occasionally seizures. Nausea and vomiting are uncommon. If large amounts of muscarine are contained in the mushroom, symptoms of cholinergic crisis also may occur.

Specific therapy must be carefully selected, and in most cases supportive care will suffice. If an exaggerated cholinergic response is observed, atropine should be administered. Conversely, because ingestions of *A. muscaria* or *A. pantherina* may cause anticholinergic findings, the acetylcholinesterase inhibitor physostigmine can be used to reverse the delirium and coma. Benzodiazepines also are used for the agitation and delirium. Seizures can be controlled with diazepam. In the majority of patients, however, early supportive care and close observation are all that is required.

Psilocybin Intoxication

Mushrooms belonging to the genus *Psilocybe* ("magic mushrooms") contain **psilocybin and psilocin,** two psychotropic compounds. Within 30 minutes after ingestion, patients experience euphoria and hallucinations, often accompanied by tachycardia and mydriasis. Fever and seizures have also been observed in children with psilocybin poisoning. These symptoms are short-lived, usually lasting for 6 hours after consumption of the mushroom. Treatment consists of rest and observation in a quiet environment. Severely agitated patients may respond to diazepam.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

762.2 Solanine Poisoning

Katherine Baranowski and Diane P. Calello

Solanine is an alkaloid found in plants of the nightshade family (Solanaceae), specifically tomatoes, eggplant, paprika and pepper-based spices, and most significantly, white potatoes. The majority of solanine poisoning reported has arisen from the ingestion of greened potatoes. When exposed to light and allowed to turn green and/or sprout, potatoes produce several alkaloid glycosides containing the cholesterol derivative *solanidine*. Two of these glycosides, α-solanine and α-chaconine, are found in highest concentration in the peels and sprouts. Some solanine can be removed by boiling but not by baking. The major effect of α-solanine and α-chaconine is the reversible inhibition of cholinesterase. Cardiotoxic and teratogenic effects have also been reported.

Clinical manifestations of solanine and chaconine poisoning occur within 7-19 hours after ingestion. The most common symptoms are vomiting, abdominal pain, and diarrhea; in more severe instances of poisoning, neurologic symptoms, including drowsiness, apathy, confusion, weakness, and vision disturbances, are rarely followed by coma or death.

Treatment of solanine poisoning is largely supportive. In the most severe cases, symptoms resolve within 1-2 weeks.

762.3 Seafood Poisoning

Diane P. Calello and Katherine Baranowski

CIGUATERA FISH POISONING

The most frequently reported seafood toxin illness in the world is ciguatera fish poisoning. Grouper is the most commonly identified source of the toxin, followed by snapper, kingfish, amberjack, dolphin, eel, and barracuda. Poisoning has also been associated with farm-raised salmon.

The dinoflagellate ***Gambierdiscus toxicus,*** a microscopic unicellular organism found along coral reefs, produces high concentrations of **ciguatoxin** and **maitotoxin.** The toxins are passed along the food chain from small herbivorous fish that consume the dinoflagellate to larger predatory fish and then to humans. These toxins are harmless in fish but produce distinct clinical symptoms in humans.

Ciguatoxins are odorless, colorless, and tasteless and are not destroyed by cooking or freezing. Ciguatoxins increase the sodium ion permeability of excitable membranes and depolarize nerve cells, actions that are inhibited by calcium and tetrodotoxin.

Between 2 and 30 hours after ingestion, ciguatera fish poisoning typically produces a biphasic illness. The initial symptoms are nonspecific and are of gastrointestinal origin (diarrhea, vomiting, nausea, and abdominal pain). The second phase occurs within a few days of ingestion and consists of intense itching, anxiety, myalgias, painful intercourse, feeling of loose teeth, and rash on palms and soles; the neurologic symptoms of **circumoral dysesthesias** and **cold allodynia** (reversal of hot and cold sensation) are characteristic of this disease and may last for months. Tachycardia, bradycardia, hypotension, and death occur very infrequently. Eating fish organs, roe, or viscera is associated with greater symptom severity. The diagnosis of ciguatera fish poisoning is based on clinical presentation and a compatible epidemiologic history; the diagnosis is confirmed by testing the ingested fish for toxin. There is no human biomarker to confirm ciguatera fish poisoning.

Treatment

Treatment of ciguatera fish poisoning is supportive. Intravenous fluids may be required for severe diarrhea, and careful observation for hypovolemic shock is advised. Once adequate hydration is established, mannitol (0.5-1.0 g/kg intravenously over 30-45 minutes), given within 48-72 hours of the toxic fish ingestion, is recommended for reduction of acute symptoms (especially neurologic symptoms) and possible prevention of chronic neurologic symptoms. Various other medications and herbal remedies have been tried, with variable results. Most cases are self-limited with a favorable prognosis.

SCOMBROID (PSEUDOALLERGIC) FISH POISONING

Ingestion of members of the **Scombridae** families, including albacore, mackerel, tuna, bonito, and kingfish, have been linked to major outbreaks of pseudoallergic fish poisoning. Non-scombroid fish such as mahi-mahi (dolphin fish), swordfish, and bluefish also are associated with poisoning.

The bacterial transformation of histidine to histamine is responsible for the clinical syndrome. Histidine is found in high concentrations in the flesh of scombroid fish; if refrigeration is inadequate, the action of bacterial decarboxylases during putrefaction converts histidine to histamine. Fish containing more than 20 mg of histamine per 100 g of flesh are toxic. In patients receiving isoniazid, a potent histaminase blocker, ingestion of fish flesh containing a lower concentration of histamine may be toxic.

The onset of clinical manifestations is acute and occurs within 10 minutes to 2 hours of ingestion. The most common symptoms and signs are diarrhea, erythema, sweating, flushing, diaphoresis, urticaria, nausea, and headache (Fig. 762.1). Abdominal pain, tachycardia, oral burning or numbness, dizziness, respiratory distress, hives, and facial swelling also occur. The illness is usually self-limited, terminating within 8-24 hours.

Treatment

Treatment is mainly supportive. With severe diarrhea, fluid replacement may be necessary. Antihistamines and antiemetics have been variably successful.

PARALYTIC SHELLFISH POISONING

Mussels, clams, oysters, scallops, and other filter-feeding mollusks may become contaminated during dinoflagellate blooms or **"red tides."** During periods of contamination, water in coastal areas can be colored red by the algae; this sign is the origin of the term *red tide*. (Such discoloration does not necessarily indicate the presence of toxin, and toxin may be present in high quantities without discoloration. Nonetheless, discolored water should be regarded with suspicion.) The dinoflagellates *Alexandrium* spp. and *Gymnodinium catenatum* often are responsible for these red tides and contain several potent neurotoxins. Paralytic shellfish poisoning is a distinctive neurologic illness caused by 20 closely related heat-stable paralytic shellfish toxins, generally referred to as **saxitoxins.** These compounds prevent nerve conduction by inhibiting the sodium-potassium pump. Consumption of bivalves, such as mussels, scallops, and clams, is the usual pathway of intoxication, although crustaceans and fish have been implicated as well.

The onset of clinical manifestations of paralytic shellfish poisoning occurs rapidly, 30 minutes to 2 hours after ingestion. Abdominal pain and nausea are common. Paresthesias are common and occur circumorally or in a stocking-glove distribution, or both. Perioral numbness or tingling, diplopia, ataxia, dysarthria, and the sensation of floating are seen less commonly. In severe cases, respiratory failure from diaphragmatic paralysis may result. Swimming in the water during a red tide episode does not appear to have neurologic sequelae, although skin or mucosal irritation may result.

Treatment

No antidote for paralytic shellfish poisoning is known. Supportive care, including mechanical ventilation, may be needed. Although the symptoms are usually self-limited and short-lived, weakness and malaise may persist for weeks after ingestion.

NEUROTOXIC SHELLFISH POISONING

Neurotoxic shellfish poisoning is a rare disease that occurs after consumption of molluscan shellfish contaminated with brevetoxins. Shellfish harvested along the Gulf of Mexico during or right after a red tide are at risk of contamination with brevetoxins produced by the

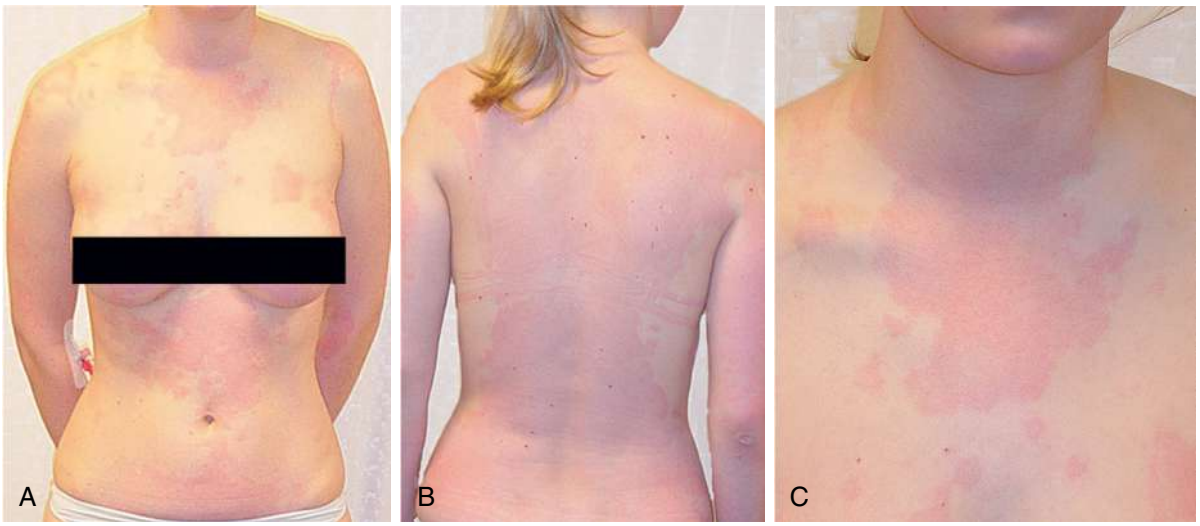

Fig. 762.1 Scombroid fish poisoning. A and B, Widespread erythematous rash predominantly on the face (not shown) and trunk of patient 1. C, Close-up view of the upper chest area. Note the absence of wheals. *(Modified from Jantschitsch C, Kinaciyan T, Manafi M, et al. Severe scombroid fish poisoning: an underrecognized dermatologic emergency. J Am Acad Dermatol. 2011;65[1]:246–247. Fig. 1.)*

dinoflagellate *Karenia brevis;* some raphidophytes (*Chattonella* spp.) also produce brevetoxins. **Brevetoxins** are a group of more than 10 lipid-soluble neurotoxins that activate sodium ion channels, causing nerve membrane depolarization. Shellfish are not affected by brevetoxins. Rinsing, cleaning, cooking, and freezing do not destroy the toxins, which also cannot be detected by taste or smell.

The onset of clinical manifestations of neurotoxic shellfish poisoning occurs from within a few minutes up to 18 hours after consumption. Most symptoms are gastrointestinal (nausea, vomiting, and diarrhea) or neurologic (numbness and tingling of the lips, mouth, face, and extremities, ataxia, partial limb paralysis, reversal of hot and cold sensation, slurred speech, headache, and fatigue). Neurotoxic shellfish poisoning is similar to a mild case of paralytic shellfish poisoning.

Treatment

There are no specific antidotes for brevetoxins. Treatment involves mostly supportive care. Brevenal, a natural antagonist of brevetoxin produced by *K. brevis,* may be used as a form of treatment in the future.

DIARRHETIC SHELLFISH POISONING

Several outbreaks of diarrhetic shellfish poisoning have been reported in Europe after consumption of mussels, cockles, and other shellfish. The dinoflagellates *Dinophysis* and *Prorocentrum* produce **okadaic acid** and its derivatives, the **dinophysistoxins.** These compounds inhibit protein phosphatases. The intracellular accumulation of phosphorylated proteins causes increased fluid secretion by gut cells via calcium influx, which is mediated by cyclic adenosine monophosphate and prostaglandins.

Patients have severe diarrhea. Care is supportive and directed at rehydration. The illness is self-limited, and recovery occurs in 3-4 days; few patients require hospitalization.

AMNESIC SHELLFISH POISONING

Amnesic shellfish poisoning has been identified after consumption of shellfish from the United States, Spain, and the United Kingdom. The responsible toxin, **domoic acid,** comes from a diatom, *Pseudonitzschia multiseries,* and is a potent glutamate agonist, disrupting neurochemical transmission in the brain. It also binds to glutamate receptors, which increase calcium influx, producing neuronal swelling in the hippocampal area of the brain and death.

The initial clinical manifestations are gastrointestinal with nausea, vomiting, diarrhea, and abdominal cramps within 24 hours of ingestion. Neurologic symptoms may follow including headache, confusion, and short-term memory loss. Memory loss is closely related to advanced age with those >50 years more likely to suffer from memory loss lasting months to years.

PUFFERFISH POISONING

The consumption of pufferfish (blowfish) in certain geographic areas such as Japan and the Indo-Pacific Ocean is associated with a lethal neurotoxic illness due to **tetrodotoxin**. Fugu, a Japanese delicacy, is sought after in part because of the subtle neurotoxic effects experienced upon eating, including perioral paresthesias and a dissociative feeling. While a trained fugu chef will remove the most toxic parts of the fish, the toxin is still found in varying degrees.

Tetrodotoxin, which is also found in the blue-ringed octopus, causes a paralytic illness due to the blockade of voltage-dependent sodium channels. Early symptoms include paresthesias, nausea, and dizziness, which progresses to weakness, numbness, and incoordination. Autonomic compromise may also occur with bradycardia and hypotension. In the most severe of cases, respiratory compromise requires assisted ventilation.

There is no specific antidote for tetrodotoxin pufferfish poisoning.

AZASPIRACID POISONING

The azaspiracids are a class of algal toxins associated with **harmful algal blooms (HABs).** Azaspiracid poisoning results from ingestion of contaminated bivalve shellfish, especially mussels. Azaspiracid toxins are distributed throughout the muscle tissue in the shellfish. Azaspiracid is cytotoxic to cells and an inhibitor of Ca^{2+} channels in plasma membranes. Symptoms start 6-18 hours after ingestion and include nausea, vomiting, severe stomach cramps, and diarrhea, which often persist up to 5 days.

Cyanobacteria (blue-green algae) also produce HABs; exposure is usually during recreational water sports and may be cutaneous or gastrointestinal. Symptoms include rash, cough, abdominal pain, diarrhea, nausea, emesis, muscle aches, watery eyes, weakness, or sore throat.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

762.4 Melamine Poisoning

Katherine Baranowski and Diane P. Calello

Melamine (1,3,5-triazine-2,4,6-triamine, or $C_3H_6N_6$) is found in many plastics, adhesives, laminated products, cement, cleansers, fire retardant paint, and more. Melamine poisoning from food products was unheard of until 2007, when melamine-tainted pet food caused the death of many dogs and cats in the United States. In 2008, feeding of melamine-tainted infant formula to more than 300,000 children resulted in urolithiasis and resultant kidney injuries, 50,000 hospitalizations, and 6 deaths in China. This was the first reported epidemic of melamine-tainted milk products.

Melamine contains 66% nitrogen by mass. The illegal addition of melamine to infant formula can give the formula a milky appearance and falsely raise the protein content as measured by nitrogen testing. Melamine, combined with cyanuric acid, forms cyanurate crystals in the kidneys. Along with protein, uric acid, and phosphate, melamine forms renal calculi. The melamine stones and gravel can be treated with hydration, alkalinization, or lithotripsy. Acute renal failure requires supportive care and dialysis if needed.

Clinical manifestations are initially subtle and nonspecific. The severity is dose related. The first symptoms in affected infants are unexplained crying (especially when urinating), vomiting, and discolored urine caused by the formation of stones and gravel in the urinary tract. Urinary obstruction and acute renal failure follow. In the absence of a specific diagnosis, death from renal failure may occur. Whether children with melamine-induced renal failure will have chronic renal sequelae is currently unknown.

In addition to the more well-known renal toxicity, cognitive defects can be seen after acute, chronic, or prenatal exposure. Dissolved and insoluble melamine and its insoluble metabolites all have the potential to cause neurotoxicity.

Chapter 763

Biological and Chemical Terrorism

*Theodore J. Cieslak, Jonathan Newmark, and Mark G. Kortepeter**

In April of 2017, an attack on the town of Khan Shaykhun in Syria employed a poisonous "nerve agent" (likely sarin) that resulted in the deaths of at least 92 civilians, many of them young children. The attack intentionally targeted civilian neighborhoods at the time children were getting ready for school, which is strong evidence that its purpose was terror, not warfare. Terrorist actions targeting children are not novel. Brought to the forefront of American consciousness by Timothy McVeigh's references to child fatalities as "collateral damage" during the Oklahoma City bombing in April 1995, the intentional targeting of children became a global reality with the attack upon a school in Beslan, Russia, in September 2004. The attack, which left 334 dead (including 186 children), presaged additional attacks specifically directed against children. School shootings have become an all too frequent occurrence in the United States with over 175 children dying from mass shootings on school grounds since 1999.

Paralleling the targeting of children is an apparent trend toward the use of "unconventional" weapons of terror. In 1984, members of the Rajneeshee cult employed *Salmonella typhi* in a wave of intentional poisonings that affected 751 persons, including 142 teenage patrons of a popular pizza parlor. In 1995, the Aum Shinrikyo cult killed 12 and sickened thousands by intentionally releasing sarin nerve agent in the Tokyo subway system. A disgruntled scientist allegedly deployed anthrax spores via the U.S. mail in October 2001, killing 5 and injuring 17 in an attack upon a nation already reeling in the wake of the 9/11 attacks. Conflicts in Afghanistan, Syria, and Iraq from 2012 to 2016 led to another spike in chemical attacks.

These developments remind us that terrorists can strike at any time, utilizing any number of unconventional weapons, including biologic and chemical agents. Children will not be spared in these attacks on civilians, and indeed schools and daycare sites may be the targets of these actions.

ETIOLOGY

Although terrorists may choose to use **weapons of opportunity,** agents that are readily available to some member of the terrorist group, the motives of terrorists often are obscure and difficult to predict. Prevention and response strategies should thus concentrate not on those agents most likely to be used but, rather, on those agents that, if used, would constitute the gravest potential threats to public health and security.

Biologic threat agents, including pathogens and toxins, have been divided by the Centers for Disease Control and Prevention (CDC) into three categories, with **category A** including diseases caused by those six agents posing the greatest threat: anthrax, plague (see Chapter 249.3), tularemia (see Chapter 252), smallpox, botulism (see Chapter 256), and the viral hemorrhagic fevers, including Ebola (see Chapter 317).

Terrorists could also procure and release a vast array of potentially harmful chemicals. The Chemical Threat Risk Assessment prepared by the U.S. Department of Homeland Security lists over 170 chemical compounds as potential threats in accidental or deliberate scenarios. Tank cars full of flammable industrial gases and liquids, corrosive industrial acids and bases, poisonous compounds such as cyanides and nitrites, pesticides, dioxins, and explosives traverse our railways and roads daily. Four classes of "military-grade" chemicals with a history of use in warfare or manufactured specifically for use as weapons include the organophosphate-based nerve agents, vesicants, cyanides (misleadingly referred to as "blood agents"), and certain pulmonary irritants or "choking agents."

EPIDEMIOLOGY AND PEDIATRIC-SPECIFIC CONCERNS

Large-scale attacks on civilian targets will likely involve pediatric victims. Children may be more susceptible than adults to the effects of certain biologic and chemical agents (see Chapter 759). A thinner and less-keratinized epidermis makes dermally active agents, such as mustard or trichothecene mycotoxins, a greater risk to children than to adults. A larger surface area per unit volume further increases the problem. A small relative blood volume makes children more susceptible to the volume losses associated with enteric infections such as cholera and to gastrointestinal intoxications such as might be seen with exposure to the staphylococcal enterotoxins. The high minute ventilation of children, compared with that of adults, increases the threat of agents delivered via the inhalational route. The fact that children live "closer to the ground" compounds this effect when heavier-than-air chemicals are involved.

*The views expressed herein are those of the authors and do not necessarily reflect the position of the University of Nebraska, the U.S. Department of Defense, Health and Human Services, and Veterans' Affairs, or their component entities.

An immature blood-brain barrier may heighten the risk of central nervous system toxicity from nerve agents. Developmental considerations make it less likely that a child would readily flee an area of danger, thereby increasing exposure to these various adverse effects. Moreover, children are more likely to be terrified at the sight of responders in personal protective ensembles.

Children appear to have a unique susceptibility to certain agents that might be used by terrorists. Although adults generally suffer only a brief, self-limited incapacitating illness after infection with Venezuelan equine encephalitis virus, young children are more likely to experience seizures, permanent neurologic sequelae, and death. In the case of smallpox, waning herd immunity may disproportionately affect children. Vaccine-induced immunity to smallpox diminishes significantly after 3-10 years. Although most adults are considered susceptible to smallpox given that routine civilian immunization ceased in the early 1970s, older adults may have some residual protection from death, if not from the development of disease. Today's children are among the first to grow up in a world without any individual or herd immunity to smallpox.

Children also may experience unique disease manifestations not seen in adults. Suppurative parotitis is a common characteristic finding among children with melioidosis but is not generally seen in adults with *Burkholderia pseudomallei* infection (see Chapter 251.2). Seizures, often the presenting symptom of cyanide or nerve agent poisoning, may be much more difficult to recognize clinically in children than in adults, more likely presenting as unresponsiveness or change in mental status than tonic-clonic episodes.

Pediatricians are likely to experience unique problems in managing childhood victims of a biologic or chemical attack. Many of the drugs useful in treating such casualties are unfamiliar to pediatricians or have relative contraindications in childhood. The fluoroquinolones and tetracyclines are commonly cited as agents of choice in the treatment and prophylaxis of anthrax, plague, tularemia, brucellosis, and Q fever. Both drug classes are often avoided in children, although the risk of morbidity and mortality from diseases induced by agents of bioterrorism far outweighs the minor risk associated with short-term use of these agents. Ciprofloxacin received, as its first licensed pediatric indication, approval from the FDA for use in the prophylaxis of anthrax after inhalational exposure during a terrorist attack; doxycycline and levofloxacin are licensed specifically in children for the same indication. Levofloxacin is also licensed for postexposure prophylaxis of children against plague, and moxifloxacin is considered an acceptable alternative to first-line therapies for the treatment of plague in those less than 18 years of age. Immunizations potentially useful in preventing biologic agent–induced diseases are often not approved for use in pediatric patients. The available anthrax vaccine is licensed only for those between 18 and 65 years. The plague vaccine, currently out of production and probably ineffective against inhalational exposures, was approved only for individuals ages 18-61 years. The live replicating smallpox vaccine (ACAM2000), a live vaccine employing vaccinia virus, can cause fetal demise when given to pregnant women. A nonreplicating smallpox (and mpox) vaccine (Jynneos) was introduced in 2019.

Many otherwise useful pharmaceutical agents are not available in pediatric dosing regimens. The military distributes nerve agent antidote kits consisting of prefilled autoinjectors designed for the rapid administration of atropine and pralidoxime. Many emergency departments and some ambulances stock these kits. The doses of agents contained in the nerve agent antidote kit are calculated for soldiers and thus are inappropriate for young children, and pediatric pralidoxime autoinjectors are not yet available. Atropine autoinjectors specifically formulated for children are approved by the FDA, although their availability is limited. Unfortunately, there is no pediatric combination autoinjector containing atropine and pralidoxime, the backbone of acute nerve agent treatment in adults. Moreover, children smaller than 7 kg (15 pounds) are too small for safe use of atropine autoinjectors, while obtaining venous access may be time-consuming and extremely difficult in a contaminated environment.

Although physical protective measures and devices (e.g., "gas masks") are likely to be of little utility in a civilian terrorism setting, such commercially available devices are not often available in pediatric sizes. The Israeli experience during the first Gulf War suggests that frightened parents may improperly use such masks on their children, resulting in inadvertent suffocation.

In the event of a large-scale terrorist attack, there may be an insufficient number of pediatric hospital beds. In any large disaster, excess bed capacity might potentially be provided at civilian and veterans hospitals under the auspices of the National Disaster Medical System. Although that system now specifically tracks pediatric beds, none of these would be found in the Veterans Administration system and few are likely to exist elsewhere. The situation is even more dire regarding burn unit beds, which may be needed in an attack with vesicants such as sulfur mustard.

CLINICAL MANIFESTATIONS

Should a terrorist attack occur, clinicians may be called on to make prompt diagnoses and render rapid lifesaving treatments before the results of confirmatory diagnostic tests are available. Although each potential agent of terrorism produces its own unique clinical manifestations, it is useful for the frontline clinician to consider their effects in terms of a limited number of distinct clinical syndromes. This approach helps clinicians make prompt, rational decisions regarding empirical therapy. Casualties resulting from a terrorist attack would either experience symptoms immediately upon exposure to an agent (or within the first several hours after exposure) or would see their symptoms develop slowly over a period of days to weeks. In the former case, the sinister nature of the event is often obvious and the etiology more likely to be conventional or chemical in nature.

Biologic agents differ from conventional, chemical (see Chapter 759), and nuclear (see Chapter 758) weapons in that they have inherent incubation periods. Consequently, patients are likely to present distant in time and place from the point of an unannounced and unnoticed exposure to a biologic agent. Whereas traditional first responders, such as firefighters and paramedics, may be at the forefront of a conventional or chemical terrorism response, the primary care physician or emergency room is likely to constitute the first line of defense against the effects of a biologic agent.

Casualties can thus be categorized as either immediate or delayed in presentation. Within each of these categories, patients can be further classified as having primarily respiratory, neuromuscular, or dermatologic manifestations (Table 763.1). A limited number of agents may cause each particular syndrome, permitting institution of empiric therapy targeted at a short list of potential etiologies. The viral hemorrhagic fevers might manifest as fever and a bleeding diathesis; these agents are considered separately in Chapter 317. In most cases, supportive care is the mainstay of hemorrhagic fever treatment, although two drugs (Inmazeb, Ebanga) have recently been licensed for the treatment of adults and children with Ebola.

Sudden-Onset Neuromuscular Syndrome: Nerve Agents

The very rapid onset of neuromuscular symptoms after an exposure should lead the clinician to consider nerve agent intoxication. The nerve agents (*tabun, sarin, soman, and VX)* are **organophosphate** analogs of common pesticides that act as potent inhibitors of the enzyme acetylcholinesterase. The so-called "Novichok" agents, used in deliberate attacks upon Russian targets in Salisbury, UK (2018) and Tomsk, Russia (2020), also belong to this agent class. The nerve agents are hazardous via ingestion, inhalation, or cutaneous absorption (see Chapter 94).

The inhibition of cholinesterase by these compounds results in the accumulation of acetylcholine at neural and neuromuscular junctions, causing excess stimulation. The resultant **cholinergic**

Table 763.1 Diseases Caused by Agents of Chemical and Biologic Terrorism, Classified by Syndrome

	NEUROMUSCULAR SYMPTOMS PROMINENT	RESPIRATORY SYMPTOMS PROMINENT	DERMATOLOGIC FINDINGS PROMINENT
Sudden-onset or intermediate-onset	Nerve agents	Chlorine Phosgene Cyanide	Mustard Lewisite
Delayed-onset	Botulism	Anthrax Plague Tularemia Ricin	Smallpox

syndrome involves central, nicotinic, and muscarinic effects. Central effects are both muscarinically and nicotinically mediated and include altered mental status progressing rapidly to lethargy and coma, as well as ataxia, convulsions, and central respiratory depression. Studies on pesticide exposure suggest that children may be more prone to central neurologic dysfunction with organophosphate toxicity than adults. The most lethal effects are respiratory, which result not only from central effects but also from direct paralysis of the diaphragm and other respiratory muscles (nicotinic effects), as well as bronchospasm and bronchorrhea (muscarinic effects). Nicotinic effects include muscle fasciculations and twitching, followed by weakness, which can progress to flaccid paralysis as muscles fatigue. Importantly, flaccid paralysis is not present initially, as in a patient with botulinum toxin poisoning. In botulinum toxin poisoning, neurotransmitter cannot be released from the presynaptic terminal, whereas in nerve agent poisoning, excess neurotransmitter accumulates because acetylcholinesterase, the enzyme that turns off the transmitter, is inhibited. Muscarinic effects include miosis (the clinical hallmark of a patient who has suffered a non–life-threatening nerve agent challenge), visual blurring, profuse lacrimation, and watery rhinorrhea. Bronchospasm and increased bronchial secretions lead to cough, wheezing, dyspnea, and cyanosis. Cardiovascular manifestations include bradycardia, hypotension, and atrioventricular block. Flushing, sweating, salivation, nausea, vomiting, diarrhea, abdominal cramps, and urinary incontinence are also seen. In the absence of prompt intervention, death can quickly result from a combination of central effects and respiratory muscle paralysis.

The classic neuromuscular syndrome of extremely acute symptoms most commonly results from an aerosol or vapor exposure, the most likely route in a terrorist attack. But nerve agents are liquids at standard temperature and pressure and do not cause immediate irritation to skin. Liquid nerve agent may thus pass through the skin and enter the systemic circulation, causing cholinergic crisis. This can be delayed by minutes to hours, depending upon dose and body site. In children, because the stratum corneum of the skin forms only gradually, skin transit time will be reduced. Miosis may be a late development. *If the clinician suspects that the child may have been exposed to nerve agent via the cutaneous route, they should immediately treat, even if miosis has not yet developed.*

Cyanide poisoning is a major differential diagnosis of nerve agent poisoning in an attack scenario. Cyanide poisons cytochrome a3 in the mitochondrial electron transport chain and can cause an almost immediate and rather similar syndrome of loss of consciousness, immediate rapid breathing, status epilepticus, and rapid progression to cardiac arrest. Important clinical differential points include miosis, which is usually absent in cyanide poisoning, and the usual lack of cyanosis (ironically) due to the tissues' inability to use oxygen from the blood, causing venous blood to retain oxygen and remain red. In an emergency, it may be necessary to treat for both nerve agent and cyanide poisoning until the cause is definitively identified.

Delayed-Onset Neuromuscular Syndrome: Botulism

The delayed onset (hours to days after exposure) of neuromuscular symptoms is characteristic of botulism. Botulism, an intoxication rather than an infection, occurs after exposure to one of eight related neurotoxins produced by certain strains of *Clostridium botulinum,* a strictly anaerobic, spore-forming, gram-positive bacillus commonly found in soil. Naturally occurring botulism (see Chapter 256) usually follows ingestion of preformed toxin (food poisoning) or results from intestinal toxin production (infantile botulism). An aerosol exposure to the toxin would likely result in a case of clinical botulism indistinguishable from that caused by natural exposures.

Following exposure to botulinum toxin, clinical manifestations typically begin with bulbar palsies, causing patients to complain of ptosis, photophobia, and blurred vision resulting from difficulty in accommodation. Symptoms can progress to include dysarthria, dysphonia, dysphagia, and finally, a descending symmetric paralysis. Sensation and sensorium are typically not affected. In the absence of intervention, death often results from respiratory muscle failure. The mechanism of action of botulinum toxin is, in many ways, the opposite of that of nerve agent intoxication. Seizures, loss of consciousness, and peripheral twitching and fasciculations, typical of nerve agent poisoning, are not seen in botulism.

Sudden-Onset Respiratory Syndrome: Chlorine, Phosgene, and Cyanide

The acute onset of respiratory symptoms shortly after exposure should prompt the clinician to consider a range of potential chemical agents. Of note, nerve agents, discussed previously, may affect respiration via massive bronchial hypersecretion, bronchospasm, and respiratory muscle paresis. However, the nerve agent casualty will likely have generalized muscle involvement and central nervous system manifestations. In contrast, the toxic inhalants chlorine and phosgene produce respiratory distress without neuromuscular involvement or other features of cholinergic crisis. Several other pulmonary toxicants may produce similar clinical toxidromes.

Chlorine is a dense, acrid, yellow-green gas that is heavier than air. After mild to moderate exposure, ocular and nasal irritation occurs, followed by cough, a choking sensation, bronchospasm, and substernal chest tightness. Pulmonary edema, mediated by hydrochloric acid and free oxygen radical generation, follows moderate to severe exposures within 30 minutes to several hours. Hypoxemia and hypovolemia secondary to noncardiogenic pulmonary edema are the factors responsible for death.

Phosgene, like chlorine, is a common industrial compound that was used as a weapon on the battlefields of World War I. Its odor has been described as similar to "new-mown hay." Like chlorine, phosgene exposure also is thought to result in the generation of hydrochloric acid, contributing particularly to upper airway, nasal, and conjunctival irritation. Acylation reactions caused by the effects of phosgene on the pulmonary alveolar-capillary membrane lead to pulmonary edema. Phosgene lung injury also may be mediated, in part, by an inflammatory reaction associated with leukotriene production. Patients with mild to moderate exposures to phosgene

may be asymptomatic, a fact that may cause victims to remain in a contaminated area. Noncardiogenic pulmonary edema or "dry land drowning" occurs 4-24 hours after exposure and is dose dependent, with heavier exposures causing earlier symptoms. Dyspnea may precede radiologic findings. In severe exposures, pulmonary edema may be so marked as to result in hypovolemia and hypotension. As in the case of chlorine, death results from hypoxemia and asphyxia.

Cyanide, by contrast, is a cellular poison capable of causing protean clinical manifestations, not a pulmonary toxicant. Initially, cyanide toxicity is most likely to manifest as tachypnea and hyperpnea, progressing rapidly to apnea in cases with significant exposure (see Chapter 94). The efficacy of cyanide as a chemical terrorism agent is limited by its volatility in open air and relatively low lethality compared with nerve agents. Released in a closed room, however, cyanide could have devastating effects, as evidenced by its use in the Nazi gas chambers during World War II. Cyanide inhibits cytochrome a3, interfering with normal mitochondrial oxidative metabolism and leading to cellular anoxia and lactic acidosis. In addition to respiratory distress, early findings among cyanide victims include tachycardia, flushing, dizziness, headache, diaphoresis, nausea, and vomiting. With greater exposure, seizures, coma, apnea, and cardiac arrest may follow within minutes. An elevated anion gap metabolic acidosis is typically present and decreased peripheral oxygen utilization leads to an elevated mixed venous oxygen saturation value.

Delayed-Onset Respiratory Syndrome: Anthrax, Plague, Tularemia, and Ricin

A delayed onset of respiratory symptoms (days after exposure) is characteristic of several infectious diseases and at least one toxin that might be adapted for sinister purposes by terrorists. Among the most threatening and problematic of these are anthrax, plague, tularemia, and ricin.

Anthrax is caused by infection with the gram-positive spore-forming rod *Bacillus anthracis*. Its ability to form a spore enables the anthrax bacillus to survive for long periods in the environment and enhances its potential as a weapon.

The vast majority of naturally occurring anthrax cases are cutaneous, acquired by close contact with the hides, wool, bone, and other by-products of infected ruminants (principally cattle, sheep, and goats). Cutaneous anthrax is amenable to therapy with a variety of antibiotics and is readily recognizable to experienced clinicians in endemic areas; consequently, it is rarely fatal. Although it is common in parts of Asia and sub-Saharan Africa, only two cases of cutaneous anthrax had occurred in the United States in the 9 years that preceded the attacks of 2001 (when 11 cutaneous cases were seen). Gastrointestinal anthrax has been described only once in the United States, in a drum circle participant whose drum heads were made from imported animal hides. In general, however, it occurs after the ingestion of contaminated meat. In the past, inhalational anthrax, or **woolsorters' disease,** was an occupational hazard of abattoir and textile workers. Now eliminated as a naturally occurring disease in the United States, it is this inhalational form of anthrax that poses the greatest terror threat. Following an inadvertent release in 1979 from a bioweapons facility at Sverdlovsk in the former Soviet Union, 66 of 77 (86%) known adult victims of inhalational anthrax died. In the 2001 attacks involving contaminated mail in the United States, 5 of 11 (46%) patients with inhalational anthrax died. Whether better intensive care modalities, changes in antibiotic therapy, or earlier recognition accounted for this improved mortality rate remains unknown.

Symptomatic *inhalational* anthrax typically begins 1-6 days after exposure, although incubation periods of up to several weeks have been reported. The disease begins as a flulike illness, characterized by fever, myalgia, headache, and cough. A brief intervening period of improvement sometimes follows, but rapid deterioration then ensues; high fever, dyspnea, cyanosis, and shock mark this second phase. Hemorrhagic meningitis occurs in up to 50% of cases. Chest radiographs obtained late in the course of illness may reveal a widened mediastinum or prominent mediastinal lymphadenopathy; pleural effusions also may be seen. Bacteremia is often so profound that Gram stains of peripheral blood may demonstrate the organism at this stage. Prompt treatment is imperative. Death occurs in as many as 95% of inhalational anthrax cases if such treatment is begun more than 48 hours after the onset of symptoms.

Whereas inhalational anthrax is a disease primarily of mediastinal lymphatic tissue, exposure to aerosolized plague bacilli typically leads to a primary pneumonia. Endemic **plague** is usually transmitted via the bites of fleas and is discussed in Chapter 249.3. The causative organism of all forms of human plague, *Yersinia pestis,* is a bipolar-staining, gram-negative facultative intracellular bacillus. An ability to survive within the macrophage aids its dissemination to distant sites following inoculation or inhalation. "Buboes," markedly swollen, exquisitely tender regional lymph nodes in the distribution of a bite, are the hallmark feature of bubonic plague. Fever and malaise are typically present, and septicemia often develops as bacteria gain access to the circulation. Petechiae, purpura, and overwhelming disseminated intravascular coagulopathy commonly occur, and 80% of bubonic plague victims ultimately have positive blood cultures. Plague is extremely lethal, as illustrated by the fact that the "Black Death" eliminated one-third of the population of Europe during the Middle Ages.

Intentional aerosol dissemination of *Y. pestis* would likely result in a preponderance of pneumonic plague cases. Pneumonic plague may also arise secondarily after seeding of the lungs of septicemic patients. Symptoms include fever, chills, malaise, headache, and cough. Chest radiographs may reveal a patchy consolidation, and the classic clinical finding is blood-streaked sputum. Disseminated intravascular coagulation and overwhelming sepsis typically develop as the disease progresses. Untreated pneumonic plague has a fatality rate approaching 100%.

Tularemia is a highly infectious disease caused by the gram-negative coccobacillus *Francisella tularensis.* Naturally occurring tularemia is discussed in Chapter 252. The high degree of infectivity of *F. tularensis* (<10 organisms are thought to be necessary to produce infection via inhalation), as well as its survivability in the environment, contributes to its inclusion on the CDC's list of Category A agents. Several clinical forms of endemic tularemia are known, but inhalational exposure resulting from a terrorist attack would likely lead to a plaguelike primary pneumonia or to typhoidal tularemia, manifesting as a variety of nonspecific symptoms, including fever, malaise, and abdominal pain.

Ricin is a protein toxin derived from the castor bean plant *(Ricinus communis)* that inhibits ribosomal protein synthesis. It is highly toxic in animal studies when inhaled and may result in the delayed onset of respiratory distress, pulmonary edema, and acute respiratory failure. If injected, it may cause a sepsis-like syndrome that may progress to multiorgan system failure; ingestion can lead to severe gastroenteritis. Ricin-containing letters were mailed to a U.S. Senate office building in 2004, to President Obama and New York City Mayor Bloomberg in 2013, and to President Trump in 2020, although no persons were sickened in any of the attacks.

Intermediate-Onset Dermatologic Syndrome: Mustard and Lewisite

The development of skin lesions within hours to days of exposure is characteristic of the chemical vesicants. These compounds, often referred to as **blistering agents**, are cellular poisons and include the alkylating agent mustard and the organic arsenical agent lewisite. Injury to rapidly reproducing cells begins within minutes of contact with these agents. Clinical effects typically become evident several hours after exposure to mustard, whereas patients exposed to lewisite feel immediate pain. Both mustard and lewisite affect the eyes and respiratory tract, and their inadvertent ingestion may produce significant gastrointestinal symptoms. Mustard exposure may lead, several days later, to bone marrow suppression. With

a large inhalational challenge, mustard may also cause an acute respiratory syndrome, particularly affecting the upper airway and presenting with laryngospasm and stridor.

Delayed-Onset Dermatologic Syndrome: Smallpox

The appearance of an exanthem days to weeks after exposure is likely to be a presenting feature of smallpox. Caused by infection with variola virus, a member of the *Orthopoxvirus* family, smallpox has an incubation period of 7-17 days. This would likely permit the wide dispersal of asymptomatic exposed persons, thus contributing to the spread of an outbreak. During the incubation period, the virus replicates in the upper respiratory tract. A primary viremia ensues, during which time seeding of the liver and spleen occurs. A secondary viremia then develops, the skin is seeded, and the classic exanthem of smallpox appears.

Symptoms of smallpox begin abruptly during the phase of secondary viremia and include fever, rigors, vomiting, headache, backache, and extreme malaise. Within 2-4 days, macules appear on the face and extremities and then progress in synchronous fashion to papules, pustules, and finally scabs. As the scabs separate, survivors often are left with disfiguring, depigmented scars. The synchronous nature of the rash and its centrifugal distribution distinguish smallpox from chickenpox, which has a centripetal distribution. Historically, smallpox had a 30% mortality rate, with death typically resulting from visceral organ involvement.

DIAGNOSIS

In some cases, the terrorist nature of a chemical or biologic attack may be obvious; for example, a chemical attack in which victims succumb in close temporal and geographic proximity to a dispersal device or when terrorists announce their attack. In other instances, the clinician may need to rely on epidemiologic clues to suspect an intentional release of chemical or biologic agents. The presence of large numbers of victims clustered in time and space should raise the index of suspicion, as should cases of unexpected death or unexpectedly severe disease. Diseases unusual in a given locale, in a given age group, or during a certain season likewise may warrant further investigation. Simultaneous outbreaks of a disease in noncontiguous areas should cause one to consider an intentional release (as in the 2001 mail-borne anthrax attacks), as should outbreaks of multiple diseases in the same area. Even a single case of a rare disorder such as anthrax or certain viral hemorrhagic fevers would be suspicious, and a single case of smallpox would almost certainly be the result of an intentional dissemination. Large numbers of dying animals might provide evidence of an unnatural aerosol release, as would evidence of disparate attack rates between those known to be indoors and outdoors at a given time.

In a mass casualty setting, diagnoses may be made largely on clinical grounds. The diagnosis of nerve agent intoxication is based primarily on clinical recognition and patient response to antidotal therapy. Several simple rapid detection devices developed for military use can detect the presence of nerve agents in the environment. Some of these are now commercially available and are stocked in certain emergency departments and public safety vehicles. Measurements of acetylcholinesterase in plasma or erythrocytes of nerve agent victims may be helpful in long-term prognostication, but the correlation between cholinesterase levels and clinical effects is often poor, and the test is rarely available on an emergency basis.

Botulism should be suspected clinically among patients presenting with a symmetric, descending, flaccid paralysis. Although the differential diagnosis of botulism includes other uncommon neurologic disorders, such as myasthenia gravis and the Guillain-Barré syndrome, the presence of multiple casualties with similar symptoms should aid in the determination of a botulism outbreak. Electromyography is useful in supporting the diagnosis.

Initially the diagnosis of cyanide poisoning also will likely be made on clinical grounds in the presence of the appropriate toxidrome. An unusually high anion gap metabolic acidosis with elevated serum lactate and an oxygen concentration greater than expected in mixed venous blood lend support to the clinical diagnosis. Elevated blood cyanide concentrations can confirm the clinical suspicion.

Of all the chemical and biological agents, the only ones for which immediate therapy without waiting for definitive diagnosis is potentially lifesaving and mandatory are nerve agents and cyanide poisoning. If these are suspected, they should be treated before waiting for further diagnostic certainty.

Anthrax should be suspected upon finding gram-positive bacilli in skin biopsy material (in the case of cutaneous disease), blood smears, pleural fluid, or spinal fluid. Chest radiographs demonstrating a widened mediastinum in the context of fever and constitutional signs and, in the absence of another obvious explanation (e.g., blunt trauma or postsurgical infection), should also lead one to consider the diagnosis. Confirmation can be obtained by blood culture.

A diagnosis of plague can be suspected on finding bipolar "safety-pin"–staining bacilli in Gram or Wayson stains of sputum or aspirated lymph node material; confirmation is obtained by culturing *Y. pestis* from blood, sputum, or lymph node aspirate. The organism grows on standard blood or MacConkey TRA agars, but it is often misidentified by automated systems. *F. tularensis,* the causative agent of tularemia, grows poorly on standard media; its growth is enhanced on media containing cysteine. Because of its extreme infectivity, however, many laboratories prefer to make a diagnosis via polymerase chain reaction or serologically using an enzyme-linked immunosorbent assay or serum agglutination assay.

Smallpox should be suspected on clinical grounds and can be confirmed by culture or electron microscopy of scabs or vesicular fluid, although the manipulation of clinical material from suspected smallpox victims should be attempted only at public health laboratories able to employ maximum biocontainment (Biosafety Level 4) precautions. Similar caution should be exercised with specimens from patients with various viral hemorrhagic fevers.

PREVENTION

Preventive measures can be considered in both a preexposure and a postexposure context. **Preexposure protection** against a chemical or biologic attack may consist of physical, chemical, or immunologic measures. **Physical protection** against primary attack often involves gas masks and protective suits; such equipment is used by the military and by certain hazardous materials response teams, but it is unlikely to be available to civilians at the precise moment that a release occurs. Medical personnel need to understand the principles of physical protection as they apply to infection control and the spread of contamination.

Pneumonic plague is spread through respiratory droplets. Droplet precautions, including the use of simple surgical masks, are thus warranted for providers caring for patients with plague. Smallpox is transmitted by droplet nuclei. Airborne precautions, including (ideally) a high-efficiency particulate air filter mask, are thus warranted with smallpox victims. Patients with certain viral hemorrhagic fevers, such as those caused by filoviruses (Ebola, Marburg) and arenaviruses, should be managed using a combination of droplet and contact precautions, ideally in a specialized biocontainment unit. Most other biologic agent victims can be safely cared for with the use of standard precautions. In the case of chemical agents, residual mustard or nerve agent on the skin or clothing of victims might potentially pose a hazard to medical personnel. For such victims, whenever possible, clothing should be removed, and the patients decontaminated using copious amounts of water before extensive medical care is rendered. Most other chemical agents are volatile enough that spread of an agent among patients or from patient to caregiver is unlikely.

Preexposure chemical prophylaxis might be used on the basis of credible intelligence reports. Should officials deem that the threatened release of a specific biologic agent appears imminent, antibiotics might be distributed to a population before exposure. Opportunities to employ such a strategy are likely to be limited, although federal and state officials are examining various mechanisms for such employment. In military settings, pyridostigmine is FDA-approved as pretreatment against expected nerve agent attack. It is not approved for use in children, and it is not likely to be recommended in civilian settings.

Although licensed vaccines **(preexposure immunologic measures)** against anthrax and smallpox have been developed, widespread use of either vaccine is likely to be problematic, especially in children. The anthrax vaccine is licensed only for those persons age 18 years and older, is given as a five-dose series over 18 months, and requires annual booster doses. These considerations make civilian employment of the current anthrax vaccine on a large scale unlikely, although recombinant anthrax vaccines requiring fewer doses are in development.

Significant obstacles to the widespread employment of smallpox vaccine also exist, although public health officials have contemplated the resumption of a smallpox vaccination campaign. Whereas in the past, the live replicating smallpox vaccine (prepared from vaccinia virus, an *Orthopoxvirus* related to variola) was used safely and successfully in young infants, it has a relatively high rate of serious complications in certain patients. *Fetal vaccinia* and demise can occur when pregnant women are vaccinated. *Vaccinia gangrenosa*, an often fatal complication, can occur when immunocompromised persons are vaccinated. *Eczema vaccinatum* occurs in those with preexisting dermatoses (atopic dermatitis). Severe vaccine-related encephalitis was well known during the era of widespread vaccination; because it occurs only in primary vaccines, it would disproportionately affect pediatric patients. Autoinoculation can occur when the virus present at the site of vaccination is manually transferred to other areas of skin or to the eye. Young children would presumably be at greater risk for such inadvertent transmission. Myocarditis has been reported following vaccinations of military recruits. A new nonreplicating vaccine may alleviate some of these concerns.

To manage complications associated with use of the replicating vaccine, vaccinia immune globulin should be available when one is undertaking a vaccination campaign. Vaccinia immune globulin (6000 U/kg intravenously) may be given to vaccine recipients who experience severe complications or to significantly immunocompromised individuals exposed to smallpox and in whom vaccination would be unsafe. In 2018, tecovirimat was approved by the FDA for the treatment of persons (including children) experiencing severe complications from vaccine. Vaccine, as well as vaccinia immune globulin and tecovirimat, can be obtained as needed upon consultation with officials at the CDC. In addition to a potential role in preexposure prophylaxis, vaccination may be effective in postexposure prophylaxis if given within the first 4 days after exposure.

Anthrax vaccine might similarly be employed in a postexposure setting. Some authorities recommend three doses of this vaccine as an adjunct to postexposure chemoprophylaxis after documented exposure to aerosolized anthrax spores. Nonetheless, postexposure administration of oral antibiotics constitutes the mainstay of management for asymptomatic victims believed to have been exposed to anthrax as well as to other bacterial agents such as plague and tularemia. Table 763.2 lists appropriate prophylactic regimens for various biologic exposures.

TREATMENT

Although Tables 763.2, 763.3, and 763.4 provide recommended therapies for overt diseases caused by various chemical and biologic agents, it is likely that the clinician attending to victims will need to make therapeutic decisions before the results of confirmatory diagnostic tests are available and in situations in which the diagnosis is not known with certainty. In particular, decontamination by hospital personnel in appropriate personal protective equipment is required for patients exposed to chemical agents who have not been adequately decontaminated in the prehospital setting (see Table 763.4). In such cases, it is useful to note that many diseases and symptoms caused by chemical and biologic agents will resolve with supportive care. Most cases of chlorine or phosgene exposure can be successfully managed by providing meticulous attention to oxygenation and fluid balance. Mustard victims may require intensive multisystem support, but no specific antidote or therapy is available. Many viral diseases, including most viral hemorrhagic fevers, as well as equine encephalitides, are also managed supportively.

In addition to ensuring adequate oxygenation, ventilation, and hydration, the clinician may need to provide specific empiric therapies on an urgent basis. Patients suffering from the sudden onset of severe neuromuscular symptoms may have nerve agent intoxication and should be given atropine (0.05-0.1 mg/kg) promptly for its antimuscarinic effects. Although atropine relieves bronchospasm and bradycardia, reduces bronchial secretions, and ameliorates the gastrointestinal effects of nausea, vomiting, and diarrhea, it does not improve skeletal muscle paralysis. 2-Pralidoxime chloride (*2-PAM*) cleaves the organophosphate moiety from cholinesterase and regenerates intact enzyme if "aging" has not occurred. The effect is most prominent at the neuromuscular junction and leads to improved muscle strength. Its prompt use (at a dose of 25-50 mg/kg) as an adjunct to atropine is recommended in all serious cases.

Ideally, both atropine and pralidoxime should be administered intravenously (IV) in severe cases, although the intraosseous route is acceptable. In the field, as time is of the essence in treating nerve agent poisoning, first responders are trained to administer atropine IM via autoinjector. Some experts also recommend that atropine be given IM in the presence of hypoxia to avoid arrhythmias associated with IV administration. Many emergency management services stock military-style autoinjector kits consisting of atropine and 2-PAM for IM injection. Pediatric atropine autoinjectors containing 0.5 or 1 mg of atropine are licensed and held in the Strategic National Stockpile, although kits intended for adults (with 2 mg of atropine and 600 mg of pralidoxime) may be used in children >2-3 years of age (Table 763.5). Autoinjectors cannot easily be used in the smallest infants.

Animal studies support the routine prophylactic administration of anticonvulsant doses of benzodiazepines, even in the absence of observable convulsive activity. Although diazepam has long been employed for this purpose, midazolam was recently granted FDA approval, and animal studies have shown it to have superior efficacy in treating acute nerve agent poisoning. Military and civilian stocks of diazepam autoinjectors are being replaced by midazolam autoinjectors.

Delayed neuromuscular symptoms in the setting of terrorism might be due to botulism. Supportive care, with meticulous attention to ventilatory support, is the mainstay of botulism treatment. Such support may be necessary for several months, making the management of a large-scale botulism outbreak especially problematic in terms of medical resources. A licensed heptavalent antitoxin (types A-G) is available through the CDC (1-800-232-4636). Administration of this antitoxin is unlikely to reverse disease in symptomatic patients but may prevent further progression. In addition, a pentavalent product (containing antibody against toxin types A-E but licensed only for treatment of type A or B intoxication), Botulism Immune Globulin Intravenous (Human; BabyBIG), is available through the California Department of Health Services (1-510-231-7600) specifically for the treatment of infant botulism.

The *rapid onset of respiratory symptoms* may signal an exposure to chlorine, phosgene, cyanide, or a number of other toxic industrial chemicals. Although the mainstay of therapy in virtually all of these exposures consists of removal to fresh air and intensive supportive care, cyanide intoxication often requires the administration of specific antidotes.

Table 763.2 CDC Category A Agents of Bioterrorism

DISEASE	CLINICAL FINDINGS	INCUBATION PERIOD (DAYS)	ISOLATION PRECAUTIONS	INITIAL TREATMENT	PROPHYLAXIS
Anthrax (inhalational) Patients who are clinically stable after 14 days can be switched to a single oral agent (as described in the prophylaxis section of this table) to complete a 60-day course	Febrile prodrome with rapid progression to mediastinal lymphadenitis and mediastinitis, sepsis, shock, and meningitis	1-5	Standard	See Table 763.3.	**Ciprofloxacin 30 mg/kg/day PO divided q12h*** (max 500 mg/dose) *or* **doxycycline 4.4 mg/kg/day PO divided q12h** (max 100 mg/dose) *or* clindamycin 30 mg/kg/day PO divided q8h (max 900 mg/dose) *or* levofloxacin 16 mg/kg/day PO divided q12h (max 250 mg/dose) *or* **amoxicillin 75 mg/kg/day PO divided q8h†** (max 1 g/dose) or penicillin VK 50-75 mg/kg/day divided q6-8h
Plague (pneumonic)	Febrile prodrome with rapid progression to fulminant pneumonia, hemoptysis, sepsis, disseminated intravascular coagulation	2-3	Droplet (for first 3 days of therapy)	Gentamicin** 1.25- 2.5 mg/kg IV q8h *or* doxycycline 2.2 mg/kg IV q12h *or* ciprofloxacin 15 mg/kg IV q12h *or* levofloxacin 8 mg/kg IV/PO q12h	Doxycycline 2.2 mg/kg PO q12h *or* ciprofloxacin 20 mg/kg PO q12h *or* levofloxacin 8 mg/kg PO q12h
Tularemia	Pneumonic: abrupt onset of fever with fulminant pneumonia Typhoidal: fever, malaise, abdominal pain	2-10	Standard	Options same as for plague‡, gentamicin preferred	Same as for plague‡
Smallpox	Febrile prodrome with synchronous, centrifugal, vesiculopustular exanthema	7-17	Airborne (+ contact)	Tecovirimat *Oral dosage by body weight:* 13 kg to <25 kg: 200 mg q12h 25 kg to <40 kg: 400 mg q12h 40 kg to <120 kg: 600 mg q12h ≥120 kg: 600 mg q8h *Intravenous infusion dosage by body weight:* 3 kg to <35 kg: 6 mg/kg q12h by IV infusion over 6 hr 35 kg to <120 kg: 200 mg q12h by IV infusion over 6 hr ≥120 kg: 300 mg q12h by IV infusion over 6 hr	Vaccination may be effective if given within the first several days after exposure
Botulism	Afebrile descending symmetric flaccid paralysis with cranial nerve palsies	1-5	Standard	Supportive care; antitoxin (see text) may halt the progression of symptoms but is unlikely to reverse them	No licensed preexposure prophylaxis is available; postexposure administration of antitoxin may prevent the development of symptoms
Viral hemorrhagic fevers	Febrile prodrome with rapid progression to shock, purpura, and bleeding diatheses	4-21	Contact (consider airborne in cases of massive hemorrhage)	Supportive care; ribavirin may be beneficial in treating Lassa fever, and perhaps other arenaviral hemorrhagic fevers	Ribavirin has been shown to be efficacious in the postexposure prophylaxis of Lassa fever

*Preferred drugs are shown in **bold**.
**Some experts say 4.5-7.5 mg/kg/day.
†Penicillin and amoxicillin should only be used when the strain of *Bacillus anthracis* is known to be susceptible.
‡Levofloxacin (as well as moxifloxacin) is licensed by the U.S. Food and Drug Administration for the prophylaxis and treatment of plague in the setting of a bioterror attack, but not tularemia.
PO, By mouth; IV, intravenously.

Table 763.3 Treatment of Inhalational Anthrax in Children

WHEN MENINGITIS PRESENT OR HAS NOT RULED OUT*	WHEN MENINGITIS CAN BE RULED OUT*
1. A bactericidal fluoroquinolone: **Ciprofloxacin 30 mg/kg/day IV divided q8h**† (max 400 mg/dose) *or* Levofloxacin 24 mg/kg/day IV divided q12h (max 250 mg/dose) *or* Moxifloxacin 12 mg/kg/day IV divided q12h (max 200 mg/dose; for children 3 mo to 2 yr); 10 mg/kg/day IV divided q12h (for children 2-5 yr); 8 mg/kg/day IV divided q12h (for children 6-11 yr); 400 mg IV qd (for children >12 yr and >45 kg)	1. A bactericidal antimicrobial: **Ciprofloxacin 30 mg/kg/day IV divided q8h** (max 400 mg/dose) *or* Levofloxacin 20 mg/kg/day IV divided q12h (max 250 mg/dose) *or* Imipenem 100 mg/kg/day IV divided q6h (max 1 g/dose) *or* Vancomycin 60 mg/kg/day IV divided q8h *or* **Penicillin G 400,000 U/kg/day IV divided q4h** (max 4 MU/dose) [if PCN sensitive] *or* Ampicillin 200 mg/kg/day IV divided q6h (max 3 g/dose)
2. A second bactericidal antimicrobial: **Meropenem 120 mg/kg/day IV divided q8h** (max 2 g/dose) *or* Imipenem 100 mg/kg/day IV divided q6h (max 1 g/dose) *or* Doripenem 120 mg/kg/day IV divided q8h (max 1 g/dose) *or* Vancomycin 60 mg/kg/day IV divided q8h *or* **Penicillin G** 400,000 U/kg/day IV divided q4h**‡ (max 4 MU/dose) [if PCN sensitive] *or* Ampicillin 400 mg/kg/day IV divided q6h (max 3 g/dose)	
3. A protein synthesis inhibitor: **Linezolid 30 mg/kg/day IV divided q8h** (for children <12 yr); 30 mg/kg/day IV divided q12h (for children >12 yr; max 600 mg/dose) *or* Clindamycin 40 mg/kg/day IV divided q8h (max 900 mg/dose) *or* Rifampin 20/mg/kg/day IV divided q12h (max 300 mg/dose) *or* Chloramphenicol 100 mg/kg/day IV divided q6h	2. A protein synthesis inhibitor: **Clindamycin 40 mg/kg/day IV divided q8h (max 900 mg/dose)** *or* Linezolid 30 mg/kg/day IV divided q8h (for children <12 yr); 30 mg/kg/day IV divided q12h (for children >12 yr; max 600 mg/dose) *or* Rifampin 20/mg/kg/day IV divided q12h (max 300 mg/dose) *or* Doxycycline 4.4 mg/kg/day IV loading dose (for children <45 kg; max 200 mg), followed by 4.4 mg/kg/day IV divided q12h; 200 mg IV loading dose, followed by 100 mg IV q12h (for children >45 kg)

*Meningitis occurs in approximately 50% of patients with inhalational anthrax.
**Some experts provide a range of 400,000–600,000 U/kg/d.
†Preferred drugs are shown in **bold**.
‡Penicillin and amoxicillin should only be used when the strain of *Bacillus anthracis* is known to be susceptible.
IV, Intravenous; qd, every day; PCN, penicillin.
Data from Bradley JS, Peacock G, Krug SE, et al. Pediatric anthrax clinical management. *Pediatrics*. 2014;133:e1411–e1436. Appendices 3 & 4.

The classic **cyanide antidote** utilizes a nitrite along with sodium thiosulfate and is given in two stages. The methemoglobin-forming agent (e.g., sodium nitrite) is administered first, because methemoglobin has a high affinity for cyanide and causes it to dissociate from cytochrome oxidase. Nitrite dosing in children should be based on body weight to avoid excessive methemoglobin formation and nitrite-induced hypotension. For the same reasons, nitrites should be infused slowly over 5-10 minutes. A sulfur donor, such as sodium thiosulfate, is given next. This compound is used as a substrate by the hepatic enzyme rhodanese, which converts cyanide to thiocyanate, a less toxic compound excreted in the urine. Thiosulfate treatment itself is efficacious and relatively benign and may be used alone for mild to moderate cases. Sodium nitrite and sodium thiosulfate are packaged together in standard antidote kits, along with amyl nitrite, a sodium nitrite substitute that can be inhaled in prehospital settings in which IV access is not available.

Many first responder agencies in the United States have replaced the traditional two-part cyanide antidote kit with hydroxocobalamin, which exchanges its hydroxy group for cyanide, forming harmless cyanocobalamin (vitamin B_{12}) that is subsequently excreted by the kidneys. Hydroxocobalamin use is not complicated by the potential for nitrite-induced hypotension or methemoglobinemia, and it has low toxicity. The recommended dose is 5 g in adults or 70 mg/kg in children, administered IV over 15 minutes. A second dose (5 g in adults; 70 mg/kg in children) may be repeated in severely affected patients. Side effects include modest hypertension and reddening of skin, mucous membranes, and urine that may last several days. Although no human controlled trials are currently available to compare hydroxocobalamin with nitrite/thiosulfate-based therapies, many authorities believe that hydroxocobalamin's efficacy and safety profile favor it as the cyanide antidote of choice, especially for children in the mass casualty context. To use hydroxocobalamin, however, the solution must be mixed immediately before use, in the field if need be, so first responders need to be properly trained to employ it.

Animal research suggests a modest benefit of steroid therapy in mitigating lung injury after chlorine inhalation; thus steroids may be considered for patients with chlorine exposure, especially as an adjunct to bronchodilators in those with bronchospasm and/or a history of asthma. Symptomatic relief has also been reported following chlorine exposure with nebulized 3.75% sodium bicarbonate therapy, though the impact of this regimen on pulmonary damage is unknown. Animal models have also suggested a benefit from antiinflammatory agents, including ibuprofen and *N*-acetylcysteine, which appear to ameliorate phosgene-induced pulmonary edema, as well as the utilization of low tidal volume ventilation (protective ventilation), although the results of such interventions have not yet been reported in clinical trials.

In cases in which the delayed onset of respiratory symptoms may be the result of a terrorist attack, consideration should be given to the empirical administration of an antibiotic effective against anthrax, plague, and tularemia. Ciprofloxacin (10-15 mg/kg IV q12 hours), levofloxacin (8 mg/kg IV q12 hours), or doxycycline (2.2 mg/kg IV q12 hours) is a reasonable choice. Although naturally occurring strains of *B. anthracis* usually are quite sensitive to penicillin G, these agents are chosen because penicillin-resistant strains of *B. anthracis* exist. Moreover, ciprofloxacin and doxycycline are effective against almost all known strains of *Y. pestis* and *F. tularensis*. Concerns about inducible β-lactamases in *B. anthracis* have led experts to recommend one to two additional antibiotics in patients with inhalational anthrax. Rifampin, vancomycin, penicillin or ampicillin, clindamycin, and imipenem are reasonable choices based on in vitro sensitivity data. Because *B. anthracis* relies on the production of two protein toxins, edema toxin and lethal toxin, for its virulence, drugs that act at the ribosome to disrupt protein synthesis (e.g., clindamycin, the macrolides) provide a theoretical advantage. Frequent meningeal involvement among inhalational anthrax victims makes agents with superior central nervous system penetration desirable. The treatment of anthrax is detailed in Table 763.3.

Table 763.4 Critical Chemical Agents of Terrorism

AGENT	TOXICITY	CLINICAL FINDINGS	ONSET	DECONTAMINATION*	MANAGEMENT
NERVE AGENTS					
Tabun, sarin, soman, VX	Anticholinesterase: muscarinic, nicotinic, central nervous system effects	Vapor: miosis, rhinorrhea, dyspnea Liquid: diaphoresis, vomiting Both: coma, paralysis, seizures, apnea	Seconds: vapor Minutes to hours: liquid	Vapor: fresh air, remove clothes, wash hair Liquid: remove clothes, wash skin, hair with copious soap and water, ocular irrigation	ABCs. Atropine: 0.05-0.1 mg/kg IV†, IM‡ (min: 0.1 mg, max: 5 mg), repeat q2-5 min prn for marked secretions, bronchospasm AND Pralidoxime: 25-50 mg/kg IV, IM§ (max: 1 g IV; 2 g IM), may repeat within 30-60 min prn, then again q1h for one or two doses prn for persistent weakness, high atropine requirement AND Diazepam: 0.3 mg/kg (max: 10 mg) IV *or* Lorazepam: 0.1 mg/kg IV, IM (max: 4 mg) *or* Midazolam: 0.2 mg/kg (max: 10 mg) IM prn for seizures or severe exposure
VESICANTS					
Mustard	Alkylation	Skin: erythema, vesicles Eye: inflammation Respiratory tract: inflammation	Hours	Skin: soap and water Eyes: water (effective only if done within minutes of exposure)	Symptomatic care
Lewisite	Arsenical		Immediate pain	Skin: soap and water Eyes: water (effective only if done within minutes of exposure)	Possibly British antilewisite (BAL) 3 mg/kg IM q4-6h for systemic effects of lewisite in severe cases
PULMONARY AGENTS					
Chlorine, phosgene	Liberate hydrochloric acid, alkylation	Eye, nose, and throat irritation (especially chlorine) Respiratory: bronchospasm, pulmonary edema (especially phosgene)	Minutes: eye, nose, and throat irritation, bronchospasm Hours: pulmonary edema	Fresh air Skin: water	Symptomatic care (see text)
CYANIDE					
	Cytochrome oxidase	Tachypnea, coma, seizures, apnea	Seconds	Fresh air	ABCs, 100% oxygen
	Inhibition: cellular anoxia, lactic acidosis			Skin: soap and water	Na bicarbonate prn metabolic acidosis; hydroxocobalamin 70 mg/kg IV (max: 5 g) *or* nitrite/thiosulfate, given as follows (see text): *Na nitrite (3%): dose (mL/kg)* (max: 10 mL) — *Estimated hemoglobin concentration (g/dL)* 0.27 — 10 0.33 — 12 (estimated for average child) 0.39 — 14 Followed by Na thiosulfate (25%): 1.65 mL/kg (max: 50 mL)

*Decontamination, especially for patients with significant nerve agent or vesicant exposure, should be performed by healthcare providers garbed in adequate personal protective equipment. For emergency department staff, this equipment consists of a nonencapsulated, chemically resistant body suit, boots, and gloves with a full-face air-purifier mask/hood.
†Intraosseous route is likely equivalent to intravenous.
‡Atropine might have some benefit via endotracheal tube or inhalation, as might aerosolized ipratropium. See also Table 741.5.
§Pralidoxime is reconstituted to 50 mg/mL (1 g in 20 mL water) for IV administration, and the total dose infused over 30 min, or may be given by continuous infusion (loading dose 25 mg/kg over 30 min, and then 10 mg/kg/hr). For IM use, it might be diluted to a concentration of 300 mg/mL (1 g added to 3 mL water—by analogy to the U.S. Army's Mark 1 autoinjector concentration) to effect a reasonable volume for injection. See also Table 741.5.
ABCs, Airway, breathing, and circulatory support; IM, intramuscularly; IV, intravenously; max, maximum; min, minimum; prn, as needed.
Adapted from Henretig FH, Cieslak TJ, Eitzen EM. Biological and chemical terrorism. *J Pediatr.* 2002;141:311–326.

Table 763.5 Pediatric Autoinjector Recommendations for Mass Casualties or Prehospital Care*

ATROPINE AUTOINJECTOR THERAPY		
APPROXIMATE AGE	**APPROXIMATE WEIGHT (KG)**	**AUTOINJECTOR SIZE (MG)**
<6 mo	<7.5	0.25
6 mo to 4 years	7.5-18	0.5
5-10 years	18-30	1.0
>10 years	>30	2.0

PRALIDOXIME AUTOINJECTOR THERAPY			
APPROXIMATE AGE (YEARS)	**APPROXIMATE WEIGHT (KG)**	**NUMBER OF AUTOINJECTORS**	**PRALIDOXIME DOSE (MG/KG)**
3-7	13-25	1	24-46
8-14	26-50	2	24-46
>14	>50	3	<35

*Consider adult pralidoxime autoinjector use for severely affected mass casualties when intravenous (IV) access or more precise mg/kg intramuscular (IM) dosing is logistically impractical. The initial dose using atropine autoinjectors is one autoinjector of each recommended size. The initial dose using pralidoxime autoinjectors is the recommended number of (adult-intended, 600 mg) autoinjectors. These latter may also be injected into an empty sterile vile; the contents redrawn through a filter needle into a small syringe may then provide a ready source of concentrated (300 mg/mL) pralidoxime solution for IM injection to infants. Autoinjectors may become available that provide adult doses of both atropine and pralidoxime in one injector; these could be used in children ≥3 years in lieu of two individual injectors and dosed as noted above for pralidoxime alone.

Raxibacumab, a monoclonal antibody that inhibits anthrax antigen binding to cell receptors, thus preventing toxins from entering cells, is approved for the treatment of inhalation anthrax in combination with antibiotics, as is obiltoxaximab, which neutralizes anthrax toxins. The adult dose of raxibacumab is 40 mg/kg given IV over 2 hours and 15 minutes. The dose for children is weight based: ≤15 kg, 80 mg/kg; >15-50 kg, 60 mg/kg; >50 kg, 40 mg/kg. Premedication with diphenhydramine IV or by mouth (PO) is recommended 1 hour before the infusion.

In patients with an established diagnosis of tularemia, gentamicin (5 mg/kg IV/IM divided 2 or 3 times/day) is the preferred choice for therapy due to the limited availability of streptomycin (15 mg/kg IM q12 hours). Bioterrorism-related plague should be treated with two distinct antibiotic classes until sensitivity patterns are known; gentamicin, streptomycin, ciprofloxacin, and levofloxacin are all approved agents for treatment of pneumonic plague in children (see Table 763.2). To be effective, therapy for pneumonic plague must be initiated within 24 hours of the onset of symptoms. There is little clinical experience with ricin-induced pulmonary injury. The mainstay of therapy is expected to be supportive care.

The management of **vesicant-induced injury** is similar to that for burn victims and is largely symptomatic (see Chapter 89). The major difference between thermal burns and vesicant burns is that vesicant casualties do not need the large volumes of fluid required by thermal burn victims, as their epidermis remains intact. These patients are at risk of overhydration if treated using thermal burn protocols. Mustard victims will benefit from the application of soothing skin lotions such as calamine and the administration of analgesics. Early intubation of severely exposed patients is warranted to guard against edematous airway compromise. Oxygen and mechanical ventilation may be needed, and meticulous attention to hydration is of paramount importance. Ongoing research suggests a role for oral *N*-acetylcysteine in mitigating chronic pulmonary effects due to mustard injury. Lewisite victims can be managed in much the same manner as mustard victims. Dimercaprol (British antilewisite) in peanut oil, given IM, may help ameliorate the systemic effects of lewisite, although few hospitals or pharmacies are likely to have this drug on hand.

The management of symptomatic smallpox victims also is largely supportive, with attention to pain control, hydration status, and respiratory sufficiency of primary importance. The parenteral antiviral compound cidofovir, licensed for the treatment of cytomegalovirus retinitis in HIV-infected patients, has in vitro efficacy against variola and other orthopoxviruses. Its utility in treating smallpox victims is untested. Moreover, in the face of a large outbreak of disease, wide parenteral use of this drug would be problematic. Tecovirimat demonstrates excellent in vitro activity against orthopoxviruses, but its utility in treating patients with smallpox is likewise untested.

In all chemical casualties, but especially if a liquid agent such as VX or mustard is suspected, decontamination is crucial and should be considered a primary medical intervention. Although this has been part of casualty doctrine in the civilian and military environments for decades, a 2016 study showed that disrobing eliminated 90% of contamination in normal volunteers; following this with showering using water or soap and water eliminated 99% of contamination. This has huge implications for the hospital management of possibly contaminated casualties, including children, and hospitals must plan to execute the decontamination mission at all levels.

For those faced with an acute chemical emergency, especially a mass casualty situation, a useful resource is the Chemical Hazard Emergency Medical Management website (https://chemm.hhs.gov), maintained by the Assistant Secretary for Preparedness and Response within the U.S. Department of Health and Human Services. Among its features is a decision support tool, CHEMM-IST, which aids in identification of the chemical a patient was exposed to.

Chapter 764

Mass Psychogenic Illness

Jonathan W. Mink

Mass psychogenic illness refers to the rapid spread of illness signs and symptoms affecting members of a cohesive group, originating from a nervous system disturbance involving excitation, loss, or alteration of function, whereby physical complaints that are exhibited unconsciously have no corresponding organic etiology. Mass psychogenic illness shares features in common with **conversion disorder (functional neurologic system disorder)** (see Chapter 35) in that the symptoms are not consciously produced and are typically sensorimotor in nature. The physical symptoms are associated with significant distress and impairment; they commonly interfere with function at school or home and affect peer relationships. Some experts have argued that "functional" is a better used term than "psychogenic" because it does not imply etiology and does not reinforce dualist thinking about the mind being separate from the brain.

Much less is known about the biologic underpinnings and clinical features of mass psychogenic illness than is known about conversion disorder and other somatic symptom disorders. However, there are some important features in common with conversion disorder. These include sudden abrupt onset, inconsistency with known anatomy and physiology, atypical features, and inconsistency of symptoms over time. Specific features of mass psychogenic illness are the occurrence of these symptoms in a cohesive group; the presence of increased anxiety; spread of symptoms via sight, sound, or oral communication (including social media); and a high female:male ratio.

CLINICAL FEATURES AND DIAGNOSIS

There are many examples of mass psychogenic illness throughout history. The best known is perhaps that of the Salem "witches." Most widely reported examples of mass psychogenic illness are in adults, but there are several reports in children as well. In 2004, 10 teenage females from a school in rural North Carolina developed paroxysmal episodes resembling epilepsy or syncope. These females were from a cohesive social group (school-age students in a small school) and had similar symptoms. The symptoms were shown not to be consistent with either syncope or epilepsy, and they eventually resolved after a two-week holiday break from school. Another episode in Le Roy, New York, was an outbreak of a "tic-like" illness among high school students. The symptoms were atypical for tics because they were not preceded by a premonitory urge and could not be suppressed with effort. In addition, the symptoms were remarkably similar across the affected patients. Symptoms resolved over time. In the Le Roy example, there was likely an exacerbating role of both social media and mass media, which amplified the cohesiveness of the group. There has been a surge of cases of "tic-like" symptoms in adolescents during the COVID-19 pandemic. It has been suggested that social media, especially videos presented on the TikTok platform, has played an important role in the spread of these symptoms.

In a study of 280 environmental chemical incidents in the United Kingdom between 2007 and 2008, 7% were classified as mass psychogenic illness according to five diagnostic criteria: (1) presence of somatic (bodily) symptoms, (2) preexisting social connection between two or more of the affected people, (3) epidemic spread of symptoms, (4) attribution of symptoms by affected individuals (or by their parents or caregivers) to a threatening external agent of a physical (usually chemical, biologic, or radiologic) or spiritual nature, and (5) symptoms and signs that are not compatible with the environmental exposure specified by the affected individuals nor with any other environmental exposure that could reasonably be expected to have been present at the time of (or shortly before) the onset of symptoms.

One study has examined experimentally induced mass psychogenic illness. In a randomized controlled experiment, participants were assigned to one of three groups to study the effects of a simulated biologic threat and elements of social contagion. The three groups were (1) no-intervention control group, (2) psychogenic illness induction group, and (3) psychogenic illness induction plus media group. Groups 2 and 3 were told that the purpose of the study was to test the side effects of a carrier compound for an antiinfluenza medication. They were told that the compound did not produce serious side effects but was being evaluated with regard to mild side effects. In groups 2 and 3, professional actors were placed among the participants to feign illness during the study with symptoms of nausea, dizziness, and headache. Group 3 was also shown a documentary about the 1918 flu pandemic. The video contained interviews with survivors and vivid images of death and illness. The two psychogenic induction groups had 11 times more symptoms than did the control group. If a subject had a lifetime history of a traumatic event or depression, he or she was more likely to have symptoms. The documentary viewing was not associated with a higher rate of symptoms. This study confirmed the role of **"social contagion"** in mass psychogenic illness and provided a model for future studies of factors leading to such contagion.

TREATMENT STRATEGIES

Mass psychogenic illness is usually self-limited, but treatment requires careful reassurance and communication between physician and patient. Explanation models should be communicated in a sensitive manner so as not to appear dismissive of symptoms. When doctors and patients do not agree on the "reality" of the illness, the prognosis is worse. Thus media attention, medical and scientific disagreement, and legal proceedings must be managed in a way that does not exacerbate the symptoms or the illness.

In the Le Roy illness, treatment varied across individuals. The treatment strategies included cognitive-behavioral therapy, supportive psychotherapy, education, pharmacotherapy for coexisting anxiety, and alteration of social setting. Many of the patients sought multiple medical opinions. There were frequent discussions among public health and other medical officials and the local media outlets. Reduced media attention seemed to lead to more rapid improvement of symptoms in some patients.

It is helpful for healthcare providers to avoid the dichotomy of approaching illness using a medical model in which diseases are considered as being either physically *or* psychologically based. In contrast, a biobehavioral continuum of disease better characterizes illness as occurring across a spectrum ranging from a predominantly biologic etiology on one end to a predominantly psychosocial etiology on the other. It is beneficial to the patient for the treating physician to try to shift the emphasis from understanding the etiology to a path toward recovery.

Chapter 765

Animal and Human Bites

David A. Hunstad

Many animals, besides domestic and stray dogs and cats, inflict bites on humans. The profile of such bites varies by country and region, based on community and living conditions, indigenous species, and opportunity for encounter.

EPIDEMIOLOGY

Worldwide there are tens of millions of dog bites each year, resulting in nearly 60,000 deaths annually from rabies (see Chapter 320). **Dog bites** represent approximately 80–90% of all bites in the United States, while 5–15% are from cats, 2–5% from rodents, and the remainder from rabbits, ferrets, farm animals, monkeys, and reptiles. An estimated 4.5 million persons in the United States are bitten by dogs annually; over 800,000 of those seek medical care. Bites from dogs are also most common in Bangladesh, India, Pakistan, and Myanmar, whereas in Nepal cattle and buffalo account for more than half of bites, followed by dogs, pigs, and horses. Approximately 1% of dog bite wounds and 6% of cat bite wounds in the United States require hospitalization. During the past three decades, there have been several dozen deaths per year in the United States from dog-inflicted injuries; the majority of these occurred in children under 11 years of age. Various studies have examined the incidence of dog bite injuries by dog breed. Compared with other breeds, bites by pit bull terriers and mixed-breed dogs account for higher rates of hospital admission, lower Glasgow Coma Scores at admission, and an increased risk of death. Unaltered male dogs account for approximately 75% of attacks, while nursing female dogs may inflict injury when humans attempt to handle their puppies.

The majority of dog attacks on children in the United States occur between the ages of 6 and 11 years, with a slight predominance in males. Approximately 65% of attacks occur around the home, 75% of biting animals are known by the children, and 50% of attacks are said to be unprovoked. Similar statistics apply in Canada, where 70% of all bites reported in one study were sustained by children age 2-14 years; 65% of dogs involved in biting were part of the family or extended family.

Of the approximately 450,000 reported **cat bites** per year occurring in the United States, nearly all are inflicted by known household animals. Because rodent bites (rat, mouse, gerbil) do not represent reportable conditions, little is known about the epidemiology of these injuries or the incidence of infection after rodent-inflicted bites or scratches.

Few data exist on the incidence and demographics of **human bite** injuries in pediatric patients; however, preschool and early school-age children appear to be at greatest risk of sustaining an injury from a human bite, often in daycare or preschool settings. In some series, the proportion of human bites is highest among adolescents, an age group in which fist-to-teeth injuries (so-called "fight bites") become more common.

CLINICAL MANIFESTATIONS

Dog bite–related injuries can be divided into three categories of almost equal incidence: abrasions, puncture wounds, and lacerations with or without an associated avulsion of tissue. Bites from larger dogs may also involve crush injury to tissues. In contrast, the most common type of injury from cat bites is a puncture wound, often penetrating deep into tissue or joint spaces. Human bite injuries are of two types: an occlusion injury that is incurred when the upper and lower teeth come together on a body part, or a clenched-fist injury that occurs when the injured fist, usually on the dominant hand, strikes the teeth of another individual.

DIAGNOSIS

Management of the bite victim should begin with a thorough history and physical examination. Careful attention should be paid to the circumstances surrounding the bite event (e.g., species and number of animals, type of animal [domestic or wild], whether the attack was provoked or unprovoked, location of the attack), a history of drug allergies, and the immunization status of the child (tetanus) and animal (rabies). During physical examination, meticulous attention should be paid to the type, size, and depth of the injury; the presence of any foreign material in the wound; the status of underlying structures; and, when the bite is on an extremity, the exact location of the injury, an assessment of possibly involved structures, and the range of motion of the affected area. Photographs of the injury should be recorded in the patient's medical record. Radiographs of the affected part should be considered if it is likely that a bone or joint was penetrated or fractured or if foreign material is present in the wound. The possibility of a fracture or penetrating injury of the skull should particularly be considered in infants who have sustained dog bite injuries to the face or head.

COMPLICATIONS

Infection is the most common complication of bite injuries regardless of the species of biting animal. In most cases, culture specimens from a fresh dog bite wound are not likely to be clinically useful. Although potentially pathogenic bacteria have been isolated from up to 80% of dog bite wounds that are brought to medical attention within 8 hours of the bite, the infection rate for wounds receiving medical attention in <8 hours is relatively low (2.5–20%). Cultures should be obtained from the wound if there is clinical evidence of infection or if the patient is immunocompromised. *Capnocytophaga canimorsus* is isolated from approximately 5% of infected wounds in immunocompromised patients (especially asplenia) and can cause serious systemic infection in these individuals. In contrast to dogs, the infection rate in cat bite wounds, even those that receive prompt medical attention, is >50%; therefore cat bites should be closely monitored for signs of infection.

The rate of infection after rodent bite injuries is not known. Most of the oral flora of rats is similar to that of other mammals; however, up to 50% of rats, depending on worldwide geography, may harbor strains of *Streptobacillus moniliformis* and *Spirillum minus,* both of which cause rat bite fever (see Chapter 766).

All human bite wounds, regardless of the mechanism of injury, should be considered high risk for infection. Current recommendations do not support obtaining cultures at the time of the bite as it does not change empiric antibiotic therapy; however, any infected wounds should be cultured.

Table 765.1 lists common causes of soft tissue bacterial infections after dog, cat, or other animal bites. Bites of humans or cats, those in which treatment is delayed, those in immunocompromised patients, and those associated with deep puncture wounds or significant crush injury carry a higher risk for infection. An elevated risk for infection is also present if the bite is to certain anatomic regions (e.g., hand, foot, or genitals) or there is penetration of bone or tendons.

TREATMENT

Table 765.2 outlines the management of human or animal bite wounds to reduce risk for infection. The wound should be anesthetized, cleaned, and irrigated with sterile saline using moderate pressure. Irrigation with antibiotic-containing solutions provides no advantage over saline alone and may cause local irritation of the tissues. Puncture wounds should be thoroughly cleansed and

Table 765.2 Initial Management of Bite Wounds

HISTORY
Animal bite: Ascertain the type of animal, whether the bite was provoked or unprovoked, and the situation/environment in which the bite occurred. Follow rabies guidelines (see Chapter 320) for details on management of bites that carry a risk of rabies.
Patient: Obtain information on antimicrobial allergies, current medications, splenectomy, liver disease, or immunosuppressive conditions.

PHYSICAL EXAMINATION
If possible, photograph the wound and record its location, type, and approximate depth; range of motion; possibility of joint penetration; presence of edema or crush injury; nerve and tendon function; and signs of infection.

CULTURE
Aerobic and anaerobic cultures should be taken from infected wounds (not from fresh wounds).

IRRIGATION AND DEBRIDEMENT
Irrigate with water or sterile saline and debride devitalized or necrotic tissue.

RADIOGRAPHS
Plain radiographs should be obtained if bony penetration is possible or suspected; radiographs can also provide a baseline for future evaluation of osteomyelitis.

WOUND CLOSURE
Primary wound closure is usually not advocated unless wounds are extensive and closure is necessary for cosmetic or functional reasons, especially large facial or neck wounds or those overlying the joints. When possible, delayed primary closure or allowing the wound to close by secondary intention is recommended.

ANTIMICROBIAL THERAPY
Early presenting (uninfected) wounds: provide prophylactic antimicrobials for (1) moderate-to-severe injuries, especially if preexisting edema or significant crush injury is present; (2) bone or joint space penetration; (3) deep hand wounds; (4) immunocompromised patients; (5) wounds adjacent to prosthetic material; and (6) wounds in close proximity to the genital area. In most cases, coverage should include *Pasteurella* (*Eikenella* in human bites), *Staphylococcus, Streptococcus,* and anaerobes including *Fusobacterium, Porphyromonas, Prevotella,* and *Bacteroides* spp. See Table 765.3 for recommended antibiotics.
Infected wounds: See Table 765.3 for oral antibiotic recommendations. In cases where intravenous antibiotics are deemed necessary, antimicrobial choices include ampicillin/sulbactam, piperacillin-tazobactam, cefoxitin, or ertapenem.

HOSPITALIZATION
Indications include signs and symptoms of systemic toxicity and worsening infection.

IMMUNIZATIONS
Provide tetanus and rabies immunization, if indicated.

ELEVATION
Elevation may be required if edema is present. Lack of elevation is a common cause of therapeutic failure.

IMMOBILIZATION
For significant injuries, immobilize the extremity, especially the hands, with a splint.

FOLLOW-UP
Patients should be reminded to follow up within 48 hours or sooner for worsening or unresolved infections and continued pain.

REPORTING
Reporting the incident to a local health department may be required.

Adapted from Goldstein EJC, Abrahamian FM. Bites. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, 9th ed. Philadelphia: Elsevier; 2020: Table 315-3.

Table 765.3 Recommended Empirical Oral Antibiotics for Bite Wound Prophylaxis and Treatment

ANTIBIOTIC	RECOMMENDED ADULT DOSE	RECOMMENDED CHILD DOSE*
AGENT OF CHOICE (A) Amoxicillin-clavulanate	875/125 mg twice daily	45 mg/kg per dose (amoxicillin component) twice daily
ALTERNATE COMBINATION THERAPY: B OR C (WITH ANAEROBIC ACTIVITY) PLUS E, F, G, H, OR I		
(B) Metronidazole	500 mg three times daily	10 mg/kg per dose three times daily
Or:		
(C) Clindamycin	450 mg three times daily	10 mg/kg per dose three times daily
PLUS, ONE OF THE FOLLOWING: (D) Doxycycline	100 mg twice daily	Not for use in children <8 yr old
(E) Trimethoprim-sulfamethoxazole	160/800 mg (1 DS tab) twice daily	4 to 5 mg/kg (trimethoprim component) per dose* twice daily
(F) Penicillin V potassium	500 mg four times daily	12.5 mg/kg per dose four times daily
(G) Cefuroxime	500 mg twice daily	10 mg/kg per dose twice daily
(H) Moxifloxacin	400 mg once daily	Use with caution in children

*Child dose should not exceed recommended adult dose.
From Phillips LL, Semple J: Bites and injuries inflicted by wild and domestic animals. In Auerbach PS, Cushing TA, Harris NS (editors): *Auerbach's Wilderness Medicine*, 7th ed, vol 1. Philadelphia: Elsevier, 2017; Table 30.3, p. 623.

gently irrigated with a catheter or blunt-tipped needle; blind, high-pressure irrigation should not be employed. Avulsed or devitalized tissue should be debrided and any fluctuant areas incised and drained.

Surgical approaches to management of bite wounds may include primary closure, delayed primary closure (i.e., in 3-5 days), or healing by secondary intention. Factors to be considered are the type, size, and depth of the wound; the anatomic location; the presence of infection; the time since the injury; and the potential for cosmetic disfigurement. Appropriate surgical consultation (e.g., general pediatric surgery; plastic, hand, or orthopedic surgery) should be obtained promptly for all patients with deep or extensive wounds; wounds involving the hands, face, or bones and joints; and infected wounds that require open drainage. Although there is general agreement that visibly infected wounds and those that are more than 24 hours old should not be sutured, there is a spectrum of practice regarding the closing of wounds <8 hours old with no evidence of infection. Because all bite wounds to the hand are at high risk for infection, particularly if there has been disruption of the tendons or penetration of the bones, surgical consultation is almost always indicated, and delayed primary closure is recommended for many bite wounds of the hands. Facial lacerations are at lower risk for secondary infection because of the excellent blood supply to this region. Given this fact and cosmetic considerations, many plastic surgeons advocate primary closure of facial bite wounds that have been brought to medical attention within 8 hours.

Similarly, there are few comparative trials addressing the efficacy and selection of antimicrobial agents for **prophylaxis** of bite injuries. The bacteriology of bite wound infections is more often a reflection of the oral flora of the biting animal than the skin flora of the victim (see Table 765.1). Because many aerobic and anaerobic bacterial species colonizing the oral cavity of the biting animal have the potential to invade local tissue, multiply, and cause tissue destruction, most bite wound infections are polymicrobial.

Despite substantial homology in the oral bacterial flora of humans, dogs, and cats, important differences exist among the biting species, reflected in the types of wound infections that occur. The predominant bacterial species isolated from infected dog bite wounds are *Staphylococcus aureus* (20–30%), *Pasteurella multocida* (20–30%), *Staphylococcus intermedius* (25%), and *C. canimorsus;* approximately one-half of dog bite wound infections also contain mixed anaerobes. Similar species are isolated from infected cat bite wounds; however, *P. multocida* is the predominant species in at least 50% of cat bite wound infections. At least 50% of rats harbor *S. moniliformis* in the oropharynx, and approximately 25% in Asia harbor *S. minus,* a small, uncultivatable gram-negative organism. In infected human bite wounds, nontypable strains of *Haemophilus influenzae, Eikenella corrodens, S. aureus,* α-hemolytic streptococci, and β-lactamase–producing aerobes (~50%) are the predominant species. Clenched-fist injuries are particularly prone to infection by *Eikenella* spp. (25%) and other anaerobes (50%).

The choice between oral and parenteral antimicrobial therapy should be based on the severity of the wound, the presence and degree of overt infection, signs of systemic toxicity, and the patient's immune status. **Amoxicillin-clavulanate is an excellent choice for empiric oral therapy** for human and animal bite wounds because of its activity against most bacteria that are isolated from infected bites (Table 765.3). Similarly, **ampicillin-sulbactam or piperacillin-tazobactam is preferred for patients who will receive empiric parenteral therapy**. Penicillin G is the drug of choice for prophylaxis and treatment of rat bite injuries, as this agent has excellent activity against *S. moniliformis* and *S. minus*. Because first-generation cephalosporins have limited activity against *P. multocida* and *E. corrodens,* they should not be used for prophylaxis or empiric therapy of bite wound infections. Therapeutic alternatives for bite wound infections in penicillin-allergic patients are limited; clindamycin plus trimethoprim-sulfamethoxazole is the most commonly suggested regimen for these patients. Tetracycline is the drug of choice for penicillin-allergic patients who have sustained rat bite injuries.

Although **tetanus** occurs only rarely after human or animal bite injuries, it is important to obtain a detailed immunization history and to provide tetanus toxoid to all patients who are incompletely immunized or who received their most recent tetanus immunization more than five years prior. The need for postexposure **rabies** vaccination in victims of dog and cat bites depends on whether the biting animal is known to have been vaccinated and, most importantly, on local experience with rabid animals in the community. Bites from bats, foxes, skunks, and raccoons should be considered

high risk for rabies, and postexposure prophylaxis is uniformly indicated. For dogs, cats, and other animals that are known or captured, observation for 7-10 days by the local animal control department is indicated, and rabies prophylaxis can be delayed as long as the animal remains asymptomatic. If a biting dog or cat has escaped, a decision about rabies prophylaxis can be based on the circumstances surrounding the bite and advice from local infectious disease specialists and/or health department officials. Worldwide, animal bites and contacts result annually in more than 10 million courses of rabies postexposure prophylaxis.

In human bites where the biter's blood may have contaminated the wound, risk for hepatitis B, hepatitis C, and HIV infections should be considered (see Chapters 322 and 406).

PREVENTION

It is possible to reduce the risk of animal bite injury with anticipatory guidance. Parents should be routinely counseled during prenatal visits and routine health maintenance examinations about the risks of having potentially biting pets in the household. All patients should be cautioned against harboring exotic animals as pets. All young children should be closely supervised, particularly when in the presence of animals, and from a very early age should be taught to respect animals and to be aware of their potential to inflict injury. Reduction of the rate of human bite injuries, particularly in daycare centers and schools, can be achieved by good surveillance of the children and adequate teacher-to-child ratios.

Chapter 766

Rat Bite Fever

David A. Hunstad

ETIOLOGY

Rat bite fever is a generic term that has been applied to at least two distinct clinical syndromes, each caused by a different microbial agent. Rat bite fever caused by *Streptobacillus moniliformis* is most commonly reported in the United States as well as in Brazil, Canada, Mexico, Paraguay, Great Britain, and France; it has been identified elsewhere in Europe and in Australia. *S. moniliformis* is a gram-negative bacillus that is present in the nasopharyngeal flora of many laboratory and wild rats. Infection with *S. moniliformis* most commonly occurs following the bite of a rat; however, infection has also been reported in individuals who have been scratched by rats, in those who have handled dead rats, and in those who have ingested milk contaminated with the bacterium (termed **Haverhill fever**). Rat bite fever may also be transmitted by bites from wild mice. Rat bite fever caused by *Spirillum minus,* called **sodoku** (after the Japanese for "rat" and "poison"), is most commonly reported in Asia. *S. minus* is a small, spiral, aerobic gram-negative organism. Reports of rat bite fever from Africa are rare, suggesting under recognition rather than absence of the disease.

CLINICAL COURSE

The incubation period for the streptobacillary form of rat bite fever is variable, ranging from 3-10 days. The illness is characterized by an *abrupt* onset of fever up to 41°C (105.8°F) in over 90% of reported cases, as well as severe throbbing headache, intense myalgias, chills, and vomiting. In virtually all instances, the lesion at the cutaneous inoculation site has healed by the time that systemic systems first appear. Shortly after the onset of the fever, a polymorphous rash occurs in up to 75% of patients. In most patients, the rash consists of blotchy red maculopapular lesions that often have a petechial component; the distribution of the rash is variable, but it is typically most dense on the extremities (Fig. 766.1). Hemorrhagic vesicles may develop on the hands and feet and are very tender to palpation (Fig. 766.2).

Fig. 766.1 Morbilliform rash on the hands/palms (A) and feet (B) of a patient with rat bite fever. *(From Vetter NM, Feder HM Jr, Ratzan RM. Rat bite fever caused by a kiss. Am J Emer Med. 2015;34:1190.e3–1190.e4. Figs. 1 and 3.)*

Fig. 766.2 Hemorrhagic vesicles on the first and third toes of a patient with advanced rat bite fever. *(From Elliott SP. Rat bite fever and Streptobacillus moniliformis. Clin Microbiol Rev. 22007;20:13–22. Fig. 3.)*

Approximately 50% of patients have arthritis, which first manifests toward the end of the first week of disease; early on, the arthritis may be migratory. If untreated, fever, rash, and arthritis last from 14-21 days, often with a biphasic pattern to the fever and arthritis. A wide range of complications are reported in patients with rat bite fever, the most common being pneumonia, persistent arthritis, brain and soft tissue abscesses, and, less commonly, myocarditis or endocarditis. The mortality rate in untreated rat bite fever is estimated to be 10–15%.

The incubation period of sodoku is longer (14-21 days) than that of the streptobacillary form of disease. The hallmark of *Spirillum*-induced disease is fever associated with an indurated, often suppurative, nonhealing lesion at the bite site. Lymphadenitis and lymphadenopathy are invariably present in the regional nodes that drain the inoculation site, and many patients have a generalized macular rash most prominent

when fever is present. In untreated patients, sodoku has a relapsing and remitting course; symptoms abate after 5-7 days of chills and fever but recur 7-10 days later. There may be multiple cycles if the disease is not recognized and treated.

DIAGNOSIS

Diagnosis of the streptobacillary form of rat bite fever is difficult because the disease is uncommon and can be confused with Rocky Mountain spotted fever or (less commonly) meningococcemia. Furthermore, *S. moniliformis* is difficult both to isolate and to identify with classic bacteriologic techniques. The organism is fastidious and is inhibited by sodium polyanethol sulfonate, an additive present in many commercial blood culture bottles. Therefore the clinical microbiology laboratory should be notified when this infection is suspected so that additional media can be inoculated. A definitive diagnosis is made when *S. moniliformis* is recovered from blood or joint fluid or is identified in human samples by polymerase chain reaction (PCR), which has been used successfully in humans.

Diagnosis of sodoku is made on clinical grounds because there are no diagnostic serologic tests and culture of *S. minus* has not been achieved in laboratory media. Rarely, the organism may be visualized in Gram-stained smears of pus from the inoculation site. Approximately 50% of patients exhibit a false-positive Venereal Disease Research Laboratory (VDRL) test.

TREATMENT

Penicillin is the drug of choice for both forms of rat bite fever. Intravenous penicillin G or intramuscular penicillin G procaine is recommended for 7-10 days; a regimen of IV penicillin G for 5-7 days followed by oral penicillin V for an additional 7 days has also been used. Doxycycline, gentamicin, or streptomycin represent effective alternatives for penicillin-allergic patients. Patients with endocarditis caused by *S. moniliformis* require high-dose penicillin G for 4 weeks; the addition of streptomycin or gentamicin might be helpful.

Chapter 767

Mpox (Monkeypox)

David A. Hunstad

Since the eradication of **smallpox** (variola), mpox (formerly known as monkeypox) virus has, for humans, become the most important member of the genus ***Orthopoxvirus***. Monkeys are the predominant host for the virus; however, it may be endemic in African rainforest squirrels and is present in African rats, mice, domestic pigs, hedgehogs, and opossums. It has also been identified in and transmitted by imported prairie dogs in the United States and has affected elephants in zoos. Severity of infection varies by viral strain and by host; for example, disease is relatively mild in cynomolgus monkeys but severe in orangutans.

Mpox was first observed in humans from West and Central Africa in the 1970s at the time that smallpox had been eradicated from the area. In the 1970s, the secondary attack rate was around 3% (a stark comparison to the 80% seen in unvaccinated smallpox contacts). Few cases were observed over the next 2 decades; however, during a subsequent outbreak in the 1990s, when immunity to smallpox was no longer prevalent in the population, the secondary attack rate exceeded 75%. Mpox was introduced into the United States in 2003, presumably through rodents from Ghana that infected prairie dogs that were subsequently distributed as pets. Before 2022, primary transmission of the disease was from infected animal to human by bite or by human contact with an infected animal's blood, wound discharge, or other body fluids. Human-to-human transmission was previously thought to be uncommon, but a global outbreak in 2022 was linked to a shift to human-to-human transmission.

As of early 2023, nearly 87,000 cases were documented globally. Although children have comprised up to 40% of cases in previous outbreaks, the epidemiology of the current outbreak is different; less than 700 cases (<2%) have been reported in children and adolescents ≤20 years old. Mpox is currently spread predominantly through close human-to-human contact. The most recent outbreak has affected mostly gay, bisexual, and other men who have sex with men. Patients living with advanced HIV (with low CD4 counts) are at increased risk for severe disease. Although children typically acquire mpox from household contact, sexual contact is the primary route of transmission for adolescents. Mpox virus can persist on surfaces in households with an affected person.

CLINICAL COURSE

The classic clinical signs, symptoms, and course of mpox are similar to those of smallpox, although typically milder. After an incubation period of 10-14 days, during which the mpox virus replicates in lymphoid tissues, humans experience an abrupt onset of malaise, fever, myalgia, headache, and severe backache. Nonproductive cough, nausea, vomiting, and abdominal pain may be present. Generalized lymphadenopathy, a finding unusual in smallpox, is invariably present during the acute stages of mpox illness. After a prodrome of 2-4 days, an exanthem appears on the face and progresses inferiorly, including the palms and soles. As the rash spreads, fevers begin to abate. The rash is initially macular but transforms within hours to firm papules that rapidly vesiculate and become pustular over 2-3 days (Table 767.1). Unlike smallpox lesions but similar to chickenpox lesions, the lesions of mpox tend to occur in crops (Fig. 767.1). Late into the second week of illness, the lesions begin to desiccate, crust, scab, and fall off. During the 2022 global outbreak, lesions often occurred in the genital and anorectal areas and in the mouth (Fig. 767.2); cutaneous lesions are

Table 767.1 Mpox: Lesion Progression Through the Scab Stage

STAGE	STAGE DURATION (DAYS)*	CHARACTERISTICS
Enanthem		Sometimes, lesions first form on the tongue and in the mouth.
Macules	1-2	Macular lesions appear.
Papules	1-2	Lesions typically progress from macular (flat) to papular (raised).
Vesicles	1-2	Lesions then typically become vesicular (raised and filled with clear fluid).
Pustules	5-7	Lesions then typically become pustular (filled with opaque fluid) – sharply raised, usually round, and firm to the touch (deep seated). Finally, lesions typically develop a depression in the center (umbilication). The pustules will remain for approximately 5-7 days before beginning to crust.
Scabs	7-14	By the end of the second week, pustules have crusted and scabbed over. Scabs will remain for about a week before beginning to fall off.

*This is a typical timeline, but timelines can vary.

B, Three semiconfluent pustular lesions with a depressed center located on the left side of the tongue dorsum. C, Pearly acral vesicles embedded in the thick stratum corneum of the palmar skin, shotty on palpation. D, Scattered papules, pustules, and umbilicated pustules surrounded by an erythematous halo on the lateral aspect of the chest and left arm. E, Pustules circumferentially distributed on the anal margin and perianal skin. F, A pustular lesion with a crusted center on the semimucosa of the lower lip, close to the right oral commissure. G, Primary inoculation site with a large, crusted lesion on the right cheek. H, The right palatine tonsil is reddened and enlarged and has a fibrin-covered ulcer. I, The penile glans and foreskin have lesions of varying sizes and stages of evolution, with edema surrounding the larger ulcer. *(From Tarín-Vicente EJ, Alemany A, Agud-Dios M, et al. Clinical presentation and virological assessment of confirmed human monkeypox virus cases in Spain: a prospective observational cohort study. Lancet. 2022;400[10353]:661–669. Fig. 1; Photos A–C, E–G, I taken by Eloy José Tarín-Vicente, MD; Photos D, H by Maria Ubals, MD.)*

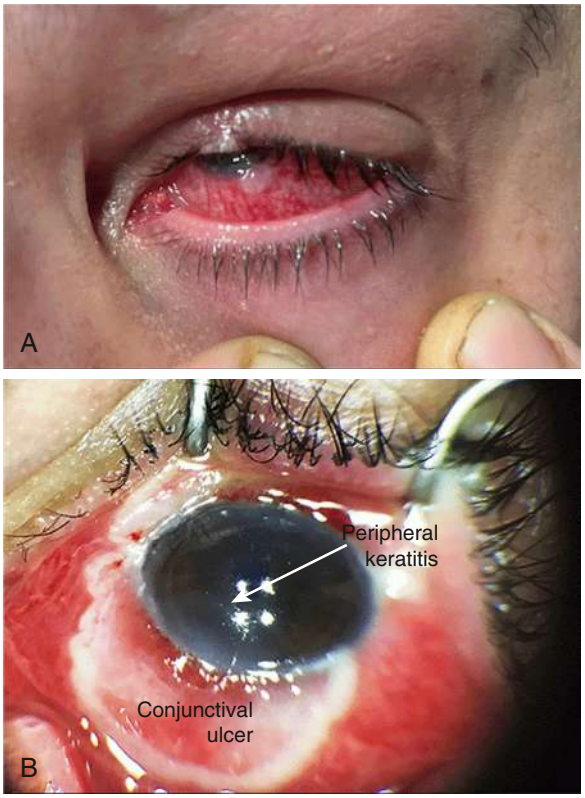

Fig. 767.3 Left eye in a patient with HIV-associated immunocompromise and ocular mpox, with conjunctivitis and conjunctival lesion earlier in the course of mpox illness (**A**), and with conjunctival ulcer and peripheral keratitis later in the course of mpox illness (**B**) — United States, August–September 2022. (*A courtesy Nathanael Adjei-Kyeremeh. B courtesy Dharmendra R. Patel; From Cash-Goldwasser S, Labuda SM, McCormick DW, et al. Ocular monkeypox – United States, July–September 2020. MMWR. 2022;71:1343–1347. Fig. 2.)*

less often disseminated with occasionally only a single lesion noted. Additionally, fever and other systemic symptoms may occur before the rash, *after* the rash, or *not at all*. Disseminated systemic or focal disease may include encephalitis, pharyngitis, myocarditis, arthritis, proctitis, lymphadenopathy, pneumonia, and ocular involvement (Fig. 767.3).

Mpox should be suspected in any child or adolescent who has the characteristic prodrome associated with a poxlike eruption and a history of close contact with someone who has been diagnosed with mpox, residence in Africa, or contact with prairie dogs or exotic mammals such as Gambian rats and rope squirrels. Diagnosis is by isolation of mpox viral DNA by polymerase chain reaction (PCR) from a skin lesion, including exudate or lesion crust. Oropharyngeal swabs may be considered in high-risk contacts of known or probable cases who have not yet developed a rash that can be swabbed (Table 767.2).

Cowpox, another *Orthopoxvirus*, often acquired from a pet rat, may produce similar cutaneous lesions. Regional lymphadenopathy and mild system features may also be present. Diagnosis is confirmed by a specific cowpox virus PCR.

PREVENTION AND TREATMENT

In 2019, the U.S. Food and Drug Administration (FDA) approved a new live-attenuated, replication-deficient vaccinia virus vaccine (branded Jynneos in the United States and Imvamune in the European Union [EU]; Bavarian Nordic) for use in patients ≥18 years old who are at risk for mpox acquisition. Despite evidence that preexposure administration of classical smallpox vaccine is 85% effective in preventing or attenuating mpox disease, the rarity of mpox infection does not warrant universal vaccination. However, following the recent 2022 outbreak, the U.S. Centers for Disease Control and Prevention recommends vaccinating high-risk patients (Table 767.3). This vaccine has a very low side effect profile and can be safely used in immunocompromised individuals, a significant advantage over classical (replication-competent) live smallpox vaccines.

For most immunocompetent patients with mild to moderate disease, supportive care is recommended. However, treatment should be considered for those with severe disease (hemorrhagic disease, large number of confluent lesions, necrotic lesions, severe lymphadenopathy that is necrotic or obstructing, involvement of multiple organ systems and comorbidities, or those who require hospitalization) or those with involvement of anatomic areas where scarring or stricture might cause serious sequelae (Fig. 767.4). In addition, treatment may be considered in patients at high risk for severe disease, including children less than 1 year old, immunocompromised or pregnant patients, or those with reduced skin integrity (e.g., eczema). Treatment options include tecovirimat, brincidofovir, cidofovir, or trifluridine ophthalmic solution; these medications were originally developed for treatment of other viral infections and

Table 767.2 Mpox Case Definitions

CLINICAL AND LABORATORY CLASSIFICATION	CRITERIA
Suspected	New characteristic rash* **OR** Meets one of the epidemiologic criteria and has high clinical suspicion† for mpox
Probable	No suspicion of other recent *Orthopoxvirus* exposure (e.g., vaccinia virus in ACAM2000 vaccination) AND demonstration of the presence of • *Orthopoxvirus* DNA by polymerase chain reaction testing of a clinical specimen **OR** • *Orthopoxvirus* using immunohistochemical or electron microscopy testing methods **OR** • Demonstration of detectable levels of anti-*Orthopoxvirus* IgM antibody during the period of 4-56 days after rash onset
Confirmed	Demonstration of the presence of mpox virus DNA by polymerase chain reaction testing or next-generation sequencing of a clinical specimen **OR** Isolation of mpox virus in culture from a clinical specimen
EPIDEMIOLOGIC CLASSIFICATION	
Within 21 days of illness onset:	Reports having contact with a person or persons with a similar appearing rash or with a person who has received a diagnosis of confirmed or probable mpox **OR** Had close or intimate in-person contact with persons in a social network experiencing mpox infections. This includes MSM who meet partners through an online website, digital application ("app"), or social event (e.g., a bar or party) **OR** Traveled, within 21 days of illness onset outside the United States to a country with confirmed cases of mpox or where mpox virus is endemic **OR** Had contact with a dead or live wild animal or exotic pet that is an African endemic species, or used a product derived from such animals (e.g., game meat, creams, lotions, powders, etc.)
EXCLUSIONS	
A case might be excluded as a suspected, probable or confirmed case if:	An alternative diagnosis* can fully explain the illness **OR** A person with symptoms consistent with mpox does not develop a rash within 5 days of illness onset **OR** A case where high-quality specimens do not demonstrate the presence of *Orthopoxvirus* or mpox virus or antibodies to *Orthopoxvirus*

*The characteristic rash associated with mpox lesions involves the following: deep-seated and well-circumscribed lesions, often with central umbilication; and lesion progression through specific sequential stages: macules, papules, vesicles, pustules, and scabs. The rash can sometimes be confused with other diseases that are more commonly encountered in clinical practice (e.g., syphilis, herpes, and varicella-zoster). Historically, sporadic accounts of patients co-infected with mpox virus and other infectious agents (e.g., varicella-zoster, syphilis) have been reported; so patients with a characteristic rash should be considered for *Mpox virus* testing, even if tests for other infectious agents are positive.

†Clinical suspicion may exist if lesions consistent with those from more common infections (e.g., syphilis, herpes, and varicella-zoster) coexist with lesions that may be characteristic of mpox.

From Centers for Disease Control and Prevention. Updated case-finding guidance: Mpox outbreak – United States, 2022. https://emergency.cdc.gov/han/2022/han00468.asp#:~text

Table 767.3 Mpox Vaccination Basics

Centers for Disease Control and Prevention recommends vaccination against mpox if:

- You had known or suspected exposure to someone with mpox
- You had a sex partner in the past 2 weeks who was diagnosed with mpox
- You are a gay, bisexual, or other man who has sex with men or a transgender, nonbinary, or gender-diverse person who in the past 6 months has had any of the following:
  - A new diagnosis of one or more sexually transmitted diseases (e.g., chlamydia, gonorrhea, or syphilis)
  - More than one sex partner
- You have had any of the following in the past 6 months:
  - Sex at a commercial sex venue (like a sex club or bathhouse)
  - Sex related to a large commercial event or in a geographic area (city or county for example) where mpox virus transmission is occurring
  - Sex in exchange for money or other items
- You have a sex partner with any of the above risks
- You anticipate experiencing any of the above scenarios
- You have HIV or other causes of immune suppression and have had recent or anticipate future risk of mpox exposure from any of the above scenarios
- You work in settings where you may be exposed to mpox:
  - You work with orthopoxviruses in a laboratory
  - You are part of an *Orthopoxvirus* and healthcare worker response team

From Centers for Disease Control and Prevention. Mpox Vaccination Basics. https://www.cdc.gov/poxvirus/mpox/vaccines/index.html

are thought to complement the immune response by reducing replication, maturation, and spread of mpox. Vaccinia immune globulin intravenous (VIGIV) may be considered in immunocompromised patients who cannot mount an appropriate immune response to clear the virus. In addition to antiviral medications, careful attention should be paid to skin hygiene, maintenance of adequate nutrition and hydration, and prompt implementation of local or systemic therapy for secondary bacterial infection that may occur. Pain management is a common reason for hospitalization because both cutaneous and mucosal lesions can be very painful. For prevention of human-to-human spread of disease, a combination of contact, droplet, and airborne infection control procedures should be implemented.

Fig. 767.4 Algorithmic approach to treatment*,†,‡ of patients with severe§ or at risk¶ for severe manifestations of mpox** : United States, February 2023.††

* Treatment includes MCMs (i.e., tecovirimat, brincidofovir, cidofovir, VIGIV, and trifluridine) and supportive therapies, including pain management. https://www.cdc.gov/poxvirus/monkeypox/clinicians/pain-management.html

† Most immunocompetent patients should display signs of clinical improvement within 4 days of antiviral initiation (i.e., tecovirimat, brincidofovir, cidofovir, and trifluridine). Tecovirimat is expected to reach steady-state concentrations by day 6 of dosing in healthy volunteers; therefore worsening clinical illness after 7 days of treatment in patients with severe illness could prompt additional evaluations.

‡ Concern for altered drug absorption includes the inability to tolerate or take oral therapy (e.g., nothing by mouth), or possibility that the oral drug absorption might be altered because of inability to consume a high-fat meal, severity of symptoms (e.g., systemic illness), comorbidities (e.g., history of gastric bypass or underlying GI disease), or other factors that might alter oral drug absorption.

§ Hemorrhagic disease, a large number of confluent or necrotic lesions, severe lymphadenopathy that is necrotizing or obstructing (e.g., of the upper airway causing airway compromise or of the GI tract necessitating parenteral feeding), edema that is obstructing (e.g., of the lower GI tract), extradermatologic manifestations (e.g., pulmonary nodules, encephalitis, myopericarditis, or ocular infections), and sepsis. Detailed characteristics of severe disease are available at https://www.cdc.gov/poxvirus/monkeypox/clinicians/treatment.html#anchor_1655488137245.

¶ Persons with underlying medical conditions (e.g., severe or moderate immunocompromise [https://www.cdc.gov/poxvirus/monkeypox/clinicians/people-with-HIV.html]); bacterial superinfections; or complications, including strictures, edema, and infections of the penile foreskin, vulva, urethral meatus, or anorectum, which could require procedural intervention (e.g., urethral catheterization, colostomy, or surgical debridement). This also includes those with or at risk for ocular lesions (i.e., presence of eyelid lesions, facial lesions near the eyes, or finger or hand lesions in patients unable to avoid touching their eyes [for whom autoinoculation is a concern]). Detailed characteristics of persons at risk for severe disease are available at https://www.cdc.gov/poxvirus/monkeypox/clinicians/treatment.html#anchor_1655488137245.

Chapter 768

Envenomations

Sing-Yi Feng

Envenomations due to snakes, spiders, scorpions, and other venomous animals can cause significant morbidity and mortality, although the majority cause only localized pain and swelling. In the 2020 report of the American Association of Poison Control Centers, approximately 42,800 out of 2.1 million phone consultations were related to bites and stings of various creatures, with approximately 14,000 involving children <20 years of age.

Not every bite from a venomous creature is harmful. In many cases, no venom is injected; these are called **dry bites**. A dry bite may occur for many reasons, including failure of the venom delivery mechanism and depletion of venom. Up to 20% of pit viper, 80% of coral snake, and approximately 50% of all venomous snake bites are dry.

GENERAL APPROACH TO THE ENVENOMATED CHILD

Children may be bitten or stung as they play and explore their environment. The evaluation may be hampered by an unclear history of the circumstances and the possible offending organism, particularly with preverbal children. The overall effects of some venomous bites and stings may be relatively more severe in children than in adults because children generally receive a similar venom load from the offending animal yet have less circulating blood volume to dilute its effects.

General Management

The majority of envenomations require local wound care, pain control, and reassurance. However, the severely envenomated child may require advanced life support interventions including endotracheal intubation and mechanical ventilation. Intravenous access should be obtained in an unaffected extremity if possible (see Chapters 91 and 92) to provide fluids and vasopressors as needed. Early hypotension is usually due to vasodilation and should be treated with volume expansion using appropriate infusion of intravenous crystalloid solution (normal saline boluses of 20 mL/kg; repeated as needed up to three times). Shock unresponsive to volume repletion may require addition of a vasopressive agent such as epinephrine or norepinephrine (in addition to antivenom administration if appropriate). If the presentation is suspicious for an anaphylactic reaction to venom, treatment (including epinephrine) should be initiated as soon as possible (see Chapter 190) along with the appropriate **antivenom**.

The affected body part should be immobilized in a position of function and any areas of edema should be marked, measured, and monitored. If antivenom is available for the envenomation, efforts should be initiated to locate and secure an adequate amount to treat the patient. In the United States, regional poison control centers are available via the national phone number 1-800-222-1222 to facilitate this effort, especially if the species is exotic. Guidance in dosing the antivenom should be obtained from experienced toxicologists via the regional poison center.

General Wound Care

Bites and stings require basic wound care, including copious tap water or normal saline irrigation under pressure when possible. For small puncture wounds, this is impractical, but the skin should still be thoroughly cleansed with soap and water. Tetanus immunization should be updated as needed. Intact bullae should be left to act as a natural sterile dressing to prevent infection, whereas ruptured bullae should be debrided. Exposed tissue should be covered with wet to dry dressings. Necrotic wounds, as seen in some snake and spider bites, should be judiciously debrided, with removal of only clearly necrotic tissue. Reconstructive surgery with skin grafts or muscle/tendon grafts may be necessary later. Prophylactic antibiotics are usually not necessary because venom is bacteriostatic. Antibiotics should generally be reserved for signs of established secondary infection.

SNAKE BITES

Most snake bites are inflicted by nonvenomous species and are of no more consequence than a potentially contaminated puncture wound. Anatomic features including head shape, pupil shape, and anal plate arrangement can be used to differentiate venomous and nonvenomous snakes (Fig. 768.1). Medically important venomous snakes in the United States belong to two families: **Crotalinae** and **Elapidae** (Table 768.1). Most snakebites occur

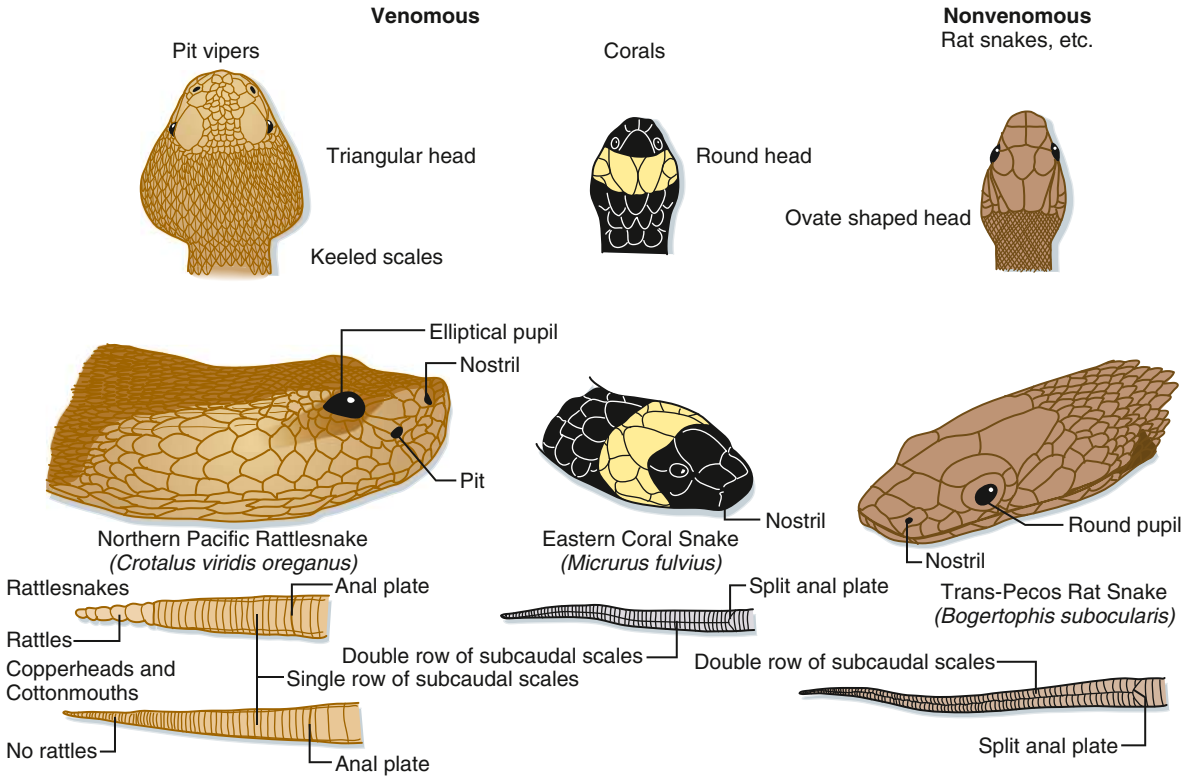

Fig. 768.1 Anatomic comparison of pit vipers, coral snakes, and nonvenomous snakes of the United States. *(Modified from Adams JG, ed. Emergency Medicine. Philadelphia: WB Saunders; 2008. Drawing by Marlin Sawyer.)*

Table 768.1 Important Venomous Snake Families in the United States

FAMILY	EXAMPLES	TOXIN EFFECTS/OTHER COMMENTS	ANTIVENOM
Crotalinae (pit vipers)	Rattlesnakes (*Crotalus* and *Sistrurus* spp.), cottonmouths and copperheads (*Agkistrodon* spp.)	Heat-sensing "pit" between each eye and nostril Toxins cause tissue damage, coagulopathy, cardiovascular collapse Exception: Mojave rattlesnake (*Crotalus scutulatus*) – neurotoxic venom	*Crotalinae* polyvalent immune Fab
Elapidae	Coral snakes (*Micrurus* spp.)	Venom is neurotoxic	Antivenin *(Micrurus fulvius)*

from April through September, when snakes are at their most active. Males sustain 75% of bites and children <5 years of age account for 10–15%. Bites are usually located on extremities, although other parts of the body have been reported. In the United States, approximately 98% of venomous snake bites are inflicted by pit vipers (Crotalinae). A small fraction of bites are caused by coral snakes (Elapidae) in the southern and southwestern states and by exotic pet snakes that have been imported.

Venoms and Effects

Snake venoms are complex mixtures of proteins including enzymes that cause local tissue destruction and other enzymes that have potentially lethal systemic effects including coagulopathy and neurotoxicity. The symptoms and severity of an envenomation vary according to the type of snake, the amount of venom injected, and the location of the bite. About 25% of snakebites are **"dry bites,"** where the patient has fang marks and puncture wounds but no pain, swelling, or systemic effects as no venom was injected. Most pit viper bites cause significant local pain, swelling, and ecchymosis and may result in necrosis of the affected extremity (Fig. 768.2). Pain and swelling typically begin quickly after the bite and may progress over hours to days. Serious envenomation may result in a consumptive coagulopathy, hypotension, and respiratory distress. In contrast, venom from the Elapidae is neurotoxic with little or no local tissue damage. These bites cause variable local pain, and the onset of systemic effects can be delayed for hours. Manifestations of neurotoxicity generally are caused by curare-like blockade at the neuromuscular junction. Symptoms usually begin with cranial nerve palsies such as ptosis, dysarthria, and dysphagia and may progress to respiratory failure and complete paralysis. Some pit vipers, including the Southern Pacific rattlesnake *(Crotalus oreganus helleri),* western diamondback rattlesnake *(Crotalus atrox),* timber rattlesnake *(Crotalus horridus),* and Mojave rattlesnake *(Crotalus scutulatus),* can also cause significant neurotoxicity, like the Elapidae. Regional poison control centers and toxicologists should be consulted early in the course of treatment.

Management

Prehospital care should focus on rapid transport to the emergency department while providing supportive care. Constrictive clothing, jewelry, and watches should be removed, and the injured body part should be immobilized in a position of function at the level of the heart. Many popularized field treatments for snake bites, such as

Fig. 768.2 Southern Pacific rattlesnake bite *(Crotalus oreganus helleri)* in a 2-yr-old child. Note the fang marks, swelling, and bruising of the tissues (photograph taken 2 hours following the bite). *(Courtesy Sean Bush, MD.)*

tourniquets, ice, electric shock, incision, and suction, have proven ineffective or deleterious.

At the hospital, supportive care should be continued as an effort is made to identify the offending snake and secure the appropriate antivenom (if applicable). In severe envenomations, advanced respiratory support may be required, including endotracheal intubation and mechanical ventilation. Intravenous access should be established in an unaffected extremity, intravenous fluids administered as needed, and standard laboratory specimens obtained, including complete blood count, coagulation studies, fibrinogen concentration, and serum chemistry analysis including total creatine kinase. Laboratory studies should initially be repeated every 4-6 hours to monitor the patient's progress and response to therapy. If tourniquets are placed in the field, they should be cautiously removed after venous access is obtained due to possible adverse effects that may follow from a sudden release of venom into the systemic circulation. The bitten extremity should be marked with the leading edge of the erythema and edema as well as the time to monitor progression of the swelling.

Assessment of the severity of the envenomation in the field and at the hospital is essential in determining the appropriateness of antivenom therapy for the snakebite victim (Table 768.2). Antivenoms are relatively specific for the genus of snake whose venom they are designed to neutralize. If it is determined that the patient requires antivenom, appropriating the correct antivenom should begin as soon as possible by discussing the matter with the hospital pharmacy, regional poison control center, and perhaps local zoos and museums that keep captive snakes because they often stock exotic snake antivenom.

Table 768.3 lists the indications for administering antivenom. CroFab, a Crotalinae polyvalent immune Fab antivenom (FabAV), is approved by the U.S. Food and Drug Administration (FDA) for use in crotalid envenomations. FabAV is derived from sheep (ovine) antibodies to crotalid snake venom, and side effects include both immediate and delayed hypersensitivity reactions. FabAV is derived from four snakes, three from the genus *Crotalus* (the eastern diamondback rattlesnake, the western diamondback rattlesnake, and the Mojave rattlesnake) and one from the genus *Agkistrodon* (the cottonmouth or water moccasin). It is effective against the venoms of all Crotalinae snakes in the United States. There is cross reactivity with FabAV against venom from copperhead snakes *(Agkistrodon contortrix)*. However, copperhead bites often do not require treatment with antivenom because they cause fewer systemic effects and less severe local tissue damage. Most copperhead envenomations cause only local tissue swelling, ecchymosis, and pain and generally do well with good supportive care and pain control. Any child with evidence of systemic toxicity should receive FabAV.

Initial dosing of FabAV is aimed at control of symptoms (progressive tissue swelling, thrombocytopenia, coagulopathy, neurotoxicity, or systemic toxicity). The dose is repeated until initial control of toxicity is achieved (see Table 768.3). Subsequent maintenance dosing may be needed to prevent or treat recurrence of venom effects because, due to its small molecular size, the half-life of FabAV is considerably shorter than that of crotalid venom constituents. Patients with significant envenomation should be followed for late hematologic abnormalities (coagulopathy) that can occur up to 2 weeks after the bite. Although these tend to be mild laboratory coagulopathies without clinical bleeding, rare cases of severe delayed bleeding have been reported. Further antivenom therapy should be considered for such delayed or recurrent coagulopathy as outlined in Table 768.4.

In April 2021, the U.S. FDA approved a crotaline immune Fab2 antivenin (Fab2AV) to treat adult and pediatric patients with North American Crotaline envenomations marketed as AnaVIP. This antidote is an equine-derived antivenin and, due to it being a Fab2 fragment, has a longer half-life than the FabAV. It has a similar side effect profile as the FabAV including anaphylactoid and hypersensitivity reactions. Initial dosing is 10 vials given intravenously over 60 minutes. If the symptoms continue to progress, then 10 vials can be given every hour until there is no further progression of symptoms. Patients should be observed for a minimum of 18 hours after the Fab2AV infusion. If a patient has reemerging symptoms including coagulopathies, then an additional four vials of the Fab2AV can be infused (Table 768.5).

Envenomation of the extremities can mimic compartment syndrome, with severe pain and swelling. It is important to treat these patients aggressively with FabAV or Fab2AV and pain control to control the severe pain and swelling. Although fasciotomy was once advocated for the treatment of crotalid snakebites of the extremities, it is now a treatment of last resort only if aggressive FabAV or Fab2AV treatment is unable to stop the progression of pain and swelling and true compartment syndrome is documented with measurement of intracompartmental pressure.

The antivenom for coral snakes *(Micrurus fulvius)* has been the recommended treatment for envenomation by the eastern coral snake *(M. fulvius)* and the Texas coral snake *(Micrurus tener)*. Indications for this antivenom are the development of any neurologic signs and symptoms of coral snake envenomation including paresthesias, slurred speech, respiratory difficulties, muscle weakness, and fasciculations. Due to it being equine in origin, its side effect profile includes anaphylaxis and allergic reactions. Most hospitals do not carry this antivenom and local poison centers should be notified to help locate supplies. Respiratory supportive care including endotracheal intubation and mechanical ventilation for respiratory failure remains the mainstay of treatment.

Disposition

If, after observation for 6-8 hours, a patient exhibits only fang-induced puncture marks with no local or systemic symptoms, the wounds can be considered dry bites and the patient can be safely discharged home. Patients with significant toxicity and those requiring treatment with antivenom should be admitted to the hospital. Patients with a history of eastern or Texas coral snakebite should be admitted to a monitored setting for 24 hours to observe for neurologic toxicity so that respiratory support can be provided as needed. Children should be admitted to an intensive care setting if they develop severe and progressive local tissue toxicity or evidence of systemic toxicity including coagulopathy, neurotoxicity, hemodynamic instability, or respiratory difficulties.

SPIDER BITES

In the United States, 18 genera of spiders have been identified that cause clinically significant envenomation. The spiders of importance in the United States include the *Latrodectus* species (the widow spiders) and the *Loxosceles* species (the recluse spiders).

Table 768.2 Pit Viper Envenomation Classification

GRADE	CLINICAL FEATURES	ANTIVENOM	DISPOSITION
0 (None)	No evidence of envenomation. A fang wound may be present. Pain is minimal, with less than 1 inch of surrounding edema and erythema. No systemic manifestations are present during the first 12 hr after the bite. No laboratory changes occur.	No	Observe for 8-12 hr. May be discharged if repeat labs are normal and no signs of envenomation develop.
I (Minimal)	Pain is moderate or throbbing and localized to the fang wound, surrounded by 1-5 inches of edema and erythema. No evidence of systemic involvement is present after 12 hr of observation. No laboratory changes occur.	No	Admission for 12-24 hr. Repeat labs every 6 hr. May be discharged if repeat labs are normal and no signs of envenomation develop.
II (Moderate)	There is more severe and widely distributed pain, edema spreading toward the trunk, and petechiae and ecchymoses limited to the area of edema. Nausea, vomiting, and a mild elevation in temperature are usually present.	Yes	Admission to intensive care unit.
III (Severe)	This may initially resemble a grade I or II; however, within 12 hr, edema spreads up the extremity and may involve part of the trunk. Petechiae and ecchymoses may be generalized. Systemic manifestations may include tachycardia and hypotension. Laboratory abnormalities may include an elevated white blood cell count, creatine phosphokinase, prothrombin time, and partial thromboplastin time, as well as elevated fibrin degradation products and D-dimer. Decreased platelets and fibrinogen are common. Hematuria, myoglobinuria, increased bleeding time, and renal or hepatic abnormalities may also occur.	Yes	Admission to intensive care unit.
IV (Very severe)	Sudden pain, rapidly progressive swelling that may reach and involve the trunk within a few hours, ecchymoses, bleb formation, and necrosis. Systemic manifestations, often commencing within 15 min of the bite, usually include weakness, nausea, vomiting, vertigo, and numbness or tingling of the lips or face. Muscle fasciculations, painful muscular cramping, pallor, sweating, cold and clammy skin, rapid and weak pulse, incontinence, convulsions, and coma may also be observed. An intravenous bite may result in cardiopulmonary arrest soon after the bite.	Yes	Admission to intensive care unit.

From Curtis AM, Erickson TB. Venomous animal injuries. Walls RM, ed. *Rosen's Emergency Medicine*, 10th ed. Philadelphia: Elsevier; 2023: Table 53.2, p. 696.

Table 768.3 Crotaline Fab Antivenom Dosing Guidelines

DOSE	RECOMMENDATIONS
Initial dose: four to six vials IV	• Reconstitute each vial of FabAV in 18 mL normal saline for injection and mix with continuous manual inversion at the rate of one to two inversions per second until no solid material is visible in the vial. • Further dilute four to six vials of reconstituted FabAV in 250 mL normal saline. • Infuse FabAV over 1 hr IV. • Start with slow infusion rate of 25-50 mL/hr for 10 min. • If no acute allergic reaction occurs, increase rate to 250 mL/hr to complete infusion. • The volume of the infusion may be decreased for the very small child or volume-sensitive patient. • Observe 1 hr after initial dose to assess for control of envenomation. • Repeat four to six vials of FabAV as needed to gain initial control.
Maintenance dose: two vials IV every 6 hr × 3 doses	• Monitor for delayed or recurrent toxicity requiring additional FabAV. • Antivenom dose requirements vary depending on the individual patient's response and clinical course. • Patients with mild envenomation may not require maintenance dosing beyond the initial dose.

Adapted from Goto CS, Feng SY. Crotalidae polyvalent immune Fab for the treatment of pediatric crotaline envenomations. *Ped Emerg Care*. 2009;25(4):273–279; and from Crofab Package Insert (revised 2018).

Table 768.4 Indications for Administration of Additional Antivenom in Patients with Recurrent Coagulopathy or Thrombocytopenia After Initial Control

- Evidence of clinically significant bleeding
- Platelet count below 25,000/mm^3
- International normalized ratio (INR) >3
- Activated partial thromboplastin time (aPTT) >50 seconds
- Fibrinogen <50 mg/dL
- Presence of multicomponent coagulopathy
- Worsening trend in a patient with prior severe coagulopathy
- High-risk behavior for trauma
- Certain comorbid conditions (e.g., systemic vasculitis, seizure disorders, prior stroke)

From Norris RL, Bush SP, Cardwell MD. Bites by venomous reptiles in Canada, the U.S. and Mexico. In: Auerbach PS, ed. *Wilderness Medicine*, 7th ed. Philadelphia: Elsevier; 2017.

Latrodectus Spiders

The *Latrodectus* species are found throughout the United States and include *L. mactans* (Fig. 768.3; **black widow** spider), *L. hesperus* (western black widow), *L. bishop* (red widow spider), *L. variolus,* and *L. geometricus* (brown widow spider). They are indigenous to every state except Alaska. The classic hourglass-shape marking is found only in *L. mactans*. They like to live close to the ground in secluded and dimly lit areas such as barns, sheds, and garages.

Venoms and Effects

Latrodectus spiders possess venoms that act at neuromuscular and autonomic nervous system synapses, resulting in excessive release of

Table 768.5	Crotaline Fab2 Antivenom Dosing Guidelines
Initial Dose: 10 vials (*no known maximum dose of Crotaline Fab2 antivenom)	• Reconstitute 10 vials for less than 1 min each using 10 mL sterile normal saline per vial • Combine all vials and dilute to a total volume of 250 mL sterile normal saline • Infuse at 25-50 mL/hr for 10 min; if tolerated at 250 mL/hr to completion
Evaluate for control	60 minutes after infusion, check for: • Local injury not progressing • Coagulation parameters improving • Systemic effects resolved
Observe	• Observe for at least 18 hr after initial control • If symptoms reemerge, can administer four vials in 250 mL

Adapted from AnaVIP package insert.

Fig. 768.3 Female black widow spider *(Latrodectus mactans).* Note the red hourglass-shaped marking on the underside of her abdomen. *(From The Centers for Disease Control and Prevention Public Health Image Library, Image #5449.)*

neurotransmitters. All of the widow spiders possess similar venoms, with the most important neurotoxin being α-latrotoxin.

Bites by the neurotoxic spiders tend to be very painful, and the offending spider is often seen. Systemic effects may include hypertension, tachycardia, bradycardia, hypersalivation, diaphoresis, and diffuse muscle spasm. Nausea, vomiting, abdominal pain, and abdominal rigidity may mimic appendicitis or another acute abdominal emergency.

Management

The management of a neurotoxic spider envenomation centers on sound supportive care. Generous doses of opioid analgesics and benzodiazepines should be utilized to ease severe pain and muscle spasm. *Latrodectus* antivenom (Wyeth) is equine-derived and may be considered to reverse severe systemic effects of widow spider envenomation. Although effective, it is associated with anaphylaxis, serum sickness, and anaphylactoid reactions and should be reserved for high-risk patients such as pregnant women at risk of spontaneous abortion due to the severe pain. One vial is administered via intravenous infusion. Efficacy is usually noted within 1 hour of administration, with reversal of systemic toxicity and relief of pain. Occasionally a second vial is necessary. Due to the possibility of severe or life-threatening reactions, the risks and benefits should be carefully considered and the antivenom infused slowly with continuous monitoring and preparation to treat anaphylaxis should it occur.

Fig. 768.4 Male recluse spider (*Loxosceles* spp.). Note the distinct violin-shaped marking on the dorsum of the cephalothorax. *(Courtesy Michael Cardwell/Extreme Wildlife Photography)*

Loxosceles Spiders

Venoms and Effects

The spiders most notorious for their dermonecrotic potential are the recluse spiders of the genus *Loxosceles*. The best-known member of this genus is the **brown recluse** (*Loxosceles reclusa*; Fig. 768.4), found in the midwestern and southern regions of the United States. The venom of *Loxosceles* spiders contains a phospholipase enzyme, sphingomyelinase D, as well as hyaluronidase. Hyaluronidase is the spreading factor that enables the venom to penetrate tissues, but it does not induce tissue damage. Sphingomyelinase D causes necrosis, red blood cell hemolysis, and platelet serotonin release. The bite of this spider is generally painless and initially goes unnoticed. A few hours after the bite, the area begins to blister and bleed and become painful. Within a day or two, the site will ulcerate and develop violaceous necrosis with surrounding ecchymosis and a rim of pale ischemia ("red, white, and blue" reaction). The lesion may gradually expand over a period of days to weeks until necrotic tissue sloughs and healing begins (Fig. 768.5).

Rare cases of systemic loxoscelism appear to be more common in young children. Patients present with systemic toxicity, including fever, chills, nausea, malaise, diffuse macular rash, and petechiae; they may experience hemolysis, coagulopathy, and renal failure.

In cases of necrotic dermal lesions with no identified spider as the culprit, a broad differential diagnosis must be considered to ensure appropriate management. The differential diagnosis includes skin infections (particularly methicillin-resistant *Staphylococcus aureus;* see Chapter 227), pyoderma gangrenosum, or ecthyma gangrenosum.

Management

The management of necrotizing spider bites includes good wound care, updating of tetanus status, and administration of antibiotics if there is secondary bacterial infection. Daily wound cleansing and splinting of the affected area should be provided until the wound has healed.

No therapy has been definitively proven effective in limiting the extent of necrosis after a recluse spider bite, including steroids, dapsone, colchicine, cyproheptadine, nitroglycerin, hyperbaric oxygen, and early excision of tissue. Meticulous wound care is the mainstay of treatment, and large lesions may require delayed secondary closure with skin grafting after clear tissue demarcation has occurred.

Patients with signs and symptoms of systemic loxoscelism should be admitted to the hospital for supportive treatment of hypovolemia, coagulopathy, hemolysis, and acute kidney injury. There is no commercially available antivenom in the United States for the management of necrotizing spider bites such as those from *Loxosceles* species.

Fig. 768.5 Progression of cutaneous loxoscelism in a Brazilian patient who was bitten inside a house while putting on a shirt. Ulceration and necrosis at day 1 (A), day 9 (B), day 16 (C), and day 25 (D). *(From Isbister G, Fan HW. Spider bite. Lancet. 2011;378:2039–2046. Fig. 3. Photographs by Ceila MS Malaque.)*

Disposition

Victims with necrotic skin lesions should be monitored with frequent outpatient wound checks to determine progression of the lesion. Children with rapidly progressive dermonecrosis or systemic toxicity should be admitted to the hospital for supportive therapy, which may include intensive care admission for hemolysis, coagulopathy, renal failure, or hypotension.

SCORPION STINGS

There are more than 650 species of scorpions worldwide, some of which are capable of causing severe or lethal envenomation. In the United States, there are two clinically significant scorpions: ***Centruroides exilicauda*** (the bark scorpion) and ***Centruroides vittatus.*** Most scorpion envenomations occur in the southwestern United States, and fatalities are rare. In other regions of the world, especially Latin America, Africa, the Middle East, and Asia, a number of scorpions regularly cause fatalities.

Venoms and Effects

Centruroides scorpion venom contains phospholipase, acetylcholinesterase, hyaluronidase, serotonin, and neurotoxins, resulting in severe pain and paresthesia as well as systemic symptoms of excessive nerve depolarization and release of acetylcholine and catecholamines. The manifestations of scorpion stings in children vary from mild to severe and can include autonomic and somatic toxicity. Autonomic toxicity includes hypertension, tachycardia, hypersalivation, emesis, diaphoresis, and bronchoconstriction, although respiratory failure is rare. Somatic motor toxicity includes ataxia, fasciculations, myoclonus, and opsoclonus. Patients are often restless or agitated, and cranial nerve dysfunction may occur.

Management

Most scorpion stings do not produce severe effects and require only wound care and orally administered pain medications. However, patients with more severe symptoms may require intravenous opioids for analgesia and benzodiazepines for severe muscle spasm or agitation.

A bark scorpion–specific antivenom, Anascorp (Bioclon, Mexico), is approved by the FDA. This antivenom is recommended for critically ill patients with neurotoxicity or other severe symptoms, including intractable pain that is not responsive to adequate doses of opioid analgesics. Small children are more likely than adults to develop such severe symptoms. It is best to discuss antivenom therapy with the regional poison control center for guidance.

Disposition

Patients who have had mild scorpion stings with only local effects can be safely discharged home with wound care instructions, analgesics, and close outpatient follow-up. Patients with evolving symptoms, intractable pain, neurotoxicity, or other systemic toxicity should be admitted to the hospital, especially if scorpion antivenom is being considered. Those with severe toxicity should be admitted to an intensive care unit.

HYMENOPTERA STINGS

The insect order Hymenoptera includes the stinging ants, bees, and wasps, which are characterized by the presence of a modified ovipositor (the "sting" or "stinger") at the end of the abdomen through which venom is injected. Various members of the order can be found throughout the world.

Venoms and Effects

Hymenoptera venom is a complex mixture of proteins, enzymes, and vasoactive substances that result in local tissue injury and inflammation. Most stings cause only local pain, redness, and swelling followed by itching and resolution. Some patients experience a large local reaction in which swelling progresses beyond the sting site, possibly involving the entire extremity. Approximately 0.4–0.8% of children and 3% of adults are at risk for acute, life-threatening allergic reactions as a result of Hymenoptera venom sensitivity; anaphylaxis due to Hymenoptera envenomation causes an average of 62 deaths annually in the United States (see Chapter 187). Rare cases of delayed serum sickness can follow Hymenoptera stings (see Chapter 191). Africanized honeybees *(Apis mellifera scutellata)*, an aggressive hybrid of western honeybee species with African bee species, can cause massive stinging episodes resulting in systemic venom toxicity with hypotension, respiratory failure, shock, hemolysis, and renal failure.

Management

Patients with typical local reactions can be treated with supportive care including analgesics and antihistamines as needed. Patients with large local reactions should also receive a course of oral corticosteroids and a prescription for an epinephrine autoinjection kit including instructions in its use before discharge. Patients presenting with urticaria, angioedema, wheezing, or hypotension should be treated with aggressive supportive care including standard therapy for anaphylaxis such as intramuscular epinephrine, corticosteroids, antihistamines, intravenous fluids, oxygen, and airway management as needed (see Chapter 190). Patients suffering massive stinging episodes may also require critical care resuscitation.

Disposition

Patients with local reactions can be discharged with continued outpatient care that may include analgesia and antihistamines. More difficult disposition decisions are involved for children with systemic manifestations. Children with only diffuse urticaria who are stable after a period of observation can be discharged home to continue a short course of antihistamines and steroids and to carry an epinephrine self-administration kit. These children are at low risk for progressing to systemic anaphylaxis with future stings. Children suffering more than simple urticaria (e.g., wheezing, evidence of laryngeal edema or cardiovascular instability) should be treated aggressively and admitted for at least 24 hours of observation. They should receive a referral to allergy/immunology to test for Hymenoptera venom sensitivity and possible immunotherapy. Immunotherapy reduces the risk of systemic anaphylaxis from future stings in high-risk patients from 30–60% to <5%.

MARINE ENVENOMATION

The classes of venomous marine animals that cause the most morbidity and mortality in humans are the **Cnidaria** (including jellyfish, the Portuguese man-of-war, Pacific blue bottle, fire coral, sea nettles, anemones, and others), Mollusca (blue-ringed octopus and cone snails), Chondrichthyes (stingrays), and members of the family Scorpaenidae (lionfish, scorpionfish, and stonefish).

Venoms and Effects

All members of the Cnidaria have unique stinging cells called nematocysts. These cells contain a highly folded tubule that discharges on contact, penetrates the skin, and injects venom. The venom is antigenic and can be dermonecrotic, hemolytic, cardiotoxic, or neuropathic, depending on the species. The **Pacific box jellyfish** *(Chironex fleckeri)* of Australia, with its cardiotoxic venom, is known to cause stings that are rapidly fatal due to cardiac arrest and pulmonary edema. Although fatal anaphylaxis to jellyfish stings has been reported in coastal waters of the United States, these events are rare. For clinicians in the Americas, the primary concern with Cnidaria envenomation is localized pain that may be associated with paresthesias or pruritus. Occasionally, victims may have systemic symptoms such as nausea, vomiting, headache, and chills.

The phylum **Mollusca** includes octopi and cone snails (*Conus* sp.). The **octopus** of toxicologic significance is the *Hapalochlaena maculosa* (blue-ringed octopus), which is primarily found in Australian waters. The blue-ringed octopus secretes **tetrodotoxin** (the same toxin found in pufferfish) in its salivary gland. The beak of the octopus punctures the skin and delivers the tetrodotoxin. Tetrodotoxin blocks sodium channels in neurons, leading to paralysis. The venom also contains other toxins, including vasoactive agents and enzymes that cause local tissue injury. Cone snails have a hollow proboscis with a tooth that can be extended to inject venom into the victim. Venom of the *Conus* species contains conotoxins that target multiple receptors, including voltage, ligand, and G-mediated receptors. Conotoxins cause a variety of symptoms including severe pain, weakness, tissue ischemia, cyanosis, and numbness. Systemic symptoms are usually neurologic and include aphonia, aphasia, weakness, paralysis, respiratory failure, cardiovascular collapse, and ultimately death.

The **stingray** has a sharp, retroserrated spine and associated venom gland at the base of its tail. Envenomation often occurs when the victim steps on the animal hidden in the surf and the tail is whipped around to puncture the lower extremity. Injuries involve jagged lacerations from the spine, often with retained debris (spine fragments, glandular tissue, and sand). The venom has vasoconstrictive properties that can result in tissue necrosis and poor wound healing. Stingray envenomations are noteworthy for immediate and intense pain at the site of injury that lasts 24-48 hours. Some patients experience nausea, vomiting, and muscle cramps. Rarely, hypotension or seizures occur.

The Scorpaenidae have venomous dorsal, pelvic, and anal spines that become erect when the animal is threatened. The venom glands associated with these spines contain multiple toxins, enzymes, and vasoactive substances. Envenomation causes immediate severe pain that may persist for hours or days. Victims may experience local tissue destruction, and superinfections are common. Systemic symptoms include diaphoresis, nausea, vomiting, diarrhea, abdominal pain, muscle cramping, and headache. In severe cases, paralysis, respiratory failure, hypotension, dysrhythmias, and cardiovascular collapse have been reported.

Management

Treatment of Cnidaria stings should begin immediately after envenomation. Dousing the sting site with vinegar has been shown to inhibit nematocyst discharge. If vinegar is not immediately available, the area should be washed with seawater; freshwater should be avoided as it is thought to stimulate firing of remaining nematocysts. Visible tentacle fragments should be removed with a gloved hand or forceps, and microscopic fragments may be removed by gently shaving the affected area. Folk remedies such as rubbing the sting with sand and applying urine are not helpful and cause more irritation. Meat tenderizer is usually not effective. Antihistamines and corticosteroids are indicated for swelling and urticaria. An acute anaphylactic reaction should be treated with intramuscular epinephrine. Antibiotics are usually not necessary.

Patients who have been envenomated by Mollusca are treated supportively. There are no antivenoms available for either the blue-ringed octopus or the cone snails. Adequate pain control should be provided as needed. Cardiovascular support may be required, and severe neurologic toxicity such as respiratory failure should be managed via airway management and mechanical ventilation.

Treatment of stingray and Scorpaenidae stings is similar. These toxins are heat-labile, and immersion in hot water (approximately 42°C [107.6°F]) for 30-60 minutes denatures the protein constituents and decreases pain significantly. The wounds should be thoroughly cleansed and explored with use of local or regional anesthesia to rule out retention of spine or integument fragments. Stingray spines are radiopaque and may be seen on radiographs or identified by ultrasonography. Lacerations should be treated with delayed primary closure or allowed to heal by secondary intention. Systemic analgesia should be provided as needed. Because of the risk of secondary bacterial infection, there should be a low threshold for administering prophylactic antibiotics to cover *Staphylococcus, Streptococcus,* and *Vibrio* species, and wounds should be rechecked at 3 and 7 days postinjury. An equine Fab stonefish antivenom is available for severe stonefish envenomation with systemic toxicity or intractable pain.

Disposition

After wound care and effective analgesia, most victims can be discharged home. If there are significant systemic effects, the patient should be admitted for monitoring and further care as needed.

Chapter 769

Laboratory Testing in Infants and Children

Stanley F. Lo and Stephen M. Roper

Normal values **(reference intervals)** are difficult to establish within the pediatric population. Differences in genetic composition, physiologic development, environmental influences, and subclinical disease are variables that need to be considered when developing reference intervals. Other considerations for further defining reference intervals include partitioning based on sex and age. The most commonly used reference range is generally given as the **mean** of the reference population ±2 standard deviations (SD). This is acceptable when the distribution of results for the tested population is essentially gaussian (normal). The serum sodium concentration in children, which is tightly controlled physiologically, has a distribution that is essentially gaussian; the mean value ±2 SD gives a range very close to that actually observed in 95% of children (Table 769.1). However, not all analytes have a gaussian distribution. The serum creatine kinase level, which is subject to diverse influences and is not actively controlled, does not show a gaussian distribution, as evidenced by the lack of agreement between the range actually observed and that predicted by the mean value ±2 SD. In these cases, a reference interval defining the 2.5-97.5 percentiles is typically used.

Reference cutoffs are typically established from large studies with a healthy reference population. Examples of these cutoffs are illustrated by reference cutoffs established for cholesterol, lipoproteins, and neonatal bilirubin. Patient results exceeding these cutoffs have a future risk of acquiring disease. A final modification needed for reporting reference intervals is referencing the Tanner stage of sexual maturation (sexual maturity rating scale), which is most useful in assessing pituitary and gonadal function.

The establishment of common reference intervals remains an elusive target. Although some patient results are directly comparable between laboratories and methods, most are not. Careful interpretation of patient results must consider when testing was performed and what method was used. **Higher-order methods**, methods that are more accurate and precise, continue to be slowly developed. These will be critical to the standardization of tests and the establishment of common reference intervals.

COMMON CHALLENGES IN PEDIATRIC LABORATORY MEDICINE

There are several challenges in pediatric lab medicine that are encountered infrequently, are less consequential, or do not apply to adult populations. For example, the rate of in-vitro hemolysis is increased in children because of the use of inappropriate needle or tubes sizes, applying too much pressure to the site of a finger or heel-stick collection, or simply drawing a specimen rapidly to minimize the discomfort of the child. Hemolyzed specimens can lead to inaccurate results for several analytes because of spectrophotometric interference caused by hemoglobin, dilution effects, or because of the release of other red blood cell components (e.g., lactate dehydrogenase [LDH]). A related issue is the frequent occurrence of physiologic jaundice. Like hemoglobin, bilirubin can absorb light and influence with spectrophotometric analyses. Although many chemistry analyzers can detect these interferences and suppress affected results, specimens frequently must be recollected. Likewise, the increased hematocrit common in the first month of life can lead to decreased amount of plasma/serum from a given blood volume. This phenomenon can result in the need for repeat phlebotomy or larger starting volumes of whole blood. In addition to blood, urine is another difficult fluid to work with in children. Noninvasive urine collections from infants often require special collection techniques (bags, cotton balls) that may only capture small volumes. Coupled with the relatively dilute urine typically produced by newborns, urine specimens may require concentration, or analyzer measurement ranges may need to be adjusted to provide useful information. Other challenges in pediatric lab medicine include, but are not limited to, the use of small ("bullet") blood collection tubes that are incompatible with automated sample handlers, the need for specialized testing (e.g., sweat test, newborn screening), and working with specimens drawn from indwelling catheters that may be contaminated with IV or total parenteral nutrition (TPN) fluid.

ACCURACY AND PRECISION OF LABORATORY TESTS

Technical accuracy, or trueness, is an important consideration in interpreting the results of a laboratory test. Because of improvements in methods of analysis and elimination of analytic interference, the accuracy of most tests is limited primarily by their precision. **Accuracy** is a measure of the nearness of a test result to the actual value, whereas **precision** is a measure of the reproducibility of a result. No test can be more accurate than it is precise. Analysis of precision by repetitive measurements of a single sample gives rise to a gaussian distribution with a mean and an SD. The estimate of precision is the coefficient of variation (CV):

$$CV = \frac{SD}{Mean} \times 100$$

The CV is not likely to be constant over the full range of values obtained in clinical testing, but it is approximately 5% in the normal range. The CV is generally not reported but is always known by the laboratory. It is particularly important in assessing the significance of changes in laboratory results. For example, a common situation is the need to assess hepatotoxicity incurred because of the administration of a therapeutic drug and reflected in the serum alanine transaminase (aminotransferase) (ALT) value. If serum ALT increases from 25 units/L to 40 units/L, is the change significant? The CV for ALT is 7%. Using the value obtained ±2 × CV to express the extremes of imprecision, a value of 25 units/L is unlikely to reflect an actual concentration of >29 units/L, and a value of 40 units/L is unlikely to reflect an actual concentration of <34 units/L. Therefore the change in the value as obtained by testing is likely to reflect a real change in circulating ALT levels. Continued monitoring of serum ALT is indicated, even though both values for ALT are within normal limits. *Likely* in this case is only a probability. Inherent biologic variability is such that the results of two successive tests may suggest a trend that will disappear on further testing.

Table 769.1 Gaussian and Nongaussian Laboratory Values in 458 Normal Schoolchildren 7-14 Years Old

	SERUM SODIUM (MMOL/L)	SERUM CREATINE KINASE (UNITS/L)
Mean	141	68
Standard deviation (SD)	1.7	34
Mean ±2 SD	138-144	0-136
Actual 95% range	137-144	24-162

The precision of a test may also be indicated by providing *confidence limits* for a given result. Usually, 95% confidence limits are used, indicating that it is 95% certain that the value obtained lies between the two limits reported. Confidence limits are calculated using the mean and SD of replicate determinations:

$$95\%\ \text{confidence limits} = \text{Mean} \pm t \times \text{SD}$$

where t is a constant derived from the number of replications. In most cases, $t = 2$.

Accuracy is expressed by determining the difference, or **bias**, between results from a comparative method and a definitive or reference method. A **definitive** or **reference** method provides results with increased precision and accuracy compared with the clinical laboratory. When these methods are used, along with highly purified materials (i.e., Standard Reference Materials from the National Institute of Standards and Technology) to establish values for assay calibrators used in the clinical laboratory, the accuracy of patient results is improved. Creatinine, hemoglobin A_{1c}, and neonatal bilirubin are examples in which the accuracy of these tests has been improved.

SENSITIVITY, ACCURACY, AND ANALYTIC TESTING

In some circumstances, the sensitivity and accuracy of an analysis are reduced or increased as functions of clinical purpose. For example, ion exchange chromatography of plasma amino acids for the diagnosis of inborn errors of metabolism is usually performed at an analytic sensitivity that allows measurement of all the amino acids with a single set of standards. The range of values is approximately 20-800 µmol/L, and accuracy is poor at values ≤20 µmol/L. The detection of homocysteine in this type of analysis suggests an inborn error of methionine metabolism. If the analysis is adjusted to achieve greater analytic sensitivity, it is possible to measure homocysteine accurately in normal plasma (3-12 µmol/L). This more sensitive test is used to assess cobalamin and folate status.

PREDICTIVE VALUE OF LABORATORY TESTS

Predictive value (PV) theory deals with the usefulness of tests as defined by their clinical **sensitivity** (ability to detect a disease) and **specificity** (ability to define the absence of a disease).

$$\text{Sensitivity} = \frac{\text{Number positive by test}}{\text{Total number positive}} \times 100$$

$$\text{Specificity} = \frac{\text{Number negative by test}}{\text{Total number without disease}} \times 100$$

$$\text{PV of positive test result} = \frac{\text{True-positive results}}{\text{Total positive results}} \times 100$$

$$\text{PV of negative test result} = \frac{\text{True-negative results}}{\text{Total negative results}} \times 100$$

The problems addressed by PV theory are *false-negative* and *false-positive* test results. Both are major considerations in interpreting the results of screening tests in general and neonatal screening tests in particular.

Testing for human immunodeficiency virus (HIV) seroreactivity illustrates some of these considerations. If it is assumed that approximately 1,100,000 of 284,000,000 residents of the United States are infected with HIV (prevalence = 0.39%) and that 90% of those infected demonstrate antibodies to HIV, then we can consider the usefulness of a simple test with 99% sensitivity and 99.5% specificity (see Chapter 322). If the entire population of the United States were screened, it would be possible to identify most of those infected with HIV:

$$1{,}100{,}000 \times 0.9 \times 0.99 = 980{,}100\ \ (89.1\%)$$

However, there will be 119,900 false-negative test results. And even with 99.5% specificity, the number of false-positive test results would be larger than the number of true-positive results:

$$284{,}000{,}000 \times 0.005 = 1{,}420{,}000$$

In addition, there will be 281,480,000 true-negative results:

$$\text{PV of positive test result} = \frac{980{,}100}{(980{,}100 + 1{,}420{,}000)} \times 100 = 41\%$$

$$\text{PV of negative test result} = \frac{281{,}480{,}000}{(281{,}480{,}000 + 119{,}900)} \times 100 = 99.96\%$$

Given the high cost associated with follow-up and the anguish produced by a false-positive result, it is easy to see why universal screening for HIV seropositivity received a low priority immediately after the introduction of testing for HIV infection.

By contrast, we can consider the screening of 100,000 individuals from groups at increased risk for HIV in whom the overall prevalence of disease is 10%, with all other considerations being unchanged.

$$\text{True-positive results} = 0.9 \times 0.99 \times 10{,}000 = 8{,}910$$

$$\text{False-positive results} = 0.005 \times 90{,}000 = 450$$

$$\text{False-negative results} = 10{,}000 - 8{,}910 = 1{,}090$$

$$\text{PV of positive test result} = \frac{8{,}910}{8{,}910 + 450} \times 100 = 95\%$$

$$\text{PV of negative test result} = \frac{89{,}500}{89{,}550 + 1{,}090} \times 100 = 99\%$$

These two hypothetical testing strategies show that the diagnostic efficiency of testing depends heavily on the prevalence of the disease being tested for, even with a superior test, such as the test for HIV antibodies. Because the treatment of pregnant women infected with HIV is effective in preventing vertical transmission, screening has now been expanded to all pregnant women. The proven effectiveness of current therapy in preventing neonatal infection has intensified screening for HIV early in pregnancy.

However, because of the long time needed to test for HIV antibodies, it was difficult to screen women during labor and provide the necessary therapy. Rapid HIV antibody testing procedures using a fingerstick or venipuncture to obtain whole blood, plasma, or serum, and tests using oral fluid were approved (Table 769.2). The HIV test results are usually obtained in <20 minutes. The collection of oral fluid samples provides an alternative for individuals who avoid HIV testing because of their dislike of needlesticks. HIV testing using whole blood or oral fluid is classified as a waived test under the **Clinical Laboratory Improvement Amendments of**

Table 769.2 Rapid HIV Antibody Tests and Status Under CLIA

RAPID HIV TEST	SPECIMEN TYPE	CLIA CATEGORY	TIME FOR PERFORMING ASSAY	WAIT TIME TO READ RESULTS	MANUFACTURER

Ag/Ab, Antigen/antibody; CLIA, Clinical Laboratory Improvement Amendments of 1988; HIV, human immunodeficiency virus.

1988 (CLIA), and these tests are allowed in a point-of-care setting. *Waived tests* are laboratory procedures that use methodologies that are so simple and accurate as to render the likelihood of an erroneous result by the user negligible. A positive rapid HIV test result is then confirmed by nucleic acid amplification testing or immunofluorescence assay.

According to the U.S. Centers for Disease Control and Prevention (CDC), 174 infants were born with HIV in 2014 in the United States. Rapid HIV testing during labor allows for implementation of antiretroviral therapy for HIV-infected women who have not been tested or are unaware of their HIV status. The initiation of therapy at the time of labor or within the first 12 hours of an infant's birth significantly reduces the risk of mother-to-child transmission. In the mother–infant rapid intervention at delivery study, it was shown that the sensitivity and specificity of a rapid whole blood test for HIV during labor were 100% and 99.9%, respectively, with a positive PV of 90%. The median turnaround time for obtaining results from blood collection to patient notification was only 66 minutes. The performance of the rapid blood test was better than that of the standard HIV enzyme immunoassay, which had a sensitivity and specificity of 100% and 99.8%, respectively, with a positive PV of 76%. In addition, the median turnaround time from blood collection to patient notification was 28 hours. As a result, rapid whole blood HIV testing is now the standard of care for women in labor with undocumented HIV status.

Rapid HIV testing can also be used in developing countries. In resource-poor settings, because of the lack of properly equipped laboratories, skilled technologists, and basic resources, such as electricity and water, these self-contained, point-of-care HIV tests are very attractive. In areas of Asia and Africa where HIV is epidemic, screening pregnant women with rapid HIV tests and offering antiretroviral therapy can significantly reduce the transmission of HIV to hundreds of thousands of infants.

NEONATAL SCREENING TESTS

Almost all the diseases detected in neonatal screening programs have a very low prevalence, and for the most part, the tests are *quantitative* rather than qualitative. In general, the strategy is to use the initial screening test to separate a highly suspect group of patients from normal infants (i.e., to increase the prevalence) and then to follow this suspect group aggressively. Two common strategies are used to detect congenital hypothyroidism (see Chapter 603): one uses thyroid-stimulating hormone for the initial screen, and the other uses thyroxine. In the **thyroxine** strategy for congenital hypothyroidism, which has a prevalence of 25 in 100,000 liveborn infants, the initial test performed is for thyroxine in whole blood. Infants with the lowest 10% of test results are considered suspect. If all infants with hypothyroidism were included in the suspect group, the prevalence of disease in this group would be 250 in 100,000 infants. The original samples obtained from the suspect group are retested for thyroxine and are tested for thyroid-stimulating hormone. This second round of testing results in an even more highly suspect group composed of 0.1% of the infants screened and having a prevalence of hypothyroidism of 25,000 in 100,000 individuals. This final group is aggressively pursued for further testing and treatment. Even with a 1,000-fold increase in prevalence, 75% of the aggressively tested population is euthyroid. The justifications advanced for the program are that treatment is easy and effective and that the alternative if congenital hypothyroidism is undetected and untreated—long-term custodial care—is both unsatisfactory and expensive.

At its inception, newborn screening was driven by the selection of genetic diseases whose clinical manifestations developed postnatally, such as phenylketonuria, galactosemia, and hypothyroidism. Diseases selected for screening typically had to meet certain criteria. The prevalence of disease had to meet a minimum, typically 1 in 100,000. Disease selection required demonstrated reduction in morbidity and mortality in the neonatal period. Effective therapies needed to be available, and the cost of screening and the feasibility of laboratory testing were also considerations in this selection process.

More common diseases have also become targets for neonatal screening programs. **Sickle cell disease** (see Chapter 511.1), easily detected using liquid chromatography or isoelectric focusing, can be treated more effectively if it is diagnosed before clinical signs appear. In addition, the results of neonatal screening for **cystic fibrosis** (CF; see Chapter 454) show clear benefits associated with preclinical diagnosis but also some inherent difficulties associated with genetic screening for complex autosomal recessive diseases that are common and are caused by a rather large number of pathogenic variants (>1,500) of a single gene. The definitive diagnostic test for CF is the measurement of concentrations of chloride in sweat, a test that is not practical during the first week of life. Neonates with CF generally have elevations in whole blood trypsinogen. This test allows the identification of a group of neonates at risk for CF. Unfortunately, trypsinogen as an initial screening test has a high false-positive rate, an unfavorable characteristic that creates unnecessary anxiety among newborn parents and families and is costly because of the time and expense for medical follow-up. Performing DNA analysis for common variants that cause CF reduces the size of the suspect group and identifies neonates with a higher likelihood of disease. This two-tiered strategy identifies a manageable number of infants for whom to perform sweat tests. Problems include the following: (1) uncommon variants are not included in the screening panel, and cases of CF caused by these variants can be missed; (2) common variants that cause clinically innocent elevations of whole blood trypsinogen in heterozygous neonates cause potentially alarming false-positive findings; and (3) CF in patients with normal sweat test results is rare but is likely to be missed.

Tandem mass spectrometry (MS/MS) is a technically advanced method in which many compounds are initially ionized and separated by molecular weight. Each compound is then fragmented, and the identification of compounds is based on characteristic fragments. The process requires approximately 2 minutes per sample and can detect 20 or more inborn errors of metabolism. The effects of prematurity, neonatal illness, and intensive neonatal management on metabolites in blood complicate the interpretation of results. The PV of a positive screening result is likely to be <10%; that is, 90% of positive results are not indicative of a genetic disorder of metabolism. Nonetheless, MS/MS permits a diagnosis to be made before clinical illness develops and has revolutionized the purpose and ability of newborn screening. MS/MS is not directed toward diseases defined as treatable, but it is directed toward all the diseases, each of which is rare, that the technique can identify.

MS/MS permits the detection of rare inborn errors of metabolism and has been introduced as a newborn screening tool worldwide. Since 1998, when mass spectrometry was implemented in Australia, the rate of detection per 100,000 births has been 15.7, significantly higher than the rate of 8.6-9.5 in the six preceding 4-year periods. Disorders of fatty acid oxidation, particularly medium-chain acyl coenzyme A dehydrogenase deficiency (see Chapter 106.1), accounted for the majority of increased diagnoses. Expanded newborn screening programs using MS/MS increase the detection of inherited metabolic disorders. All states in the United States use MS/MS in their neonatal screening programs; the metabolic conditions screened range from 31 to >50.

In an attempt to standardize newborn screening programs, the American College of Medical Genetics (ACMG) recommended that every baby born in the United States be screened for a core panel of 29 disorders (Table 769.3). An additional 25 conditions were recommended as secondary targets because they may be identified while screening for the core panel disorders. The March of Dimes and the American Academy of Pediatrics also endorse the ACMG recommendations. However, expansion of the screening test menu raises several issues. The cost of implementation can be significant because many states will need multiple MS/MS systems. Staffing the laboratory with qualified technical personnel to run the MS/MS system and qualified clinical scientists to interpret the profiles can be a challenge. A number of false-positive results will also be obtained with these newborn screening programs. Many of these findings are the result of parenteral nutrition, biologic variation, or treatment and are *not* the result of an inborn error of metabolism. Consequently, qualified staff will be needed to ensure that patients with abnormal results are contacted and receive follow-up testing and counseling, if needed. Even with these concerns, the ACMG report is a step in the right direction toward standardizing guidelines for state newborn screening programs.

TESTING IN REFINING A DIFFERENTIAL DIAGNOSIS

The use of laboratory tests in refining a differential diagnosis satisfies PV theory because a correct differential diagnosis should result in a relatively high prevalence of the disease under consideration. An example of testing in refining a differential diagnosis is the measurement of urinary vanillylmandelic acid (VMA) for the diagnosis of **neuroblastoma** (see Chapter 547). A simple spot test for VMA is not useful in general screening programs because of the low prevalence of neuroblastoma (3 cases/100,000) and the low sensitivity of the test (69%). Even though the specificity of urinary VMA is 99.6%, testing of 100,000 children would produce 2 true-positive test results, 400 false-positive results, and 1 false-negative result. The PV of a positive result in this setting is 0.5%, and the PV of a negative result is 99.99%, not much different from the assumption

Table 769.3 American College of Medical Genetics Core Panel of Neonatal Screening Tests

Isovalericacidemia
Glutaric aciduria type 1
3-Hydroxy-3-methylglutaricaciduria
Multiple coenzyme A (CoA) carboxylase deficiency
Methylmalonic acidemia (mutase deficiency)
3-Methylcrotonyl CoA carboxylase deficiency
Methylmalonic acidemia (cobalamin [Cbl] A, B)
Propionic acidemia
β-Ketothiolase deficiency
Medium-chain acyl-CoA dehydrogenase deficiency
Very-long-chain acyl-CoA dehydrogenase deficiency
Long-chain L-3-hydroxy acyl-CoA dehydrogenase deficiency
Trifunctional protein deficiency
Carnitine uptake deficiency
Phenylketonuria
Maple syrup urine disease
Homocystinuria (because of cystathionine β-synthase deficiency)
Citrullinemia
Argininosuccinic acidemia
Tyrosinemia type 1
Sickle cell anemia (Hb SS disease)
Hemoglobin (Hb) S/β-thalassemia
Hb S/C disease
Congenital hypothyroidism
Biotinidase deficiency
Congenital adrenal hyperplasia (21-hydroxylase deficiency)
Classic galactosemia
Hearing loss
Cystic fibrosis

that neuroblastoma is not present. Testing for urinary VMA in a 3-year-old child with an abdominal mass, however, gives a useful result because the prevalence of neuroblastoma is at least 50% in 3-year-old children with abdominal masses. If 100 such children are tested and the prevalence of neuroblastoma in the group is assumed to be 50%, a satisfactory PV is obtained.

$$\text{PV of positive test result} = \frac{0.69 \times 50}{0.69 \times 50 + (0.004 \times 50)} \times 100 = 99\,\%$$

$$\text{PV of negative test result} = \frac{0.996 \times 50}{0.996 \times 50 + (0.31 \times 50)} \times 100 = 76\,\%$$

Thus, in this situation, a test with low sensitivity is powerful in refining the differential diagnosis because the PV of a positive result is almost 100% in the setting of high prevalence.

Serologic Testing

Using laboratory testing to refine a differential diagnosis poses problems, as exemplified by serologic testing for **Lyme disease**, which is a tick-borne infection by *Borrelia burgdorferi* that has various manifestations in both early and late stages of infection (see Chapter 268). Direct demonstration of the organism is difficult, and serologic test results for Lyme disease are not reliably positive in young patients presenting early with erythema chronicum migrans. These results become positive after a few weeks of infection and remain positive for a number of years. In an older population being evaluated for late-stage Lyme disease, some individuals will have recovered from either clinical or subclinical Lyme disease, and some will have active Lyme disease, with both groups having true-positive serologic test results. Of individuals without Lyme disease, some will have true-negative serologic test results, but a significant percentage will have antibodies to other organisms that cross-react with *B. burgdorferi* antigens.

This set of circumstances gives rise to a number of problems. First, the protean nature of Lyme disease makes it difficult to ensure a high prevalence of disease in persons to be tested. Second, the most appropriate antibodies to be detected are imperfectly defined, leading to a wide variety of tests with varying false-positive and false-negative rates. Third, the natural history of the antibody response to infection and the difficulty of showing the causative organism directly combine to make laboratory diagnosis of early Lyme disease difficult. Fourth, in the diagnosis of late-stage Lyme disease in older individuals, the laboratory diagnosis is plagued by misleading positive (either false-positive or true-positive, but not clinically relevant) results, typically an enzyme-linked immunosorbent assay (ELISA) that uses whole *B. burgdorferi* organisms. In a review of 788 patients referred to a specialty clinic with the diagnosis of Lyme disease, the diagnosis was correct in 180 patients, 156 patients had true seropositivity without active Lyme disease, and 452 had never had Lyme disease, even though 45% of them were found to be seropositive by at least one test before referral.

A two-step approach, similar to that used in HIV testing, is often used: a screening test that has high sensitivity (e.g., ELISA) and excellent negative PV, followed by a very specific confirmatory test for verification of positive screening test results (e.g., Western blot to detect antibodies to selected bacterial antigens). Negative screening test results and negative verification test results are reported as negative. Positive verification test results are reported as positive. However, standardization of the testing procedures is difficult in North America, where only one pathogenic strain of *B. burgdorferi* is found, and is more difficult elsewhere in the Northern hemisphere, where as many as three pathogenic strains are present. Identification of microbial DNA in body fluids by polymerase chain reaction is definitive but invasive.

Table 769.4 Laboratory Profile as a Review of Systems

LABORATORY TEST	ASSESSMENT FACILITATED BY TESTS
Complete blood cell count and platelets	Nutrition, status of formed elements
Complete urinalysis	Renal function/genitourinary tract inflammation
Albumin and cholesterol	Nutrition
ALT, bilirubin, GGT	Liver function
BUN, creatinine	Renal function, nutrition
Sodium, potassium, chloride, bicarbonate	Electrolyte homeostasis
Calcium and phosphorus	Calcium homeostasis

ALT, Alanine transaminase; BUN, blood urea nitrogen; GGT, γ-glutamyltransferase.

Laboratory Screening

Screening profiles are used as part of a complete review of systems, to establish a baseline value, or to facilitate patient care in specific circumstances, such as (1) when a patient clearly has an illness, but a specific diagnosis remains elusive; (2) when a patient requires intensive care; (3) for postmarketing surveillance and evaluation of a new drug; and (4) when a drug is used that is known to have systemic adverse effects. Laboratory screening tests should be used in a targeted manner to supplement, not supplant, a complete history and physical examination (Table 769.4).

Chapter 770

Reference Intervals for Laboratory Tests and Procedures

Stanley F. Lo and Stephen M. Roper

In Tables 770.1-770.5, the reference intervals apply to infants, children, and adolescents when possible. For many analyses, separate reference intervals for children and adolescents are not well delineated. When interpreting a test result, the reference interval supplied by the laboratory performing the test should always be used because these intervals are instrument and/or method dependent. Figures 770.1 and 770.2 provide estimations related to dosages. Figure 770.3 is a nomogram for risk assessment of hyperbilirubinemia.

Table 770.1 Prefixes Denoting Decimal Factors in Table 770.5

PREFIX	SYMBOL	FACTOR
mega-	M	10^6
kilo-	k	10^3
hecto-	h	10^2
deka-	da	10^1
deci-	d	10^{-1}
centi-	c	10^{-2}
milli-	m	10^{-3}
micro-	μ	10^{-6}
nano-	n	10^{-9}
pico-	p	10^{-12}
femto-	f	10^{-15}

Table 770.2 Abbreviations Used in Table 770.5

Ab	Absorbance	mm^3	Cubic millimeter, microliter (μL)
AU	Arbitrary unit	mm Hg	Millimeters of mercury
BB	Brain isoenzyme of creatine kinase	mmol	Millimole
cap	Capillary	mo	Month, months
CH_{50}	Dilution required to lyse 50% of indicator red blood cells; indicates complement activity	mol	Mole
		mOsm	Milliosmole
		MW	Relative molecular weight
Cr	Creatinine	ND	Not detected
CSF	Cerebrospinal fluid	nm	Nanometer (wavelength)
F	Female	Pa	Pascal(s)
g	Gram, grams	pc	Postprandial
G6PD	Glucose-6-phosphate dehydrogenase	RBC	Red blood cell(s), erythrocyte(s)
Hb	Hemoglobin	RT	Room temperature
HbCO	Carboxyhemoglobin	SD	Standard deviation
hpf	High-power field	sec	Second, seconds
hr	Hour, hours	Tr	Trace
IU	International unit(s) of hormone activity	U	International unit(s) of enzyme activity
L	Liter	V	Volume
M	Male	WBC	White blood cell(s)
MB	Heart isoenzyme of creatine kinase	WHO	World Health Organization
mEq/L	Milliequivalents per liter	wk	Week, weeks
min	Minute, minutes	yr	Year, years

Table 770.3 Abbreviations for Specimens in Table 770.5

S	Serum
P	Plasma
(H)	Heparin
(LiH)	Lithium heparin
(E)	Ethylenediaminetetraacetic acid (EDTA)
(C)	Citrate
(O)	Oxalate
W	Whole blood
(NH_4H)	Ammonium heparinate

Table 770.4 Key to Comments Section of Table 770.5

30°C, 37°C	Temperature of enzymatic analysis (Celsius)	l	Fluorometric method
a	Values obtained are significantly method dependent	m	Fluorescence-activated cell sorting (FACS)
b	Values in older males are higher than those in older females	n	Fluorescence polarization
c	Values in older females are higher than those in older males	o	Gas chromatography
d	Atomic absorption	p	High-performance liquid chromatography (HPLC)
e	Borate affinity chromatography	q	Indirect fluorescence antibody (IFA) assay
f	Cation-exchange chromatography	r	Ion-selective electrode
g	Vitros, a proprietary analytic system of Ortho Clinical Diagnostics	s	Nephelometry
i	Electrophoresis	t	Optical density
j	Enzymatic assay	u	Radial immunodiffusion (RID)
k	Enzyme-amplified immunoassay	v	Radioimmunoassay (RIA)
		w	Spectrophotometry

*In preparing the reference range listings, a number of abbreviations, symbols, and codes were used (see Table 770.2).
†Reference values are shown in SI units (International System of Units) and U.S. units (Traditional Units).

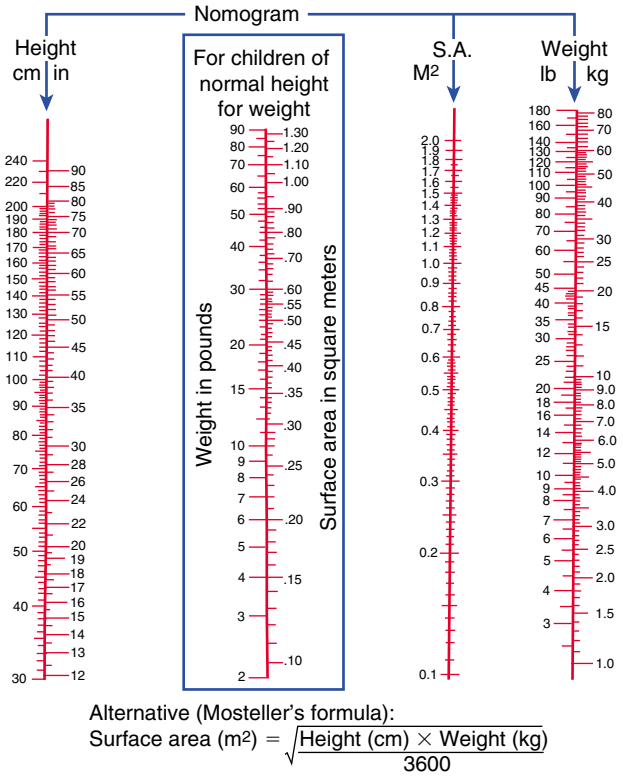

Fig. 770.1 Nomogram for the estimation of surface area. The surface area is indicated where a straight line that connects the height and weight levels intersects the surface area column, or if the patient is roughly of average size, from the weight alone *(enclosed area)*. *(Nomogram modified from the data of E. Boyd by CD West. See also Briars GL, Bailey BJ. Surface area estimation: pocket calculator v nomogram. Arch Dis Child. 1994;70:246–247.)*

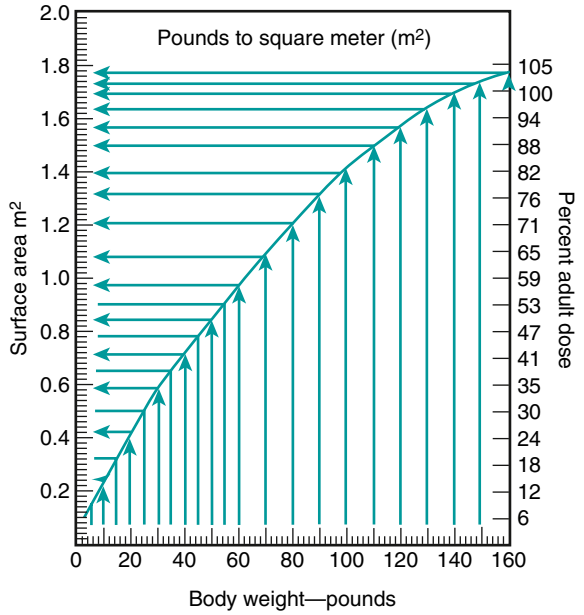

Fig. 770.2 Relationships between body weight (lb), body surface area, and adult dosage. The surface area values correspond with those set forth by Crawford JD, Terry ME, Rourke GM. Simplification of drug dosage calculation by application of the surface area principle. *Pediatrics*. 1950;5:783–790. Note that the 100% adult dose is for a patient weighing approximately 140 lb and having a surface area of approximately 1.7 m². *(From Talbot NB, Richie RH, Crawford JH. Metabolic homeostasis: a syllabus for those concerned with the care of patients. Cambridge, MA: Harvard University Press, 1959.)*

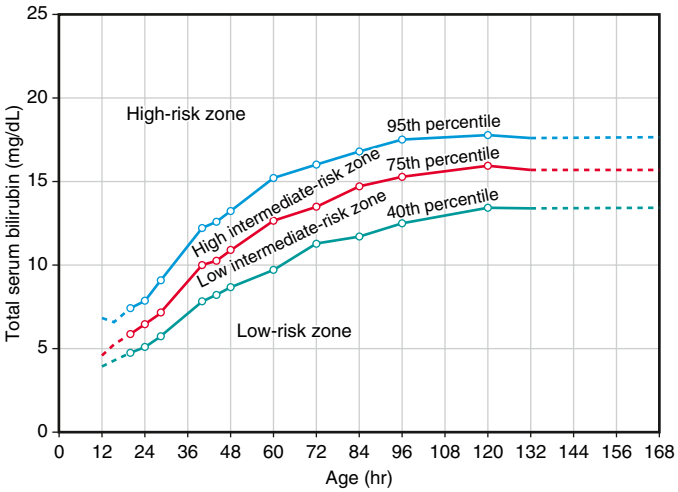

Fig. 770.3 Nomogram for risk assessment of hyperbilirubinemia. *(From Bhutani VK, Johnson L, Sivieri EM. Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. Pediatrics. 1999;103:6–14. Fig 2.)*
