certain underlying electrical derangements. In patients presenting with extreme degrees of heart failure or circulatory collapse, intensive care measures are often required, including intravenous inotropes and diuretics, mechanic ventilatory support, and on occasion, mechanical circulatory support, which may include a ventricular assist device (VAD), total artificial heart, extracorporeal membrane oxygenation (ECMO), and ultimately cardiac transplantation. In patients with DCM and atrial or ventricular arrhythmias, specific antiarrhythmic therapy should be instituted.

Table 488.5 Mitochondrial DNA Abnormalities Associated with Cardiomyopathy and Arrhythmias or Conduction Defects*

CONDITION	GENETIC DEFECT	HEART FINDINGS	OTHER CLINICAL FEATURES
Kearns-Sayre syndrome	mtDNA deletion	HCM, DCM, heart block, PMVT	Progressive external ophthalmoplegia, pigmentary retinopathy, cerebellar ataxia, hearing loss, increased CSF protein, diabetes mellitus, renal tubulopathy
MELAS	$tRNA^{Lou}$ point variant	HCM, DCM, LVNC, RCM, heart block, WPW	Encephalopathy, seizures, strokelike episodes, headaches, hearing loss, myopathy
MERRF	$tRNA^{Lys}$ point variant	HCM, DCM, HiCM, WPW	Myoclonus, seizures, ataxia, optic atrophy, hearing loss, short stature
Complex I deficiency	Multiple complex I subunit genes	HCM, DCM	Leigh syndrome, leukoencephalopathy, seizures, optic atrophy
Complex III deficiency	*MTCYB*	HCM, DCM, HiCM	Exercise intolerance, myopathy, seizures, optic atrophy, short stature
Complex IV deficiency	*MT-CO1, MT-CO2, MT-CO3*	HCM, DCM, HiCM	Encephalopathy, seizures, pigmentary retinopathy, hearing loss, myopathy, liver dysfunction
Complex V deficiency	*MT-ATP6, MT-ATP8*	HCM	Ataxia, peripheral neuropathy

*Relatively common conditions that are associated with heart disease and feature abnormal mtDNA are shown, along with the most common molecular defects and clinical findings. Although the most common molecular defects are indicated in the table, in most cases, multiple genetic abnormalities can cause similar clinical presentations.

CSF, Cerebrospinal fluid; DCM, dilated cardiomyopathy; HCM, hypertrophic cardiomyopathy; HiCM, histiocytoid cardiomyopathy; LVNC, left ventricular noncompaction; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes; MERRF, myoclonic epilepsy with ragged red fibers; mtDNA, mitochondrial DNA; PMVT, polymorphic ventricular tachycardia; RCM, restrictive cardiomyopathy; WPW, Wolff-Parkinson-White syndrome.

Table 488.6 Gene Variants and Cardiac Manifestations of Neuromuscular Disorders

DISORDER	GENE VARIANT	CARDIOMYOPATHY	ECG	ARRHYTHMIA
Duchenne muscular dystrophy (DMD)	Dystrophin	Dilated	Short PR interval, prolonged QT interval, increased QT:PT ratio, right ventricular hypertrophy, deep Q waves II, III, aVF, V_5, V_6	Increased baseline HR, decreased rate variability, premature ventricular beats (58% of patients by 24 yr of age)
DMD—female carrier	Dystrophin	Dilated	None	Uncommon
Becker muscular dystrophy	Dystrophin	Dilated	Conduction system disease	Similar to DMD
Emery-Dreifuss autosomal dominant or proximal dominant limb-girdle muscular dystrophy IB	Lamin A/C	Dilated	Conduction abnormalities: prolonged PR interval, sinus bradycardia	Atrial fibrillation or flutter and atrial standstill; ventricular dysrhythmias
Limb-girdle muscular dystrophy	α, β, γ, δ sarcoglycans	Dilated	Incomplete right bundle branch block, tall R waves in V_1 and V_2, left anterior hemiblock	Uncommon
Congenital muscular dystrophy	Laminin α_2	Dilated	None	None
Limb-girdle muscular dystrophy 21	Fukutin	Dilated	AV node and bundle branch block; age at onset: late teens and early 20s	Atrial arrhythmias and/or ventricular arrhythmias
Emery-Dreifuss X-linked	Emerin	Rare	Conduction abnormalities: prolonged PR interval, sinus bradycardia	Atrial fibrillation or flutter and atrial standstill
Friedreich ataxia	Frataxin	Hypertrophic	T-wave inversion, left axis deviation, repolarization abnormalities	Ventricular arrhythmias
Myotonic dystrophy type 1, infantile	Myotonic dystrophy protein kinase gene	Hypertrophic	Conduction disease, prolonged PR interval, widening of QRS complex	Atrial fibrillation and flutter, complete heart block
Myotonic dystrophy type 1	Myotonic dystrophy protein kinase gene	LVNC	Conduction disease, prolonged PR interval, widening of QRS complex	Atrial fibrillation and flutter, complete heart block

AV, Atrioventricular; HR, heart rate; LVNC, left ventricular noncompaction.

488.2 Hypertrophic Cardiomyopathy

John J. Parent and Stephanie M. Ware

Hypertrophic cardiomyopathy **(HCM)** is a heterogeneous, relatively common, and potentially life-threatening form of cardiomyopathy. The causes of HCM include inborn errors of metabolism, neuromuscular disorders, syndromic conditions, and genetic abnormalities of the structural components of the cardiomyocyte (see Tables 488.1 and 488.2). Both the age of onset and the associated features are helpful in identifying the underlying etiology.

HCM is a genetic disorder and frequently occurs because of pathogenic variants in sarcomere or cytoskeletal components of the cardiomyocyte (see Fig. 488.2). Pathogenic variants of the genes encoding cardiac β-myosin heavy-chain *(MYH7)* and myosin-binding protein C *(MYBPC3)* are the most common (see Table 488.3). Pathogenic variants are inherited in an autosomal dominant pattern with a high penetrance but variable expressivity. Additional genetic causes for HCM include nonsarcomeric protein pathogenic variants, such as the γ_2-regulatory subunit of adenosine monophosphate–activated protein kinase *(PRKAG2)* and the lysosome-associated membrane protein 2α-galactosidase (**Danon disease**, a form of glycogen storage disease). Syndromic conditions, such as **Noonan syndrome**, may present with HCM at birth, and recognition of extracardiac manifestations is important in making the diagnosis. Medical therapy directed at the Ras signaling pathway is in the initial phases of use in patients with Noonan syndrome and related RASopathies.

Glycogen storage disorders such as **Pompe disease** often present in infancy with a heart murmur, abnormal ECG, systemic signs and symptoms, and occasionally heart failure. Many states have Pompe testing on the newborn screening, facilitating early diagnosis and therapy, which has improved the prognosis. The characteristic ECG in Pompe disease demonstrates prominent P waves, a *short* P-R interval, and massive QRS voltages. The echocardiogram confirms severe, often concentric, LV hypertrophy.

PATHOGENESIS

HCM is characterized by the presence of increased LV wall thickness in the absence of structural heart disease or hypertension. Often the interventricular septum is disproportionately involved, leading to the previous designation of *idiopathic hypertrophic subaortic stenosis* or the current term of **asymmetric septal hypertrophy**. In the presence of a resting or provocable outflow tract gradient, the term **hypertrophic obstructive cardiomyopathy** is used. Although the left ventricle is predominantly affected, the right ventricle may be involved, particularly in infancy. The mitral valve can demonstrate systolic anterior motion and mitral insufficiency. Left ventricular outflow tract (LVOT) obstruction occurs in 25% of patients, is dynamic in nature, and may in part be secondary to the abnormal position of the mitral valve as well as the obstructing subaortic hypertrophic cardiac muscle. The cardiac myofibrils and myofilaments demonstrate disarray and myocardial fibrosis.

Typically, systolic function is preserved or even hyperdynamic, although systolic dysfunction may occur late and is a predictor for death or need for cardiac transplant. LVOT obstruction with or without mitral insufficiency may be provoked by physiologic manipulations such as the Valsalva maneuver, positional changes, and physical activity. Frequently, the hypertrophic and fibrotic cardiac muscle demonstrates relaxation abnormalities (diminished compliance), and LV filling may be impaired (diastolic dysfunction).

CLINICAL MANIFESTATIONS

Many patients are asymptomatic; 50% of cases present with a heart murmur or during screening when another family member has been diagnosed with HCM. Symptoms of HCM may include palpitations, chest pain, easy fatigability, dyspnea, dizziness, and syncope. Sudden death is a well-recognized but uncommon manifestation that occurs during physical exertion but may also occur at rest or during sleep. Characteristic physical examination findings include an overactive precordial impulse with a lift or heave, a systolic ejection murmur in the aortic region *not* associated with an ejection click, and an apical blowing murmur of mitral insufficiency.

DIAGNOSIS

The ECG typically demonstrates LV hypertrophy with ST segment and T-wave abnormalities (particularly T-wave inversion in the left precordial leads). Intraventricular conduction delays and signs of ventricular preexcitation **(Wolff-Parkinson-White syndrome)** may be present and should raise the possibility of PRKAG2-related HCM, Danon disease, or Pompe disease. Chest radiography demonstrates normal or mildly increased heart size with a prominence of the left ventricle. Echocardiography is diagnostic in identifying, localizing, and quantifying the degree of myocardial hypertrophy (see Fig. 488.3). Doppler interrogation defines, localizes, and quantifies the degree of LVOT obstruction and demonstrates and quantifies the degree of mitral insufficiency and diastolic dysfunction.

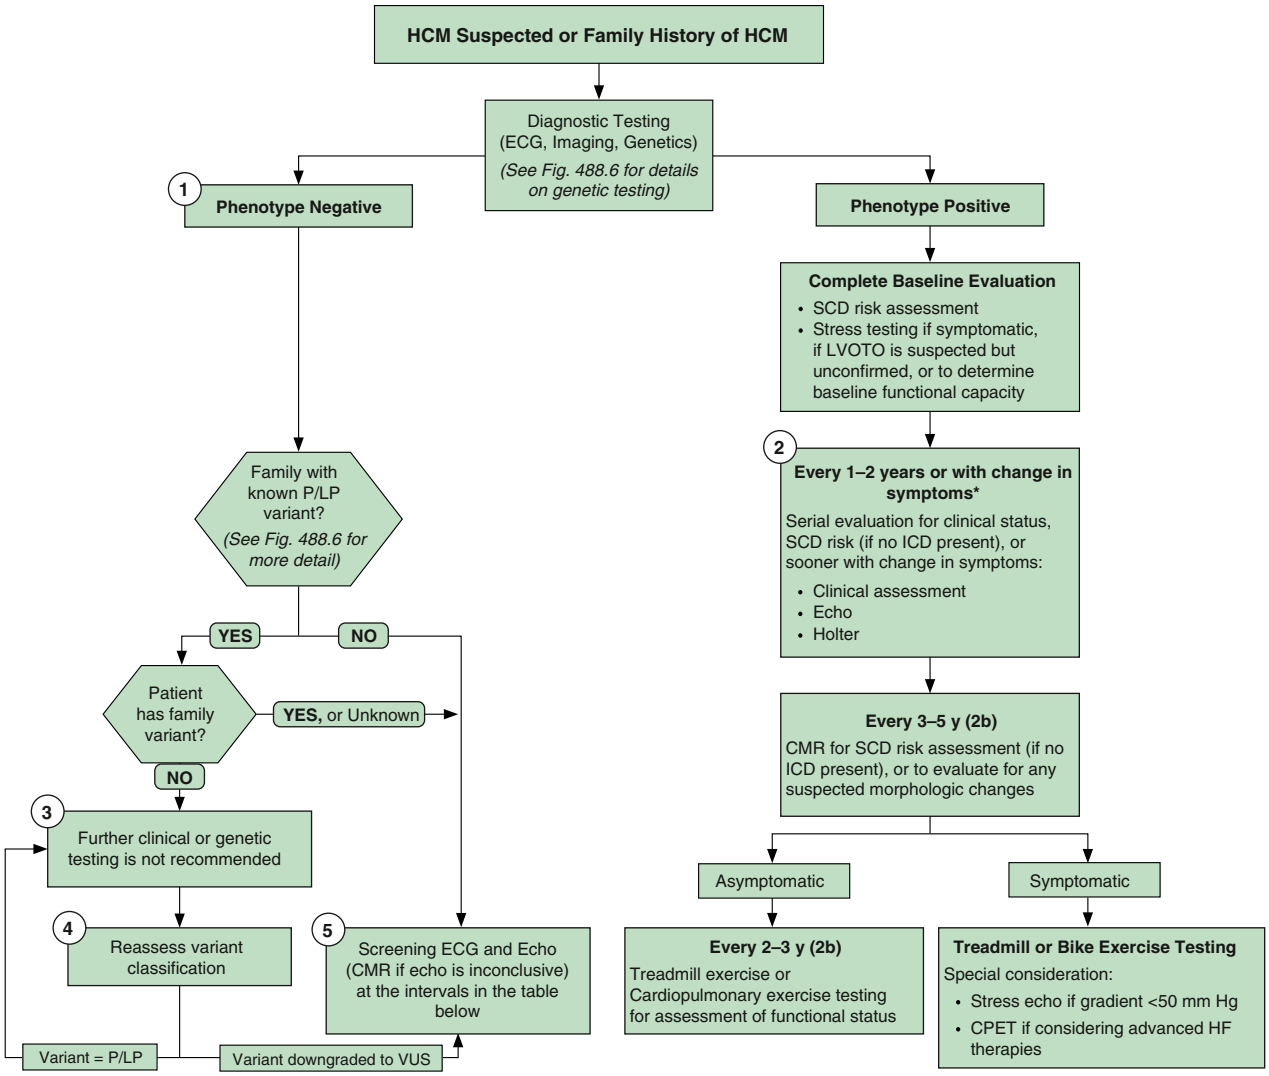
Cardiac catheterization is rarely used in the diagnosis of HCM but may be helpful if there is concern for a **myocardial bridge** (when a coronary artery runs through vs on top of the myocardium) that may be causing intermittent coronary insufficiency during dynamic obstruction. Myocardial bridges can be seen on coronary angiography. Additionally, cardiac catheterization may occasionally be used to better define hemodynamics in patients.

Additional diagnostic studies include metabolic testing, genetic testing for specific syndromes, or genetic testing for pathogenic variants in genes known to cause isolated HCM (see Table 488.3). Clinical genetic testing panels continue to expand. Genetic diagnosis is also useful in identifying at-risk family members who require ongoing surveillance (Figs. 488.5 and 488.6).

PROGNOSIS AND MANAGEMENT

Children <1 year of age or with inborn errors of metabolism or malformation syndromes or those with a mixed HCM/DCM have a significantly poorer prognosis. The risk of sudden death in older patients is greater in those with a personal or family history of cardiac arrest, ventricular tachycardia, exercise hypotension, syncope, or excessive (>3 cm) ventricular wall thickness. Although intrafamilial variability in symptoms occurs, a family history of sudden death is a highly significant predictor of risk. Restriction from competitive sports and strenuous physical activity is highly recommended, and additional recreational exercise activities should be tailored to each individual based on their overall clinical status. β-Adrenergic blocking agents (propranolol, atenolol, metoprolol) or calcium channel blockers (verapamil) may be useful in diminishing LVOT obstruction, modifying LV hypertrophy, and improving ventricular filling. They also confer an antiarrhythmic benefit and may reduce symptoms. In patients with atrial or ventricular arrhythmias, specific antiarrhythmic therapy should be used. Patients with documented, previously aborted sudden cardiac arrest, strong family histories of sudden death, ventricular wall end-diastolic dimensions of ≥3 cm, unexplained syncope, nonsustained ventricular tachycardia, apical aneurysm, ejection fraction ≤50%, or blunted or hypotensive blood pressure response to exercise should be considered for treatment with an **implantable cardioverter-defibrillator** (ICD). Early identification of HCM, family screening/surveillance, appropriate activity restriction, and use of ICDs have greatly reduced the mortality of HCM to approximately 0.5% per year in the modern era.

Innovative interventional procedures have been used to reduce the degree of LVOT obstruction anatomically or physiologically. Dual-chamber pacing, alcohol septal ablation, surgical septal



Screening Asymptomatic First-Degree Relatives of Patients With HCM		
Age of First-Degree Relative	**Initiation of Screening**	**Surveillance Interval**
Children and adolescents from genotype-positive family and/or family with early onset HCM	At the time of diagnosis in another family member	Every 1–2 y
All other children and adolescents	At any time after the diagnosis in the family, but no later than puberty	Every 2–3 y
Adults	At the time of diagnosis in another family member	Every 3–5 y

Fig. 488.5 Algorithm for recommended evaluation and testing modified for HCM. *The interval may be extended, particularly in adult patients who remain stable after multiple evaluations. CMR, Cardiovascular magnetic resonance; CPET, cardiopulmonary exercise test; ECG, electrocardiography/electrocardiogram; HCM, hypertrophic cardiomyopathy; HF, heart failure; ICD, implantable cardioverter-defibrillator; LVOTO, left ventricular outflow tract obstruction; P/LP, pathogenic or likely pathogenic variant; SCD, sudden cardiac death; VUS, variant of unknown significance. *(Modified from Ommen SR, Mital S, Burke MA, et al. 2020 AHA/ACC guideline for the diagnosis and treatment of patients with hypertrophic cardiomyopathy: executive summary. J Amer Coll Cardiol. 2020;142:e533–e557, Fig. 1.)*

myomectomy, and mitral valve replacement have all met with some success but are typically reserved for patients with significant symptoms despite medical therapy (Fig. 488.7). Mavacamten, a selective myosin inhibitor, has been an effective therapy in adults. Enzyme replacement therapy for Pompe disease is an effective therapy after birth (see Chapter 107.1). Preliminary trials of in utero enzyme replacement therapy for Pompe disease have also demonstrated efficacy.

First-degree relatives of patients identified as having HCM should be screened with ECG and echocardiogram. Genetic testing is available clinically and is of high utility. It is important first to test the affected individual in the family rather than "at-risk" individuals, because 20–50% of cases of HCM will not demonstrate pathogenic variants in currently available panels of genes. If a causative genetic variant is identified, at-risk members of the family can be effectively tested. In families with HCM without demonstrable pathogenic variants, repeat noninvasive cardiac screening with ECG and echocardiogram should be undertaken in at-risk individuals yearly until young adulthood (age 21 years) and then every 3 years if no prior evidence of HCM is present. Gene-positive but phenotype-negative pediatric patients may remain asymptomatic during childhood but require careful and frequent follow-up.

488.3 Restrictive Cardiomyopathy

John J. Parent and Stephanie M. Ware

Restrictive cardiomyopathy **(RCM)** accounts for <5% of cardiomyopathy cases. Incidence increases with age and is more common in females. In equatorial Africa, RCM accounts for a large number of deaths. Infiltrative myocardial causes and storage disorders frequently result in associated LV hypertrophy and may represent HCM with restrictive physiology. Noninfiltrative causes include pathogenic variants in genes encoding sarcomeric or cytoskeletal proteins. Although there has been significant success in discovering pathogenic gene variants causing RCM, the majority of cases are considered idiopathic. Potential etiologies include sarcoidosis and Gaucher, Hurler, or Fabry diseases.

PATHOGENESIS

RCM is characterized by normal ventricular chamber dimensions, normal myocardial wall thickness, and preserved systolic function. Dramatic atrial dilation can result from the abnormal ventricular myocardial compliance and high ventricular diastolic pressure. Autosomal dominant inheritance has been demonstrated for families with pathogenic gene variants in sarcomeric and cytoskeletal genes.

CLINICAL MANIFESTATIONS

Abnormal ventricular filling, sometimes referred to as *diastolic heart failure,* is manifest in the systemic venous circulation with edema, hepatomegaly, or ascites. Elevation of left-sided filling pressures results in cough, dyspnea, or pulmonary edema. With activity, patients may experience chest pain, shortness of breath, syncope/near-syncope, or even sudden death. Pulmonary hypertension and pulmonary vascular disease develop and may progress rapidly. Heart murmurs are typically absent, but a gallop rhythm may be prominent. In the presence of pulmonary hypertension, an overactive RV impulse and pronounced pulmonary component of the second heart sound (S_2) are present in RCM.

DIAGNOSIS

The characteristic electrocardiographic finding of prominent P waves (reflective of atrial enlargement) is usually associated with normal QRS voltages and nonspecific ST and T-wave changes. RV hypertrophy occurs in patients with pulmonary hypertension. The chest radiograph may be normal or may demonstrate a prominent atrial shadow and pulmonary vascular redistribution. The echocardiogram is often diagnostic, demonstrating normal-sized ventricles with preserved systolic function and dramatic enlargement of the atria (see Fig. 488.4). Flow and tissue Doppler interrogation reveal abnormal filling parameters. It is critical to differentiate RCM from **constrictive pericarditis**, which can be treated surgically (see Chapter 489.2). MRI may be necessary to demonstrate the thickened or calcified pericardium often present in constrictive pericardial disease.

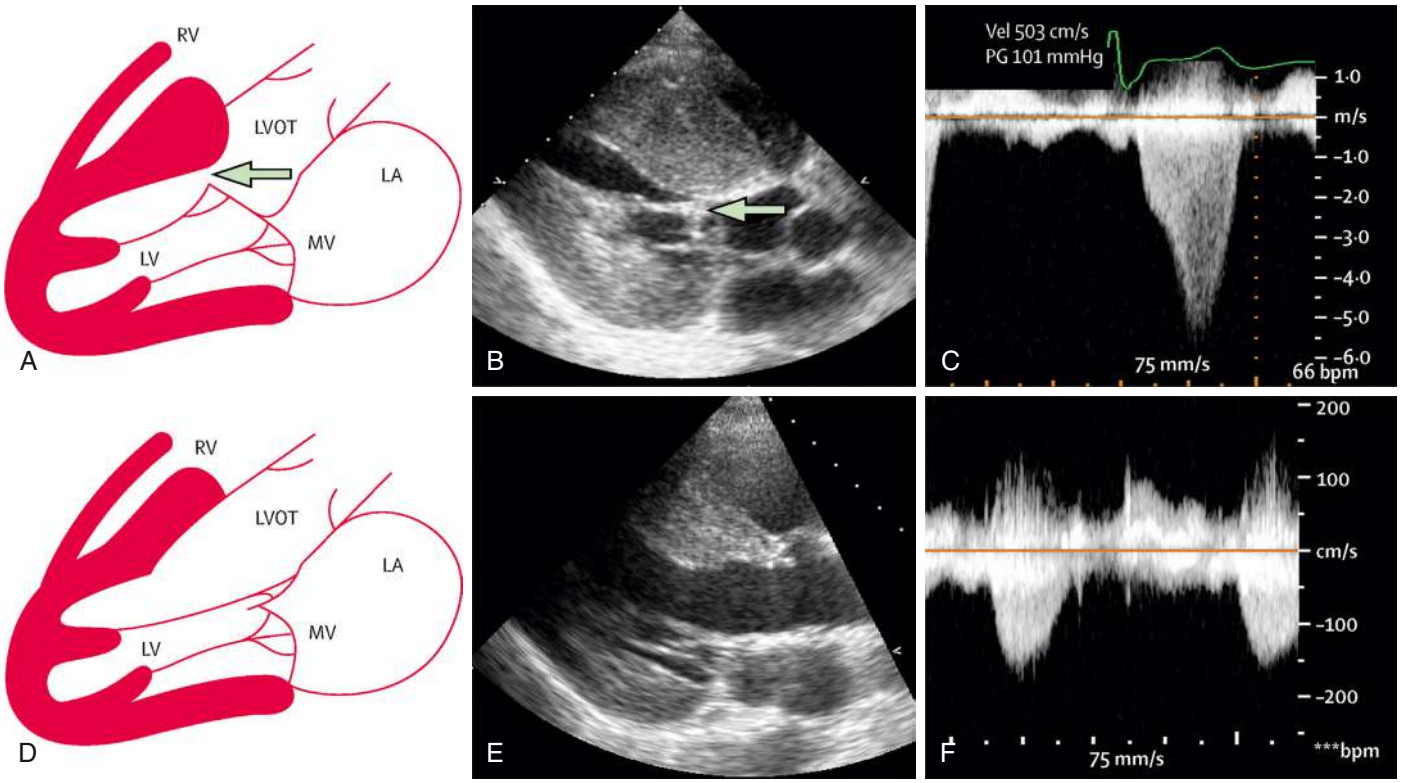

Fig. 488.7 Scheme of septal reduction therapy. **A,** Left ventricular outflow tract (LVOT) obstruction *(arrow)* created by hypertrophied basal septum and systolic anterior motion. **B,** Transthoracic echocardiography with systolic anterior motion *(arrow)*. **C,** Continuous-wave Doppler imaging of dynamic LVOT obstruction. **D,** Schematic finding after septal reduction. **E,** Transthoracic echocardiography after septal reduction procedure. **F,** Absence of LVOT obstruction in continuous-wave Doppler imaging after septal reduction therapy. LA, Left atrium; LV, left ventricle; MV, mitral valve; RV, right ventricle. *(From Veselka J, Anavekar NS, Charron P. Hypertrophic obstructive cardiomyopathy. Lancet. 2017;389:1253–1264, Fig. 5, p. 1259.)*

PROGNOSIS AND MANAGEMENT

Pharmacologic modalities are of limited use, and the prognosis of patients with RCM is generally poor, with often progressive clinical deterioration. Sudden death is a significant risk, with a 2-year survival of 50%. When signs of heart failure exist, judicious use of diuretics can result in clinical improvement. As a result of the dramatic atrial enlargement and ventricular scarring, these patients are predisposed to the development of atrial tachyarrhythmias, complete heart block, and thromboemboli. Antiarrhythmic agents may be necessary, and anticoagulation with platelet inhibitors or warfarin (Coumadin) is indicated.

Cardiac transplantation is the treatment of choice in many centers for patients with RCM, and the results are excellent in patients without pulmonary hypertension, pulmonary vascular disease, or severe congestive heart failure. Some patients may need bridging to transplant with a VAD if they have elevated pulmonary pressures or significant heart failure.

488.4 Left Ventricular Noncompaction, Arrhythmogenic Right Ventricular Cardiomyopathy, Endocardial Fibroelastosis, and Takotsubo Cardiomyopathy

John J. Parent and Stephanie M. Ware

Left ventricular noncompaction (LVNC) is characterized by a distinctive trabeculated or spongy-appearing left ventricle commonly associated with LV dysfunction and/or dilation and at times hypertrophy, diastolic dysfunction, and arrhythmias (Fig. 488.8). LVNC may be isolated or associated with structural congenital cardiac defects. Patients may present with signs of heart failure, arrhythmias, syncope, sudden death, or as an asymptomatic finding during screening of family members.

Imaging studies using ultrasound or MRI can demonstrate the characteristic pattern of deeply trabeculated LV myocardium, most characteristically within the apex. ECG findings are nonspecific and include chamber hypertrophy, ST and T-wave changes, or arrhythmias. In some patients, preexcitation is notable, and giant QRS voltages occur in approximately 30% of younger children. Metabolic screening should be considered, especially in young children. Elevated serum lactate and urine 3-methylglutaconic acid may be seen in **Barth syndrome**, an X-linked disorder of phospholipid metabolism caused by a pathogenic variant in the *TAZ* gene. Clinical testing for *TAZ* variants is available and should be considered, especially in males. Patients with mitochondrial disorders frequently demonstrate signs of LVNC. These children are at risk for atrial or ventricular arrhythmias and thromboembolic complications. Treatment includes anticoagulation, antiarrhythmic therapy if needed, and treatment of heart failure if present. In patients refractory to medical therapy, cardiac transplantation has been used successfully.

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is relatively uncommon in North America compared with the high prevalence in Europe, especially Italy (see Chapter 484.4). Autosomal dominant inheritance is common. In addition, recessive forms associated with severe ARVC and skin manifestations are known. Comprehensive genetic screening has been reported to identify a cause in up to 50% of cases. ARVC is typically characterized by a dilated right ventricle with fibrofatty infiltration of the RV wall; increasingly, LV involvement is being recognized. Global and regional RV and LV dysfunction and ventricular tachyarrhythmias are the major clinical findings. Syncope or aborted sudden death can occur and should be treated with antiarrhythmic medications and placement of an ICD. In patients with ventricular dysfunction, heart failure management as indicated for patients with DCM may be of use.

Endocardial fibroelastosis (EFE), once an important cause of heart failure in children, is uncommon. The decline in primary EFE is likely related to the abolition of mumps virus infections by immunization practices. Rare familial cases exist, but the causative genes are unknown. Secondary EFE can occur with severe left-sided obstructive lesions such as aortic stenosis or atresia, hypoplastic left heart

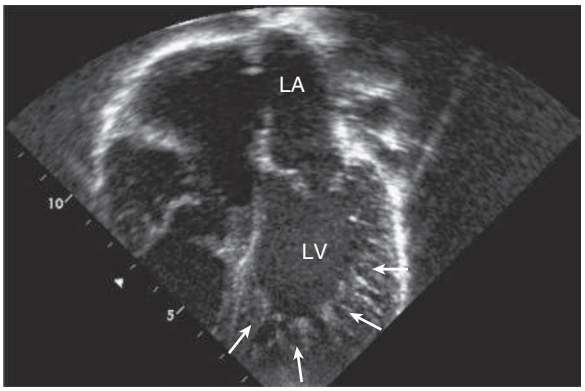

Fig. 488.8 Echocardiogram of a patient with left ventricular noncompaction cardiomyopathy. Apical view showing abnormal trabeculations of left ventricle at the apex *(arrows)*. For comparison, see the smooth-walled LV in Figure 488.2. LA, Left atrium; LV, left ventricle.

syndrome, or coarctation of the aorta. EFE is characterized by an opaque, white, fibroelastic thickening on the endocardial surface of the ventricle, which leads to systolic and/or diastolic dysfunction. Surgical removal of the endocardial fibrosis has been successfully done to improve cardiac function. Standard heart failure management, including transplantation, has been used in the management of EFE.

Takotsubo cardiomyopathy is a reversible stress-induced syndrome associated with transient systolic and diastolic dysfunction and regional ventricular wall motion abnormalities characterized by ventricular apical ballooning. Physical or emotional stress and associated etiologies (see Table 488.2) precipitate transient episodes of chest pain or heart failure. Treatment includes that for heart failure (β blockers, ACE inhibitors, diuretics) and addressing the precipitating event (thyrotoxicosis, pheochromocytoma, drug ingestion).

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

488.5 Myocarditis

John J. Parent and Stephanie M. Ware

Acute or chronic inflammation of the myocardium is characterized by inflammatory cell infiltrates, myocyte necrosis, or myocyte degeneration and may be caused by infectious, connective tissue, granulomatous, toxic, immune, or idiopathic processes. There may be associated systemic manifestations of the disease, and occasionally the endocardium or pericardium is involved. Patients may be asymptomatic, have nonspecific prodromal symptoms, or present with overt congestive heart failure, compromising arrhythmias, or sudden death. It is assumed that viral infections are the most common etiology, although myocardial toxins, drug exposures, hypersensitivity reactions, and immune disorders may also lead to myocarditis (Table 488.7).

ETIOLOGY AND EPIDEMIOLOGY

Viral Infections

Coxsackievirus and other enteroviruses, adenovirus, parvovirus B19, Epstein-Barr virus, parechovirus, influenza virus, and cytomegalovirus are the most common causative agents in children. COVID-19 infections, particularly during multisystem inflammatory syndrome in children (MIS-C) and, rarely, after mRNA COVID-19 vaccinations, have been associated with myocarditis. In Asia, hepatitis C virus appears to be significant as well. The true incidence of viral myocarditis is unknown because mild cases probably go undetected. The disease is typically sporadic but may be epidemic. Manifestations are, to some degree, age dependent: in neonates and young infants, viral myocarditis can be fulminant; in children, it often occurs as an acute, myopericarditis with heart failure; and in older children and adolescents, it may present with signs and symptoms of acute or chronic heart failure or chest pain.

Table 488.7 Etiology of Myocarditis

INFECTIOUS CAUSES
Viral: adenoviruses, echoviruses, enteroviruses (e.g., coxsackieviruses), herpesviruses (human cytomegalovirus, Epstein-Barr virus, human herpesvirus 6), hepatitis C virus, human immunodeficiency virus, influenza virus, parvovirus B19, SARS-CoV-2 (COVID-19) disease and vaccine, smallpox vaccine
Bacterial: *Borrelia burgdorferi* (Lyme disease), *Chlamydia, Corynebacterium diphtheriae, Legionella, Mycobacterium tuberculosis, Mycoplasma, Staphylococcus,* streptococcus A, *Streptococcus pneumoniae,* Whipple disease
Fungal: *Actinomyces, Aspergillus, Candida, Cryptococcus*
Helminthic: *Echinococcus granulosus, Trichinella spiralis*
Protozoal: *Toxoplasma gondii, Trypanosoma cruzi*
Rickettsial: *Coxiella burnetii, Rickettsia typhi*
Spirochetal: *Borrelia burgdorferi, Leptospira, Treponema pallidum*
AUTOIMMUNE DISEASES
Rheumatic fever, celiac disease, Churg-Strauss syndrome, Crohn disease, dermatomyositis, giant cell myocarditis, hypereosinophilic syndrome, Kawasaki disease, lupus erythematosus, lymphofollicular myocarditis, rheumatoid arthritis, sarcoidosis, scleroderma, ulcerative colitis
HYPERSENSITIVITY REACTIONS
Penicillin, ampicillin, cephalosporins, tetracyclines, sulfonamides, antiphlogistics, benzodiazepines, clozapine, loop and thiazide diuretics, methyldopa, smallpox vaccine, tetanus toxoid, tricyclic antidepressants
TOXIC REACTIONS TO DRUGS
Amphetamines, anthracyclines, catecholamines, cocaine, cyclophosphamide, 5-fluorouracil, phenytoin, trastuzumab, immune checkpoint inhibitors
TOXIC
Ethanol, snakebite, scorpion bite, electric shock, spider bite
OTHER CAUSES
Arsenic, copper, iron, radiotherapy, thyrotoxicosis, immune modulation

Adapted from Canter CE, Simpson KE. Diagnosis and treatment of myocarditis in children in the current era. *Circulation.* 2014;129:115–128, Table 1.

Bacterial Infections

Bacterial myocarditis has become much less common with the advent of advanced public health measures, which have minimized infectious causes such as diphtheria. Diphtheritic myocarditis is unique because bacterial toxin may produce circulatory collapse and toxic myocarditis characterized by atrioventricular block, bundle branch block, or ventricular ectopy (see Chapter 233). Lyme disease may present as myocarditis; rheumatic fever (poststreptococcal) may also manifest with valve, myocardium, and pericardium involvement. Any overwhelming systemic bacterial infection can manifest with circulatory collapse and shock with evidence of myocardial dysfunction, characterized by tachycardia, gallop rhythm, and low cardiac output. Additional nonviral infectious causes of myocarditis include rickettsiae, protozoa, parasitic infections, and fungal disease.

PATHOPHYSIOLOGY

Myocarditis is characterized by myocardial inflammation, injury or necrosis, and ultimately fibrosis. Cardiac enlargement and diminished systolic function are a direct result of the myocardial damage. Typical signs of congestive heart failure occur and may progress rapidly to shock, atrial or ventricular arrhythmias, and sudden death. Viral myocarditis may also become a chronic process, with persistence of viral nucleic acid in the myocardium and the perpetuation of chronic inflammation secondary to altered host immune response, including activated T lymphocytes (cytotoxic and natural killer cells) and antibody-dependent cell-mediated damage. Additionally, persistent viral infection may alter the expression of major histocompatibility complex (MHC) antigens with resultant exposure of neoantigens to the immune system. Some viral proteins share antigenic epitopes with host cells, resulting in autoimmune damage to the antigenically related myocyte. Cytokines such as tumor necrosis factor-α and interleukin-1 are inhibitors of myocyte response to adrenergic stimuli and result in diminished cardiac function. The final result of viral-associated inflammation can be DCM.

CLINICAL MANIFESTATIONS

Manifestations of myocarditis range from asymptomatic or nonspecific generalized illness to acute cardiogenic shock and sudden death. Infants and young children more often have a fulminant presentation with fever, respiratory distress, tachycardia, hypotension, gallop rhythm, and cardiac murmur. Associated findings may include a rash or evidence of end-organ involvement such as hepatitis or aseptic meningitis.

Patients with acute or chronic myocarditis may present with chest discomfort, fever, palpitations, easy fatigability, or syncope/near-syncope. Cardiac findings include overactive precordial impulse, gallop rhythm, and apical systolic murmur of mitral insufficiency. In patients with associated pericardial disease, a rub may be noted. Hepatic enlargement, peripheral edema, and pulmonary findings such as wheezes or rales may be present in patients with decompensated heart failure.

DIAGNOSIS

Electrocardiographic changes are nonspecific and may include sinus tachycardia, atrial or ventricular arrhythmias, heart block, diminished QRS voltages, and nonspecific ST and T-wave changes, often suggestive of acute ischemia. Chest radiographs in severe, symptomatic cases reveal cardiomegaly, pulmonary vascular prominence, overt pulmonary edema, or pleural effusions. Echocardiography often shows diminished ventricular systolic function, cardiac chamber enlargement, mitral insufficiency, and occasionally, evidence of pericardial infusion.

Cardiac MRI is a standard imaging modality for the diagnosis of myocarditis; information on the presence and extent of edema, gadolinium-enhanced hyperemic capillary leak, myocyte necrosis, LV dysfunction, and evidence of an associated pericardial effusion assist in the cardiac MRI diagnosis of myocarditis (Table 488.8 and Fig. 488.9).

Endomyocardial biopsy may be useful in identifying inflammatory cell infiltrates or myocyte damage and performing molecular viral analysis using polymerase chain reaction techniques. Catheterization and biopsy, although not without risk (perforation and arrhythmias), should be performed by experienced personnel in patients suspected to have myocarditis or if unusual forms of cardiomyopathy are strongly suspected, such as storage diseases or mitochondrial defects. Nonspecific tests include erythrocyte sedimentation rate, CPK isoenzymes, cardiac troponin I, and BNP levels. A novel microRNA derived from type 17 helper (Th17) cells may be another useful specific test for viral myocarditis.

DIFFERENTIAL DIAGNOSIS

The predominant diseases mimicking acute myocarditis include carnitine deficiency, other metabolic disorders of energy generation, hereditary mitochondrial defects, idiopathic DCM, pericarditis, EFE, and anomalies of the coronary arteries (see Table 488.2).

TREATMENT

Primary therapy for acute myocarditis is supportive. Acutely, the use of inotropic agents, preferably milrinone, should be considered but used with caution because of their proarrhythmic potential. Diuretics are often required as well. If in extremis, mechanical ventilatory support and mechanical circulatory support with VAD implantation or ECMO may be needed to stabilize the patient's hemodynamic status and serve as a bridge to recovery or cardiac transplantation. Diuretics, β blockers, ACE inhibitors, and ARBs are of use in patients with compensated congestive heart failure in the outpatient setting but may be contraindicated in those presenting with fulminant heart failure and cardiovascular collapse. In patients manifesting with significant atrial or ventricular arrhythmias, specific antiarrhythmic agents (e.g., amiodarone) should be administered and ICD placement considered if persistent after a period of recovery is observed.

Table 488.8 MRI Findings Suggestive of Myocarditis

- T2-weighted edema (global or regional)
- Regional hyperemia/capillary leak by early gadolinium enhancement ratio (EGEr)
- Myocardial fibrosis or necrosis on late gadolinium enhancement (LGE)
- Features often present in a midmyocardial, subepicardial, and nonvascular distribution
- Repeat MRI if no *early* MRI evidence present but clinical manifestation suggests myocarditis

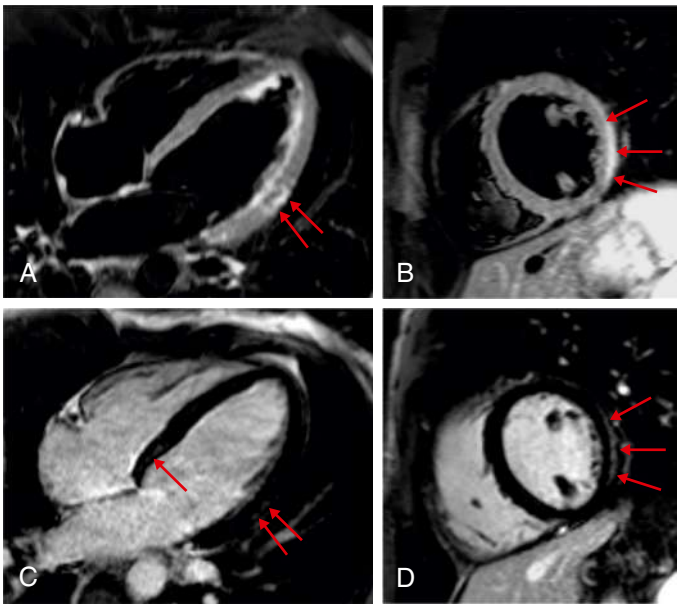

Fig. 488.9 MRI findings in patients with myocarditis. Cardiac MR images of a young patient presenting with acute chest pain syndrome caused by acute myocarditis. (**A**) Long-axis and (**B**) short-axis T2-weighted images demonstrating focal myocardial edema in subepicardium of left midventricular lateral wall *(red arrows)*. Corresponding (**C**) long-axis and (**D**) short-axis T1-weighted images demonstrate the presence of typical late gadolinium enhancement in subepicardium of left midventricular lateral wall and basal septum *(red arrows)*. *(From Kindermann I, Barth C, Mahfoud F, et al. Update on myocarditis. J Am Coll Cardiol. 2012;59:779–792, Fig. 3, p. 783.)*

Immunomodulation of patients with myocarditis is controversial. Intravenous immunoglobulin (IVIG) may have a role in the treatment of acute or fulminant myocarditis, and corticosteroids have been reported to improve cardiac function, but this remains controversial in children. Relapse has been noted in patients receiving immunosuppression who were weaned from therapy. There are no studies to recommend specific antiviral therapies for myocarditis.

If there is an identifiable and treatable condition, its specific therapy should be employed. If a medication is the etiology, it should be withdrawn and an alternative drug added if needed.

PROGNOSIS

The prognosis of symptomatic acute enteroviral myocarditis in newborns is poor, with a 75% mortality. The prognosis is better for children and adolescents, although patients who have persistent evidence of DCM often progress to the need for cardiac transplantation; recovery of ventricular function, however, has been reported in 10–50% of patients.

The prognosis for COVID-19 immunization–associated myocarditis is excellent with full recovery noted by 90 days. Patients with COVID-19 requiring intensive care unit (ICU) admission and those with MIS-C must be followed by a pediatric cardiologist (including follow-up echocardiography) and refrain from exercise for 3-6 months. Return to full activity requires clearance from a cardiologist.

Chapter 489
Diseases of the Pericardium

John J. Parent and Stephanie M. Ware

The heart is enveloped in a bilayer membrane, the *pericardium,* which normally contains a small amount of serous fluid. The pericardium is not vital to normal function of the heart, and primary diseases of the pericardium are uncommon. However, the pericardium may be affected by a variety of

CLINICAL MANIFESTATIONS

Manifestations of myocarditis range from asymptomatic or nonspecific generalized illness to acute cardiogenic shock and sudden death. Infants and young children more often have a fulminant presentation with fever, respiratory distress, tachycardia, hypotension, gallop rhythm, and cardiac murmur. Associated findings may include a rash or evidence of end-organ involvement such as hepatitis or aseptic meningitis.

Patients with acute or chronic myocarditis may present with chest discomfort, fever, palpitations, easy fatigability, or syncope/near-syncope. Cardiac findings include overactive precordial impulse, gallop rhythm, and apical systolic murmur of mitral insufficiency. In patients with associated pericardial disease, a rub may be noted. Hepatic enlargement, peripheral edema, and pulmonary findings such as wheezes or rales may be present in patients with decompensated heart failure.

DIAGNOSIS

Electrocardiographic changes are nonspecific and may include sinus tachycardia, atrial or ventricular arrhythmias, heart block, diminished QRS voltages, and nonspecific ST and T-wave changes, often suggestive of acute ischemia. Chest radiographs in severe, symptomatic cases reveal cardiomegaly, pulmonary vascular prominence, overt pulmonary edema, or pleural effusions. Echocardiography often shows diminished ventricular systolic function, cardiac chamber enlargement, mitral insufficiency, and occasionally, evidence of pericardial infusion.

Cardiac MRI is a standard imaging modality for the diagnosis of myocarditis; information on the presence and extent of edema, gadolinium-enhanced hyperemic capillary leak, myocyte necrosis, LV dysfunction, and evidence of an associated pericardial effusion assist in the cardiac MRI diagnosis of myocarditis (Table 488.8 and Fig. 488.9).

Endomyocardial biopsy may be useful in identifying inflammatory cell infiltrates or myocyte damage and performing molecular viral analysis using polymerase chain reaction techniques. Catheterization and biopsy, although not without risk (perforation and arrhythmias), should be performed by experienced personnel in patients suspected to have myocarditis or if unusual forms of cardiomyopathy are strongly suspected, such as storage diseases or mitochondrial defects. Nonspecific tests include erythrocyte sedimentation rate, CPK isoenzymes, cardiac troponin I, and BNP levels. A novel microRNA derived from type 17 helper (Th17) cells may be another useful specific test for viral myocarditis.

DIFFERENTIAL DIAGNOSIS

The predominant diseases mimicking acute myocarditis include carnitine deficiency, other metabolic disorders of energy generation, hereditary mitochondrial defects, idiopathic DCM, pericarditis, EFE, and anomalies of the coronary arteries (see Table 488.2).

TREATMENT

Primary therapy for acute myocarditis is supportive. Acutely, the use of inotropic agents, preferably milrinone, should be considered but used with caution because of their proarrhythmic potential. Diuretics are often required as well. If in extremis, mechanical ventilatory support and mechanical circulatory support with VAD implantation or ECMO may be needed to stabilize the patient's hemodynamic status and serve as a bridge to recovery or cardiac transplantation. Diuretics, β blockers, ACE inhibitors, and ARBs are of use in patients with compensated congestive heart failure in the outpatient setting but may be contraindicated in those presenting with fulminant heart failure and cardiovascular collapse. In patients manifesting with significant atrial or ventricular arrhythmias, specific antiarrhythmic agents (e.g., amiodarone) should be administered and ICD placement considered if persistent after a period of recovery is observed.

Table 488.8 MRI Findings Suggestive of Myocarditis

- T2-weighted edema (global or regional)
- Regional hyperemia/capillary leak by early gadolinium enhancement ratio (EGEr)
- Myocardial fibrosis or necrosis on late gadolinium enhancement (LGE)
- Features often present in a midmyocardial, subepicardial, and nonvascular distribution
- Repeat MRI if no *early* MRI evidence present but clinical manifestation suggests myocarditis

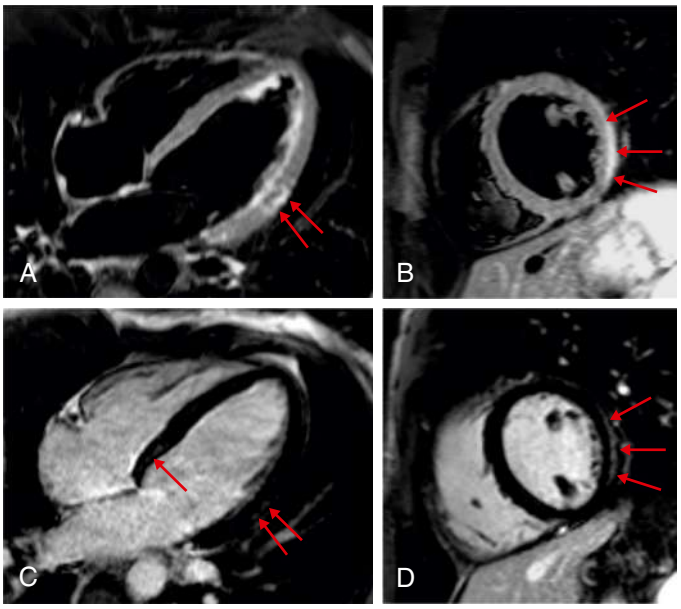

Fig. 488.9 MRI findings in patients with myocarditis. Cardiac MR images of a young patient presenting with acute chest pain syndrome caused by acute myocarditis. (**A**) Long-axis and (**B**) short-axis T2-weighted images demonstrating focal myocardial edema in subepicardium of left midventricular lateral wall *(red arrows)*. Corresponding (**C**) long-axis and (**D**) short-axis T1-weighted images demonstrate the presence of typical late gadolinium enhancement in subepicardium of left midventricular lateral wall and basal septum *(red arrows)*. *(From Kindermann I, Barth C, Mahfoud F, et al. Update on myocarditis. J Am Coll Cardiol. 2012;59:779–792, Fig. 3, p. 783.)*

Immunomodulation of patients with myocarditis is controversial. Intravenous immunoglobulin (IVIG) may have a role in the treatment of acute or fulminant myocarditis, and corticosteroids have been reported to improve cardiac function, but this remains controversial in children. Relapse has been noted in patients receiving immunosuppression who were weaned from therapy. There are no studies to recommend specific antiviral therapies for myocarditis.

If there is an identifiable and treatable condition, its specific therapy should be employed. If a medication is the etiology, it should be withdrawn and an alternative drug added if needed.

PROGNOSIS

The prognosis of symptomatic acute enteroviral myocarditis in newborns is poor, with a 75% mortality. The prognosis is better for children and adolescents, although patients who have persistent evidence of DCM often progress to the need for cardiac transplantation; recovery of ventricular function, however, has been reported in 10–50% of patients.

The prognosis for COVID-19 immunization–associated myocarditis is excellent with full recovery noted by 90 days. Patients with COVID-19 requiring intensive care unit (ICU) admission and those with MIS-C must be followed by a pediatric cardiologist (including follow-up echocardiography) and refrain from exercise for 3-6 months. Return to full activity requires clearance from a cardiologist.

Chapter 489
Diseases of the Pericardium

John J. Parent and Stephanie M. Ware

The heart is enveloped in a bilayer membrane, the *pericardium,* which normally contains a small amount of serous fluid. The pericardium is not vital to normal function of the heart, and primary diseases of the pericardium are uncommon. However, the pericardium may be affected by a variety of

conditions, often as a manifestation of a systemic illness, and can result in serious, even life-threatening, cardiac compromise (Table 489.1).

489.1 Acute Pericarditis

John J. Parent and Stephanie M. Ware

Inflammation of the pericardium may have only minor pathophysiologic consequences in the absence of significant fluid accumulation in the pericardial space. When the amount of fluid in the nondistensible pericardial space becomes excessive, pressure within the pericardium increases and is transmitted to the heart, resulting in impaired filling by compressing the chambers (atria or ventricles). Although small to moderate amounts of **pericardial effusion** can be well tolerated and clinically silent, once the noncompliant pericardium has been distended maximally, any further fluid accumulation causes abrupt impairment of cardiac filling, and this can impair cardiac output and is termed **cardiac tamponade**. When untreated, tamponade can lead to shock and death. Pericardial effusions may be serous/transudative, exudative/purulent, fibrinous, or hemorrhagic.

Pericarditis may present without an obvious pericardial effusion on echocardiography. In addition, pericarditis may be associated with myocarditis (**myopericarditis**), in which case either pericarditis or myocarditis may be the dominant finding.

CLINICAL MANIFESTATIONS

The most common symptom of acute pericarditis is chest pain, typically described as sharp/stabbing, positional, radiating, worse with inspiration, and relieved by sitting upright, leaning forward, or prone. Cough, fever, dyspnea, abdominal pain, and vomiting are nonspecific symptoms associated with pericarditis. Additionally, signs and symptoms of organ system involvement may occur in the presence of generalized systemic disease.

Muffled or distant heart sounds, tachycardia, narrow pulse pressure, jugular venous distention, and a pericardial friction rub provide clues to the diagnosis of acute pericarditis. Cardiac tamponade is recognized by the excessive fall of systolic blood pressure (>10 mm Hg) with inspiration. This pulsus paradoxus can be assessed by careful auscultatory blood pressure determination (automated blood pressure cuffs are inadequate), arterial pressure line waveform, or pulse oximeter tracing inspection. Doppler assessment during echocardiography can also indirectly suggest pulsus paradoxus is present. Conditions other than cardiac tamponade that may result in pulsus paradoxus include severe dyspnea, obesity, and positive pressure ventilator support.

Table 489.1 Etiology of Pericardial Disease

CONGENITAL
Absence (partial, complete)
Cysts
Mulibrey nanism (*TRIM 37* gene variant)
Camptodactyly-arthropathy–coxa vara–pericarditis syndrome (*PRG4* gene variant)
Myhre syndrome (*SMAD4* gene variant)
INFECTIOUS
Viral: coxsackievirus B, Epstein-Barr virus, influenza, adenovirus, parvovirus, HIV, mumps, COVID-19, and mRNA COVID-19 and HPV vaccines
Bacterial: *Haemophilus influenzae,* streptococcus, pneumococcus, staphylococcus, meningococcus, mycoplasma, tularemia, *Listeria,* leptospirosis, tuberculosis, Q fever, salmonella
Immune complex mediated: meningococcus, *H. influenzae*
Fungal: actinomycosis, histoplasmosis
Parasitic: toxoplasmosis, echinococcosis
NONINFECTIOUS
Idiopathic
Systemic inflammatory diseases: acute rheumatic fever, juvenile idiopathic arthritis, systemic lupus erythematosus, mixed connective tissue disorders, systemic sclerosis, Kawasaki disease, eosinophilic granulomatosis with polyangiitis, Behçet syndrome, sarcoidosis, familial Mediterranean fever and other recurrent fever syndromes, pancreatitis, granulomatosis with polyangiitis
Metabolic: uremia, hypothyroidism, Gaucher disease, very-long-chain acyl-CoA dehydrogenase deficiency
Traumatic: surgical, catheter perforation, blunt trauma
Postpericardiotomy syndrome
Oncologic: lymphomas, leukemia, radiation therapy, primary pericardial tumors

DIAGNOSIS

The electrocardiogram is often abnormal in acute pericarditis, although the findings are nonspecific. Low-voltage QRS amplitude may be seen as a result of pericardial fluid accumulation. Tachycardia and abnormalities of the ST segments (diffuse ST segment elevation), PR segments, and T waves (inversion or flattening) may be present as well. Elevated troponin levels may be present in myopericarditis.

Although the chest x-ray findings in a patient with pericarditis without effusion are usually normal in the presence of a significant effusion, cardiac enlargement will be seen and the cardiac contour may be unusual (Erlenmeyer flask or water bottle appearance) (Fig. 489.1). Echocardiography is the most sensitive technique for identifying the size and location of a pericardial effusion. Compression and collapse of the right atrium and/or right ventricle are present with cardiac tamponade (Fig. 489.2). Abnormal diastolic filling parameters have also been described in cases of tamponade. Advanced imaging modalities like computed tomography or cardiac magnetic resonance imaging are useful for diagnosis in unclear cases (Fig. 489.3).

DIFFERENTIAL DIAGNOSIS

Chest pain similar to that present in pericarditis can occur with lung diseases, especially pleuritis, and with gastroesophageal reflux or costochondritis, with the latter being reproducible on palpation. Pain related to myocardial ischemia is usually more severe and prolonged and occurs with exercise, allowing distinction from pericarditis-induced pain. The presence of pericardial effusion on echocardiography is highly suggestive of pericarditis but does not determine the etiology.

Infectious Pericarditis

A number of viral agents are known to cause pericarditis, and the clinical course of the majority of these infections is mild and spontaneously resolving. The term *acute benign pericarditis* is synonymous for viral pericarditis. Agents identified as causing pericarditis include the enteroviruses, influenza, adenovirus, respiratory syncytial virus, and parvovirus. Because the course of this illness is usually benign, symptomatic treatment with nonsteroidal antiinflammatory drugs (NSAIDs) is often sufficient. Persistent or early recurrence episodes may need courses of colchicine or, rarely, corticosteroids. Anakinra and the interleukin-1

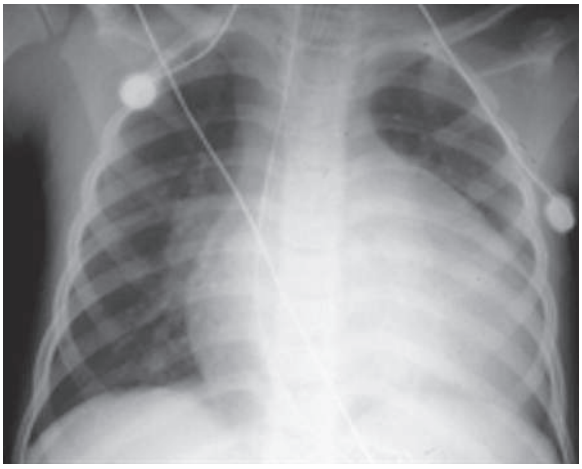

Fig. 489.1 "Water bottle" silhouette. This chest radiograph shows marked cardiomegaly, also known as a water bottle silhouette, which is seen in the presence of large pericardial effusions. Also note the associated pulmonary edema from associated high left atrial and left ventricular filling pressures. *(Courtesy Dr. Steven M. Selbst, Wilmington, DE; from Durani Y, Giordani K, Goudie BW. Myocarditis and pericarditis in children. Pediatr Clin North Am 2010;57:1281–1303, Fig. 7.)*

The view shows circumferential PE with diastolic collapse of RV free wall *(arrow)* during expiration. **C,** M-mode image from subcostal window in the same patient that shows IVC plethora without inspiratory collapse. IVC, Inferior vena cava; IVS, interventricular septum; LA, left atrium; LV, left ventricle; PE, pericardial effusion; RV, right ventricle. *(From Troughton RW, Asher CR, Klein AL. Pericarditis. Lancet. 2004;363:717–727.)*

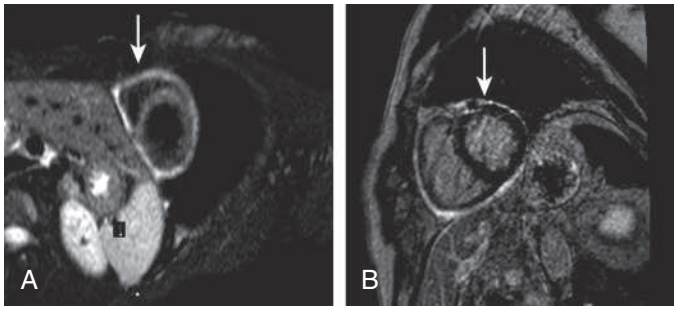

Fig. 489.3 Cardiac magnetic resonance T2 STIR (**A**) and delayed gadolinium (**B**) sequences showing enhancement of the pericardium signifying acute or active inflammation *(arrow). (Modified from Chetrit M, Xu B, Kwon DH, et al: Imaging-guided therapies for pericardial diseases. JACC: Cardiovascular Imaging. 2019;13(6):1422–1437; Fig. 1E and 1F, p. 1424.)*

cytokine trap agent rilonacept have been effective in colchicine-nonresponsive acute or recurrent pericarditis. Patients with large effusions and tamponade may require pericardiocentesis. Presumed viral but often idiopathic pericarditis may have an autoimmune component. Up to 30% of patients may have recurrences of pericarditis. Treatment *and* prevention of recurrences with colchicine improve symptoms and avoid recurrences in most of these patients. If the condition becomes chronic or relapsing, surgical pericardiectomy or creation of a pericardial window may be necessary.

Echocardiography is useful in differentiating pericarditis from *myocarditis,* which will show evidence of diminished myocardial contractility or valvular dysfunction (see Chapter 488.5). Pericarditis and myocarditis may occur together in some cases of viral infection.

Purulent pericarditis, often caused by bacterial infections, has become much less common with the advent of new immunizations for *Haemophilus influenzae* and pneumococcal disease. Historically, purulent pericarditis was seen in association with severe pneumonias, epiglottitis, meningitis, or osteomyelitis. Patients with purulent pericarditis are acutely ill. Unless the infection is recognized and treated expeditiously, the course can be fulminant, leading to tamponade and death. **Tuberculous pericarditis** is rare in developed countries but can be a relatively common complication of HIV infection in regions where tuberculosis is endemic and access to antiretroviral therapy is limited. **Immune complex–mediated pericarditis** is a rare complication that may result in a nonpurulent (sterile) effusion after systemic bacterial infections such as meningococcus or *Haemophilus.*

Noninfectious Pericarditis

Systemic inflammatory diseases such as autoimmune, rheumatologic, and connective tissue disorders may involve the pericardium and result in serous pericardial effusions. Pericardial inflammation may be a component of the type II hypersensitivity reaction seen in patients with acute rheumatic fever. It is often associated with rheumatic valvulitis and responds quickly to antiinflammatory agents, including corticosteroids. Tamponade is quite uncommon (see Chapters 229.1 and 487).

Juvenile idiopathic arthritis, usually systemic-onset disease, can manifest with pericarditis. Differentiating rheumatoid pericardial inflammation from that seen with systemic lupus erythematosus is difficult and requires careful rheumatologic evaluation. Aspirin and corticosteroids can result in rapid resolution of a pericardial effusion but may be needed on a chronic basis to prevent relapse. Many of the autoinflammatory recurrent fever syndromes present with pericarditis, usually with other manifestations of those disorders (see Chapter 204).

Patients with chronic renal failure or hypothyroidism may have pericardial effusions. Clinical suspicion warrants careful screening with physical examination and, if indicated, imaging studies during the course of their illness.

Especially common in referral centers with hematology/oncology units is the presence of pericardial effusion related to neoplastic disease. Conditions resulting in effusion include Hodgkin disease, lymphomas, and leukemia. Radiation therapy directed to the mediastinum of patients with malignancy can result in pericarditis and, later, constrictive pericardial disease.

The **postpericardiotomy syndrome** occurs in patients who have undergone cardiac surgery and is characterized by fever, lethargy, anorexia, irritability, and chest/abdominal discomfort beginning 1-4 weeks postoperatively (see Table 483.2 in Chapter 483). There can be associated pleural effusions. Postpericardiotomy syndrome is effectively treated with aspirin, NSAIDs, colchicine, and in severe cases, corticosteroids. Pericardial drainage is necessary in those patients with cardiac tamponade.

In many patients the etiology of pericarditis is not known. Approximately 30% of these patients have multiple occurrences and are treated with colchicine to reduce the risk of recurrent pericarditis. Other less frequently used treatments have included NSAIDs and corticosteroids. Refractory idiopathic recurrent pericarditis may require pericardiectomy; anakinra and rilonacept have demonstrated promise for difficult-to-treat patients.

489.2 Constrictive Pericarditis

John J. Parent and Stephanie M. Ware

Rarely, chronic pericardial inflammation can result in fibrosis, calcification, and thickening of the pericardium. Pericardial scarring may lead to impaired cardiac distensibility and filling and is termed *constrictive pericarditis.* Constrictive pericarditis can result from recurrent or chronic pericarditis, cardiac surgery, or radiation to the mediastinum as a treatment for malignancies, most often Hodgkin disease or lymphoma.

Clinical manifestations of systemic venous hypertension predominate in cases of restrictive pericarditis. Jugular venous distention, peripheral edema, hepatomegaly, and ascites may precede signs of more significant cardiac compromise, such as tachycardia, hypotension, and pulsus paradoxus. A pericardial knock, rub, and distant heart sounds might be present on auscultation. Abnormalities of liver function tests, hypoalbuminemia, hypoproteinemia, and lymphopenia may be present. On occasion, chest radiographs demonstrate calcifications of the pericardium.

Constrictive pericarditis may be difficult to distinguish clinically from restrictive cardiomyopathy because both conditions result in impaired myocardial filling (see Chapter 488.3). Echocardiography may be helpful in distinguishing constrictive pericardial disease from restrictive cardiomyopathy, but cardiac MRI and CT are more sensitive in detecting abnormalities of the pericardium. In rare cases, exploratory thoracotomy with direct examination of the pericardium may be required to confirm the diagnosis.

Although acute pericardial constriction is reported to respond to antiinflammatory agents, the more typical chronic constrictive pericarditis will respond only to pericardiectomy with extensive resection of the pericardium.

Chapter 490

Tumors of the Heart

John J. Parent and Stephanie M. Ware

Although cardiac tumors occur rarely in pediatric patients, they may result in serious hemodynamic or electrophysiologic abnormalities depending on tumor type and location.

The vast majority of tumors originating from the heart are benign. **Rhabdomyomas** are the most common pediatric cardiac tumors and are associated with tuberous sclerosis in 70–95% of cases (see Chapter 636.2). Rhabdomyomas may occur at any age, from fetal life through late adolescence. They are often multiple, can occur in any cardiac chamber, and originate within the myocardium, often extending into the atrial or ventricular cavities (Fig. 490.1). Depending on their location and size, rhabdomyomas can result in inflow or outflow obstruction, leading to cyanosis or cardiac failure; many are asymptomatic. Atrial and ventricular arrhythmias have been reported with rhabdomyomas, and on occasion, ventricular preexcitation (Wolff-Parkinson-White syndrome) is present on electrocardiogram (ECG).

Fibromas are the second most common pediatric cardiac tumor and, in contrast to rhabdomyomas, are usually solitary and intramyocardial. The size and location of fibromas can lead to heart failure, cyanosis, or rhythm disturbances. Loss of the tumor suppressor *PTCH1* is associated with the development of cardiac fibromas in sporadic cases. There is an increased incidence in patients with **Gorlin syndrome** (3%).

Myxomas, the most common cardiac tumor seen in adults, occur infrequently in the pediatric population. Myxomas are predominantly intraatrial, appear pedunculated, and are rather mobile (Fig. 490.2); however, they may also be ventricular (Fig. 490.3). They may cause obstruction to inflow or outflow and may present with a murmur, heart failure, or syncope. On occasion, atrial myxomas are associated with systemic symptoms of fever, malaise, and arthralgia. **Carney complex** is a familial autosomal dominant multiple neoplasia (often endocrine: pituitary adenoma, thyroid, testis, ovarian) and lentiginosis syndrome in which cardiac myxomas can occur at a young age in any or all cardiac chambers. Pathogenic variants in the *PRKAR1A* gene are causative in some families.

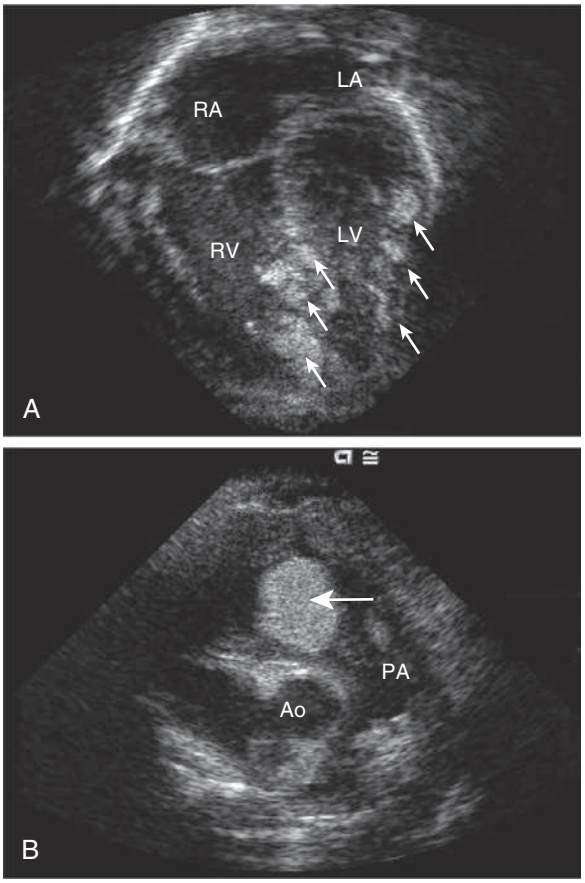

Fig. 490.1 Echocardiograms demonstrating rhabdomyomas. **A,** Apical four-chamber view showing multiple rhabdomyomas *(arrows)* within the septum and left ventricular myocardium. **B,** Short-axis view showing a large rhabdomyoma *(arrow)* extending into the right ventricular outflow tract. Ao, Ascending aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

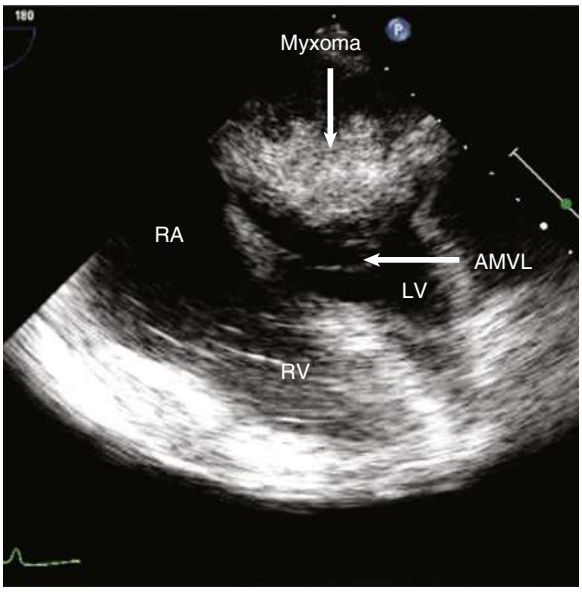

Fig. 490.2 A large left atrial myxoma prolapsing across the mitral valve, resulting in heart failure symptoms. AMVL, anterior mitral valve leaflet; LV, left ventricle; RA, right atrium; RV, right ventricle. *(From Zipes DP, Libby P, Bonow RO, et al., eds. Braunwald's Heart Disease, 11th ed. Philadelphia: Elsevier; 2019, Fig. 95.8, p. 1871.)*

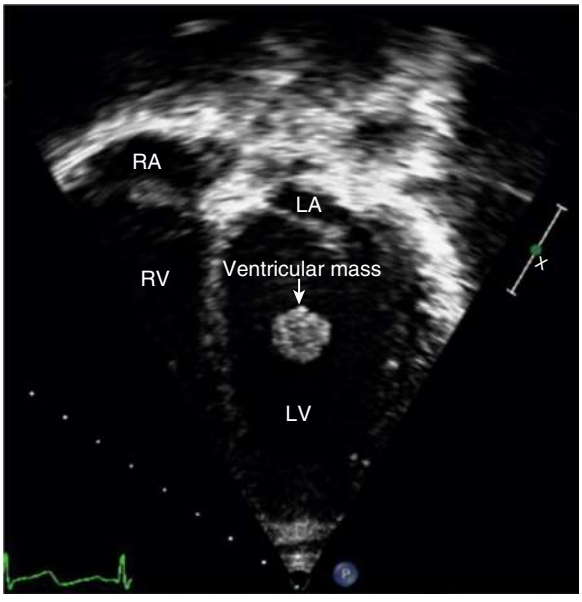

Fig. 490.3 Left ventricular myxoma. TTE apical four-chamber view of mass within the left ventricle. RA, right atrium; RV, right ventricle; LA, left atrium; LV, left ventricle. *(From Schroeder L, Zyblewski S, Forbus G, et al. Left ventricular myxoma. J Pediatr. 2016;168:249–249.e2, Fig. 1.)*

Other benign tumors include hemangiomas, Purkinje cell tumors, papillomas, lipomas, and mesotheliomas. Depending on their location, these benign tumors can result in valvular function abnormalities, myocardial dysfunction, or heart block and other arrhythmias.

Malignant pediatric cardiac tumors are much less common than benign tumors; the majority of such malignancies are sarcomas, including angiosarcomas, rhabdosarcomas, or fibrosarcomas. Lymphomas and pheochromocytomas are reported but rare. Tumors originating from noncardiac sources that invade, extend, or metastasize to the heart are more frequently seen than primary malignant cardiac tumors. In pediatric patients, Wilms tumor and lymphoma/leukemia are the most common causes of such secondary tumors.

Although the manifestations of cardiac tumors in pediatric patients are protean, when a tumor is suspected, noninvasive imaging with echocardiography and/or MRI may be diagnostic and can determine tumor type, location, extent, and hemodynamic impact. ECG and Holter studies are valuable adjuncts when rhythm abnormalities are suspected. Cardiac catheterization is rarely indicated but may be used to confirm tumor location, assess intracardiac hemodynamics, and perform biopsy for histologic assessment. Such risks as blood loss, perforation, arrhythmia, and vessel injury should be considered when discussing catheterization and biopsy.

Because the natural history of rhabdomyomas is one of spontaneous diminution or complete resolution, treatment of the majority of cardiac tumors in pediatric patients is usually unnecessary. *Everolimus,* an inhibitor of the mammalian target of rapamycin (mTOR), may enhance resolution in symptomatic patients with cardiac rhabdomyomas. Careful clinical follow-up and imaging are important. **Antiarrhythmic medications** may be prescribed to control rhythm disorders. Surgical removal of a cardiac tumor may be indicated to relieve obstruction, improve myocardial or valve function, or control arrhythmias. **Heart transplantation** has been performed in cases of unresectable tumors with significant hemodynamic compromise. Wilms tumors extending from the inferior vena cava into the atrium may require cardiopulmonary bypass support during the course of primary resection of the renal tumor. Radiation or chemotherapy can improve cardiac function in rare cases of lymphoma or leukemia compressing the heart with hemodynamic compromise.

Section 7

Cardiac Therapeutics

Chapter 491

Heart Failure

Danielle S. Burstein and Joseph W. Rossano

The International Society for Heart and Lung Transplantation (ISHLT) defines heart failure as follows:

> A clinical and pathological syndrome that results from ventricular dysfunction, volume, or pressure overload, alone or in combination. It leads to characteristic signs and symptoms, such as poor growth, feeding difficulties, respiratory distress, exercise intolerance, and fatigue, and is associated with circulatory, neurohormonal, and molecular abnormalities. Heart failure has numerous etiologies that are a consequence of cardiac and noncardiac disorders, either congenital or acquired.

PATHOPHYSIOLOGY

The heart can be viewed as a pump with an output proportional to its filling volume and inversely proportional to the resistance against which it pumps. As ventricular end-diastolic volume increases, a healthy heart increases cardiac output until a maximum is reached and cardiac output can no longer be augmented (the **Frank-Starling principle**; Fig. 491.1). The increased stroke volume obtained in this manner is a result of stretching of myocardial fibers, but it also results in increased wall tension, which elevates myocardial oxygen consumption. Hearts working under various types of stress function along different Frank-Starling curves. Cardiac muscle with compromised intrinsic contractility requires a greater degree of dilation to produce increased stroke volume and does not achieve the same maximal cardiac output as normal myocardium does. If a cardiac chamber is already dilated because of a lesion causing increased preload (e.g., a left-to-right shunt or valvular insufficiency), there is little room for further dilation as a means of augmenting cardiac output. The presence of lesions that result in increased afterload to the ventricle (e.g., aortic or pulmonic stenosis, coarctation of the aorta) decreases cardiac performance, thereby resulting in a depressed Frank-Starling relationship.

Systemic oxygen transport is calculated as the product of cardiac output and oxygen content of systemic blood. **Cardiac output** can be calculated as the product of heart rate and stroke volume. The primary determinants of stroke volume are the *afterload* (pressure work), *preload* (volume work), and *contractility* (intrinsic myocardial function). Abnormalities in heart rate can also compromise cardiac output; for example, tachyarrhythmias shorten the diastolic time interval for ventricular filling. Alterations in the oxygen-carrying capacity of blood (e.g., anemia or hypoxemia) also lead to a decrease in systemic oxygen transport and, if compensatory mechanisms are inadequate, can result in decreased delivery of substrate to tissues.

In some cases of heart failure, cardiac output is normal or increased, yet because of decreased systemic oxygen content (e.g., secondary to anemia) or increased oxygen demands (e.g., secondary to hyperventilation, hyperthyroidism, or hypermetabolism), an inadequate amount of oxygen is delivered to meet the body's needs. This condition, **high-output failure**, results in the development of signs and symptoms of heart failure when there is no basic abnormality in myocardial function and cardiac output is greater than normal. It is also seen with large systemic arteriovenous fistulas (e.g., vein of Galen malformation). These conditions reduce peripheral vascular resistance and cardiac afterload and increase myocardial contractility. Heart failure results when the demand for cardiac output exceeds the ability of the heart to respond.

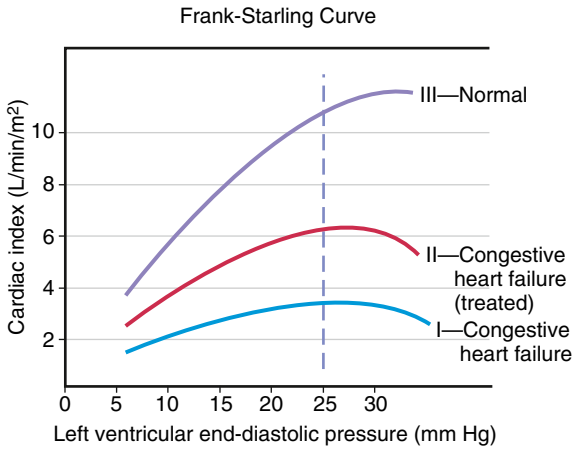

Fig. 491.1 The Frank-Starling relationship. As left ventricular end-diastolic (LVED) pressure increases, the cardiac index increases, even in the presence of congestive heart failure, until a critical level of LVED pressure is reached. Adding an inotropic agent (digoxin) shifts the curve from I to II. *(From Gersony WM, Steep CN. In: Dickerman JD, Lucey JF, eds. Smith's The Critically Ill Child: Diagnosis and Medical Management, 3rd ed. Philadelphia: Saunders; 1984.)*

Chronic severe high-output failure may eventually result in a decrease in myocardial performance as the metabolic requirements of the myocardium are not met.

Multiple systemic compensatory mechanisms are used by the body to adapt to chronic heart failure. Some are mediated at the molecular/cellular level, such as upregulation or downregulation of various metabolic pathway components leading to changes in efficiency of oxygen and other substrate utilizations. Others are mediated by neurohormones such as the renin-angiotensin system and the sympathoadrenal axis. One of the principal mechanisms for increasing cardiac output is an increase in sympathetic tone secondary to increased secretion of circulating epinephrine by the adrenals and increased release of norepinephrine at the neuromuscular junction. The *initial* beneficial effects of sympathetic stimulation include an increase in heart rate and myocardial contractility, mediated by these hormones' action on cardiac β-adrenergic receptors, increasing cardiac output. These hormones also cause vasoconstriction, mediated by their action on peripheral arterial α-adrenergic receptors. Some vascular beds may constrict more readily than others, so that blood flow is redistributed from the cutaneous, visceral, and renal beds to the heart and brain. Whereas these acute effects are beneficial, *chronically* increased sympathetic stimulation can have deleterious effects, including hypermetabolism, increased afterload, arrhythmogenesis, and increased myocardial oxygen requirements. Peripheral vasoconstriction can result in decreased renal, hepatic, and gastrointestinal tract function. Chronic exposure to circulating catecholamines leads to a decrease in the number of cardiac β-adrenergic receptors (downregulation) and also causes direct myocardial cell damage. Therapeutic agents for heart failure are directed at restoring balance to these neuroendocrine systems.

Based on these physiologic and clinical principles, heart failure has been described by different **classification** and **stage** definitions (Tables 491.1-491.3 and Fig. 491.2). These definitions help describe the degree of cardiac impairment and help direct therapy.

Table 491.1 Classification of Heart Failure Based on LVEF

HF CLASS ACCORDING TO LVEF (MUST HAVE SIGNS AND SYMPTOMS)	ACRONYM	LVEF, %
HF with reduced ejection fraction	HFrEF	≤40
HF with mildly reduced ejection fraction	HFmrEF	41–49
HF with preserved ejection fraction	HFpEF	≥50
HF with preserved ejection fraction, improved	HFpEF, improved	Prior <40, now ≥40

LVEF, Left ventricular ejection fraction.

Table 491.2 New York Heart Association (NYHA) Functional Classification (FC)

NYHA FC	FUNCTIONAL CAPACITY
I	No limitations. Can perform high level of activity without symptoms (for example, running, cycling, weightlifting).
II	Slight limitations. Tolerate lower or moderate level activities well, may have limitations with higher-level activities (for example, regular walking causes no symptoms, but a run may cause shortness of breath).
III	Significant limitations. Symptoms with low-level activities such as with daily activities such as walking and household chores.
IV	Symptoms at rest, dyspnea with any physical activity.

From Kellerman RD, Rakel DP, Heidelbaugh JJ, Lee EM, eds. *Conn's Current Therapy 2023.* Philadelphia: Elsevier; 2023: Table 3, p. 117.

ETIOLOGY OF HEART FAILURE

There are many causes of heart failure in the pediatric population, and the etiologies of heart failure are age-dependent (Table 491.4). Pediatric heart failure can occur because of ventricular systolic or diastolic dysfunction caused by an underlying cardiomyopathy. This may be the result of a primary cardiomyopathy from an underlying genetic mutation in cardiac proteins or secondary due to conditions including metabolic and neuromuscular diseases. Ischemic cardiomyopathy caused by congenital coronary anomalies or acquired disease, such as Kawasaki disease, can also result in heart failure. Inflammatory or infectious diseases of the myocardium (e.g., myocarditis) can present with a range of heart failure severity from mild symptoms of chest pain to severe disease with fulminant cardiogenic shock. Persistent atrial and ventricular arrhythmias, particularly tachyarrhythmias, may also result in ventricular dysfunction and heart failure. High-output heart failure can occur in the setting of severe anemia or large arteriovenous malformations.

Heart failure in children can also occur in the setting of underlying congenital heart disease with outflow tract obstructive lesions, shunt lesions with overcirculation of the pulmonary vascular system (e.g., ventricular septal defect), or ventricular volume overload caused by significant valve regurgitation. Heart failure in children can also occur because of valvar heart disease resulting in significant valve regurgitation that causes ventricular volume overload and ventricular dilation with eventual systolic dysfunction. Single ventricle heart disease, including hypoplastic left heart syndrome, has increased the risk of developing heart failure due to multiple mechanisms that influence appropriate blood flow through the single ventricle palliated circulation.

CLINICAL MANIFESTATIONS

The clinical manifestations of heart failure depend in part on the degree of the child's cardiac reserve. A critically ill infant or child who has exhausted the compensatory mechanisms to the point that cardiac output is no longer sufficient to meet the basal metabolic needs of the body may present in **cardiogenic shock**. Other patients may be comfortable when quiet but are incapable of increasing cardiac output in response to even mild activity without experiencing significant symptoms. Conversely, it may take rather vigorous exercise to compromise cardiac function in children who have less severe heart disease.

A thorough **history** is extremely important in making the diagnosis of heart failure and in evaluating the possible causes. Parents or caregivers who observe their child on a daily basis may not recognize subtle changes that have occurred over the course of days or weeks. Gradually worsening perfusion or increasing respiratory effort may not be recognized as an abnormal finding, or may be misattributed to other diagnoses such as asthma. Edema, which is generally absent in infants and young children, may be passed off as normal weight gain, and exercise intolerance as lack of interest in an activity. The history of a young infant should also focus on **feeding**. An infant with heart failure often takes less volume per feeding, becomes dyspneic while sucking, and may perspire profusely. Eliciting a history of fatigue in an older child requires detailed questions about activity level and its course over several months.

In children and adolescents, the signs and symptoms of heart failure may be similar to those in adults and include fatigue, exercise intolerance, anorexia, nausea, vomiting, dyspnea, edema, wheezing, and cough. Many children, however, may have primarily abdominal symptoms (abdominal pain, nausea, vomiting, anorexia) and a surprising lack of respiratory complaints. Attention to the cardiovascular system may come only after an abdominal radiograph unexpectedly catches the lower end of an enlarged heart.

The **physical examination** for a child with suspected heart failure includes evaluation of vital signs and physical exam. Abnormal vital signs sometimes seen in pediatric heart failure include tachypnea, tachycardia, and desaturation caused by pulmonary edema. The elevation in systemic venous pressure may be gauged by clinical assessment of jugular venous pressure and liver enlargement. Orthopnea and

Table 491. 3 Classification of HF According to the American Heart Association (AHA) and American College of Cardiology (ACC)

HEART FAILURE STAGE		AHA/ACC DESCRIPTION
Stage A	At risk	Patients without identified structural or functional cardiac abnormality or ventricular function abnormality but at high risk of developing HF because of the presence of a condition (hypertension) strongly associated with the development of HF. Examples: anthracycline exposure, known pathogenic sarcomeric gene variant including dystrophinopathies.
Stage B	Pre-HF	Patients with structural heart disease or ventricular function abnormality that is strongly associated with the development of HF but without HF signs or symptoms, past or present. Examples: asymptomatic patient with CHD status postsurgical correction with residual lesion, isolated left ventricle noncompaction, elevated BNP or troponin if exposed to cardiotoxins.
Stage C	HF	Patients with current or prior symptoms of HF associated with underlying structural heart disease or ventricular function abnormality (elevated filling pressure, systolic dysfunction). Examples: acute myocarditis, dilated cardiomyopathy, mitral or aortic regurgitation.
Stage D	Advanced HF	Patients with advanced structural heart disease and refractory symptoms of HF requiring specialized interventions. Example: Inotropic dependency patient in end stage of dilated cardiomyopathy: may require VAD or transplant.

BNP, B-type natriuretic protein; CHD, congenital heart defect; VAD, ventricular assist devices; HF, heart failure
Modified from Hunt SA, Baker DW, Chin MH, Cinquegrani MP, Feldman AM, Francis GS, et al. ACC/AHA guidelines for the evaluation and management of chronic heart failure in the adult: executive summary. A report of the American college of cardiology/American heart association task force on practice guidelines (committee to revise the 1995 guidelines for the evaluation and management of heart failure). *J Am Coll Cardiol.* 2001;38:2101–13.

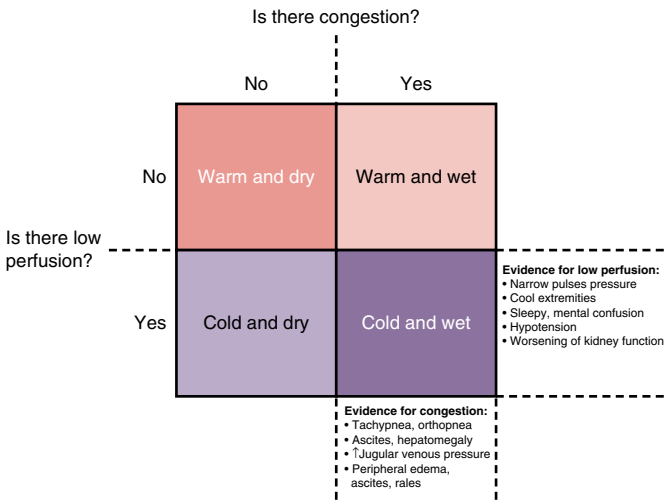

Fig. 491.2 Clinical assessment in acute decompensated heart failure should answer the two questions suggested by this diagram: First, does the patient present with significant congestion? Second, does the patient present with significant underperfusion? Using this construct, patients will segregate into one of four categories in accordance with clinical findings. Typically, patients move in a clockwise fashion through these categories, first becoming congested (warm and wet) and then vasoconstricted to maintain blood pressure (cold and wet). Once vasoactive support and diuresis are achieved, movement is generally counterclockwise, from cold and wet, to warm and wet, and then warm and dry. However, some patients will remain underperfused despite restoration of normovolemia, representing the cold and dry group, for whom mechanical support may be needed. *(Modified from Kantor PF, Mertens LL. Clinical practice: heart failure in children. Part I: clinical evaluation, diagnostic testing, and initial medical management. Eur J Pediatr. 2010;169[3]:269–279.)*

basilar rales are variably present; edema is usually discernible in dependent portions of the body, or anasarca may be present. Cardiomegaly is invariably noted based on a hyperactive precordium, ventricular heave, or displaced apical impulse. A **gallop rhythm** is common; when ventricular dilation is advanced, the **holosystolic murmur** of mitral or tricuspid valve regurgitation may be heard. **Pulsus alternans** is an ominous physical exam finding usually seeing in a state of low stroke volume with variable cardiac output with each ventricular contraction. Impaired systemic perfusion with poor capillary refill or decreased pulses is a concerning sign for cardiogenic shock.

In infants, heart failure may be difficult to distinguish from other causes of respiratory distress or gastrointestinal diseases. Prominent manifestations of heart failure include tachypnea, feeding difficulties, vomiting, poor weight gain, excessive perspiration, irritability, weak cry, and noisy, labored respirations with intercostal and subcostal retractions, as well as flaring of the alae nasi. The signs of cardiac-induced pulmonary congestion may be indistinguishable from those of bronchiolitis; wheezing is often a more prominent finding in young infants with heart failure than rales. Hepatomegaly usually occurs, and cardiomegaly is invariably present. Despite pronounced tachycardia, a gallop rhythm can frequently be recognized. The other auscultatory signs are those produced by the underlying cardiac lesion. Clinical assessment of jugular venous pressure in infants may be difficult because of the shortness of the neck and the difficulty of observing a relaxed state; palpation of an enlarged liver is a more reliable sign.

DIAGNOSIS

Chest radiograph (CXR) may be helpful in pediatric heart failure. It can assess the cardiac silhouette for cardiac enlargement. Pulmonary vascularity is variable and depends on the cause of the heart failure. Infants and children with large left-to-right shunts have exaggeration of the pulmonary arterial vessels to the periphery of the lung fields, whereas patients with cardiomyopathy may have a relatively normal pulmonary vascular bed early in the course of disease. Fluffy perihilar pulmonary markings suggestive of venous congestion and acute pulmonary edema are seen only with more severe degrees of heart failure. Pleural effusions may also be present. Cardiac enlargement as a marker of heart failure may be noted on a chest radiography performed to evaluate for a possible pulmonary infection, bronchiolitis, or asthma.

Electrocardiography (ECG) may be helpful in assessing the cause of heart failure but does not establish the diagnosis. In cardiomyopathies, exaggerated left or right ventricular voltages may be suggestive of underlying cardiomyopathy, and ischemic changes may correlate with other noninvasive parameters of ventricular function. Low-voltage QRS morphologic characteristics with ST-T–wave abnormalities may also suggest myocardial inflammatory disease (myocarditis) but can be seen with pericarditis as well. ECG is the best tool for evaluating rhythm disorders as a potential cause of heart failure, especially tachyarrhythmias. Ambulatory ECG monitoring can evaluate for occult arrhythmias that may be present in heart failure.

Echocardiography is the standard technique for assessing ventricular function (Fig. 491.3). Ventricular function can be quantitated simply and reliably with commonly used parameters such as fractional shortening (a single-dimensional variable) and an ejection fraction. The *fractional shortening* is determined as the difference between

Table 491.4 Etiology of Heart Failure

Sickle cell anemia
Endocarditis
Cor pulmonale (cystic fibrosis)
Genetic/metabolic cardiomyopathy (hypertrophic, dilated)

end-systolic and end-diastolic diameter divided by end-diastolic diameter. Normal fractional shortening is between approximately 28% and 42%. The *ejection fraction* uses two-dimensional data to calculate a three-dimensional volume; the normal range is 55–65%. In children with right ventricular enlargement or other cardiac pathology resulting in flattening of the interventricular septum, ejection fraction is used because fractional shortening measured in the standard echocardiographic short-axis view will not be accurate. Doppler studies can also be used to estimate cardiac output. Doppler assessment of transmitral inflow and tissue characterization can also be used as a noninvasive assessment of diastolic function.

Cardiac magnetic resonance imaging (CMR) is also useful in quantifying left and right ventricular function, volume, and mass along with coronary artery anatomy. If valvular regurgitation is present, CMR can quantify the regurgitant fraction. CMR can also provide details about tissue characterization such as fibrosis and inflammation, which is helpful for assessing conditions such as myocarditis.

J Amer Coll Cardiol. 2022;79[17]:1757–1780, Fig. 4.)*

Cardiac catheterization is an invasive test that can be helpful for assessing heart failure by evaluating intracardiac hemodynamics and shunt lesions. Angiography can be performed to evaluate for structural heart defects. Endomyocardial biopsy may sometimes be performed as part of an evaluation of myocarditis.

Laboratory testing is important for evaluating end-organ function and systemic perfusion. This includes evaluating renal function, liver function, lactate levels, and electrolytes. Heart failure may result in hyponatremia caused by compensatory activation of the renin-angiotensin-aldosterone pathway with renal water retention, which may be compounded by further salt wasting due to chronic diuretic treatment. When heart failure is severe, respiratory acidosis or metabolic acidosis, or both, may be present. The cardiac serum **biomarker B-type (brain) natriuretic peptide (BNP)** (or N-terminal pro-BNP) is a cardiac neurohormone released in response to increased ventricular wall tension that is elevated in patients with heart failure. In children with heart failure, BNP may be elevated as a result of systolic dysfunction (e.g., cardiomyopathy) and in children with volume overload (e.g., left-to-right shunts such as ventricular septal defect). Table 491.5 lists other causes of an elevated BNP.

TREATMENT

The underlying cause of cardiac failure must be removed or alleviated if possible. If the cause is a congenital cardiac anomaly amenable to surgery, medical treatment of the heart failure is indicated to prepare the patient for surgery. With the current excellent outcomes of primary surgical repair of congenital heart defects, even in the neonatal period,

few children require aggressive heart failure management to grow big enough for surgery. In contrast, if the cause of heart failure is cardiomyopathy, medical management provides temporary relief from symptoms and may allow the patient to recover if the insult is reversible (e.g., myocarditis). If the lesion is not reversible, heart failure management usually allows the child to return to normal activities for some period and to delay, sometimes for months or years, the need for heart transplantation.

General Measures

Heart failure management focuses on maintaining adequate cardiac output to allow for appropriate end-organ function while reducing volume overload and venous or pulmonary congestion. Encouraging regular physical activity is important for preventing acquired cardiovascular comorbidities, but it is important that the child be allowed to rest as needed and monitor for cardiac symptoms. Formal **cardiopulmonary exercise** testing can be used to assess the patient's ability to perform exercise in a controlled environment and is useful for providing exercise recommendations. Malnutrition is common in patients with heart failure because of gastrointestinal symptoms related to mesenteric venous congestion, and patients often require supplemental nutrition either with caloric fortification and/or nasogastric supplementation. For patients with pulmonary edema, positive pressure ventilation (PPV) may be required along with other drug therapies. For those in low-output heart failure, PPV can significantly reduce total body oxygen consumption by eliminating the work of breathing and help to reverse metabolic acidosis. Reverse remodeling agents, including β blockers, angiotensin-blockers, combination angiotensin receptor/neprilysin inhibitors, and aldosterone antagonists, can provide long-term myocardial reverse remodeling. Appropriate blood pressure control is important to reduce afterload and stress on the myocardium. In patients with advanced heart failure and/or cardiogenic shock, providing adequate cardiac output to meet the metabolic demands and provide adequate end-organ perfusion may require inotropic agents and, potentially, mechanical circulation support (Table 491.6).

Diet

Infants with heart failure usually fail to thrive because of a combination of increased metabolic demands and decreased caloric intake. Increasing daily calories is an important aspect of their management. Increasing the number of calories per ounce of infant formula (or supplementing breastfeeding) may be beneficial. Many infants do not tolerate an increase beyond 24 calories/oz because of diarrhea or because these formulas provide too large a solute load for compromised kidneys.

Severely ill infants and children may lack sufficient strength for effective sucking because of extreme fatigue, rapid respirations, and generalized weakness. In these circumstances, nasogastric feedings may be helpful. In many patients with cardiac enlargement, **gastroesophageal reflux** is a major problem. The use of continuous drip nasogastric feedings at night, administered by pump, may improve caloric intake while decreasing problems with reflux. Continued **malnutrition** may be an important factor in the decision to undertake earlier surgical intervention in patients who have an operable congenital heart lesion or to proceed with mechanical circulatory support and/or listing for transplantation in patients with cardiomyopathy. *Iron supplementation should be initiated in the presence of iron deficiency even in the absence of anemia.*

The use of low-sodium formulas in the routine management of infants with heart failure is not recommended because these preparations are often poorly tolerated and may exacerbate diuretic-induced hyponatremia. Human breast milk is the ideal low-sodium nutritional source. The use of more potent diuretic agents allows more palatable standard formulas to be used for nutrition while controlling salt and water balance by chronic diuretic administration. Most older children can be managed with generally heart-healthy diets that have low fat and sugar content, although caloric supplementation may be needed if there is significant malnutrition.

Diuretics

Diuretics are an important component of heart failure management by reducing volume overload and congestion. Diuretics interfere with reabsorption of water and sodium by the kidneys, which results in a reduction in circulating blood volume and thereby reduces pulmonary fluid overload and ventricular filling pressure. Diuretics are usually the first mode of therapy initiated in patients with congestive heart failure.

Loop diuretics, including Furosemide and bumetanide, are the most commonly used diuretics in pediatric patients with heart failure. It inhibits the reabsorption of sodium and chloride in the distal tubules and the loop of Henle. Patients requiring acute diuresis should be given intravenous (IV) furosemide at an initial dose of 1-2 mg/kg, which usually results in rapid diuresis and prompt improvement in clinical status, particularly if symptoms of pulmonary congestion are present. Chronic furosemide therapy is then prescribed at a dose of 1-4 mg/kg/24 hr given between 1 and 4 times a day. Careful monitoring of electrolytes is necessary with long-term furosemide therapy because of the potential for significant loss of potassium. Potassium chloride supplementation is usually required unless the potassium-sparing diuretics are given concomitantly. Chronic administration of furosemide may cause contraction of the extracellular fluid compartment and result in "contraction alkalosis" (see Chapter 73.7). Diuretic-induced hyponatremia may become difficult to manage in patients with severe heart failure.

Thiazide diuretics, including chlorothiazide, are also used for diuresis in children with heart failure. It is less immediate in action and less potent than furosemide, and it affects the reabsorption of electrolytes in the renal tubules only. The usual dose is 10-40 mg/kg/24 hr in two divided doses. Potassium supplementation is often required if chlorothiazide is used alone. **Sodium glucose cotransporter 2 (SGLT2) inhibitors** (dapagliflozin, empagliflozin) also produce a natriuresis and have other beneficial direct cardiac effects and have been recommended for some etiologies of heart failure.

Table 491.6 Dosage of Drugs Commonly Used for the Treatment of Congestive Heart Failure

DRUG	DOSAGE*
DIGOXIN	
Digitalization (1/2 initially, followed by 1/4 q12h × 2)	Premature: 20 μg/kg Full-term neonate (up to 1 mo): 20-30 μg/kg Infant or child: 25-40 μg/kg Adolescent or adult: 0.5-1 mg in divided doses *Note:* These doses are PO; IV dose is 75% of PO dose
Maintenance digoxin†	5-10 μg/kg/day, divided q12h *Note:* These doses are PO; IV dose is 75% of PO dose
DIURETICS	
Furosemide (Lasix)	IV: 0.5-2 mg/kg/dose PO: 1-4 mg/kg/day, divided qd-qid
Bumetanide (Bumex)	IV: 0.01-0.1 mg/kg/dose PO: 0.01-0.1 mg/kg/day q24-48h
Chlorothiazide (Diuril)	PO: 20-40 mg/kg/day, divided bid or tid
Spironolactone (Aldactone)	PO: 1-3 mg/kg/day, divided bid or tid
ADRENERGIC AGONISTS (ALL IV)	
Dobutamine	2-20 μg/kg/min
Dopamine	2-20 μg/kg/min
Epinephrine	0.01-1.0 μg/kg/min
PHOSPHODIESTERASE INHIBITORS (ALL IV)	
Milrinone	0.25-1.0 μg/kg/min
AFTERLOAD-REDUCING AGENTS	
Captopril (Capoten), all PO	Premature: start at 0.01 mg/kg/dose; 0.1-0.4 mg/kg/day, divided q6-24h Infant: start at 0.15-0.3 mg/kg/dose; 1.5-6 mg/kg/day, divided q6-12h Child: start at 0.3-0.5 mg/kg/dose; 2.5-6 mg/kg/day, divided q6-12h
Enalapril (Vasotec), all PO	0.08-0.5 mg/kg/day, divided q12-24h
Hydralazine (Apresoline)	IV: 0.1-0.5 mg/kg/dose (maximum: 20 mg) PO: 0.75-5 mg/kg/day, divided q6-12h
Nitroglycerin	IV: 0.25-0.5 μg/kg/min start; increase to 20 μg/kg/min maximum
Nitroprusside (Nipride)	IV: 0.5-8 μg/kg/min
β-ADRENERGIC BLOCKERS	
Carvedilol (Coreg)	PO: initial dose: 0.1 mg/kg/day (maximum: 6.25 mg) divided bid (may use tid in infants), increase gradually (usually 2-wk intervals) to maximum of 0.5-1 mg/kg/day over 8-12 wk as tolerated; adult maximum dose: 50-100 mg/day
Metoprolol (Lopressor, Toprol-XL)	PO, non–extended-release form: 0.2 mg/kg/day divided bid, increase gradually (usually 2-wk intervals) to maximum dose of 1-2 mg/kg/day PO, extended-release form (Toprol-XL): given once daily; adult initial dose: 25 mg/day, maximum: 200 mg/day

*Pediatric doses based on weight should not exceed adult doses. Because recommendations may change, these doses should always be double-checked. Doses may also need to be modified in any patient with renal or hepatic dysfunction.
†Maintenance digitalis therapy is started approximately 12 hr after full digitalization. The daily dosage, one quarter of the total digitalizing dose, is divided in two and given at 12-hr intervals. The oral maintenance dose is usually 20–25% higher than when digoxin is used parenterally. The normal daily dose of digoxin for older children (>5 yr of age) calculated by body weight should not exceed the usual adult dose of 0.125-0.5 mg/24 hr.
IV, Intravenous; PO, oral; bid, twice daily, tid, 3 times daily; qid, 4 times daily; qd, every day.

Cardiac Reverse Remodeling

Angiotensin Antagonists

The renin-angiotensin-aldosterone pathway becomes active as a compensatory response to heart failure, but these compensatory effects can result in increased afterload and adverse remodeling of the myocardium, including development of cardiac fibrosis. Angiotensin antagonists, including angiotensin-converting enzyme inhibitors (ACEIs) and aldosterone II receptor blockers (ARBs), reduce ventricular afterload by decreasing peripheral vascular resistance and thereby improving myocardial performance. Afterload reducers may be useful in children with heart failure secondary to cardiomyopathy and in patients with severe mitral or aortic insufficiency. They may also be effective in patients with heart failure caused by left-to-right shunts. ACEIs and ARBs may have additional beneficial effects on cardiac remodeling independent of their influence on afterload by directly influencing adverse cardiac intracellular signaling pathways and decreasing the formation of myocardial fibrosis. In adult patients with dilated cardiomyopathy, the addition of an ACEI to standard medical therapy reduces both morbidity and mortality.

The orally active ACEIs **captopril**, **enalapril,** and **lisinopril** produce arterial dilation by blocking the production of angiotensin II, thereby resulting in significant afterload reduction. Venodilation and consequent preload reduction also have been reported. In addition, these agents interfere with aldosterone production and therefore also help control salt and water retention. ACEIs have additional beneficial effects on cardiac structure and function that may be independent of

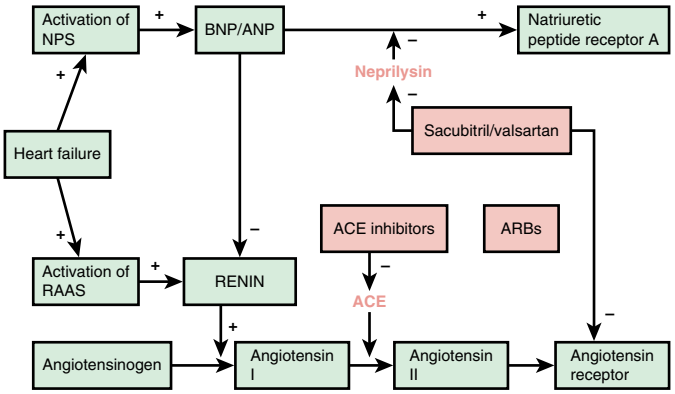

Fig. 491.4 Systems activated in heart failure and pathways blocked by angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and neprilysin inhibitors (sympathetic nervous system activation pathway is not shown in the figure). ANP, Atrial natriuretic peptide; BNP, B-type natriuretic peptide; NPS, natriuretic peptide system; RAAS, renin angiotensin aldosterone system. *(From Arya A, Azad S, Sitaraman R. Angiotensin receptor and neprilysin inhibitor: a new drug in pediatric cardiologist's armamentarium. Ann Pediatr Cardiol. 2020;13[4]:334–336, Fig. 1.)*

Table 491.7 Valsartan/Sacubitril Recommended Dose* (Twice Daily)

	STARTING	SECOND	FINAL
Pediatric patients <40 kg** (mg/kg)	1.6	2.3	3.1
Pediatric patients at least 40 kg, <50 kg (mg)	24/26	49/51	72/78#
Pediatric patients at least 50 kg (mg)	49/51	72/78#	97/103

*Available as 24/26, 49/51, and 97/103 mg tablets, where the first drug is sacubitril and the second drug is valsartan.
#Doses of 72/78 mg can be achieved using three 24/26 mg tablets. Titration: titrate dose every 2 wk and target final dose.
**An oral suspension can be substituted at the recommended tablet dosage in patients unable to swallow tablets.
From Arya A, Azad S, Sitaraman R. Angiotensin receptor and neprilysin inhibitor: a new drug in pediatric cardiologist's armamentarium. *Ann Pediatr Cardiol.* 2020;13(4):334–336, Table 1.

their effect on afterload. Adverse reactions to ACEIs include hypotension and its sequelae (weakness, dizziness, syncope) and hyperkalemia. A maculopapular pruritic rash is encountered in a small number of patients, but the drug may be continued because the rash often disappears spontaneously with time. Neutropenia, renal toxicity, and chronic cough also occur. Angioedema is a rare side effect of ACEIs and is related to inhibiting breakdown of bradykinin. If patients have had side effects related to bradykinin effect from ACEIs, including chronic cough, ARBs may be an alternative therapy and include **losartan** and **valsartan.**

An angiotensin receptor combined with neprilysin inhibition (ARNI) (valsartan/sacubitril) is approved for children 1-18 years of age with New York Heart Association class II-IV and a left ventricular ejection fraction ≤40%. The mechanism of action is noted in Figure 491.4 and the dosing in Table 491.7.

Aldosterone Antagonists

Spironolactone and **eplerenone** inhibit aldosterone and act both as a reverse remodeling agent and a weak diuretic. They also enhance potassium retention, often eliminating the need for oral potassium supplementation in patients receiving diuretics. Aldosterone antagonists blunt the adverse cardiac remodeling effects and may reduce cardiac fibrosis that results in heart failure. Spironolactone is usually given orally in two divided doses of 2 mg/kg/24 hr. Adults with heart failure have improved survival when an aldosterone inhibitor is included in the diuretic regimen, likely through multiple effects, including a favorable effect on cardiac fibrosis. Eplerenone is an alternative to spironolactone and does not have the side effect of gynecomastia.

β Blockers

Studies in adults with dilated cardiomyopathy show that β-adrenergic blocking agents, introduced gradually as part of a comprehensive heart failure treatment program, improve exercise tolerance, decrease hospitalizations, and reduce overall mortality. The agents most often used are **carvedilol**, with both α- and β-adrenergic receptor–blocking and free radical–scavenging effects, and **metoprolol**, a β_1-adrenergic receptor–selective antagonist. β Blockers are used for the chronic treatment of patients with heart failure and should not be administered when patients are still in the acute phase of heart failure (i.e., receiving IV adrenergic agonist infusions). Although highly efficacious in adults, clinical studies in children have shown mixed results, potentially from the significant heterogeneity of the populations being studied and differences in the types of β-blocking agents.

Although ACEIs/ARBs along with β-adrenergic–blocking agents and aldosterone antagonists have been shown in multiple prospective, randomized, controlled trials in adults to improve symptoms and mortality in adult heart failure patients, it is unclear if these medications improve the natural history of heart failure in children. Nonetheless, these medications are commonly used for the treatment of heart failure and are recommended by consensus guidelines from the ISHLT and Canadian Cardiovascular Society.

Afterload Reduction

Afterload reduction is an important component of heart failure management to reduce workload on the myocardium. Oral afterload-reducing agents, including ACEIs and ARBs, are often used for both cardiac reverse remodeling and afterload reduction benefits. If renal insufficiency is present, alternative oral afterload-reducing agents may be considered, including calcium channel blockers such as **amlodipine**, although they have potential side effects including peripheral edema and gingival hyperplasia.

Intravenously administered afterload-reducing agents, including **milrinone** (see later section on "Phosphodiesterase Inhibitors"), **nicardipine**, and **nitroprusside**, should be initiated only in a closely monitored clinical care setting. Nitroprusside's short IV half-life makes it ideal for titrating the dose in critically ill patients. Peripheral arterial vasodilation and afterload reduction are the major effects, but venodilation causing a decrease in venous return to the heart may also be beneficial. Blood pressure must be continuously monitored because sudden hypotension can occur. Consequently, nitroprusside is contraindicated in patients with preexisting hypotension. Because the drug is metabolized, small amounts of circulating cyanide are produced and detoxified in the liver to thiocyanate, which is excreted in urine. When high doses of nitroprusside are administered for several days, toxic symptoms related to *thiocyanate poisoning* may occur (fatigue, nausea, disorientation, acidosis, and muscular spasm). If nitroprusside use is prolonged, blood thiocyanate levels should be monitored.

Phosphodiesterase Inhibitors

Milrinone is useful in treating patients with low cardiac output who are refractory to standard therapy. It has been shown to be highly effective in managing the low-output state present in children after open heart surgery. It works by inhibiting phosphodiesterase, which prevents the degradation of intracellular cyclic adenosine monophosphate. Milrinone has both positive inotropic effects on the heart and peripheral vasodilatory effects and has generally been used as an adjunct to dopamine or dobutamine therapy in the intensive care unit. It is given by IV infusion at 0.25-1 μg/kg/min. A major side effect is **hypotension** secondary to peripheral vasodilation. The hypotension can generally be managed by the administration of IV fluids to restore adequate intravascular volume. Because of renal clearance of milrinone, caution must be used in the setting of renal insufficiency. Long-term milrinone

is often used to support patients while listed for heart transplantation, and in select patients can be used in the outpatient setting.

α- and β-Adrenergic Agonists

The α- and β-adrenergic receptor agonists may be needed for advanced heart failure with impaired cardiac output and are usually administered in an intensive care setting, where the dose can be carefully titrated to hemodynamic response. Continuous determinations of arterial blood pressure and heart rate are performed; measuring serial mixed venous oxygen saturations or cardiac output directly with a pulmonary thermodilution (Swan-Ganz) catheter may be helpful in assessing drug efficacy, although this technique is used much less in children than in adults. These agents increase myocardial oxygen consumption and are associated with increased arrhythmogenic burden and have been shown to increase morbidity and mortality in adults with heart failure; thus they are usually avoided as a long-term therapy.

Dopamine is a predominantly β-adrenergic receptor agonist, but it has α-adrenergic effects at higher doses. Dopamine has less chronotropic and arrhythmogenic effect than the pure β-agonist isoproterenol. At a dose of 2-10 μg/kg/min, dopamine results in increased contractility with little peripheral vasoconstrictive effect. If the dose is increased beyond 15 μg/kg/min, however, its peripheral α-adrenergic effects may result in vasoconstriction.

Dobutamine, a derivative of dopamine, is also useful in treating low cardiac output. It has direct inotropic effects and causes a moderate reduction in peripheral vascular resistance. Dobutamine can be used alone or as an adjunct to dopamine therapy to avoid the vasoconstrictive effects of higher-dose dopamine. Dobutamine is also less likely to cause cardiac rhythm disturbances.

Epinephrine is a mixed α- and β-adrenergic receptor agonist that is usually reserved for patients with cardiogenic shock and low arterial blood pressure. Although epinephrine can raise blood pressure effectively, it also increases systemic vascular resistance, and therefore increases the afterload against which the heart has to work and is associated with an increased risk of arrhythmia. Additionally, epinephrine is proarrhythmic and can result in direct cardiac toxicity, including myocardial necrosis and apoptosis.

Digitalis Glycosides

Digoxin, once the mainstay of heart failure management in both children and adults, is currently used less frequently as a result of the introduction of other therapies and the recognition of its potential toxicities. Some cardiologists will use digitalis as an adjunct to ACEIs and diuretics in patients with symptomatic heart failure, whereas others have stopped using it altogether. Despite multiple clinical studies, predominantly in adults, the controversy over digitalis remains. Some data suggest a beneficial effect of digoxin on reducing death among infants with single ventricle heart disease.

Digoxin is the digitalis glycoside used most often in pediatric patients. It has a half-life of 36 hours and is absorbed well by the gastrointestinal tract (60–85%), even in infants. An initial effect is seen as early as 30 minutes after administration, and the peak effect for oral digoxin occurs at 2-6 hours. When the drug is administered intravenously, the initial effect is seen in 15-30 minutes, and the peak effect occurs at 1-4 hours. The kidney eliminates digoxin, so dosing must be adjusted according to the patient's renal function. The half-life of digoxin may be up to 6 days in patients with anuria because slower hepatic excretion pathways are used in these patients.

Rapid digitalization of infants and children may be carried out intravenously. This should be done with caution in patients with severe heart failure. The dose depends on the patient's age (see Table 491.6). The recommended digitalization schedule is to give half the total digitalizing dose immediately and the succeeding two one-quarter doses at 12-hours intervals later. The ECG must be closely monitored and rhythm strips obtained before each of the three digitalizing doses. Digoxin should be discontinued if a new rhythm disturbance is noted. Prolongation of the P-R interval is not necessarily an indication to withhold digitalis, but a delay in administering the next dose or a reduction in the dosage should be considered, depending on the patient's clinical status. Minor ST segment or T-wave changes are frequently noted with digitalis administration and should not affect the digitalization regimen. Baseline serum electrolyte levels should be measured before and after digitalization. **Hypokalemia** and **hypercalcemia** exacerbate digitalis toxicity. Because hypokalemia is relatively common in patients receiving diuretics, potassium levels should be monitored closely in those receiving a potassium-wasting diuretic in combination with digitalis. In patients with active myocarditis, some cardiologists recommend avoiding digitalis altogether, and if used, maintenance digitalis should be started at half the normal dose without digitalization because of the increased risk of arrhythmia in these patients.

Patients who are not critically ill may be given digitalis initially by the oral route, and in most instances, digitalization is completed within 24 hours. When slow digitalization is desirable, for example, in the immediate postoperative period, initiation of a maintenance digoxin schedule without a previous loading dose achieves full digitalization in 7-10 days.

Measurement of serum digoxin levels is useful in the following circumstances: (1) when an unknown amount of digoxin has been administered or ingested accidently, (2) when renal function is impaired or if drug interactions are possible, (3) when questions regarding compliance are raised, and (4) when a toxic response is suspected. In suspected toxicity, elevated serum digoxin levels are not in themselves diagnostic of toxicity but must be interpreted as an adjunct to other clinical and electrocardiographic findings (rhythm and conduction disturbances). Hypokalemia, hypomagnesemia, hypercalcemia, cardiac inflammation secondary to myocarditis, and prematurity may all potentiate digitalis toxicity. A cardiac arrhythmia that develops in a child who is taking digitalis may also be related to the primary cardiac disease rather than the drug; however, any arrhythmia occurring after the institution of digitalis therapy must be considered to be drug related until proven otherwise. Many drugs interact with digoxin and may increase levels or risk of toxicity, so care should be taken when a patient receiving digoxin is being considered for any additional pharmacologic therapy.

Additional Therapies

Several medications that have shown promise in the treatment of adult patients with heart failure are being studied in pediatric patients. For chronic heart failure, **ivabradine** has been studied in patients with elevated heart rates despite optimized β blocker use. Ivabradine is a selective inhibitor of the I_f current in the sinus node and lowers heart rates without decreasing myocardial contractility. The use of ivabradine was associated with improved outcomes in adults with heart failure, and a recent study of children with heart failure caused by dilated cardiomyopathy demonstrated improved left ventricular systolic function and clinical status.

Sodium-glucose co-transporter 2 (SGLT2) inhibitors, which blocks reabsorption of glucose in the proximal renal tubule, are the newest class of adult heart failure medications and, though developed as a treatment for diabetes, have shown dramatic improvement in cardiac mortality and morbidity in adults with heart failure with reduced ejection fraction. Given the mechanism of action, which includes glucosuria, there is a risk for urinary tract infection and yeast infection. Additional possible side effects include acute kidney injury and bone fracture as well as development of diabetic ketoacidosis in patients with diabetes. Further studies are needed to determine what role, if any, these medications will have in the treatment of pediatric heart failure.

ELECTROPHYSIOLOGIC APPROACHES TO HEART FAILURE MANAGEMENT

Significant improvements in symptomatology and functional capacity have been achieved in select adult patients with cardiomyopathy using **biventricular resynchronization pacing**. This technique improves cardiac output by restoring normal synchrony between right and left ventricular contraction, which is often lost in patients with dilated cardiomyopathy (these patients usually manifest a left bundle branch block on ECG). There is growing experience with resynchronization pacing in children, but it remains uncertain which population of patients with heart failure benefit from this therapy.

Arrhythmias are a leading cause of sudden death in patients with severe cardiomyopathy (both dilated and hypertrophic). Although antiarrhythmic medications can sometimes reduce this risk, for patients at particularly high risk (e.g., those with a condition known to be associated with a high risk of ventricular arrhythmia or those who have already

Table 491.8 Treatment of Cardiogenic Shock*

	DETERMINANTS OF STROKE VOLUME

Parameters measured	CVP, PCWP, LAP, cardiac chamber size on echocardiography	CO, BP, fractional shortening or ejection fraction on echocardiography, MV O_2 saturation	BP, peripheral perfusion, SVR
Treatment to improve cardiac output	Volume expansion (crystalloid, colloid, blood)	β-Adrenergic agonists, phosphodiesterase inhibitors	Afterload-reducing agents: milrinone, nitroprusside, ACEIs

*The goal is to improve peripheral perfusion by increasing cardiac output, where cardiac output = heart rate × stroke volume.
ACEIs, Angiotensin-converting enzyme inhibitors; BP, blood pressure; CO, cardiac output (measured with a thermodilution catheter); CVP, central venous pressure; LAP, left atrial pressure (measured with an indwelling LA line); MV O_2 saturation, mixed venous oxygen saturation (measured with a central venous catheter); PCWP, pulmonary capillary wedge pressure (measured with a thermodilution catheter); SVR, systemic vascular resistance (calculated from CO and mean BP).

experienced a "missed sudden death" episode), use of an **implantable cardioverter-defibrillator** can be lifesaving (see Chapter 485).

491.1 Cardiogenic Shock

Joseph W. Rossano and Danielle S. Burstein

Cardiogenic shock may be caused by (1) severe cardiac dysfunction before or after cardiac surgery, (2) septicemia, (3) severe burns, (4) anaphylaxis, (5) cardiomyopathy, (6) myocarditis, (7) myocardial infarction or stunning, and (8) acute central nervous system (CNS) disorders. It is characterized by low cardiac output and results in inadequate tissue perfusion (see Chapter 85).

Treatment is aimed at restoring adequate cardiac output to prevent the untoward effects of prolonged ischemia on vital organs, as well as management of the underlying cause. Under normal physiologic conditions, cardiac output is increased as a result of sympathetic stimulation, which increases both contractility and heart rate. If contractility is depressed, cardiac output may be improved by increasing the heart rate, increasing ventricular filling pressure (preload) through the Frank-Starling mechanism, or decreasing systemic vascular resistance (afterload). Optimal filling pressure is variable and depends on a number of extracardiac factors, including ventilatory support and intraabdominal pressure. The increased pressure necessary to fill a relatively noncompliant ventricle should also be considered, particularly after open heart surgery or in patients with restrictive or hypertrophic cardiomyopathies. If carefully administered incremental fluid does not result in improved cardiac output, abnormal myocardial contractility or an abnormally high afterload, or both, must be implicated as the cause of the low cardiac output. Although an increase in heart rate *may* improve cardiac output, an excessive increase in heart rate may reduce cardiac output because of decreased time for diastolic filling. Additionally, high heart rates will increase myocardial oxygen demand, which may be counterproductive in a state of limited tissue oxygen supply.

Myocardial contractility usually improves when treatment of the basic cause of shock is instituted, hypoxia is eliminated, and acidosis is corrected. β-Adrenergic agonists such as dopamine, epinephrine, and dobutamine improve cardiac contractility, increase heart rate, and ultimately increase cardiac output. However, some of these agents also have α-adrenergic effects, which cause peripheral vasoconstriction and increase afterload, so careful consideration of the balance of these effects in an individual patient is important. The use of cardiac glycosides and β blockers to treat acute low-cardiac-output states should be avoided.

Patients in cardiogenic shock may have a marked increase in systemic vascular resistance (SVR) resulting in high afterload and poor peripheral perfusion. If the increased SVR is persistent and the administration of positive inotropic agents alone does not improve tissue perfusion, the use of afterload-reducing agents may be appropriate, such as nitroprusside or milrinone in combination with a β-adrenergic agonist. Milrinone, a phosphodiesterase inhibitor (see earlier), is also a positive inotropic agent, and combined with a β-adrenergic agonist, it works synergistically to increase levels of myocardial cyclic adenosine monophosphate.

Sequential evaluation and management of cardiovascular shock are mandatory (see Chapter 85). Table 491.8 outlines the general treatment principles for acute cardiac circulatory failure under most circumstances. In addition to cardiac-specific medications, other treatments aimed at improving oxygen capacity (e.g., blood transfusion for patients with anemia) and decreasing oxygen demand (e.g., intubation, mechanical ventilation, sedation, antipyretics) can be beneficial. Treatment of infants and children with low cardiac output after cardiac surgery also depends on the nature of the operative procedure, any intraoperative complications, and the physiology of the circulation after repair or palliation (see Chapter 483). If cardiogenic shock does not respond rapidly to medical therapy, consideration of mechanical support is warranted.

MECHANICAL CIRCULATORY SUPPORT

Extracorporeal membrane oxygenation (ECMO), which can provide total cardiopulmonary support, is the most common *short-term* modality to support circulatory failure in children. In experienced centers, children can be placed on ECMO rapidly, and therefore the modality can be used in multiple settings, including low cardiac output syndrome (low-output heart failure) after cardiac surgery, rapidly deteriorating hemodynamics in several scenarios (e.g., myocarditis), and as resuscitation from refractory cardiac arrest. The modality is ideal for short-term support when the underlying disease requiring ECMO is expected to resolve within days to weeks. For multiple reasons, including the relatively high complication rate and decreased mobility of many patients on ECMO, it is not an ideal support modality for long-term myocardial support.

Given the limitations of ECMO, there is a need to develop long-term support options for children with refractory heart failure. **Ventricular assist devices (VADs)** include both short-term and long-term mechanical circulatory support and can be deployed either percutaneously or surgically. In children, most of these devices are used with the intention of subsequently performing a heart transplantation, although the devices can be removed if myocardial function recovers. This is in contrast to adult patients, many of whom are placed on these devices with no plan for heart transplantation, the so-called *destination therapy.* Successfully managing patients on VAD support requires a dedicated multidisciplinary team.

For infants and small children, the most commonly used VADs are paracorporeal devices, including paracorporeal pulsatile-flow VADs (e.g., Berlin Heart EXCOR) and paracorporeal continuous-flow VADs (e.g., Pedimag). These devices can be used for left, right, or biventricular support. They are classified as a paracorporeal device because the pump sits outside the body. In older children and adolescents, intracorporeal continuous flow devices (e.g., HeartMate3) are preferred. These VADs are completely internalized except for a drive line that connects to the power source (Fig. 491.5). These VADs have fewer complications and can provide long-term durable support outside the hospital. These devices are often used in older children and adolescents, with many of these patients discharged home on VAD support. Other types of devices, including **temporary percutaneous VAD** (e.g., Impella) for short-term support and the **total artificial heart** for long-term support, have also been used in children.

Pediatric Heart and Heart-Lung Transplantation

492.1 Pediatric Heart Transplantation

Danielle S. Burstein and Joseph W. Rossano

Pediatric heart transplantation is considered the standard therapy that offers long-term survival for end-stage heart disease in children. In adults, ventricular assist devices (VADs) are usually employed as a long-term therapy for patients not eligible for heart transplantation, but in children the vast majority of VADs are used as a *bridge* to transplantation as opposed to an alternative to transplantation. According to the International Society for Heart and Lung Transplantation, as of January 2019, over 14,000 heart transplants had been performed on children in the world, with about 400 transplants annually—a quarter of these in children <1 year of age. Survival rates have improved significantly over time, with most of the improvement occurring in the early period after transplant. This period continues to the associated with the greatest risk of death, and many patients who survive the first year after transplant are alive 20 years later (Fig. 492.1). Indeed, a growing number of patients receiving a heart transplant in childhood are approaching their 15-, 20-, and 30-year posttransplant anniversaries. Current (2011-2023) 1-year survival is ~90% and 5-year survival ~80%.

INDICATIONS

Heart transplantation is performed (1) in infants and children with end-stage cardiomyopathy who have become refractory to medical therapy, (2) in patients with previously repaired or palliated congenital heart disease (CHD) who have developed ventricular dysfunction or other nonoperable late-term complications, and (3) less frequently in patients with complex CHD—pulmonary atresia with intact septum and coronary arterial stenoses and some forms of hypoplastic left heart syndrome (HLHS)—for whom standard surgical procedures are extremely high risk. Additionally, **retransplantation** accounts for approximately 5% of transplants annually.

Cardiomyopathies account for >50% of heart transplants in pediatric patients older than 1 year, with the percentage of patients with previously repaired complex CHD at approximately 30%. In infants younger than 1 year, CHD previously represented >80% of transplants; this has decreased to 60% as standard surgical results for complex CHD (e.g., HLHS) have improved.

RECIPIENT AND DONOR SELECTION

Potential heart transplant recipients must be free of serious noncardiac medical problems such as neurologic disease, active systemic infection, severe hepatic or renal disease, and severe malnutrition. Many children with ventricular dysfunction are at risk for the development of **pulmonary vascular disease**, which, if severe enough, would also preclude heart transplantation. Therefore pulmonary vascular resistance (PVR) is measured at cardiac catheterization in heart transplant candidates, both at rest and, if elevated, in response to vasodilators. Patients with fixed elevated PVR above 6 index Wood units are at higher risk for heart transplantation and may be considered candidates for heart-lung transplantation (see Chapter 492.2). However, with advances in postoperative management of pulmonary hypertension (e.g., inhaled nitric oxide), many patients with moderate elevation in PVR can undergo heart transplant alone. A comprehensive social services evaluation is an important component of the recipient evaluation. Because of the complex posttransplantation medical regimen, the family must have a history of compliance. Detailed informed consent must be obtained, indicating that the family (and, if old enough, the patient) understand the lifelong commitment to immunosuppressive medication and careful monitoring.

Chapter 492

Pediatric Heart and Heart-Lung Transplantation

492.1 Pediatric Heart Transplantation

Danielle S. Burstein and Joseph W. Rossano

Pediatric heart transplantation is considered the standard therapy that offers long-term survival for end-stage heart disease in children. In adults, ventricular assist devices (VADs) are usually employed as a long-term therapy for patients not eligible for heart transplantation, but in children the vast majority of VADs are used as a *bridge* to transplantation as opposed to an alternative to transplantation. According to the International Society for Heart and Lung Transplantation, as of January 2019, over 14,000 heart transplants had been performed on children in the world, with about 400 transplants annually—a quarter of these in children <1 year of age. Survival rates have improved significantly over time, with most of the improvement occurring in the early period after transplant. This period continues to the associated with the greatest risk of death, and many patients who survive the first year after transplant are alive 20 years later (Fig. 492.1). Indeed, a growing number of patients receiving a heart transplant in childhood are approaching their 15-, 20-, and 30-year posttransplant anniversaries. Current (2011-2023) 1-year survival is ~90% and 5-year survival ~80%.

INDICATIONS

Heart transplantation is performed (1) in infants and children with end-stage cardiomyopathy who have become refractory to medical therapy, (2) in patients with previously repaired or palliated congenital heart disease (CHD) who have developed ventricular dysfunction or other nonoperable late-term complications, and (3) less frequently in patients with complex CHD—pulmonary atresia with intact septum and coronary arterial stenoses and some forms of hypoplastic left heart syndrome (HLHS)—for whom standard surgical procedures are extremely high risk. Additionally, **retransplantation** accounts for approximately 5% of transplants annually.

Cardiomyopathies account for >50% of heart transplants in pediatric patients older than 1 year, with the percentage of patients with previously repaired complex CHD at approximately 30%. In infants younger than 1 year, CHD previously represented >80% of transplants; this has decreased to 60% as standard surgical results for complex CHD (e.g., HLHS) have improved.

RECIPIENT AND DONOR SELECTION

Potential heart transplant recipients must be free of serious noncardiac medical problems such as neurologic disease, active systemic infection, severe hepatic or renal disease, and severe malnutrition. Many children with ventricular dysfunction are at risk for the development of **pulmonary vascular disease**, which, if severe enough, would also preclude heart transplantation. Therefore pulmonary vascular resistance (PVR) is measured at cardiac catheterization in heart transplant candidates, both at rest and, if elevated, in response to vasodilators. Patients with fixed elevated PVR above 6 index Wood units are at higher risk for heart transplantation and may be considered candidates for heart-lung transplantation (see Chapter 492.2). However, with advances in postoperative management of pulmonary hypertension (e.g., inhaled nitric oxide), many patients with moderate elevation in PVR can undergo heart transplant alone. A comprehensive social services evaluation is an important component of the recipient evaluation. Because of the complex posttransplantation medical regimen, the family must have a history of compliance. Detailed informed consent must be obtained, indicating that the family (and, if old enough, the patient) understand the lifelong commitment to immunosuppressive medication and careful monitoring.

Donor shortage is a serious problem for both adults and children. At the national registry of transplant recipients in the United States, the **United Network for Organ Sharing (UNOS)**, allografts are matched by ABO blood group and body weight. However, ABO matching may not be required for young infants less than 2 years of age because of the immaturity of the immune system. Patients, especially with a history of CHD, who have undergone prior operations may have antibodies against human leukocyte antigens (HLAs). Patients with elevated anti-HLA antibodies are at risk for a positive cross match and early graft dysfunction. These antibodies can also contribute to late graft dysfunction through antibody-mediated rejection and development of cardiac allograft vasculopathy. For patients with these elevated antibodies, there are strategies to avoid a positive cross match through a prospective cross match or a virtual cross match, although this may prolong the waiting list time. There are also desensitization therapies that may reduce circulating HLA antibody production, although they do not affect historical antibodies, and current data remain unclear how effective desensitization therapy is for reducing posttransplant rejection risk. Contraindications to organ donation include prolonged cardiac arrest with persistent moderate to severe cardiac dysfunction, ongoing systemic illness or infection, and preexisting severe cardiac disease. Physicians caring for a patient who may be a potential donor should always contact the organ donor coordinator at their institution, who can best judge the appropriateness of organ donation and has experience in interacting with potential donor families. A history of resuscitation alone or reparable CHD is not an automatic exclusion for donation.

The decision of when to place a patient on the transplant waiting list is based on many factors, including degree of ventricular function, markedly decreased exercise tolerance as determined by cardiopulmonary exercise testing (see Chapter 472.5), poor response to medical heart failure therapy, multiple hospitalizations for heart failure, arrhythmia, progressive deterioration in renal or hepatic function, early stages of pulmonary vascular disease, and poor nutritional status. Patients with severe ventricular dysfunction are often started on a regimen of anticoagulation to reduce the risk of mural thrombosis and thromboembolism. Patients with progressive heart failure resulting in decreases in end-organ (renal or hepatic) function unresponsive to standard pharmacologic treatment may be candidates for a VAD. The use of these devices has increased dramatically over the past decade, and currently over half of patients with dilated cardiomyopathy are on VAD support before transplant. VADs can improve hemodynamics and end-organ function, allow for rehabilitation, and allow some patients to be discharged home on VAD support (see Chapter 491).

PERIOPERATIVE MANAGEMENT

Heart transplantation in children can be performed either with a *biatrial* or *bicaval* anastomosis. In the *biatrial* anastomosis, both donor and recipient hearts are excised so that the posterior portions of the atria containing the venae cavae and pulmonary veins are left intact. The aorta and pulmonary artery are divided above the level of the semilunar valves. The anterior portions of the donor's atria are then connected to the remaining posterior portions of the recipient's atria, thereby avoiding the need for delicate suturing of the venae cavae or pulmonary veins. Previously, the donor and recipient great vessels were connected via end-to-end anastomoses. This has been supplanted in many centers by the *bicaval* anastomosis, with the donor right atrium (and sinus node) left intact and the suture lines at the superior and inferior vena cavae; the left atrial connection is still performed as in the *biatrial* anastomosis.

In the immediate postoperative period, **immunosuppression** is achieved with induction therapy that includes an antilymphocyte therapy for the first 5-7 days; common agents include antithymocyte globulin (ATG) and the humanized anti–interleukin-2 receptor antibodies (basiliximab). Steroids are also commonly used within the first 5-7 days and then are often weaned off or discontinued. Antiproliferative agents (mycophenolate mofetil [MMF]) are also started immediately after transplant and are transitioned to an oral compound once enteral medications are tolerated. The most common combinations of chronic immunosuppression are a *calcineurin inhibitor* (CNI; tacrolimus or cyclosporine) plus an *antiproliferative agent* (MMF or azathioprine). Mammalian target of rapamycin (mTOR) inhibitors (sirolimus or everolimus) may be added to decrease the dose of CNI if renal insufficiency occurs. Many centers do not use steroids as part of maintenance immunosuppression but do use them as bolus treatment for acute rejection episodes. Immunosuppression levels are usually reduced after the first year posttransplant if there are no significant concerns for rejection. An ongoing U.S. multicenter pediatric trial called the TEAMMATE trial is comparing conventional immunosuppression therapy (tacrolimus and mycophenolate) with low-dose tacrolimus with everolimus and mycophenolate to determine which combination of immunosuppression is better at improving long-term pediatric post–heart transplant outcomes.

Many pediatric heart transplant recipients can be extubated from endotracheal intubation and mechanical ventilation support within the first 48 hours after transplantation and are out of bed in several days. In patients with preexisting high-risk factors, postoperative recovery may be considerably prolonged. For those with preoperative pulmonary hypertension, the use of nitric oxide in the postoperative period can allow the donor right ventricle to hypertrophy in response to elevated pulmonary artery pressures. Occasionally, these patients will require extracorporeal membrane oxygenation (ECMO) for primary graft dysfunction.

DIAGNOSIS AND MANAGEMENT OF ACUTE GRAFT REJECTION

Posttransplantation management consists of adjusting medications to maintain a balance between the risk of rejection and the side effects of over-immunosuppression. **Acute graft rejection** is a leading cause of death in pediatric heart transplant recipients. The incidence of acute rejection is greatest in the first 3 months after transplantation and decreases considerably thereafter. Many pediatric patients experience at least one episode of acute rejection in the first 2 years after transplantation, although modern immunosuppressive regimens have decreased the frequency of severe rejection episodes. Because the symptoms of rejection can mimic many routine pediatric illnesses (e.g., pneumonia, gastroenteritis), the transplant center should be notified whenever a heart transplant recipient is seen in the pediatrician's office or emergency department for acute illnesses.

Clinical manifestations of acute rejection may include fatigue, fluid retention, fever, diaphoresis, abdominal symptoms, and a gallop rhythm. The electrocardiogram (ECG) may show reduced voltage, atrial or ventricular arrhythmias, or heart block but is usually nondiagnostic. X-ray examination may show an enlarged heart, effusions, or pulmonary edema but typically only in the more advanced stages of rejection. Natriuretic peptide levels are usually increased during episodes of acute rejection. Most rejection episodes occur without any detectable clinical symptoms. On echocardiography, indices of systolic left ventricular function may be decreased; however, these usually do not deteriorate until rejection is at least moderately severe. Techniques to evaluate wall thickening and left ventricular diastolic function have not fulfilled their promise as predictors of early rejection. Most transplant centers do not rely on echocardiography alone for rejection surveillance.

Myocardial biopsy is the most reliable method of monitoring patients for rejection. Biopsy specimens are taken from the right ventricular side of the interventricular septum and can be harvested relatively safely, even in small infants. In infants, surveillance biopsies are usually performed less often and may be as infrequent as once or twice per year. Children may have clinically unsuspected rejection episodes even 5-10 years after transplantation; most pediatric transplant centers continue routine surveillance biopsies, although at less frequent intervals. Cardiac MRI evaluation has been an effective noninvasive method to perform rejection surveillance and to diagnose actual rejection.

Gene expression profiling of peripheral blood mononuclear cells has been validated in adults as a highly sensitive, moderately selective method of rejection surveillance. These results have not been confirmed in children. Other promising current techniques include the profiling of donor cell–free DNA released in the serum of patients during episodes of graft injury. Progress has also been made in genetic profiling as a means to determine which patients are most at risk for rejection. Children who have single nucleotide polymorphisms (SNPs) leading to greater activity of inflammatory cytokines or decreased activity of regulatory cytokines are at increased risk of rejection.

Cardiac rejection can be classified as cellular, antibody-mediated, or mixed. Criteria for grading cellular rejection are based on a system developed by the **International Society for Heart and Lung Transplantation (ISHLT)** that considers the degree of cellular infiltration and whether myocyte necrosis is present. ISHLT rejection grade 1R is usually mild enough that it is often not treated with bolus steroids, and many of these episodes resolve spontaneously. For patients with ISHLT grade 2R rejection, treatment is instituted with either intravenous (IV) methylprednisolone or a "bump and taper" of oral prednisone. Asymptomatic patients further out from transplant with normal echocardiograms may be treated as outpatients. Patients with grade 3R, or anyone with hemodynamic instability, are admitted to the hospital for IV corticosteroid and potentially more aggressive antirejection therapy. For rejection episodes resistant to steroid therapy, additional therapeutic regimens include antilymphocyte preparation (antithymocyte globulin), methotrexate, or total lymphoid irradiation. Refractory rejection is often considered a contraindication for retransplantation because of the relatively poor outcomes compared with other indications for retransplantation.

Criteria for grading antibody-mediated rejection are based on a system developed by the ISHLT that considers histologic and immunopathologic findings. In contrast to cellular rejection, antibody-mediated rejection is mediated by circulating donor-specific antibodies (DSAs) and can be detected by immunostaining of the biopsy specimen for the complement component C4d, for macrophages expressing CD68, and for evidence of histologic damage. Antibody-mediated rejection is less responsive to standard therapies for acute cellular rejection (e.g., bolus corticosteroids) and has been treated with plasmapheresis, intravenous immunoglobulin (IVIG), the anti–CD20 monoclonal antibody rituximab, and the proteasome inhibitor bortezomib, all with mixed results. The long-term outcome of patients with persistent DSAs or antibody-mediated rejection is poor, with many having early graft failure and premature development of graft vasculopathy.

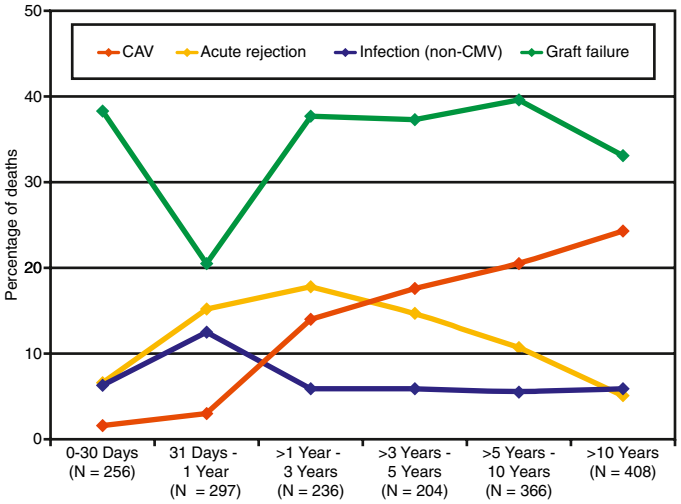

Fig. 492.2 Major causes of death after pediatric heart transplantation by time since transplant. CAV, Cardiac allograft vasculopathy; CMV, cytomegalovirus. *(From Rossano JW, Dipchand AI, Edwards LB, et al. J Heart Lung Transplant. 2016;35[10]:1185–1195, Fig. 10.)*

COMPLICATIONS OF IMMUNOSUPPRESSION

Infection

Infection is also a leading cause of death in pediatric transplant patients (Fig. 492.2). The incidence of infection is greatest in the first 3 months after transplantation, when immunosuppressive doses are highest. **Viral** infections are most common and account for as many as 25% of infectious episodes. **Cytomegalovirus (CMV)** infection was once a leading cause of morbidity and mortality and may occur as a primary infection in patients without previous exposure to the virus or as a reactivation. Severe CMV infection can be disseminated or associated with pneumonitis or gastroenteritis and may provoke an episode of acute graft rejection or graft coronary disease. Most centers use IV ganciclovir or CMV immune globulin (Cytogam), or both, as prophylaxis in any patient receiving a heart from a donor who is positive for CMV or in any recipient who has serologic evidence of previous CMV disease. Oral preparations of ganciclovir with improved absorption profiles are available for chronic therapy, usually for 3-6 months after transplant, and have largely replaced IV preparations for prophylaxis. These regimens have significantly reduced the burden of CMV disease in heart transplant patients. Polymerase chain reaction (PCR) enhances the ability to diagnose CMV infection and monitor the efficacy of therapy serially.

Most normal childhood viral illnesses are well tolerated and do not usually require special treatment. Otitis media and routine upper respiratory tract infections can be treated in the outpatient setting, although fever or symptoms that last beyond the usual course require further investigation. **Gastroenteritis**, especially with vomiting, can result in greatly reduced absorption of immunosuppressive medications and provoke a rejection episode. In this setting, drug levels should be closely monitored and use of IV medications considered. Gastroenteritis can also be a sign of rejection, so a high index of suspicion must always be maintained. Varicella is another childhood illness of concern for immunosuppressed patients. If a heart transplant recipient acquires clinical varicella infection, treatment with IV acyclovir usually attenuates the illness.

Bacterial infections occur next in frequency after viral, with the lung the most common site of infection, followed by blood, urinary tract, and less often, the sternotomy site. Other sources of posttransplantation infection include fungi and protozoa. Many centers use trimethoprim-sulfamethoxazole for prophylaxis during the first several months after transplant to prevent *Pneumocystis jiroveci* infection.

Growth Stunting

Patients requiring chronic corticosteroid therapy usually have decreased linear growth. Thus many pediatric transplant programs aim for steroid-free immunosuppression within the first year after transplant. In patients who experience rejection when steroids are withdrawn, alternate-day corticosteroid regimens may result in improved linear growth. **Total lymphoid irradiation** has also shown promise as a steroid-sparing protocol. Despite these concerns, the majority of long-term survivors of pediatric heart transplantation have normal growth.

Hypertension

Hypertension is common in patients treated with CNIs, caused by a combination of plasma volume expansion and defective renal sodium excretion. Corticosteroids usually potentiate calcineurin-induced hypertension.

Renal Function

Chronic administration of cyclosporine or tacrolimus can lead to a tubulointerstitial nephropathy in adults, but severe renal dysfunction is less common in children. Most pediatric patients gradually have an increase in serum creatinine in the first year after transplantation; if renal dysfunction occurs, it usually responds to a decrease in CNI dosage. The addition of sirolimus, an mTOR inhibitor, allows a reduction in CNI dose in patients with renal dysfunction, although it is unclear whether this strategy leads to long-term improved renal function. Infection with BK virus, a growing problem in renal transplant patients, has been described as a source of renal dysfunction in heart transplant patients. Fortunately, pediatric heart transplant patients infrequently require dialysis or renal transplantation.

Neurologic Complications

Neurologic side effects of cyclosporine and tacrolimus include tremor, myalgias, paresthesias, and, rarely, seizures. These complications can be treated with reduced doses of medication and occasionally with oral magnesium supplementation. A rare form of encephalopathy known as **posterior reversible encephalopathy syndrome** (PRES) can occur in patients taking CNIs (cyclosporine or tacrolimus). PRES presents with hypertension, headaches, and seizures, requires MRI for diagnosis, and is usually managed by changing CNI or, in rare cases, eliminating CNIs totally in favor of other immunosuppressive agents (e.g., sirolimus, MMF).

Tumors

One of the serious complications limiting long-term survival in pediatric heart transplant patients is the risk of neoplastic disease. The most common is **posttransplant lymphoproliferative disease** (PTLD), a condition associated with Epstein-Barr virus (EBV) infection. Patients who are EBV seronegative at transplant (usually infants and young children) are at increased risk of developing PTLD if they subsequently seroconvert, acquiring the virus either from the donor organ or from primary infection. Unlike true cancer, many cases of PTLD respond to a reduction in immunosuppression. A monoclonal antibody directed against the CD20 antigen on activated lymphocytes (rituximab), in conjunction with steroids and cyclophosphamide therapy, has been effective against some forms of PTLD. However, PTLD can behave more aggressively, and many patients eventually require chemotherapy. An increased risk of skin cancer requires that children use appropriate precautions when exposed to sunlight.

Cardiac Allograft Vasculopathy

Cardiac allograft vasculopathy (CAV) is a disease of the coronary arteries that occurs in approximately 20% of children 5 years after transplant. The cause is still unclear, although it is thought to be a form of immunologically mediated vessel injury. Multiple factors, including rejection episodes, infections, hypercholesterolemia, and hyperglycemia, are thought to increase the risk of CAV. Unlike native coronary atherosclerosis, CAV is a diffuse process with a high degree of distal vessel involvement. Because the transplanted heart has been denervated, patients may not experience symptoms such as angina pectoris during ischemic episodes, and the initial manifestation may be cardiovascular collapse or sudden death. Most centers perform coronary angiography annually to screen for coronary abnormalities; some also perform coronary intravascular ultrasound in larger children and adolescents. Standard coronary artery bypass procedures are usually not helpful because of the diffuse nature of the process, although transcatheter stenting can sometimes be effective for isolated lesions. For patients with severe CAV, repeat heart transplantation has been the only effective treatment. Thus prevention has been the focus of most current research. The cell-cycle inhibitors sirolimus and everolimus have been shown to decrease coronary arterial intimal thickening in adult transplant patients. Cholesterol-lowering HMG-CoA (3-hydroxy-3-methyl-coenzyme A) reductase inhibitors (e.g., pravastatin, atorvastatin) have been associated with a lower risk of CAV.

Other Complications

Corticosteroids usually result in cushingoid facies, steroid acne, and striae. Cyclosporine can cause a subtle change in facial features, such as hypertrichosis and gingival hyperplasia. These cosmetic features can be particularly disturbing to adolescents and may be the motivation for noncompliance, one of the leading risks for late morbidity and mortality. Most of these cosmetic complications are dose related and improve as immunosuppressive medications are weaned. Tacrolimus does not have the cosmetic side effects of cyclosporine. Osteoporosis and aseptic necrosis are additional reasons for reducing the steroid dosage as soon as possible. Diabetes and pancreatitis are rare but serious complications.

Rehabilitation

Despite the potential risks of immunosuppression, the prospect for rehabilitation in pediatric heart transplant recipients is excellent; most have no functional limitations in their daily lives. They can attend daycare or school and participate in competitive sports and other age-appropriate activities. Standardized measurements of ventricular function are close to normal. Because the transplanted heart is denervated, the increase in heart rate and cardiac output during exercise is slower in transplant recipients, and maximal heart rate and cardiac output responses are mildly attenuated. These subtle abnormalities are rarely noticeable by the patient.

Growth of the transplanted heart is excellent, although a mild degree of ventricular hypertrophy is often seen, even years after transplantation. The sites of atrial and great vessel anastomoses usually grow without the development of obstruction. In neonates who undergo transplantation for HLHS, however, juxtaductal aortic coarctation may recur.

A serious problem with noncompliance may occur once patients reach adolescence, and life-threatening rejection may result. Early intervention by social workers, counselors, and psychologists may be able to reduce this risk.

492.2 Heart-Lung and Lung Transplantation

Samuel B. Goldfarb, Danielle S. Burstein, and Joseph W. Rossano

More than 700 heart-lung and 2,500 lung (single or double) pediatric transplants have been performed and reported to ISHLT, with >100 procedures performed annually. The majority of these are lung transplantation, with only three heart-lung transplants reported in 2017. Only 16 heart-lung transplants have been performed in the United States in the past 5 years compared to over 140 lung transplants during this same time frame. Primary indications for lung transplantation include cystic fibrosis, pulmonary hypertension, interstitial lung disease, surfactant deficiencies, and retransplant. Indications for heart-lung transplant include complex CHD along with either pulmonary parenchymal or vascular disease. Patients with normal hearts are candidates for lung transplantation even in the setting of right ventricular dysfunction. This had led to the marked decline in heart-lung transplant procedures in the current era. In some patients with CHD, double-lung transplantation can be performed in combination with repair of intracardiac defects. Patients with cystic fibrosis are *not* candidates for single-lung grafts

because of the risk of infection from the diseased contralateral lung. Patients are selected according to many of the same criteria as for heart transplant recipients (see Chapter 492.1).

Posttransplant immunosuppression is usually achieved with a triple-drug regimen, combining a CNI (cyclosporine or tacrolimus) with an antiproliferative agent (MMF or azathioprine) and prednisone. Most patients receive induction therapy with an antithymocyte or anti–T-cell preparation. Unlike patients with isolated heart transplants, patients with lung or heart-lung transplants cannot be weaned totally off steroids. Prophylaxis against *P. jiroveci* infection is achieved with trimethoprim-sulfamethoxazole or aerosolized pentamidine. Ganciclovir and CMV immune globulin prophylaxis are used as in heart transplant recipients (see Chapter 492.1). Antifungal medications are used in the perioperative and posttransplant periods in patients who have pretransplant colonization.

Pulmonary rejection is common in lung or heart-lung transplant recipients, whereas heart rejection is encountered much less often than in patients with isolated heart transplants. Acute cellular rejection (ACR) occurs in approximately 10–30% of patients in the first year after transplant depending on the recipient's age. Younger recipients have a lower incidence of ACR. Antibody-mediated rejection (AMR) and chronic lung allograph dysfunction (CLAD) are other forms of rejection. Symptoms of lung rejection may include fever and fatigue, although many episodes are minimally symptomatic. Signs of rejection could include changes in lung function testing and radiographic findings. Surveillance for acute rejection is performed by monitoring pulmonary function (forced vital capacity; forced expiratory volume in 1 second [FEV_1]; forced expiratory flow, midexpiratory phase [$FEF_{25–75\%}$]), systemic arterial oxygen tension, chest radiographs, chest CT, transbronchial biopsy, and open lung biopsy. The gold standard for ACR is tissue diagnosis, generally performed with transbronchial biopsies. AMR is diagnosed based on findings of donor-specific antibodies and tissue biopsy often associated with graft dysfunction. CLAD is a form of chronic rejection. It can present as an obstructive lung disease in the form of obliterative bronchiolitis. CLAD can also present with significant pulmonary fibrosis in the form of restrictive allograft dysfunction (RAD). In heart-lung transplant recipients, hearts are assessed for rejection similar to the approach described in Chapter 492.1.

Actuarial survival rates after lung or heart-lung transplantation in children are currently 75–80% at 1 year and 50% at 5 years after transplant; improved patient selection and postoperative management are continually improving these survival statistics from prior eras. In the analysis of survival at 5 years conditional on survival at 12 months, rates significantly improve for both lung and heart-lung regardless of underlying condition. One year conditional survival rates at 5 years for both are roughly 70%. Some groups, such as patients with CHD in the absence of Eisenmenger syndrome, have particularly poor outcomes with transplant. Graft failure and infection are the leading cause of early death, whereas a form of chronic rejection in the form of CLAD or RAD accounts for almost 50% of cases of late mortality. Other causes of early morbidity and mortality include technical complications, multiorgan failure, primary graft dysfunction, and cardiovascular causes. Additional late complications include the development of late graft failure, malignancies, infection, and other side effects of chronic immunosuppression.

Postoperative indices of cardiopulmonary function and exercise capacity show significant improvement. Problems of donor availability are even more severe with lung transplantation than with isolated heart transplantation. However, significant advances in ex vivo lung perfusion have great potential to expand the number of organs available for transplantation.

Section 8

Diseases of the Peripheral Vascular System

Chapter 493

Diseases of the Blood Vessels (Aneurysms and Fistulas)

493.1 Aneurysms

Daniel Bernstein

See also Chapter 208.

Aneurysms of the coronaries and occasionally the systemic arteries may complicate Kawasaki disease and are the leading cause of morbidity in this disease (Figs. 493.1 and 493.2). Persistent moderate to large aneurysms carry several risks: embolism and thromboembolism (a clot developing in the aneurysm because of stagnant blood flow and obstructing flow and/or breaking off and traveling more distally down the coronary, resulting in myocardial ischemia/infarction) and stenosis (the distal end of the aneurysm tends to become narrowed over time, limiting downstream coronary blood flow). Management includes anticoagulation to prevent thrombosis and β blockers to reduce myocardial oxygen requirements (see Chapter 210).

COVID-19–associated multisystem inflammatory syndrome in children (MIS-C) typically occurs a few weeks after active SARS-CoV-2 infection and can cause coronary artery dilation and aneurysms, in addition to other significant cardiac manifestations (ventricular dysfunction, arrhythmias, and conduction abnormalities; see Chapters 311 and 449.1).

Other than in Kawasaki disease and MIS-C, aneurysms are not common in children and occur most frequently in the aorta in association with coarctation of the aorta, patent ductus arteriosus, Ehlers-Danlos syndrome type IV (vascular ecchymotic form), hyper-IgE syndrome, Marfan syndrome, and the four forms of Loeys-Dietz syndrome (see Chapter 641). Aneurysms may be seen in the arterial tortuosity syndrome and the multisystem smooth muscle dysfunction syndrome (MSMDS) (see Chapter 493.4). MSMDS is characterized by congenital mydriasis, patent ductus arteriosus, aortic and other arterial aneurysms, as well as moyamoya-like cerebrovascular disease and pulmonary hypertension. The affected gene is *ACTA2*. Aneurysms may also occur secondary to an infected embolus; infection contiguous to a blood vessel; trauma; congenital abnormalities of vessel structure, especially the medial wall; and arteritis, including polyarteritis nodosa, Behçet syndrome, and Takayasu arteritis (see Chapter 210.2).

493.2 Arteriovenous Fistulas

Daniel Bernstein

Arteriovenous fistulas may be limited and small or may be large and extensive, producing systemic complications (see Chapters 554 and 691). The most common sites in infants and children are within the

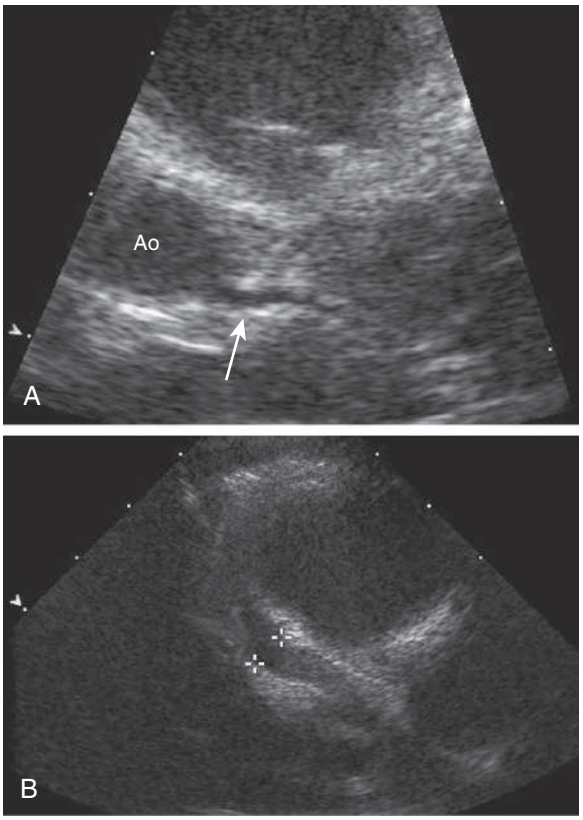

Fig. 493.1 Two-dimensional echocardiograms comparing a normal left main coronary artery (*arrow* in A) with a giant coronary artery aneurysm (outlined by *cross marks* in B) in a patient with Kawasaki disease. Ao, Aorta.

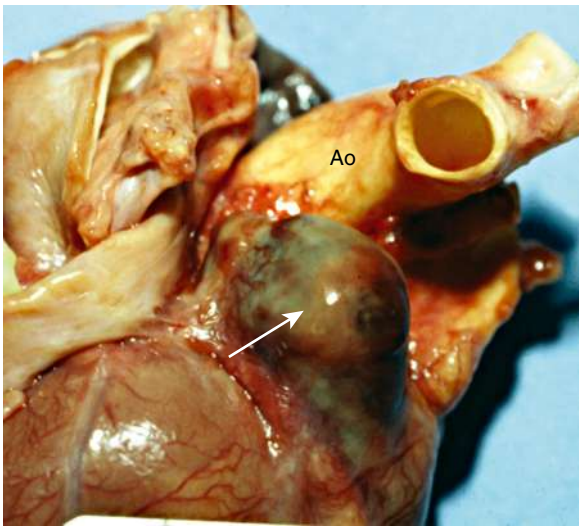

Fig. 493.2 Pathologic specimen showing giant aneurysm of left main coronary artery *(arrow)*. Ao, Ascending aorta.

cranium, in the liver, in the lung, in the extremities, and in vessels in or near the thoracic wall. These fistulas, although usually **congenital**, may follow trauma or may be a manifestation of hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease). Femoral arteriovenous fistulas are a rare complication of percutaneous femoral catheterization.

CLINICAL MANIFESTATIONS

Clinical symptoms occur only in association with large arteriovenous communications when arterial blood flows into a low-pressure venous system without the resistance of the capillary bed; local venous pressure is increased, and arterial flow distal to the fistula is decreased. Systemic arterial resistance falls because of the runoff of blood through the fistula. Compensatory mechanisms include tachycardia and increased stroke volume so that cardiac output rises. Total blood volume is also increased. In large fistulas, left ventricular dilation, a widened pulse pressure, and high-output heart failure can occur. CT, MRI, or injection of contrast material into an artery proximal to the fistula confirms the diagnosis.

Large intracranial arteriovenous fistulas most often occur in newborn infants in association with a **vein of Galen malformation**. The large intracranial left-to-right shunt results in heart failure secondary to the demand for high cardiac output. Patients with smaller communications may not have cardiovascular manifestations but may later be disposed to hydrocephalus (see Chapter 631.9) or seizures. The diagnosis can often be made by auscultation of a continuous murmur over the cranium. Older children with more diffuse intracranial arteriovenous malformations may be recognized on the basis of intracranial calcification and high cardiac output without cardiac failure.

Coronary arteriovenous fistulas can develop between a coronary artery and any of the cardiac chambers **(coronary cameral fistula)** or great vessels. These fistulas can result in steal of blood away from the heart muscle downstream of the fistula resulting in ischemia and, in rare cases, can even cause obstruction of ventricular inflow caused by physical interference with atrioventricular valve function.

Hepatic arteriovenous fistulas may be generalized or localized in the liver and may be hemangioendotheliomas or cavernous hemangiomas. The fistula may be located between the hepatic artery and the ductus venosus or portal vein. Congenital hemorrhagic telangiectasia may also be present. Large arteriovenous fistulas are associated with increased cardiac output and heart failure. Hepatomegaly is usual, and systolic or continuous murmurs may be audible over the liver.

Peripheral arteriovenous fistulas generally involve the extremities and can be associated with disfigurement, swelling of the extremity, and visible hemangiomas. Their presence can be complicated by breathing difficulties if located near the upper airways and causing obstruction. Because only a small minority results in large arterial runoff, cardiac failure is uncommon.

TREATMENT

Medical management of heart failure is initially helpful in neonates with these conditions; with time, the size of the shunt may diminish and symptoms spontaneously regress. Hemangiomas of the liver often eventually disappear completely. Large liver hemangiomas have been treated with corticosteroids, β blockers, ε-aminocaproic acid, interferon, local compression, embolization, or local irradiation; the beneficial effects of these management options are not firmly established because individual patients display marked variation in clinical course without treatment. **Transcatheter closure** is becoming the treatment of choice for many patients with a symptomatic arteriovenous fistula. Embolic agents that have been used include detachable balloons, steel (Gianturco) coils, plugs, and liquid tissue adhesives (cyanoacrylate). Often, multiple procedures are necessary before flow is significantly reduced. **Gamma knife radiosurgery** has been used successfully in patients with cerebral arteriovenous malformations. Surgical removal of a large fistula may be attempted in patients with severe cardiac failure and lack of improvement with medical treatment. Surgical treatment may be contraindicated or unsuccessful when the lesion is extensive and diffuse or is located in a position where adjoining tissue may be injured during the surgery or related procedures. β-Adrenergic blockers such as propranolol have dramatically changed the treatment for cutaneous hemangiomas, with excellent results.

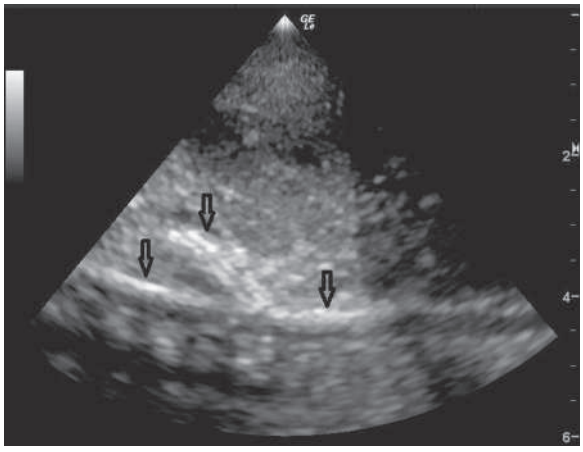

Fig. 493.4 Ultrasonography of abdominal aorta showing calcification of descending aorta and its branches *(arrows). (From Karthikeyan G. Generalized arterial calcification of infancy. J Pediatr. 2013;162:1074, Fig. 1.)*

493.3 Generalized Arterial Calcification of Infancy (Idiopathic Infantile Arterial Calcification)

Robert M. Kliegman

Generalized arterial calcification of infancy (GACI) is a rare and often lethal autosomal recessive disorder characterized by calcification of muscular arteries with fibrotic myointimal proliferation and subsequent vascular stenosis leading to tissue ischemia, poor function, or infarction. Diffuse arterial calcification may begin in utero, leading to hydrops fetalis; in the neonate, diffuse arterial calcification leads to respiratory distress and heart failure or myocardial infarction (coronary, pulmonary arteries), hypertension (renal arteries), and poor femoral pulses (aorta, femoral arteries).

Pathogenic variants in the ectonucleotide pyrophosphatase 1 gene (*ENPP1*) are noted in 75% of patients. Serum calcium, phosphate, and alkaline phosphatase levels are normal; the vascular calcification may be seen on plain x-ray films (Fig. 493.3), ultrasonography (Fig. 493.4), or CT scans (Fig. 493.5), which may reveal calcifications not visible on plain films.

A subset of patients with GACI have monoallelic or biallelic pathogenic variants in the adenosine triphosphate–binding cassette subfamily C number 6 gene (*ABCC6*), which is responsible for **pseudoxanthoma elasticum** (PXE). PXE, an autosomal recessive disorder, is classically associated with a later onset of ectopic mineralization of elastic fibers in the skin, eyes, joints, and arteries. In addition, some surviving infants with *ENPP1* variant develop PXE symptoms involving the skin and retina (angioid streaking).

Infants with GACI have been treated with bisphosphonates with variable success. In addition, some survivors with the *ENPP1* variant have developed hypophosphatemic-hyperphosphaturic rickets.

In the absence of stroke or encephalomalacia, most survivors are developmentally normal. In some survivors the vascular calcification resolves and is replaced by fibrosis. The differential diagnosis includes Singleton-Merten syndrome (aortic calcification, dental anomalies, osteopenia), hypervitaminosis D, hyperparathyroidism, congenital syphilis (aortitis), twin-twin transfusion syndrome (recipient), and idiopathic iliac artery calcification of infancy.

ARTERIAL CALCIFICATIONS CAUSED BY DEFICIENCY OF CD73

This rare autosomal recessive disorder, caused by pathogenic variants in the 5-exonucleotidase CD73 *(NT5E)*, results in joint and arterial (lower-extremity) calcification in adults. Patients present with intermittent claudication and joint pain. Onset is probably before adulthood, since patients may be undiagnosed with nonspecific findings during adolescence.

493.4 Arterial Tortuosity

Robert M. Kliegman

Arterial tortuosity may be seen in many different diseases and genes (Table 493.1). These disorders are usually recognized by their phenotype, and all may present during childhood. Tortuosity is best defined by magnetic resonance angiography (Fig. 493.6). When present, it often increases the risk for early cardiovascular morbidity for patients with Marfan or Loeys-Dietz syndrome.

Arterial tortuosity syndrome is another genetic arteriopathy caused by pathogenic variants in the *SCL2A10* gene. It has many features of other connective tissue diseases, including hyperextensible and soft velvety skin, high-arched palate, micrognathia, abdominal hernias, and joint hypermobility. The prognosis for patients with arterial tortuosity syndrome is quite variable, but the presence of vascular stenosis is associated with a poorer prognosis.

Chapter 494

Systemic Hypertension

Ian R. Macumber and Joseph T. Flynn

Hypertensive children, although frequently asymptomatic, already may manifest evidence of target organ damage. Up to 40% of hypertensive children have left ventricular hypertrophy, and hypertensive children have increased carotid intima-to-media thickness, a marker of early atherosclerosis. Primary (essential) hypertension occurring during childhood often continues into adulthood. Children with blood pressure (BP) >90th percentile exhibit a 2.4-fold greater risk of having hypertension as adults. Similarly, almost half of hypertensive adults had a BP >90th percentile as children. Adolescent hypertension is also an independent predictor of both end-stage kidney disease and left ventricular dysfunction in middle-age males.

PREVALENCE OF HYPERTENSION IN CHILDREN

In infants and young children, systemic hypertension is uncommon, with a prevalence of <1%, but, when present, often indicates an underlying disease process **(secondary hypertension)**. *Severe and symptomatic hypertension in children is usually caused by secondary hypertension.* In contrast, the prevalence of primary hypertension, mostly in older school-age children and adolescents, has increased in prevalence in parallel with the obesity epidemic. Estimates are variable, but data from the U.S. National Health and Nutrition Examination Survey (NHANES) show that approximately 9% of American youth have **elevated BP** and 3–4% have **hypertension**. A meta-analysis suggests a similar worldwide prevalence of hypertension in children. The normative data from the 2017 American Academy of Pediatrics (AAP) clinical practice guidelines have resulted in an overall trend of increased hypertension prevalence. The influence of obesity on elevated BP is evident in children as young as 2-5 years old. Approximately 20% of American youth have obesity, and up to 10% of these have hypertension.

DEFINITION OF HYPERTENSION

Normal BP in adults is <120/80 mm Hg. **Elevated** blood pressure is considered systolic BP of 120-129 *and* diastolic BP <80 mm Hg. **Stage 1** hypertension is systolic 130-139 *or* diastolic 80-89 mm Hg; **Stage 2** hypertension is systolic ≥140 *or* diastolic ≥90 mm Hg. This definition is based on potential outcomes because it relates degree of BP elevation with significant likelihood of subsequent cardiovascular events. Because hypertension-associated cardiovascular events (e.g., myocardial infarction, stroke) occur rarely in childhood, the definition of hypertension in children is statistical and based on the *distribution of BP in healthy children,* not outcomes. The AAP clinical practice guideline on childhood hypertension maintains the same statistical approach to defining and categorizing childhood BP as in previous guidelines from the **National High Blood Pressure Education Program (NHBPEP)**:

- **Normal BP:** BP <90th percentile for age, sex, and height or <120/<80 (systolic/diastolic) mm Hg for adolescents ≥13 years old
- **Elevated BP:** BP reading ≥90th percentile and <95th percentile for age, sex, and height or 120-129/<80 mm Hg for adolescents ≥13 years old
- **Hypertension:** BP >95th percentile for age, sex, and height or ≥130/80 mm Hg for adolescents ≥13 years old. Hypertensive-level BP is further staged as follows:
  - **Stage 1 hypertension:** BP >95th percentile for age, sex, and height up to the 95th percentile + 11 mm Hg or 130-139/80-89 mm Hg for adolescents ≥13 years of age
  - **Stage 2 hypertension:** BP ≥95th percentile + 12 mm Hg for age, sex, and height or >140/90 mm Hg for adolescents ≥13 years of age

The BP cut-points for adolescents ≥13 years old and use of the term *elevated BP* instead of prehypertension were chosen to align with revised BP cut-points and terminology found in the American Heart Association/American College of Cardiology (AHA/ACC) guideline for adult hypertension. The European Society of Hypertension (ESH) pediatric BP guideline also suggested that an absolute BP cutoff be used for adolescents age 16 and older, rather than using BP percentiles. For these older adolescents, the ESH guidelines define *high-normal* BP as 130-139/85-89 mm Hg and *hypertension* as ≥140/90 mm Hg.

The AAP guideline* also contains tables of normative BP values for children and adolescents based on a reanalysis of the NHBPEP database, removing all overweight and obese children. This revision results in BP values that are 2-3 mm Hg lower than the corresponding BP values in the 2004 NHBPEP Fourth Report, illustrating the impact of the childhood obesity epidemic on BP in young persons. The AAP guideline also contains a *simplified table* of BP values that may require further evaluation, which should be useful for screening (Table 494.1).

BLOOD PRESSURE MEASUREMENT IN CHILDREN

The AAP guideline recommends that children 3 years or older should have their BP measured during annual preventive visits, unless the child has risk factors such as obesity, chronic kidney disease (CKD), or diabetes, in whom it should be checked at every healthcare encounter. In contrast, the ESH pediatric guideline recommends checking BP at every healthcare encounter for all children >3 years old. Selected children <3 years old should also have their BP measured, including those with a history of prematurity, congenital heart disease, kidney disease, solid-organ transplant, cancer, treatment with drugs known to raise BP, other illnesses associated with hypertension (e.g., neurofibromatosis, tuberous sclerosis), or evidence of increased intracranial pressure. The preferred method is by auscultation using a sphygmomanometer (BP) with a cuff appropriate for the size of the child's arm.

Elevated readings should be confirmed on repeat visits before determining that a child is hypertensive. The BP should be measured with the child in the seated position after a period of quiet for at least 5 minutes, and it is recommended that the BP be checked 3 times, averaging the results. Careful attention to **cuff size** is necessary to avoid overdiagnosis, because a cuff that is too short or narrow artificially increases BP readings. An appropriate-sized cuff has an inflatable bladder whose length covers 80–100% of the upper arm circumference (measured midway between the acromion process and olecranon) and whose width is at least 40% of the arm circumference. A wide variety of cuff sizes should be available in any medical office where children are routinely seen.

Systolic blood pressure (SBP) is indicated by appearance of the *first* Korotkoff sound. Diastolic blood pressure (DBP) has been defined by consensus as the *fifth* Korotkoff sound, unless the Korotkoff sounds can be heard down to 0 mm Hg, in which case the *fourth* Korotkoff sound should be reported as the DBP. Palpation is useful for rapid assessment of SBP, although the palpated BP is generally about 10 mm Hg lower than that obtained by auscultation. Oscillometric techniques are used frequently in infants and young children, but they are susceptible to artifacts and are best for measuring mean arterial pressure (MAP). In addition, different devices use different proprietary algorithms to back-calculate SBP and DBP from the MAP, making comparison between devices difficult.

Ambulatory Blood Pressure Monitoring

Ambulatory blood pressure monitoring **(ABPM)** is frequently used as a tool to assess pediatric hypertension. The patient wears a device that records BP every 20-30 minutes throughout a 24-hour period, during usual daily activities, including sleep. This monitoring allows calculation of the mean daytime BP, sleep BP, and mean

* https://publications.aap.org/pediatrics/article/140/3/e20171904/38358/Clinical-Practice-Guideline-for-Screening-and.

BP over 24 hours. The physician can also determine the proportion of BP measurements that are in the hypertensive range (BP load) and whether there is an appropriate decrease in BP during sleep (nocturnal dip), generally considered *normal* if there is a decrease in nocturnal BP of >10% from awake values. The cuff should be placed on the patient's nondominant arm. It is recommended that the patient keep a journal of sleep and awake times, medication timing, and other events that may be relevant to BP readings. Clinicians should only perform ABPM if they have had specific training in performing and interpreting the results.

ABPM readings are more strongly correlated with target-organ damage in children than casual/office BP readings and are more sensitive for a diagnosis of hypertension than either manual or automated office blood pressures. The 2017 AAP guideline strongly recommends that ABPM be performed on all patients with elevated office readings to confirm the diagnosis of hypertension. In addition, ABPM is necessary to diagnose **white coat hypertension** (elevated office BP but normal ambulatory BP) and **masked hypertension** (normal office BP but elevated ambulatory BP). It should be noted that white coat hypertension is not a benign condition, and children with white coat hypertension may be at increased risk of developing sustained hypertension in the future. In adults, white coat hypertension has been associated with higher all-cause and cardiovascular mortality compared to normotensive individuals. ABPM is also a useful tool for evaluating effectiveness of antihypertensive therapy. ABPM is recommended to assess BP patterns in high-risk patient populations, such as children with CKD, solid-organ transplant, diabetes mellitus, and severe obesity.

ABPM is an extremely useful tool for evaluating and managing hypertension in appropriate patient populations, but it does have limitations. Not every patient will tolerate APBM, including younger children (although there are reports of successful ABPM in toddlers 18 months old) and some children with developmental delay. Nonetheless, it is usually feasible to perform ABPM in children ≥6-7 years. The most accepted normative data come from the German Working Group on Pediatric Hypertension. However, there are concerns with this dataset: (1) it includes only Central European White children and thus might not be generalizable to other ethnicities; (2) there were relatively few shorter children included, which may limit its application to patients with chronic diseases such as CKD; and (3) there was very little variability in DBP values, which is not consistent with data from other BP measurement techniques showing that DBP varies with both age and height.

From Flynn JT, Kaelber DC, Baker-Smith CM, et al. Clinical practice guideline for screening and management of high blood pressure in children and adolescents. *Pediatrics*. 2017;140(3):e20171904, Table 6.

ETIOLOGY AND PATHOPHYSIOLOGY

Blood pressure is the product of cardiac output (CO) and peripheral vascular resistance (PVR). An increase in either CO or PVR results in an increase in BP; if either of these factors increases while the other decreases, BP may not increase. When hypertension is the result of another disease process, it is referred to as *secondary hypertension*. When no identifiable cause can be found, it is referred to as *primary hypertension*.

Secondary hypertension is most common in infants and younger children. It is most often caused by kidney abnormalities; additional etiologies include cardiovascular disease and endocrinopathies. Younger age, severely elevated BP, and symptomatic hypertension make a secondary cause of hypertension more likely. Many childhood diseases can be responsible for *chronic hypertension* (Table 494.2) or *acute/intermittent hypertension* (Table 494.3). The most likely cause varies with age. Hypertension in the premature infant is sometimes

Table 494.2 Conditions Associated with Chronic Hypertension in Children

RENAL
Recurrent pyelonephritis/renal scarring
Chronic glomerulonephritis
Prematurity
Congenital dysplastic kidney
Polycystic kidney disease
Vesicoureteral reflux nephropathy
Segmental hypoplasia (Ask-Upmark kidney)
Obstructive kidney disease
Renal tumors
Renal trauma
Systemic lupus erythematosus (other connective tissue diseases)
VASCULAR
Coarctation of thoracic or abdominal aorta
Renal artery lesions (stenosis, fibromuscular dysplasia, thrombosis, aneurysm)
Umbilical artery catheterization with thrombus formation
Neurofibromatosis (intrinsic or extrinsic narrowing for vascular lumen)
Renal vein thrombosis
Vasculitis (ANCA associated, polyarteritis nodosa, Takayasu arteritis)
Arteriovenous shunt
Williams-Beuren syndrome
Moyamoya disease
ENDOCRINE
Hyperthyroidism
Congenital adrenal hyperplasia (11β-hydroxylase and 17-hydroxylase defect)
Cushing syndrome
Primary hyperaldosteronism
Apparent mineralocorticoid excess
Glucocorticoid remedial aldosteronism (familial aldosteronism type 1)
Glucocorticoid resistance (Chrousos syndrome)
Pseudohypoaldosteronism type 2 (Gordon syndrome)
Pheochromocytoma
Other neural crest tumors (neuroblastoma, ganglioneuroblastoma, ganglioneuroma)
Liddle syndrome
Geller syndrome
CENTRAL NERVOUS SYSTEM
Intracranial mass
Hemorrhage
Residual after brain injury
Quadriplegia (dysautonomia)
Sleep disordered breathing

ANCA, Antineutrophil cytoplasmic antibody.

Table 494.3 Conditions Associated with Transient or Intermittent Hypertension in Children

RENAL
Acute postinfectious glomerulonephritis
Henoch-Schönlein purpura with nephritis
Hemolytic-uremic syndrome
Acute kidney injury
After renal transplantation (immediately and during episodes of rejection)
Hypervolemia
Pyelonephritis
Renal trauma
Leukemic infiltration of the kidney
DRUGS AND POISONS
Cocaine
Oral contraceptives
Sympathomimetic agents
Amphetamines
Phencyclidine
Corticosteroids and adrenocorticotropic hormone
Cyclosporine, sirolimus, or tacrolimus treatment after transplantation
Licorice (glycyrrhizic acid)
Lead, mercury, cadmium, thallium
Antihypertensive withdrawal (clonidine, methyldopa, propranolol)
Vitamin D intoxication
Ma-huang
CENTRAL AND AUTONOMIC NERVOUS SYSTEM
Increased intracranial pressure
Guillain-Barré syndrome
Burns
Familial dysautonomia
Stevens-Johnson syndrome
Posterior fossa lesions
Porphyria
Poliomyelitis
Encephalitis
Spinal cord injury (autonomic storm)
MISCELLANEOUS
Preeclampsia
Pain, anxiety
Hypercalcemia
After coarctation repair
White blood cell transfusion
Extracorporeal membrane oxygenation

associated with umbilical artery catheterization, renal artery thrombosis, or bronchopulmonary dysplasia. Hypertension during early childhood may be caused by kidney disease, coarctation of the aorta, endocrine disorders, or medications.

Kidney disease (e.g., acute or chronic glomerulonephritis, reflux or obstructive nephropathy, hemolytic-uremic syndrome, polycystic kidney disease, congenital anomalies of the kidney and urinary tract) and **renovascular hypertension** account for approximately 90% of children with secondary hypertension. Parenchymal kidney disease and renal artery stenosis lead to water and sodium retention thought to be, in part, secondary to increased renin secretion. **Coarctation of the aorta** must always be considered, even in adolescents. **Obstructive sleep apnea** is associated with hypertension in children, and patients with hypertension and symptoms of obstructive sleep apnea (snoring, daytime somnolence, insomnia, pauses in breathing) should be referred for polysomnography. Several **endocrinopathies** are associated with hypertension, usually those involving the thyroid, parathyroid, and adrenal glands. Systolic hypertension and tachycardia are common in hyperthyroidism; DBP is not usually elevated. **Hypercalcemia**, whether secondary to hyperparathyroidism or other causes, often results in mild elevation in BP because of an increase in vascular tone. **Adrenocortical disorders** (e.g., aldosterone-secreting tumors, sodium-retaining congenital adrenal hyperplasia, Cushing syndrome) may produce hypertension in patients with increased mineralocorticoid secretion. It is important to consider conditions associated with real or apparent **mineralocorticoid excess** and thus a *suppressed* renin level (with or without hypokalemia) form of secondary hypertension (Table 494.4 and Fig. 494.1). **Pheochromocytomas** are catecholamine-secreting tumors that give rise to hypertension because of the cardiac and peripheral vascular effects of epinephrine and norepinephrine. Children with pheochromocytoma usually have sustained rather than the intermittent or exercise-induced hypertension seen in adults. Pheochromocytoma develops in approximately 5% of patients with neurofibromatosis and can also be seen in certain genetic disorders such as von Hippel-Lindau disease. Rarely, secondary hypertension can be caused by **pseudohyperaldosteronism**, which leads to elevated BP in the face of a suppressed renin level. Such disorders include Liddle syndrome, apparent mineralocorticoid excess, and glucocorticoid-remediable aldosteronism. Altered sympathetic tone can be responsible for acute or intermittent elevation of BP in children with Guillain-Barré syndrome, poliomyelitis, burns, and Stevens-Johnson syndrome. Intracranial lesions also affect sympathetic outflow from the central nervous system.

A number of **drugs of misuse**, **therapeutic agents**, and **toxins** may cause hypertension (Table 494.5). Cocaine may provoke a rapid increase in BP and can result in seizures or intracranial hemorrhage. Phencyclidine causes transient hypertension that may become persistent in chronic abusers. Tobacco use may also increase BP. Sympathomimetic agents used as nasal decongestants, appetite suppressants, and stimulants for attention-deficit disorder produce peripheral vasoconstriction and varying degrees of cardiac stimulation. Individuals vary in their susceptibility to these effects. Oral contraceptives should be suspected as a contributor to elevated BP in adolescent girls, although the incidence is lower with the use of low-estrogen preparations. Immunosuppressant agents such as cyclosporine and tacrolimus cause hypertension in organ transplant recipients, and the effect is exacerbated by the coadministration of corticosteroids. BP may be elevated in patients with poisoning by a heavy metal (lead, cadmium, mercury).

In older school-age children and adolescents, **primary hypertension** becomes increasingly common. These patients often are overweight, have a strong family history of hypertension, and have BP values at, or only slightly above, the 95th percentile for age. Isolated systolic hypertension is also more consistent with primary hypertension, whereas diastolic hypertension may suggest a secondary cause. The cause of primary hypertension is likely to be multifactorial; obesity, genetic alterations in calcium and sodium transport, vascular smooth muscle reactivity, the renin-angiotensin-aldosterone system (RAAS), sympathetic nervous system overactivity, and insulin resistance have been implicated in this disorder. Elevated uric acid levels may play a role in the pathophysiology of primary hypertension, and elevated uric acid levels have been associated with higher SBP and DBP in children. Proof-of-concept studies have confirmed that lowering of uric acid levels results in lower BP in overweight youth with hypertension or prehypertension. Some children and adolescents demonstrate *salt-sensitive hypertension*. This is more common in children with primary hypertension and may be ameliorated by weight loss and sodium restriction.

Normotensive children of hypertensive parents may show abnormal physiologic responses that are similar to those of their parents. When subjected to stress or competitive tasks, the offspring of hypertensive adults, as a group, respond with greater increases in heart rate and BP than do children of normotensive parents. Similarly, some children of hypertensive parents may excrete higher levels of urinary catecholamine metabolites or may respond to sodium loading with greater weight gain and increases in BP than do those without a family history of hypertension. The abnormal responses in children with affected parents tend to be greater in the Black population than among White individuals.

Table 494.4 Clinical Findings in Patients with Mineralocorticoid Excess

CONDITION	INVOLVED GENE	CLINICAL PRESENTATION
CAH: 11β-hydroxylase deficiency	*CYP11B1* (autosomal recessive)	Early growth spurt initially, then short adult stature, advanced bone age, premature adrenarche, acne, precocious puberty in males, amenorrhea/hirsutism/virilism in females
CAH: 17α-hydroxylase deficiency	*CYP17A1* (autosomal recessive)	Pseudohermaphroditism (male), sexual infantilism (female)
Apparent mineralocorticoid excess	*HSD11β;* deficiency of 11β hydroxysteroid dehydrogenase (autosomal recessive)	Growth stunting/short stature, nephrocalcinosis, hypokalemia, low renin, hypoaldosteronism
Liddle syndrome	*SCNN1A* *SCNN1B* *SCNN1G* (autosomal dominant)	Severe hypertension, hypokalemia, metabolic alkalosis, muscle weakness
Geller syndrome (exacerbated by pregnancy)	GOF variant in mineralocorticoid receptor gene *NR3C2* (autosomal dominant)	Early onset of hypertension (before age 20 yr), exacerbated in pregnancy: hypokalemia, low renin
Glucocorticoid remediable aldosteronism (GRA) (familial aldosteronism type 1)	Chimeric gene with ACTH responsive promoter of 11β hydroxylase fused with aldosterone synthase gene (autosomal dominant)	Early onset of hypertension, presence of family history of mortality or morbidity from early hemorrhagic stroke
Pseudohypoaldosteronism type 2 (Gordon syndrome)	*WNK1* *WNK4* *KLHL3* *CUL3* (autosomal dominant)	Short stature, hyperkalemic and hyperchloremic metabolic acidosis, borderline blood pressure, low renin
Glucocorticoid resistance (children) (Chrousos syndrome)	*NR3C1* (autosomal dominant or sporadic)	Ambiguous genitalia, precocious puberty; women may have androgen excess: acne, excessive hair, oligo/anovulation, infertility

CAH, Congenital adrenal hyperplasia; GOF, gain of function.
Modified from Melcescu E, Phillips J, Moll G, et al. 11 Beta-hydroxylase deficiency and other syndromes of mineralocorticoid excess as a rare cause of endocrine hypertension. *Horm Metab Res.* 2012;44:867–878, Table 1.

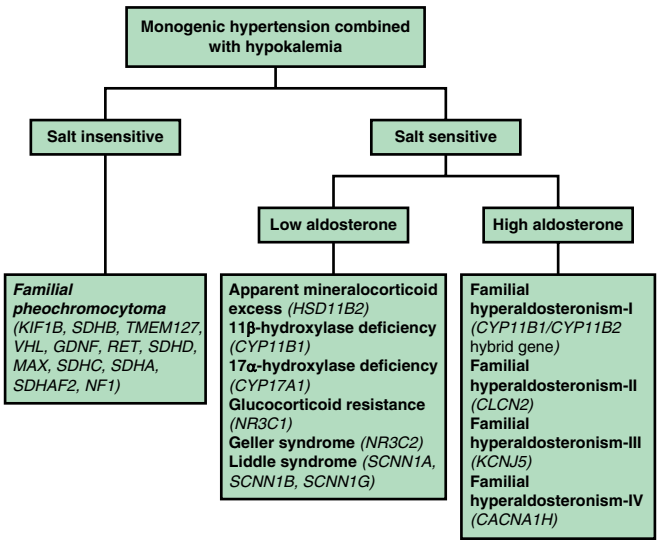

Fig. 494.1 Algorithm showing the overall categorization of monogenic hypertension combined with hypokalemia. Involved genes are italicized and in parentheses. *(From Lu YT, Fan P, Zhang D, et al. Overview of monogenic forms of hypertension combined with hypokalemia. Frontiers Pediatr. 2021;8:Article 543309, Fig. 1.)*

CLINICAL MANIFESTATIONS

Children and adolescents with primary hypertension are usually asymptomatic; the BP elevation is usually mild and is detected during a routine examination or evaluation before athletic participation. These children may also be obese. Children with secondary hypertension can have BP elevations ranging from mild to severe. Unless the BP has been sustained or is rising rapidly, hypertension does not usually produce symptoms. Therefore clinical manifestations may instead reflect the underlying disease process, such as growth failure in children with CKD. Children and adolescents with **acute severe hypertension**, in contrast, present with BP elevation well above stage 2 hypertension and severe symptoms that may represent acute target-organ injury.

Subclinical hypertensive **target-organ injury** is a common clinical manifestation in children with primary hypertension. Using echocardiography with pediatric normative data, left ventricular hypertrophy is detected in up to 40% of hypertensive children. Other markers of target-organ damage that have been demonstrated in hypertensive children include hypertensive retinopathy, increased carotid intima-to-media thickness, and increased vascular stiffness. Studies have shown that children with hypertension perform worse on tests of neurocognition than normotensive children and that these test results improve with successful treatment of hypertension. Target-organ effects of increased BP can be detected in adolescents even at BP levels below what is currently considered hypertensive.

Table 494.5 Drugs That May Elevate Blood Pressure

CLASS	DRUG
Antiinflammatory agents	COX-2 inhibitors (celecoxib) NSAIDs (ibuprofen, ketorolac)
Corticosteroids	Prednisone Hydrocortisone Dexamethasone
CNS stimulants	ADHD medications (methylphenidate, atomoxetine) Caffeine
Drugs of misuse	Amphetamines Cocaine MDMA Phencyclidine Tobacco
Estrogen- and progesterone-containing agents	HRT Oral contraceptives
Heavy metals	Cadmium Lead Mercury
Immunosuppressive agents	Cyclosporine Sirolimus Tacrolimus
Psychiatric agents	SNRI SSRI Tricyclic antidepressants
Supplements	Ephedra Guarana Ginseng Licorice St. John's wort Ma-huang
Sympathomimetic agents	Appetite suppressants Decongestants

COX-2, Cyclooxygenase-2; NSAID, nonsteroidal antiinflammatory drug; ADHD, attention-deficit/hyperactivity disorder; HRT, hormone replacement therapy; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

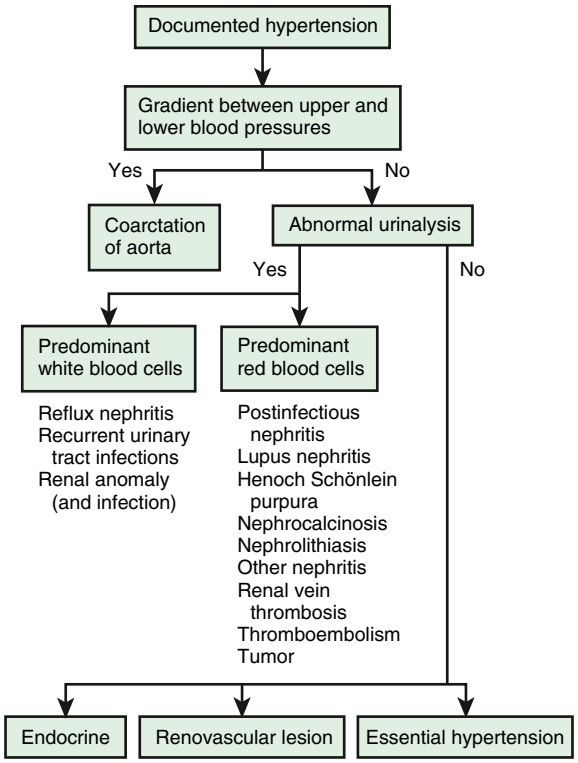

Fig. 494.2 Initial diagnostic algorithm in the evaluation of hypertension. *(From Kliegman RM, Greenbaum LA, Lye PS, eds. Practical Strategies in Pediatric Diagnosis and Therapy, 2nd ed. Philadelphia: Elsevier; 2004, p. 222.)*

DIAGNOSIS

The first step in diagnosing hypertension is recognition of elevated BP. BP readings taken in the office should be compared to normative BP tables (see 2017 AAP guidelines), indexed by height and sex, to ensure that the patient is normotensive. Multiple studies have shown substantial underrecognition of hypertension in children and adolescents, with less than half of elevated BP readings recognized, and even fewer with appropriate follow-up. This may be related to the complexity of the normative tables, although other factors such as provider experience and the presence or absence of obesity have also been shown to affect recognition of elevated BP readings. In addition to use of the simplified screening table found in the 2017 AAP guideline (see Table 494.1), this issue could also be overcome by building alerts into the electronic medical record. Elevated office BP readings should be confirmed using ABPM to identify children with white coat hypertension, who may not require further evaluation. This may require referral to an appropriate subspecialist.

Once the diagnosis of sustained hypertension is made, the evaluation should be directed toward uncovering potential underlying causes of the hypertension (Fig. 494.2), evaluating for comorbidities, and screening for evidence of target-organ damage. The extent of the evaluation for underlying causes of hypertension depends on the type of hypertension that is suspected. An extensive evaluation may be necessary when secondary hypertension is a strong consideration, such as in younger children, or in older children with severe, symptomatic hypertension. Alternatively, school-age children and adolescents with overweight/obesity and a family history of hypertension who have mild elevations of BP may only need limited testing.

In all patients, a careful **history** and **physical examination** are warranted. Birth history should be documented to screen for prematurity and other perinatal events that may affect later BP. A family history for metabolic disease, kidney disease, early cardiovascular events, and other forms of secondary hypertension should be obtained. Growth parameters should be determined to detect evidence of chronic disease. BP should be obtained in all four extremities to detect coarctation (thoracic or abdominal) of the aorta. Table 494.6 identifies other features of the physical examination that may provide evidence of an underlying cause of hypertension. Unless the history and physical examination suggest another cause, children with confirmed hypertension should have an evaluation to detect kidney disease, including urinalysis, electrolytes, blood urea nitrogen, creatinine, and complete blood count. Standard renal ultrasound should be considered in patients with a higher suspicion of secondary hypertension to assess for discrepancies in kidney size, structural abnormalities, and other potential causes of hypertension. Table 494.7 provides a more complete list of studies to consider in the clinical evaluation of a child with confirmed hypertension. Measuring serum potassium is essential because hypokalemia may be present in renovascular hypertension and many monogenic forms of hypertension (including Liddle syndrome, glucocorticoid remedial aldosteronism, and apparent mineralocorticoid excess), whereas hyperkalemia may be seen in Gordon syndrome (see Fig. 494.1). Hypokalemia may also be seen with a pheochromocytoma.

Renovascular hypertension is often associated with other diseases but may be isolated (Table 494.8). Magnetic resonance (MR) or computed tomography (CT) angiography can reveal renal artery stenosis, but formal intraarterial angiography may be needed to detect intrarenal vascular stenoses (Fig. 494.3) and in infants and young children, in whom noninvasive imaging techniques often are not helpful because of small vessel size. Doppler renal ultrasonography is of similar limited utility

Table 494.6 Physical Examination Findings in Patients with Hypertension

PHYSICAL FINDINGS	POTENTIAL RELEVANCE
GENERAL	
Pale mucous membranes, edema, growth retardation	Chronic renal disease
Elfin facies, upturned nose, short stature, cognitive impairment	Williams syndrome
Webbing of neck, low hairline, widespread nipples, wide carrying angle	Turner syndrome
Moon face, buffalo hump, hirsutism, truncal obesity, striae, acne	Cushing syndrome
HABITUS	
Thinness	Pheochromocytoma, renal disease, hyperthyroidism
Virilization	Congenital adrenal hyperplasia
Rickets	Chronic renal disease
SKIN	
Café-au-lait spots, neurofibromas	Neurofibromatosis, pheochromocytoma
Tubers, "ash-leaf" spots	Tuberous sclerosis
Rashes	Systemic lupus erythematosus, vasculitis (Henoch-Schönlein purpura), impetigo with acute nephritis
Pallor, evanescent flushing, sweating	Pheochromocytoma
Needle tracks	Illicit drug use
Bruises, striae	Cushing syndrome
Acanthosis nigricans	Type 2 diabetes, insulin resistance
EYES	
Extraocular muscle palsy	Nonspecific, chronic, severe
Fundal changes	Nonspecific, chronic, severe
Proptosis	Hyperthyroidism
HEAD AND NECK	
Goiter	Thyroid disease
Adenotonsillar hypertrophy	Sleep-disordered breathing
Webbed neck	Turner syndrome
CARDIOVASCULAR SIGNS	
Absent of diminished femoral pulses, low leg pressure relative to arm pressure	Aortic coarctation
Heart size, rate, rhythm; murmurs; respiratory difficulty, hepatomegaly	Aortic coarctation, congestive heart failure
Bruits over great vessels	Arteritis or arteriopathy
Rub	Pericardial effusion secondary to chronic renal disease
PULMONARY SIGNS	
Pulmonary edema	Congestive heart failure, acute nephritis
Picture of bronchopulmonary dysplasia	Bronchopulmonary dysplasia–associated hypertension
ABDOMEN	
Epigastric bruit	Primary renovascular disease or in association with Williams syndrome, neurofibromatosis, fibromuscular dysplasia, or arteritis
Abdominal masses	Wilms tumor, neuroblastoma, pheochromocytoma, polycystic kidneys, hydronephrosis, dysplastic kidneys
Jaundice	Alagille arteriohepatic dysplasia
NEUROLOGIC SIGNS	
Neurologic deficits	Chronic or severe acute hypertension with stroke
Muscle weakness	Hyperaldosteronism, Liddle syndrome (hypokalemic low renin hypertension)
GENITALIA	
Ambiguous, virilized	Congenital adrenal hyperplasia (11β- or 17α-hydroxylase deficiencies)
SKELETAL	
Short metacarpal (fourth, fifth) bones, short stature	Autosomal dominant hypertension with brachydactyly (Bilginturan disease)

Table 494.7 Clinical Evaluation of Confirmed Hypertension

STUDY OR PROCEDURE	PURPOSE	TARGET POPULATION
EVALUATION FOR IDENTIFIABLE CAUSES		
History, including sleep history, family history, risk factors, diet, and habits such as smoking and drinking alcohol; physical examination	History and physical examination help focus subsequent evaluation	All children with persistent BP ≥90th percentile
Blood urea nitrogen, creatinine, electrolytes, urinalysis, and urine culture	R/O renal disease and chronic pyelonephritis, mineralocorticoid excess states	All children with persistent BP ≥95th percentile
Complete blood count	R/O anemia, consistent with chronic renal disease	All children with signs of chronic kidney disease
Renal ultrasound	R/O renal scar, congenital anomaly, or disparate renal size	All children with signs or symptoms concerning for secondary cause of hypertension
EVALUATION FOR COMORBIDITY		
Fasting lipid panel, fasting glucose	Identify hyperlipidemia, identify metabolic abnormalities	Overweight patients with BP at 90th to 94th percentile; all patients with BP ≥95th percentile; family history of hypertension or cardiovascular disease; child with chronic renal disease
Drug screen	Identify substances that might cause hypertension	History suggestive of possible contribution by substances or drugs
Polysomnography	Identify sleep-disordered breathing	History of loud, frequent snoring, or daytime somnolence
EVALUATION FOR TARGET-ORGAN DAMAGE		
Echocardiogram	Identify left ventricular hypertrophy and other indications of cardiac involvement	Patients with comorbid risk factors* and BP 90th to 94th percentile; all patients with BP ≥95th percentile
Retinal exam	Identify retinal vascular changes	Patients with comorbid risk factors and BP 90th to 94th percentile; all patients with BP ≥95th percentile
ADDITIONAL EVALUATION AS INDICATED		
Ambulatory blood pressure monitoring	Identify white coat hypertension, abnormal diurnal BP pattern, BP load	All children with persistent BP ≥95th percentile
Renovascular imaging Magnetic resonance or CT angiography	Identify renovascular disease	Young children with stage 1 hypertension and any child or adolescent with stage 2 hypertension
Arteriography: digital subtraction or classic		
Plasma and urine catecholamines	Identify catecholamine-mediated hypertension	Patients with signs and symptoms concerning for pheochromocytoma

*Comorbid risk factors also include diabetes mellitus and kidney disease.
R/O, Rule out.
From National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. *Pediatrics.* 2004;114(2 Suppl 4th Report):562.

in children because of poor patient cooperation, imaging difficulties related to obesity, and operator inexperience. Doppler renal ultrasonography has a sensitivity of approximately 60–65% in patients with renovascular disease; specificity is 95%. CT angiography has a sensitivity and specificity of 88% and 81%, respectively, compared to 80% and 63% for MR angiography. *Doppler ultrasonography is not recommended when screening for renovascular hypertension in the 2017 AAP guideline except in selected patients.*

The presence of primary hypertension often clusters with other risk factors. All hypertensive children should be screened for comorbidities that may increase cardiovascular risk, including dyslipidemia and glucose intolerance. A nonfasting lipid panel is usually sufficient to screen for dyslipidemia but should be followed up by a fasting panel if abnormal. Similarly, a random fasting glucose level may be obtained initially but will need to be followed up with a fasting level if abnormal. In addition, a sleep history should be obtained in children with confirmed hypertension to screen for **sleep-disordered breathing**, an entity that is associated with high BP, particularly in overweight children. Patients with symptoms of sleep-disordered breathing should be referred to a sleep specialist for evaluation.

Left ventricular hypertrophy (LVH) is the most common manifestation of target-organ damage in hypertensive children. Left ventricular (LV) mass measurements should be indexed to height to account for the effect of body size and body surface area (BSA). LVH is defined as LV mass >51 g/m 2.7 in those 8 years of age and older, or LV mass >115 g/BSA for boys and >95 g/BSA for females <8 years of age. According to the 2017 AAP guideline, echocardiography should be obtained when treatment with antihypertensive medications is being considered.

PREVENTION

Prevention of high BP may be viewed as part of the prevention of cardiovascular disease and stroke, the leading cause of death in adults in the United States. Other risk factors for cardiovascular disease include

Table 494.8 Causes of Renovascular Hypertension in Children

Fibromuscular dysplasia
Syndromic causes
Neurofibromatosis type 1
Tuberous sclerosis
Williams syndrome
Marfan syndrome
Other syndromes

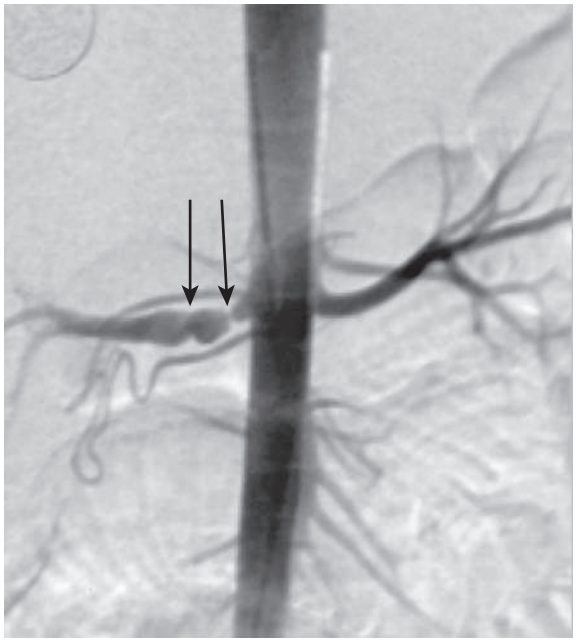

Fig. 494.3 Renal angiogram in 7-yr-old child with hypertension. Right renal artery is visible with a string-of-beads appearance characteristic of fibromuscular dysplasia *(arrows)*. The aorta and left renal artery appear normal. *(From Tullus K, Brennan E, Hamilton G, et al. Renovascular hypertension in children. Lancet. 2008;371:1453–1463, Fig 1.)*

obesity, elevated serum cholesterol levels, high dietary sodium intake, and a sedentary lifestyle, as well as alcohol and tobacco use. The increase in arterial wall rigidity and blood viscosity that is associated with exposure to the components of tobacco may exacerbate hypertension. Public health, population-based approaches to prevention of primary hypertension in both adults and children include a reduction in obesity, reduced sodium intake, avoidance of tobacco intake, and an increase in physical activity through school- and community-based programs.

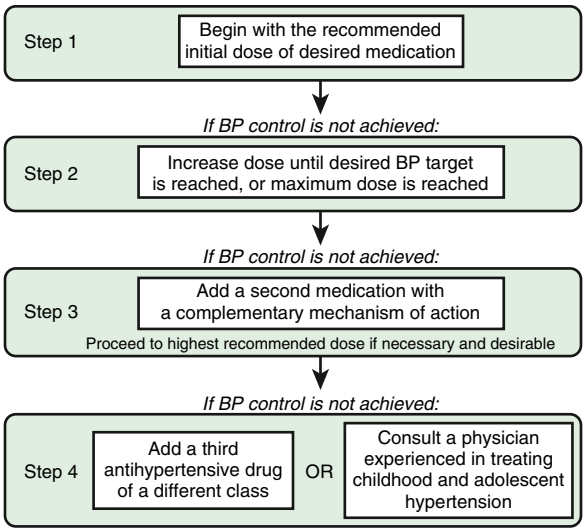

Fig. 494.4 Stepped-care approach to antihypertensive therapy in children and adolescents. BP, Blood pressure. *(From Flynn JT, Daniels SR. Pharmacologic treatment of hypertension in children and adolescents. J Pediatr. 2006;149:746–754, Fig 2.)*

TREATMENT

The mainstay of therapy for children with asymptomatic mild hypertension without evidence of target-organ damage is therapeutic **lifestyle modification** with dietary changes and regular exercise. **Weight loss** is the primary therapy in obesity-related hypertension. It is recommended that all hypertensive children have a diet increased in fresh fruits, fresh vegetables, fiber, and nonfat dairy and reduced in sodium. The **DASH** (Dietary Approaches to Stop Hypertension) diet has been suggested as a nutritional approach to prevent or treat hypertension (www.dashdiet.org). The diet focuses on lowering sodium intake and increasing potassium-, calcium-, and magnesium-containing foods, such as six to eight servings of whole grains, four to five servings of fruits, and four to five servings of vegetables per day and low-fat dairy foods. For adults, the standard DASH diet contains 2,300 mg of sodium (also recommended by the American Heart Association) and the low-sodium DASH diet recommends up to 1,500 mg of sodium per day. Studies suggest that although the DASH diet has potential beneficial effects on blood pressure, adherence to the diet remains low among adolescents. In addition, regular aerobic physical activity for at least 30-60 minutes on most days along with a reduction of sedentary activities to <2 hours a day is recommended.

Indications for **pharmacologic therapy** include symptomatic hypertension, stage 2 hypertension without a modifiable risk factor, hypertension in patients with comorbidities such as diabetes (types 1 and 2) or CKD, and persistent hypertension despite nonpharmacologic measures. When indicated, antihypertensive medication should be initiated as a single agent at a low dose (Fig. 494.4). The dose can then be increased until the goal BP is achieved. Once the highest recommended dose is reached, or if the child develops side effects, a second drug from a different class can be added.

Most classes of antihypertensive agents have been shown to reduce blood pressure in children and adolescents, although no data exist demonstrating one class to be superior. Per the 2017 AAP practice care guidelines, ACEIs, ARBs, thiazide diuretics, and calcium channel blockers are considered acceptable initial agents for use in children. The choice of antihypertensive agent for a patient should be tailored to the etiology of that patient's hypertension whenever possible. Table 494.9 gives recommended dosing information for antihypertensive agents in children and adolescents.

Table 494.9 Recommended Doses for Selected Antihypertensive Agents for Use in Hypertensive Children and Adolescents

CLASS	DRUG	STARTING DOSE	INTERVAL	MAXIMUM DOSE*
Aldosterone receptor antagonist	Eplerenone	25 mg/day	qd-bid	100 mg/day
	Spironolactone†	1 mg/kg/day	qd-bid	3.3 mg/kg/day up to 100 mg/day
Angiotensin-converting enzyme inhibitors	Benazepril†	0.2 mg/kg/day up to 10 mg/day	qd	0.6 mg/kg/day up to 40 mg/day
	Captopril†	0.5 mg/kg/dose (0.05 mg/kg/dose in infants)	tid	6 mg/kg/day up to 450 mg/day
	Enalapril†	0.08 mg/kg/day	qd	0.6 mg/kg/day up to 40 mg/day
	Fosinopril	0.1 mg/kg/day up to 10 mg/day	qd	0.6 mg/kg/day up to 40 mg/day
	Lisinopril†	0.07 mg/kg/day up to 5 mg/day	qd	0.6 mg/kg/day up to 40 mg/day
	Quinapril	5-10 mg/day	qd	80 mg/day
	Ramipril	1.6 mg/m^2/day	qd	6 mg/m^2/day up to 10 mg/day
Angiotensin receptor blockers	Candesartan	1-6 yr: 0.2 mg/kg/day 6-17 yr: <50 kg 4-8 mg qd >50 kg 8-16 mg qd	qd	1-6 yr: 0.4 mg/kg up to 4 mg/day 6-17 yr: <50 kg: 16 mg qd >50 kg: 32 mg qd
	Losartan†	0.75 mg/kg/day up to 50 mg/day	qd	1.4 mg/kg/day up to 100 mg/day
	Olmesartan	20 to <35 kg 10 mg qd; ≥35 kg 20 mg qd	qd	20 to <35 kg: 20 mg qd ≥35 kg: 40 mg qd
	Valsartan†	6-17 yr: 1.3 mg/kg/day up to 40 mg/day	qd	6-17 yr: 2.7 mg/kg/day up to 160 mg/day
α- and β-adrenergic antagonists	Labetalol†	2-3 mg/kg/day	bid	10-12 mg/kg/day up to 1.2 g/day
	Carvedilol	0.1 mg/kg/dose up to 6.25 mg bid	bid	0.5 mg/kg/dose up to 25 mg bid
β-adrenergic antagonists	Atenolol†	0.5-1 mg/kg/day	qd-bid	2 mg/kg/day up to 100 mg/day
	Bisoprolol/HCTZ	2.5/6.25 mg/day	qd	10/6.25 mg/day
	Metoprolol	1-2 mg/kg/day	bid	6 mg/kg/day up to 200 mg/day
	Propranolol	1 mg/kg/day	bid-tid	8 mg/kg/day up to 640 mg/day
Calcium channel blockers	Amlodipine†	1-5 yr: 0.1 mg/kg/day ≥6 yr: 2.5 mg/day	qd	1-5 yr: 0.6 mg/kg/day up to 5 mg/day ≥6 yr: 10 mg/day
	Felodipine	2.5 mg/day	qd	10 mg/day
	Isradipine†	0.05-0.15 mg/kg/dose	tid-qid	0.6 mg/kg/day up to 10 mg/day
	Extended-release nifedipine	0.2-0.5 mg/kg/day	qd-bid	3 mg/kg/day up to 120 mg/day
Central α-agonist	Clonidine†	5-10 μg/kg/day	bid-tid	25 μg/kg/day up to 0.9 mg/day
Diuretics	Amiloride	5-10 mg/day	qd	20 mg/day
	Chlorthalidone	0.3 mg/kg/day	qd	2 mg/kg/day up to 50 mg/day
	Chlorothiazide	10 mg/kg/day	bid	20 mg/kg/day up to 375 mg/day
	Furosemide	0.5-2.0 mg/kg/dose	qd-bid	6 mg/kg/day
	HCTZ	0.5-1 mg/kg/day	qd	3 mg/kg/day up to 37.5 mg/day
Vasodilators	Hydralazine	0.25 mg/kg/dose	tid-qid	7.5 mg/kg/day up to 200 mg/day
	Minoxidil	0.1-0.2 mg/kg/day	bid-tid	1 mg/kg/day up to 50 mg/day

*The maximum recommended adult dose should never be exceeded.

bid, Twice daily; HCTZ, hydrochlorothiazide; qd, once daily; qid, 4 times daily; tid, 3 times daily.
Adapted from Flynn JT. Management of hypertension in the young: role of antihypertensive medications. *J Cardiovasc Pharmacol*. 2011;58(2):111–120.

There have been changes in the recommended BP goals for the treatment of hypertension in children and adolescents. Data from the SPRINT (SBP intervention) trial group suggests that stricter goals (SBP goal of 120 vs 140 mm Hg) improve cardiovascular outcomes in adults. In children with CKD, the ESCAPE (Effects of Strict BP Control and Angiotensin-Converting Enzyme Inhibition on the Progress of Chronic Renal Failure in Pediatric Patients) trial group showed slower progression of CKD if the 24-hour MAP was kept below the 50th percentile on ABPM compared to the 50th to 95th percentile. It is now recommended that treatment achieve BP <90th percentile for age or <130/80 mm Hg, whichever is lower. A lower goal based on ABPM (24-hour MAP <50th percentile) is recommended for children and adolescents with CKD. ACEIs or ARBs should be used for children with diabetes and microalbuminuria or proteinuric kidney disease.

Acute severe hypertension, sometimes referred to as *accelerated hypertension* or *hypertensive crisis*, is defined as severe hypertension (often with BP values well in excess of stage 2 hypertension) accompanied by symptoms such as headache, dizziness, or nausea/

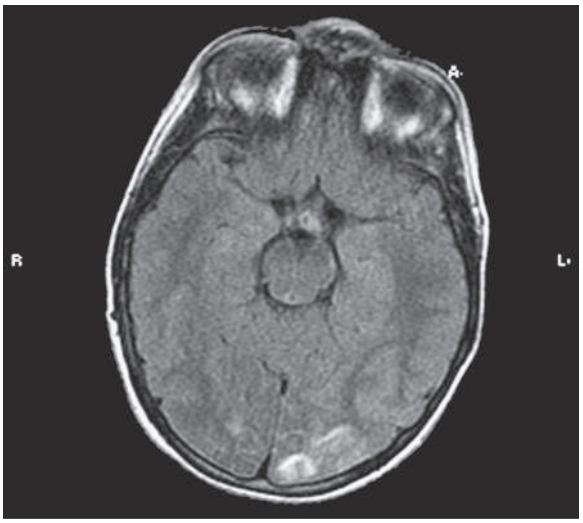

Fig. 494.5 MRI of the brain of a 6-yr-old child with end-stage kidney disease and hypertensive encephalopathy (i.e., posterior reversible leukoencephalopathy syndrome). Bilateral occipital high signal intensity is more pronounced on the left side. *(From Daroff RB, Fenichel GM, Jankovic J, et al., eds. Bradley's Neurology in Clinical Practice, 6th ed. Philadelphia: Saunders; 2012: Fig. 49B.4, p. 924.)*

vomiting, and in more severe cases, retinopathy, encephalopathy, cardiac failure, acute kidney injury, and seizures. These situations have also been described as *hypertensive urgency* and *hypertensive emergency,* respectively. This nomenclature can lead to confusion because there is often no absolute distinction between the two situations, and treatment will often depend on clinical judgment. *Hypertensive encephalopathy* (generalized or posterior reversible encephalopathy syndrome) is suggested by the presence of headache, vomiting, temperature elevation, visual disturbances, ataxia, depressed level of consciousness, imaging abnormalities, and seizures (Fig. 494.5); it is one of the more common presentations of acute severe hypertension in children and adolescents. Acute severe hypertension may also manifest with decreased vision (cortical blindness) and papilledema, congestive heart failure, or accelerated deterioration of kidney function.

For patients with acute severe hypertension and life-threatening symptoms, intensive care unit (ICU) admission and intravenous (IV) drug infusion are indicated so that decreases in BP can be carefully monitored and titrated (Table 494.10). Ideally, arterial lines should be used for continuous BP monitoring; if this is not available, oscillometric devices can be used for frequent/repeated BP measurement. Drug choices include labetalol, nicardipine, and sodium nitroprusside. Because too rapid a reduction in BP may interfere with adequate organ perfusion, a stepwise reduction in pressure should be planned. In general, BP should be reduced by

Table 494.10 Antihypertensive Drugs for Management of Severe Hypertension in Children Age 1-17 Years

DRUG	CLASS	DOSE	ROUTE	COMMENTS
USEFUL FOR SEVERELY HYPERTENSIVE PATIENTS WITH LIFE-THREATENING SYMPTOMS				
Esmolol	β-Adrenergic blocker	100-500 μg/kg/min	IV infusion	Very short acting—constant infusion preferred; may cause profound bradycardia
Hydralazine	Direct vasodilator	0.2-0.4 mg/kg/dose	IV, IM	Should be given every 4 hr when given IV bolus
Labetalol	α- and β-Adrenergic blocker	Bolus: 0.20-1.0 mg/kg/dose, up to 40 mg/dose Infusion: 0.25-3.0 mg/kg/hr	IV bolus or infusion	Asthma and overt heart failure are relative contraindications
Nicardipine	Calcium channel blocker	Bolus: 30 μg/kg up to 2 mg/dose Infusion: 0.5-4 μg/kg/min	IV bolus or infusion	May cause reflex tachycardia
Sodium nitroprusside	Direct vasodilator	0.5-10 μg/kg/min	IV infusion	Monitor cyanide levels with prolonged (>72 hr) use or in renal failure or coadminister with sodium thiosulfate
USEFUL FOR SEVERELY HYPERTENSIVE PATIENTS WITH LESS SIGNIFICANT SYMPTOMS				
Clonidine	Central α-agonist	0.05-0.1 mg/dose, may be repeated up to 0.8 mg total dose	PO	Side effects include dry mouth and drowsiness
Fenoldopam	Dopamine receptor agonist	0.2-0.8 μg/kg/min	IV infusion	Produced modest reductions in blood pressure in a pediatric clinical trial in patients up to age 12 yr
Hydralazine	Direct vasodilator	0.25 mg/kg/dose, up to 25 mg/dose	PO	Extemporaneous suspension stable for only 1 wk
Isradipine	Calcium channel blocker	0.05-0.15 mg/kg/dose, up to 5 mg/dose	PO	Stable suspension can be compounded
Minoxidil	Direct vasodilator	0.1-0.2 mg/kg/dose, up to 10 mg/dose	PO	Most potent oral vasodilator; long acting

IM, intramuscular; IV, intravenous; PO, oral.
Adapted from Flynn JT, Tullus K. Correction to severe hypertension in children and adolescents: pathophysiology and treatment. *Pediatr Nephrol.* 2012;27(3):503–504.

no more than 25% of the planned reduction over the first 8 hours, with a gradual normalization of BPs over the next 24-48 hours. For patients with less severe symptoms, such as headache or nausea/vomiting, oral medications such as clonidine or isradipine can be used if the patient can tolerate oral medications. Short-acting IV medications such as hydralazine or labetalol are acceptable if the patient cannot take oral drugs.

Treatment of secondary hypertension must also focus on the underlying disease, such as CKD, hyperthyroidism, pheochromocytoma, coarctation of the aorta, or renovascular hypertension. The treatment of renovascular hypertension includes antihypertensive medications, angioplasty, or surgery. If bilateral renovascular hypertension or renovascular disease in a solitary kidney is suspected, drugs acting on the RAAS are usually contraindicated because they may reduce glomerular filtration rate and lead to acute kidney injury.

Diseases of the Blood

PART XIX

Section 1

The Hematopoietic System

Chapter 495

Development of the Hematopoietic System

Stella T. Chou

HEMATOPOIESIS IN THE HUMAN EMBRYO AND FETUS

Hematopoiesis is the process by which the cellular elements of blood are formed. In the developing human embryo and fetus, hematopoiesis has three developmental waves and is conceptually divided into three anatomic stages: mesoblastic, hepatic, and myeloid. *Mesoblastic* hematopoiesis occurs in extraembryonic structures, principally in the yolk sac, and begins between the 10th and 14th days of gestation. By 6-8 weeks of gestation, the liver replaces the yolk sac as the primary site of blood cell production, and during this time, the placenta also contributes as a hematopoietic site. By 10-12 weeks, extraembryonic hematopoiesis has ceased. *Hepatic* hematopoiesis occurs through the remainder of gestation and then diminishes during the second trimester while bone marrow *(myeloid)* hematopoiesis increases. The liver is the predominant erythropoietic organ through 20-24 weeks of gestation.

Each hematopoietic organ houses distinct populations of cells. The yolk sac predominantly produces erythrocytes, megakaryocytes, and macrophages. The fetal liver is primarily an erythropoietic organ, while the bone marrow produces erythrocytes, megakaryocytes, and leukocytes. The types of leukocytes present in the fetal liver and marrow differ with gestation. Macrophages precede neutrophils in the marrow, and the ratio of macrophages to neutrophils decreases as gestation progresses. Regardless of gestational age or anatomic location, production of all hematopoietic tissues begins with multipotent cells capable of both self-renewal and clonal maturation into all blood cell lineages. Progenitor cells differentiate under the influence of transcription factors and hematopoietic growth factors.

The classical model of hematopoietic differentiation involves differentiation into increasingly lineage-specific progenitors, although there may also be alternate pathways that are used separately or in combination with classical pathways (Fig. 495.1). In the classical pathway, *long-term repopulating hematopoietic stem cells* (LTR-HSCs) are characterized by their ability to self-renew and differentiate into cells that are multipotent. *Multipotent progenitors* (MPPs) have reduced self-renewal capacity and differentiate into *common lymphoid progenitors* (CLPs) or *common myeloid progenitors* (CMPs). The CMP differentiates into all the blood lineages except for lymphoid. The commitment of hematopoietic cells to increasingly lineage-restricted cells requires cytokine stimulation and regulation by transcription factors.

Erythrocytes in the fetus are larger than in adults, and at 22-23 weeks' gestation, the mean corpuscular volume can be as high as 135 femtoliters (fL) (Fig. 495.2A). Similarly, the mean corpuscular hemoglobin is very high at 22-23 weeks and falls relatively linearly with advancing gestation (see Fig. 495.2B). In contrast, the mean corpuscular hemoglobin concentration is constant throughout gestation at 34 ±1 g/dL. While the size and quantity of hemoglobin in erythrocytes diminish during gestation, the hematocrit and blood hemoglobin concentration gradually increase (Fig. 495.3).

Platelet concentration in the blood increases gradually between 22 and 40 weeks' gestation (Fig. 495.4), but the platelet size, assessed by mean platelet volume, remains constant at 8 ±1 fL. No differences are observed between males and females in fetal and neonatal reference ranges for erythrocyte indices, hematocrit, hemoglobin, platelet counts, or mean platelet volume measurements.

FETAL GRANULOCYTOPOIESIS

Neutrophils are first observed in the human fetus about 5 weeks after conception as small clusters of cells around the aorta. The fetal bone marrow space begins to develop around the eighth week, and from 8-10 weeks, the marrow space enlarges, but no neutrophils appear there until 10.5 weeks. From 14 weeks through term, the most common granulocytic cell type in the fetal bone marrow space is the neutrophil. Neutrophils and macrophages originate from a common progenitor cell, but macrophages appear before neutrophils in the fetus, first in the yolk sac, liver, lung, and brain, all before the bone marrow cavity is formed.

Granulocyte colony-stimulating factor (G-CSF) and macrophage colony-stimulating factor (M-CSF) are expressed in developing fetal bone as early as 6 weeks after conception, and both are expressed in the fetal liver as early as 8 weeks. Granulocyte-macrophage colony-stimulating factor (GM-CSF) and stem cell factor (SCF) also are distributed widely in human fetal tissues. However, no changes in expression of any of these factors, or of their specific receptors, appear to be the signal for fetal production of neutrophils or macrophages.

Fetal blood contains few neutrophils until the third trimester. At 20 weeks' gestation, the blood neutrophil count is 0-500/mm^3. Although mature neutrophils are scarce, progenitor cells with the capacity to generate neutrophil clones are abundant in fetal blood. When cultured in vitro in the presence of recombinant G-CSF, they mature into large colonies of neutrophils. The physiologic role of G-CSF includes upregulating neutrophil production, and the low number of circulating neutrophils in the mid-trimester human fetus may be caused, in part, by low production of G-CSF. Monocytes isolated from the blood of adults produce G-CSF when stimulated with a variety of inflammatory mediators, such as bacterial lipopolysaccharide (LPS) or interleukin (IL)-1. In contrast, monocytes isolated from the blood or organs of fetuses up to 24 weeks' gestation generate only small quantities of G-CSF protein and messenger RNA (mRNA) after LPS or IL-1 stimulation. Despite this, G-CSF receptors on the surface of neutrophils of newborn infants are equal in number and affinity to those on adult neutrophils.

In the fetus, actions of the granulocytic factors (G-CSF, M-CSF, GM-CSF, and SCF) are not limited to hematopoiesis. Receptors for each of

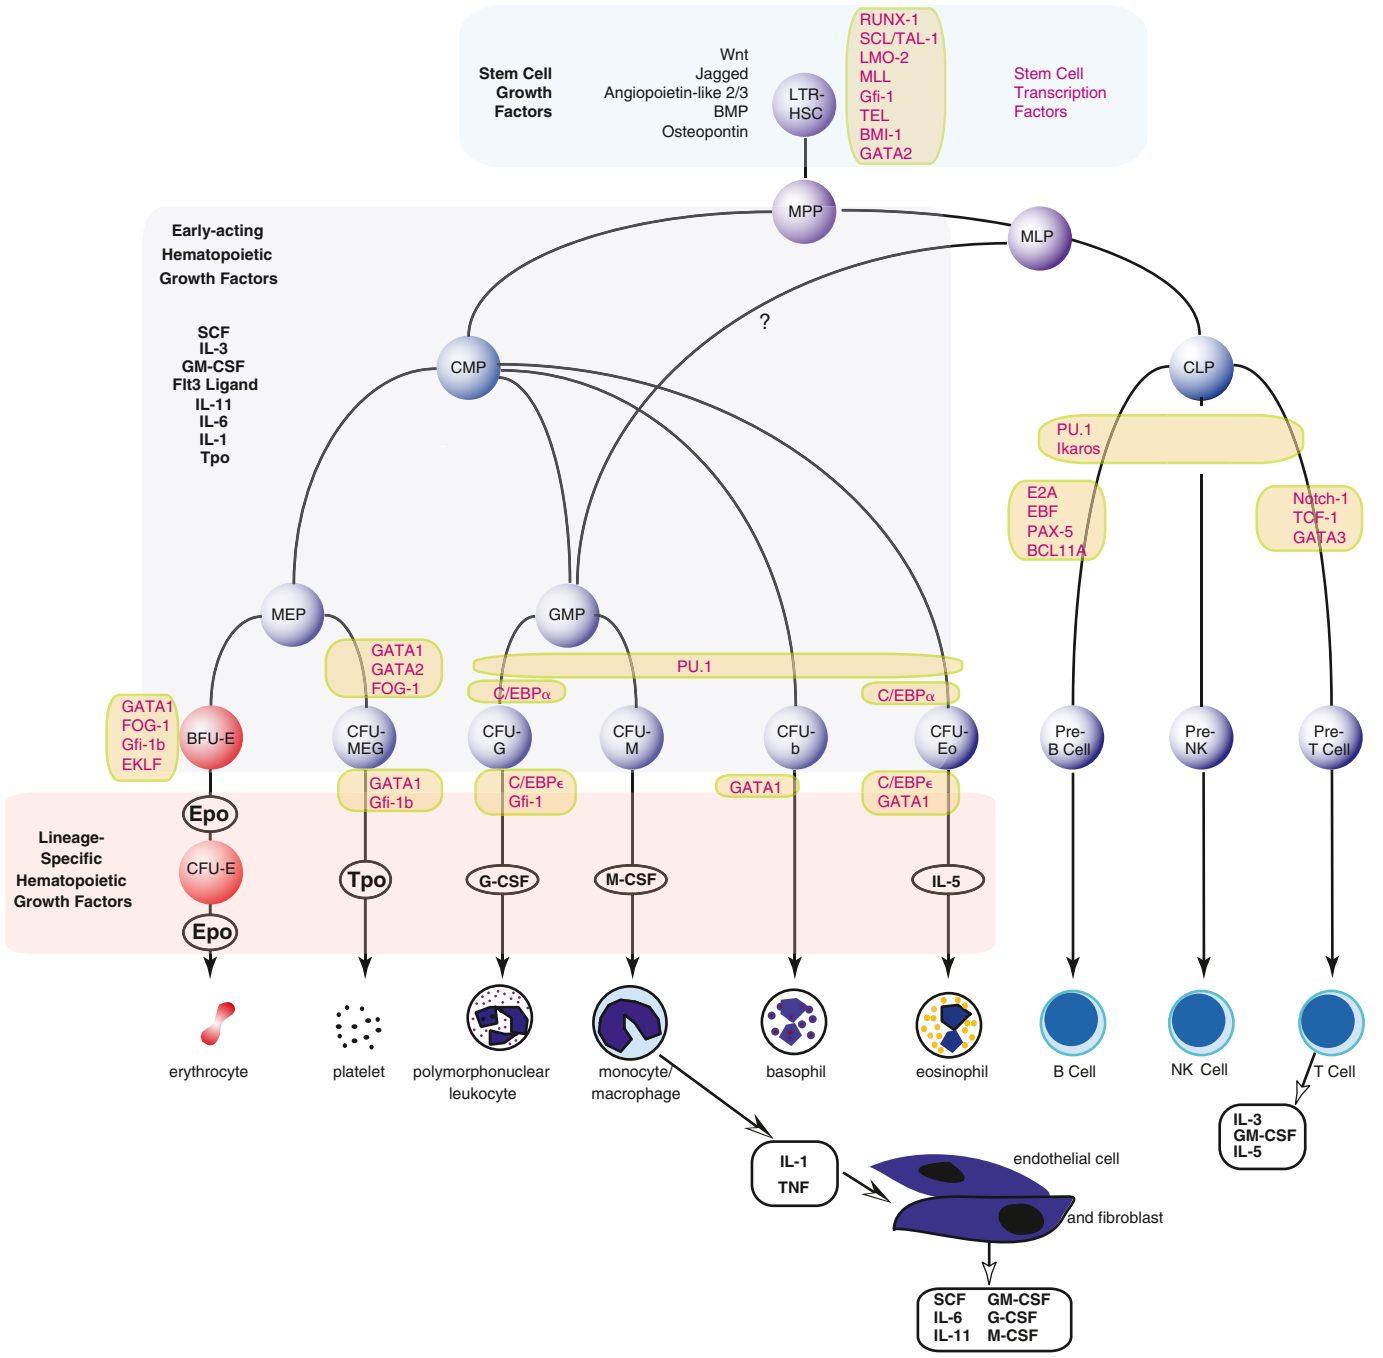

Fig. 495.1 Major cytokine sources and actions to promote hematopoiesis. Cells of the bone marrow microenvironment, such as macrophages, endothelial cells, and reticular fibroblasts, produce macrophage colony-stimulating factor (M-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and granulocyte colony-stimulating factor (G-CSF) after stimulation. These cytokines and others listed in the text have overlapping interactions during hematopoietic differentiation, as indicated; for all lineages, optimal development requires a combination of early- and late-acting factors. BFU, Burst-forming unit; BMP, bone morphogenic protein; CFU, colony-forming unit; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; Epo, erythropoietin; GMP, granulocyte-monocyte progenitor; IL, interleukin; LTR-HSC, long-term repopulating-hematopoietic stem cell; MEP, megakaryocyte-erythroid progenitor; MLP, multipotent lymphoid progenitor; MPP, multipotent progenitor; SCF, stem cell factor; TNF, tumor necrosis factor; Tpo, thrombopoietin. *(From Sieff CA, Daley GO, Zon LI. The anatomy and physiology of hematopoiesis. In Orkin SH, Fisher DE, Ginsburg D, et al., eds. Nathan and Oski's Hematology and Oncology of Infancy and Childhood, 8th ed. Philadelphia: Elsevier, 2015.)*

these are located in areas of the fetal central nervous system and gastrointestinal tract, where their patterns of expression change with development.

FETAL THROMBOPOIESIS

Several biologic differences exist between fetal, neonatal, and adult megakaryopoiesis and thrombopoiesis. There is a developmentally unique pattern of fetal/neonatal megakaryopoiesis characterized by rapid proliferation, followed by full cytoplasmic maturation without polyploidization. Fetal and neonatal megakaryocytes are significantly smaller, exhibit lower ploidy, and produce fewer platelets. However, fetal and neonatal megakaryocytes have a higher proliferative potential than adult progenitors. These differences allow fetuses and neonates to populate their rapidly expanding bone marrow space and blood volume while maintaining normal platelet counts.

Megakaryocyte progenitors are categorized as *burst-forming unit–megakaryocytes* (BFU-MK), which are primitive megakaryocyte

progenitors, and *colony-forming unit–megakaryocytes* (CFU-MK), which are more differentiated. BFU-MK produce large multifocal colonies containing ≥50 megakaryocytes, whereas CFU-MK generate smaller (3-50 cells/colony) unifocal colonies. Megakaryocytes are identified by their morphologic characteristics as they undergo endoreduplication, which results in large cells with polyploid nuclei. Megakaryocytes, unlike megakaryocyte progenitors, do not have the capacity to generate colonies. Rather, they undergo maturation, progressing from small mononuclear cells to large polyploid cells. The modal megakaryocyte *ploidy* (the number of sets of complete chromosomes) in normal adult marrow is 16N. In the fetus and neonate, ploidy is lower, primarily 2N and 4N, and mature megakaryocyte size is smaller. Large megakaryocytes generate more platelets than do small megakaryocytes; in vitro studies suggest that megakaryocytes of neonates produce fewer platelets than do their adult counterparts.

The exact mechanisms by which megakaryocytes release platelets into the circulation remain incompletely understood. In situ examination of this process suggests that mature megakaryocytes migrate to a perivascular site and extend a process through the endothelium, giving rise to proplatelets, which then release platelets. An alternate mechanism is that platelets are released from megakaryocytes in the lungs as a result of shear forces.

Thrombopoietin (TPO) is the dominant regulator of megakaryocyte development and platelet production. TPO is predominantly produced in the liver from early fetal to adult life but is also expressed by cells in the kidney, and, to a lesser extent, by smooth muscle and marrow cells. TPO concentrations are higher in healthy neonates of any gestational age than in healthy adults. TPO is a primary stimulator of megakaryocyte and platelet production, but SCF, IL-3, IL-11, IL-6, and erythropoietin also stimulate megakaryopoiesis and thrombopoiesis in vitro and in vivo. Importantly, TPO promotes expansion of hematopoietic stem cells (HSCs) and progenitor cells, and the TPO receptor is expressed on HSCs and erythroid progenitors in addition to megakaryocyte progenitors, megakaryocytes, and mature platelets.

FETAL ERYTHROPOIESIS

Similar to hematopoietic production of other cell lineages, fetal erythropoiesis is regulated by growth factors produced by the fetus, not by the mother. Erythropoietin (EPO) does not cross the human placenta. Stimulating maternal EPO production does not enhance fetal erythropoiesis, nor does suppressing maternal erythropoiesis by hypertransfusion.

EPO plays a central regulatory role on the proliferation and maturation of erythroid progenitors. Erythroid-committed progenitors consist of *burst-forming unit–erythroid* (BFU-E) and *colony-forming unit–erythroid* (CFU-E) cells. In colony-forming assays, human BFU-E cells are more proliferative, forming colonies of multiple clusters of erythroblasts, as compared with CFU-E cells, which form one or two clusters, with each containing 8-100 hemoglobinized erythroblasts. EPO is essential for erythrocyte production from CFU-E cells by inducing survival and proliferation of erythroblasts. EPO binds to specific receptors on the surface of committed erythroid precursors, and its expression is regulated by an oxygen-sensing mechanism through the hypoxia-inducible factor (HIF) family of proteins. HIF-1α and HIF-2α are regulated by oxygen tension, whereas HIF-1β is constitutively expressed. Together, HIF proteins maintain oxygen homeostasis and regulate erythropoiesis by inducing EPO under hypoxic conditions.

EPO is produced by monocytes and macrophages in the fetal liver during the first and second trimesters. After birth, the anatomic site of EPO production shifts to the kidney. The specific stimulus for this shift is unknown but may involve the increase in arterial oxygen tension that occurs at birth. Epigenetic modification of gene expression may also play a role because it appears that renal and hepatic EPO genes are methylated to different degrees. Although EPO mRNA and protein can be found in the human fetal kidney, it is not known whether this production is biologically relevant. It appears that renal production of EPO is not essential for normal fetal erythropoiesis, as evidenced by the normal serum EPO concentration and normal hematocrit of anephric fetuses.

Hemoglobins in the Fetus and Neonate

Hemoglobin is a tetramer of four *globin* chains with an iron-containing porphyrin ring called *heme* covalently bound to each chain. A dynamic interaction between heme and globin gives hemoglobin its unique properties in the reversible transport of oxygen. The hemoglobin molecule consists of two alpha (α)-like and two beta (β)-like polypeptide chains, with each chain having a heme group attached (Fig. 495.5). There are two β-globin genes and four α-globin genes. Within erythrocytes of an early embryo, fetus, child, and adult, six different hemoglobins may normally be detected (Fig. 495.6): the **embryonic** hemoglobins (Gower-1, Gower-2, and Portland), **fetal** hemoglobin (HbF), and the **adult** hemoglobins (HbA and HbA_2). The electrophoretic mobilities of hemoglobins vary with their chemical structures.

Expression and quantitative relationships among the hemoglobins are determined by complex developmental processes. Globin chain expression is developmental stage specific and occurs through two hemoglobin switches, mediated primarily through changes of the β-globin genes expressed. There are five functional β-like globin chain genes: embryonic *(HBE1)*, two fetal *(HBG1, HBG2)*, and two adult *(HBD, HBB)*; and three α-like globin chain genes: embryonic *(HBZ)* and two adult *(HBA1, HBA2)*. Primitive erythroid cells primarily express embryonic globins. The first β-globin switch occurs at approximately 6 weeks' gestation to fetal globin *(HBG)*, which coincides with the onset of definitive hematopoiesis. The major hemoglobin in the fetus (HbF) consists of two α and two gamma (γ) globin chains ($\alpha_2\gamma_2$). The second globin switch is responsible for the expression of the major hemoglobin of adults (HbA), consisting of two α and two β polypeptide chains ($\alpha_2\beta_2$) and is first expressed at mid-gestation. A key regulator of the fetal-to-adult hemoglobin switch is the transcription factor **BCL11A**, which binds to the β-globin gene and acts to silence γ-globin expression and thus HbF.

Embryonic Hemoglobins

The blood of early human embryos contains two slowly migrating hemoglobins, *Gower-1* and *Gower-2,* and *Hb Portland,* which has HbF-like mobility. The zeta (ζ) chains of Hb Portland and Gower-1 are structurally quite similar to α chains. Both Gower hemoglobins contain the epsilon (ε) β-like globin polypeptide chain. Hb Gower-1 has the structure $\zeta_2\varepsilon_2$, whereas Gower-2 has $\alpha_2\varepsilon_2$. Hb Portland has the structure $\zeta_2\gamma_2$. In embryos up to 6 weeks' gestation, the Gower hemoglobins predominate but are no longer detectable by 3 months of gestation.

Fetal Hemoglobin

By 6-8 weeks' gestation, HbF ($\alpha_2\gamma_2$) is the predominant hemoglobin; at 24 weeks' gestation, it constitutes 90% of the total hemoglobin. HbF

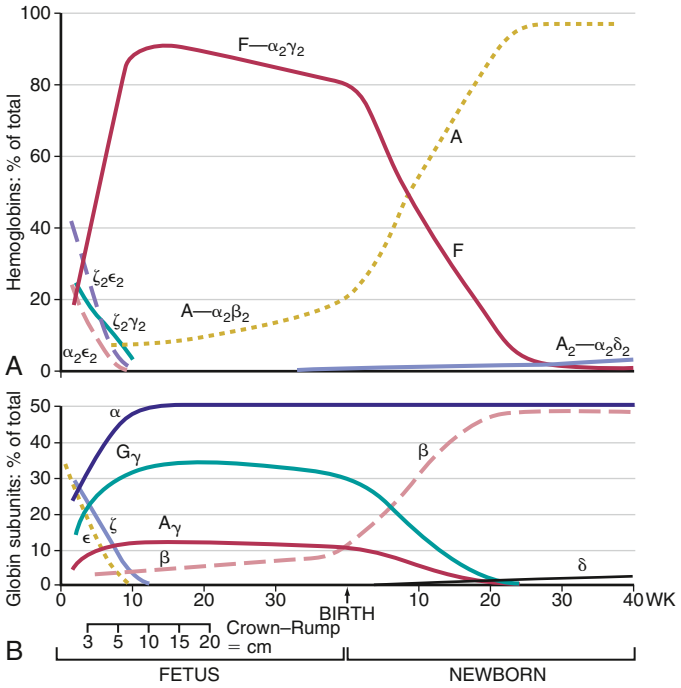

Fig. 495.6 Changes in hemoglobin tetramers (**A**) and in globin subunits (**B**) during human development from embryo to early infancy. *(From Polin RA, Fox WW. Fetal and Neonatal Physiology, 2nd ed. Philadelphia: Saunders, 1998: p. 1769.)*

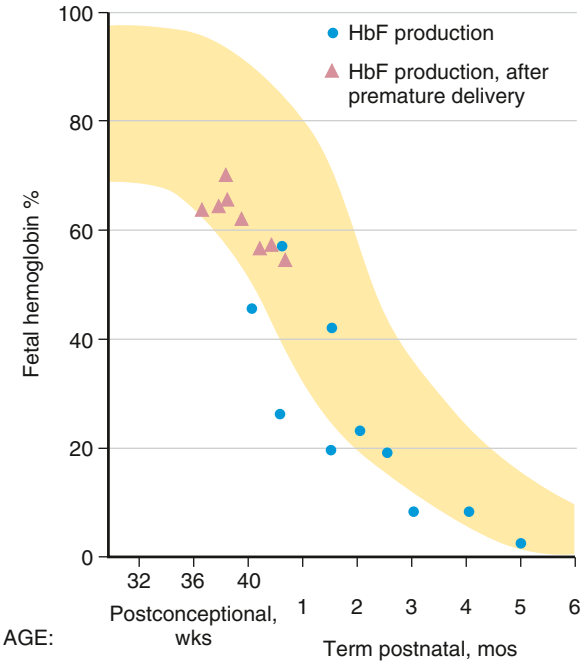

Fig. 495.7 Pre- and postnatal changes in the percentage of total hemoglobin represented by fetal hemoglobin (HbF) *(yellow)*. The *triangles* represent postnatal production by reticulocytes in premature infants, and the *circles* represent cord blood and postnatal reticulocyte production in term infants. *(From Brown MS. Fetal and neonatal erythropoiesis. In: Stockman JA, Pochedly C eds. Developmental and Neonatal Hematology. New York: Raven Press, 1988.)*

declines modestly in the third trimester, such that the HbF comprises 70–80% of the total hemoglobin. HbF production decreases rapidly postnatally (Fig. 495.7), and by 6-12 months of age declines to adult concentrations of <2%. Understanding the molecular basis of the fetal-to-adult hemoglobin switch is of interest because of the therapeutic benefits to patients with β-thalassemia and sickle cell disease, whose clinical severity is improved with modest elevation of HbF. The exact mechanisms by which BCL11A acts to repress HbF are not fully elucidated, but erythroid-specific enhancers of BCL11A have been identified and are potential targets for therapeutic HbF induction.

Adult Hemoglobins

HbA constitutes 5–10% of total hemoglobin at 24 weeks' gestation and steadily increases, so that at term, HbA averages 30% of total hemoglobin. By 6-12 months of age, individuals reach adult concentrations of HbA. The minor adult hemoglobin component, HbA_2, contains delta (δ) chains and has the structure $\alpha_2\delta_2$. At birth, <1.0% of HbA_2 is detected, but by 12 months of age the normal level is 2.0–3.4%. Throughout life, the normal ratio of HbA to HbA_2 is approximately 30:1.

Alterations of Hemoglobins

HbF levels may be elevated with hemoglobinopathies, hereditary persistence of HbF, or bone marrow failure syndromes or may be associated with stress erythropoiesis. Because the HbF level is elevated during the first years of life, knowledge of its normal pattern of decline is important (see Figs. 495.6 and 495.7). Two disorders resulting from pathogenic variants in the β-globin gene (HBB), β-thalassemia and sickle cell disease, become symptomatic postnatally as fetal γ-globin expression decreases and adult β-globin increases. In both these disorders, elevated HbF levels persist in childhood and later. In patients with the most severe type, β^0 thalassemia, except for a small amount of HbA_2, HbF is the only hemoglobin produced. At the other end of the spectrum, in individuals with β-thalassemia trait, the postnatal decrease of HbF is delayed and mildly elevated levels of HbF (>2%) may persist throughout life. Individuals with sickle cell disease, who also have a pathogenic variant in the *HBB* gene, typically demonstrate elevated levels of HbF, ranging from approximately 5% to up to 30%. In contrast, elevated HbF is not characteristic of α-thalassemia syndromes, but tetramers of γ chains (γ_4 or Hb Barts) may be found in the neonatal period. Because α-globin chains are expressed in fetal and adult hemoglobin, four α gene pathogenic variants leading to functional deletions are not compatible with life. Fetuses die in utero or shortly after birth from the severe anemia and hydrops fetalis. Inheritance of only one normal gene of the four (α –/–) results in **hemoglobin H disease**, which is usually associated with a moderate anemia. Inheritance of two or three normal α genes results in α-**thalassemia** trait or carrier status, respectively.

Hereditary persistence of HbF (HPFH) is a benign genetic condition caused by heterozygous deletions or nucleotide substitutions in regions of the β-globin locus that regulate transcription of *HBG1* and *HBG2*, causing persistent pancellular HbF expression levels of approximately 30% of total hemoglobins. Individuals with HPFH do not exhibit anemia.

Preterm infants treated with human recombinant EPO increase HbF production during active erythropoiesis. Moderate elevations of HbF may also occur in many diseases accompanied by hematologic stress, such as hemolytic anemias, leukemia, and bone marrow failure syndromes, such as Diamond Blackfan anemia.

The normal adult level of HbA_2 (2.0–3.4%) is seldom altered. Levels of HbA_2 > 3.4% are found in most persons with the β-thalassemia trait and in those with megaloblastic anemias secondary to vitamin B_{12} and folic acid deficiency. Decreased HbA_2 levels are found in those with iron-deficiency anemia (see Chapter 504) and α-thalassemia (see Chapter 511.10).

RED CELL LIFE SPAN IN THE FETUS AND NEONATE

In general, the highest hematocrit during a person's lifetime occurs at birth, and the lowest hematocrit occurs at the physiologic nadir that occurs 8-10 weeks postnatally. A shortened life span of fetal and neonatal red blood cells (RBCs) has been suggested as an important component. The average erythrocyte life span in normal adults is approximately 120 days. The life span of fetal/neonatal **erythrocytes** was once estimated to be considerably less, with an average of 60-90 days suggested by chromium (^{51}Cr)-labeled erythrocyte studies. However, newer studies indicate that the life span of fetal/neonatal RBCs is similar to that of adults. Neocytolysis is the active removal of young **erythrocytes** that were generated in relatively hypoxic conditions, after normoxic or hyperoxic conditions. This process has also been suggested as an explanation for the physiologic nadir of neonates.

Chapter 496

Anemias

Courtney D. Thornburg

Anemia is defined as a reduction of the hemoglobin concentration or red blood cell (RBC) volume below the range of values occurring in healthy persons. Normal ranges for hemoglobin and hematocrit (packed red cell volume) vary substantially with age and between males and females (Table 496.1) and by race and ethnicity (Table 496.2). Anemia is a significant global health problem affecting children and reproductive-age females (Figs. 496.1 and 496.2).

Physiologic responses to anemia include increased cardiac output, augmented oxygen extraction (increased arteriovenous oxygen difference), and shunting of blood flow toward vital organs and tissues. In addition, the concentration of 2,3-diphosphoglycerate increases within the RBC. The resultant "rightward shift" of the oxygen dissociation curve reduces the affinity of hemoglobin for oxygen and results in more complete transfer of oxygen to the tissues. This same shift in the oxygen dissociation curve can also occur at high altitude. Higher levels of erythropoietin (EPO) and consequent increased RBC production by the bone marrow further help the body to adapt.

HISTORY AND PHYSICAL EXAMINATION

A detailed history and thorough physical exam are essential when evaluating an anemic child. Important historical facts include demographics, diet, medications, chronic diseases, infections, travel, and exposures. A family history of anemia and associated difficulties (e.g., splenomegaly, jaundice, early-age onset of gallstones) is also important. Often, few physical symptoms or signs result solely from a low hemoglobin, particularly when the anemia develops slowly. Clinical findings generally do not become apparent until the hemoglobin level falls to <7-8 g/dL. Clinical features can include pallor, sleepiness, irritability, and decreased exercise tolerance. Pallor can involve the tongue, nail beds, conjunctiva, palms, or palmar creases. A flow murmur is often present. Ultimately, weakness, tachypnea, shortness of breath on exertion, tachycardia, cardiac dilation, and high-output heart failure results from increasingly severe anemia, regardless of its cause. Unusual physical findings linked to specific underlying disease etiologies are discussed in detail in sections describing the associated disorders and in Table 496.3.

Table 496.1 Normal Mean and Lower Limits of Normal for Hemoglobin, Hematocrit, and Mean Corpuscular Volume

	HEMOGLOBIN (g/dL)		HEMATOCRIT (%)		MEAN CORPUSCULAR VOLUME (fL)	
AGE (yr)	MEAN	LOWER LIMIT	MEAN	LOWER LIMIT	MEAN	LOWER LIMIT

LABORATORY STUDIES

Initial laboratory testing should include hemoglobin, hematocrit, RBC indices, white blood cell (WBC) count and differential, platelet count, reticulocyte count, and examination of the peripheral blood smear. The need for additional laboratory studies is dictated by the history, physical exam, and initial testing.

DIFFERENTIAL DIAGNOSIS

Anemia can result from many underlying pathologic processes. To narrow the diagnostic possibilities, anemias may be classified based on their morphology and physiology (Fig. 496.3).

Anemias may be morphologically categorized by red cell size (mean corpuscular volume [MCV]) and microscopic appearance. Anemias can be classified as *microcytic, normocytic,* or *macrocytic* based on whether the MCV is low, normal, or high, respectively (Table 496.4). RBC size also changes with age, and normal developmental changes in MCV should be accommodated before a designation is made (see Table 496.1). Examination of a peripheral blood smear often reveals changes in RBC appearance that will help to further narrow the diagnostic categories (Fig. 496.4 and Table 496.5). Details regarding morphologic changes associated with specific disorders are described in subsequent sections.

Anemias may also be further divided based on underlying pathophysiology. The two major categories are **decreased production** and **increased destruction** (or **loss**). These two groups are not always mutually exclusive. Decreased RBC production may be a consequence of either ineffective erythropoiesis or complete failure of erythropoiesis. Increased destruction or loss may be secondary to hemolysis, sequestration, or bleeding. The peripheral blood reticulocyte percentage or absolute number helps to distinguish between the two physiologic categories. The normal reticulocyte percentage of total RBCs during most of childhood is approximately 1%, with an absolute reticulocyte count of 25,000-75,000/mm^3. In the presence of anemia, EPO production and the absolute number of reticulocytes should rise. Low or normal numbers of reticulocytes generally represent an inadequate response to anemia that is associated with relative bone marrow failure or ineffective erythropoiesis. Increased numbers of reticulocytes represent a normal bone marrow response to ongoing RBC destruction (hemolysis), sequestration, or loss (bleeding).

Figure 496.3 presents a useful approach to assessing the common causes of anemia in the pediatric age group. Children with **microcytic anemia** and low or normal reticulocyte counts most often have defects in erythroid maturation or ineffective erythropoiesis. **Iron deficiency** is the most common cause (see Chapter 504). **Thalassemia trait** constitutes the primary differential diagnosis when iron deficiency is suspected (see Chapter 511). Distinctions between these entities are presented in Table 504.2. Chronic disease or inflammation (more often normocytic), lead poisoning, and sideroblastic anemias should also be considered and are discussed in other chapters. Microcytosis and elevated reticulocyte counts are associated with thalassemias and

Table 496.3 Physical Findings in the Evaluation of Anemia

SYSTEM	OBSERVATION	SIGNIFICANCE
Skin	Hyperpigmentation	Fanconi anemia, dyskeratosis congenita
	Café-au-lait spots	Fanconi anemia
	Vitiligo	Vitamin B_{12} deficiency
	Partial oculocutaneous albinism	Chédiak-Higashi syndrome
	Jaundice	Hemolysis, hepatitis
	Petechiae, purpura	Bone marrow infiltration, autoimmune hemolysis with autoimmune thrombocytopenia (Evans syndrome), hemolytic-uremic syndrome
	Erythematous rash	Parvovirus, Epstein-Barr virus
	Butterfly rash	Systemic lupus erythematosus
Head	Frontal bossing	Thalassemia major, severe iron deficiency, chronic subdural hematoma
	Microcephaly	Fanconi anemia Diamond-Blackfan anemia
Eyes	Microphthalmia	Fanconi anemia
	Retinopathy	Sickle cell disease, types SS and SC
	Optic atrophy, blindness	Osteopetrosis
	Blocked lacrimal gland	Dyskeratosis congenita
	Kayser-Fleischer ring	Wilson disease
	Blue sclera	Iron deficiency
Ears	Deafness	Osteopetrosis
Mouth	Glossitis	Vitamin B_{12} deficiency, iron deficiency
	Angular stomatitis	Iron deficiency
	Cleft lip, palate	Diamond-Blackfan anemia
	Pigmentation	Peutz-Jeghers syndrome (intestinal blood loss)
	Telangiectasia	Osler-Weber-Rendu syndrome (blood loss)
	Leukoplakia	Dyskeratosis congenital
Chest	Shield chest or widespread nipples	Diamond-Blackfan anemia
	Murmur	Endocarditis; prosthetic valve hemolysis
Abdomen	Hepatomegaly	Hemolysis, infiltrative tumor, chronic disease, hemangioma, cholecystitis
	Splenomegaly	Acquired hemolytic anemia, inherited hemolytic anemia (hereditary spherocytosis, pyruvate kinase deficiency, sickle cell disease [age of presentation varies based on phenotype]), thalassemia, malaria, leukemia/lymphoma, Epstein-Barr virus, portal hypertension, hemophagocytic syndromes
	Nephromegaly	Fanconi anemia
	Absent kidney	Fanconi anemia
Extremities	Absent thumbs	Fanconi anemia
	Thenar eminence hypoplasia: triphalangeal thumb	Diamond-Blackfan anemia
	Spoon nails	Iron deficiency
	Beau line (nails)	Heavy metal intoxication, severe illness
	Mees line (nails)	Heavy metals, severe illness, sickle cell disease
	Dystrophic nails	Dyskeratosis congenita
	Edema	Milk-induced protein-losing enteropathy with iron deficiency, renal failure
Rectal	Hemorrhoids	Portal hypertension
	Heme-positive stool	Intestinal hemorrhage
Nerves	Irritable, apathy	Iron deficiency
	Peripheral neuropathy	Deficiency of vitamins B_1 and B_{12}, lead poisoning
	Dementia	Deficiency of vitamins B_{12} and E
	Ataxia, posterior column signs	Deficiency of vitamins B_{12} and E
	Stroke	Sickle cell disease, paroxysmal nocturnal hemoglobinuria

hemoglobin C and E (see Chapter 511). Notably, thalassemias and hemoglobinopathies are most often seen in patients of Mediterranean, Middle Eastern, African, or Asian descent.

Normocytic anemia and low reticulocyte count characterize many anemias. The **anemia of chronic disease/inflammation** is usually normocytic (see Chapter 504). The anemia associated with renal failure, primarily a result of reduced EPO production, will invariably be associated with clinical and laboratory evidence of significant kidney disease. Decreased or absent RBC production secondary to transient erythroblastopenia of childhood (see Chapter 499), infection, medications, or endocrinopathy usually results in a normocytic anemia, as does bone marrow infiltration by malignancy. Normocytic anemia in combination with leukopenia (or significant leukocytosis with blasts) and/or thrombocytopenia should raise suspicion for malignancy. See Chapters 517 and 518 to review pancytopenias. Acute bleeding, hypersplenism, and congenital dyserythropoietic anemia type II are also normocytic (see Chapter 501).

In children with normocytic anemia and an appropriate (high) reticulocyte response, the anemia is usually caused by bleeding, hypersplenism, or ongoing hemolysis. In hemolytic conditions, reticulocytosis, indirect hyperbilirubinemia, and increased serum lactate dehydrogenase are indicators of accelerated erythrocyte destruction. Many causes of hemolysis result from conditions that are extrinsic (usually acquired) or intrinsic (usually congenital) to the erythrocyte. Abnormal RBC morphology (e.g., spherocytes, dacryocytes or sickle forms, and schistocytes) identified on the peripheral smear is often helpful in ascertaining the cause.

The anemia seen in children with macrocytic blood cells is sometimes megaloblastic, resulting from impaired DNA synthesis and nuclear development (see Chapter 503). The peripheral blood smear in **megaloblastic anemias** contains large macroovalocytes, and the neutrophils often show nuclear hypersegmentation. The major causes of megaloblastic anemia include folate deficiency, vitamin B_{12} deficiency, and rare inborn errors of metabolism. Other **macrocytic anemias** with low or normal reticulocyte counts include acquired and congenital (Diamond-Blackfan anemia and Fanconi anemia) aplastic anemias and hypothyroidism. Patients with trisomy 21 have macrocytic cells, although an accompanying anemia is generally not present. High MCV and reticulocytosis is seen in congenital dyserythropoietic anemias I and III and in situations where hemolysis results in such a large outpouring of young red cells that the MCV is abnormally high.

Section 2

Anemias of Inadequate Production

Chapter 497

Congenital Hypoplastic Anemia (Diamond-Blackfan Anemia)

Courtney D. Thornburg

Diamond-Blackfan anemia (DBA) is a rare, congenital **bone marrow failure syndrome** that usually becomes symptomatic in early infancy. More than 90% of cases are recognized in the first year of life. The disorder is characterized by anemia, usually normochromic and macrocytic; reticulocytopenia; and insufficient or absent red blood cell (RBC) precursors in an otherwise normally cellular bone marrow. Up to 50% of affected individuals have additional, extrahematopoietic anomalies.

ETIOLOGY

The most common DBA-associated pathogenic variants are in *RPS19* (Fig. 497.1). This gene encodes a component protein of the small 40S ribosomal subunit and pathogenic variants are present in approximately 25–30% of patients with additional ribosomal protein (RP) genes, each encoding a different small (40S) or large (60S) ribosomal subunit protein, implicated as well. All of these pathogenic variants are inherited in an autosomal dominant fashion, with 40–45% of cases inherited from a parent and 55–60% with a de novo pathogenic variant. Less frequently, X-linked inherited cases of DBA involve pathologic genetic variants in *GATA1* or *TSR2*. Patients with *GATA1*-related DBA usually have no extra hematopoietic manifestations (Fig. 497.2). *TSR2*-related DBA is associated with mandibulofacial dysostosis. Approximately 20% of cases do not have an identified genetic variant. Because most causative variants are in ribosomal genes, the disorder is often referred to as a **ribosomopathy**.

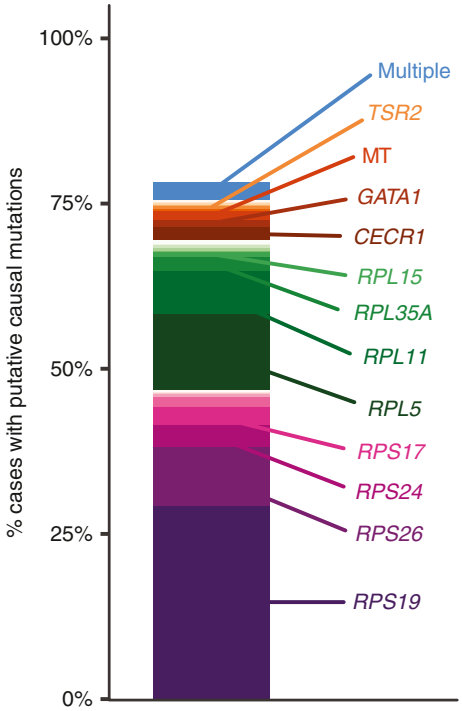

Fig. 497.1 Mutational spectrum of likely pathogenic variants in DBA. Percentage of putative causal mutations in each gene. A total of 78% of case subjects have a putative causal mutation. *(Modified from Ulirsch JC, Verboon JM, Kazerounian S, et al. The genetic landscape of Diamond-Blackfan anemia. Am J Hum Genetics 2018;103:930–947, Fig.1.)*

EPIDEMIOLOGY

DBA affects about 5-10 individuals per million live births. Notably, there is substantial phenotypic diversity in DBA, even in families whose members share the same pathologic genetic variant, suggesting that additional genetic modifiers affect phenotypic expression of the disease.

CLINICAL MANIFESTATIONS

Profound anemia usually becomes evident by 2-6 months of age, occasionally somewhat later. Approximately 25% of patients are anemic at birth, although hydrops fetalis occurs rarely; 92% are diagnosed within the first year of life. Approximately 40–50% of patients have congenital anomalies, and more than one anomaly is found in 25% of DBA patients (Table 497.1). Craniofacial abnormalities are the most common (50% of patients) and include a depressed nasal bridge and high-arched palate. Skeletal anomalies, mostly upper limb and hand, affect 30–40%. This includes thumb abnormalities, including flattening of the thenar eminence and triphalangeal thumb, that may be bilateral or unilateral. The radial pulse may be absent. Genitourinary (39%), cardiac (30%), ophthalmologic, and musculoskeletal anomalies have also been described. Short stature is common, but it is often unclear whether this characteristic results from the disease itself, related therapies, or both.

LABORATORY FINDINGS

The RBCs are usually macrocytic for age, but no hypersegmented neutrophils or other characteristics of megaloblastic anemia are appreciated on the peripheral blood smear. RBC characteristics are like those of a "fetal" RBC population, with increased expression of "i" antigen and elevated fetal hemoglobin (HbF). **Erythrocyte adenosine deaminase** (eADA) activity is increased in most patients with DBA, a finding that helps distinguish congenital RBC aplasia from acquired **transient erythroblastopenia of childhood** (TEC) (see Chapter 499). Because elevated eADA activity is not a fetal RBC feature, measurement of this enzyme may be particularly helpful when diagnosing DBA in very young infants. Thrombocytosis,

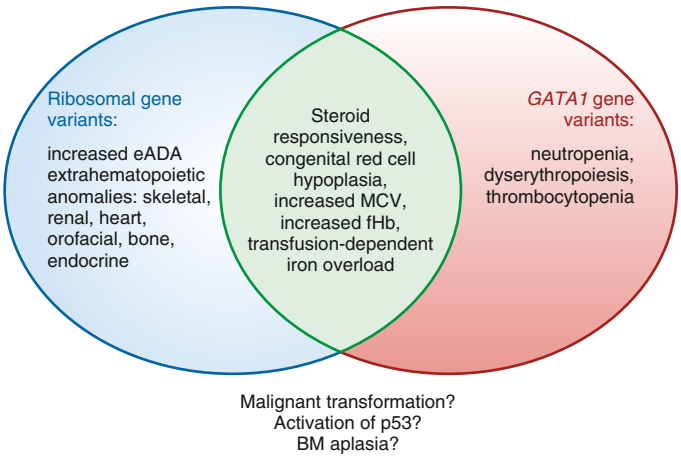

Fig. 497.2 Common and distinct phenotypes in congenital red cell aplasia caused by variants in *RP* genes and in *GATA1*. BM, Bone marrow; eADA, erythrocyte adenosine deaminase activity; fHb, fetal hemoglobin; MCV, mean corpuscular volume. *(Adapted from Weiss MJ, Mason PJ, Bessler M. What's in a name? J Clin Invest 2012;122:2346–2349.)*

or rarely thrombocytopenia, and occasionally neutropenia, may also be present. **Reticulocytopenia** is characteristic despite severe anemia. Bone marrow erythrocyte precursors are greatly reduced in most patients; other marrow elements are usually normal. Serum iron levels are elevated. Unlike Fanconi anemia, there is no increase in chromosomal breaks when lymphocytes are exposed to alkylating agents. Table 497.2 outlines suggested diagnostic criteria for "classical" DBA. Patients may be diagnosed with "nonclassical" DBA or "probable" DBA depending on their individual genetic test results, family history, and major and minor criteria.

Table 497.1 Range of Congenital Anomalies Observed in Diamond-Blackfan Anemia

TYPE/LOCATION	ANOMALIES
Craniofacial	Hypertelorism Broad, flat nasal bridge Cleft palate High-arched palate Microcephaly Micrognathia Microtia Low-set ears Low hairline Ptosis
Ophthalmologic	Congenital glaucoma Strabismus Epicanthal folds Congenital cataract
Neck	Short neck Webbed neck Sprengel deformity Klippel-Feil deformity
Thumbs	Triphalangeal Duplex or bifid Hypoplastic Flat thenar eminence Absent radial artery
Urogenital	Absent kidney Horseshoe kidney Hypospadias
Cardiac	Ventricular septal defect Atrial septal defect Coarctation of the aorta Complex cardiac anomalies
Other	Low birth weight Short stature Syndactyly Learning difficulties

Multiple anomalies, most often including craniofacial, are present in up to 25% of affected individuals. At least one anomaly is present in 40–50%.
From Vlachos A, Ball S, Dahl N, et al. Diagnosing and treating Diamond-Blackfan anaemia: Results of an international clinical consensus conference. *Br J Haematol* 2008;142:859–876, Table IV.

DIFFERENTIAL DIAGNOSIS

DBA must be differentiated from other anemias associated with reticulocytopenia. The syndrome of TEC is often the primary alternative diagnosis. Table 499.1 shows a useful comparison of findings in these two disorders (see Chapter 499). TEC often is differentiated from DBA by its relatively late onset, although it occasionally develops in infants younger than 6 months of age. Macrocytosis, congenital anomalies, fetal RBC characteristics, and elevated eADA are generally associated with DBA and not TEC.

Other inherited macrocytic bone marrow failure syndromes, particularly **Fanconi anemia** and **Shwachman-Diamond syndrome** (see Chapter 517), should also be considered, as should myelodysplastic syndrome. **Aase syndrome** includes congenital RBC aplasia with triphalangeal thumb, congenital heart disease, and cleft palate. **Hemolytic disease of the newborn** can also mimic features of DBA because it can have a protracted course and can be coupled with greatly reduced erythropoiesis. The anemia in this disorder usually resolves spontaneously at 5-8 weeks of age. Several types of chronic hemolytic diseases may be complicated by an **aplastic crisis**, characterized by reticulocytopenia and decreased numbers of RBC precursors. This event usually occurs after the first several months of life and is often caused by **parvovirus B19 infection** (see Chapter 499). Infection with parvovirus B19 in utero is also associated with pure RBC aplasia in infancy and even with hydrops fetalis at birth (see Chapter 298). When diagnosing DBA in young infants, it is important to rule out parvovirus B19 infection using a polymerase chain reaction assay because serologic testing may be inaccurate. Other infections, including HIV, as well as drugs, immune processes, and Pearson syndrome (see Chapter 498), should also be ruled out.

TREATMENT

Corticosteroids are a mainstay of therapy, and approximately 80% of patients initially respond. Because corticosteroids impair linear growth as well as physical and neurocognitive development, many hematologists maintain infants on chronic transfusion therapy and delay the start of steroids until after age 1 year. Prednisone or prednisolone in doses totaling 2 mg/kg/day is used as an initial trial. An increase in RBC precursors is usually seen in the bone marrow 1-3 weeks after therapy is begun and is followed by peripheral reticulocytosis. The hemoglobin can reach normal levels in 4-6 weeks, although the rate of response is quite variable. Once it is established that the hemoglobin concentration is increasing, the dose of corticosteroid may be reduced gradually by tapering and then by eliminating all except a single, lowest effective daily dose. This dose may

Table 497.2 Diagnostic Criteria for Diamond-Blackfan Anemia

DIAGNOSTIC CRITERIA	SUPPORTING CRITERIA	
	MAJOR CRITERIA	MINOR CRITERIA
Age younger than 1 yr	Pathogenic variant described in "classical DBA"	Elevated red cell adenosine deaminase
Macrocytic anemia with no other significant cytopenias	Positive family history	Congenital anomalies described in "classical" DBA
Reticulocytopenia		Elevated HbF
Normal marrow cellularity with paucity of bone marrow erythroid precursors		No evidence for another inherited bone marrow failure syndrome

"Classical DBA" diagnosis is made if all the diagnostic criteria are met.
DBA, Diamond Blackfan anemia, HbF, fetal hemoglobin.
From Vlachos A, Ball S, Dahl N, et al. Diagnosing and treating Diamond-Blackfan anaemia: results of an international clinical consensus conference. *Br J Haematol* 2008;142:859–876.

then be doubled, used on alternate days, and tapered still further while maintaining the hemoglobin level at ≥9 g/dL. The target maintenance dose should not exceed 0.5 mg/kg/day or 1 mg/kg every other day. In some patients, very small amounts of prednisone, as low as 2.5 mg twice a week, may be sufficient to sustain adequate erythropoiesis. Scheduled surveillance examinations and testing for corticosteroid side effects should be pursued in all patients, regardless of dose. Appropriate *Pneumocystis jiroveci* prophylaxis should be considered after the first month of high-dose steroids and continued until the patient is on low-dose alternate-day therapy. In the setting of illness, stress steroids should be considered for children on chronic corticosteroids. Many children with DBA stop taking corticosteroids, usually because of unacceptable side effects (i.e., cushingoid features, pathologic fractures, cataracts) or the evolution of corticosteroid refractoriness.

Chronic red cell transfusions are required in approximately 35% of patients, including patients who are never steroid responsive (30%), are steroid refractory (15%), or cannot be weaned to acceptable low dose (50%). Transfusions are given at intervals of 3-5 weeks to maintain a hemoglobin level >8 g/dL. Some younger children may require hemoglobin >9 g/dL to sustain normal growth and activities. Appropriate screening and ultimately the initiation of chelation therapy are required for transfusion-related iron overload.

L-leucine (700 mg/m^2 orally three times per day) has been evaluated in a phase I/II trial patients with DBA 2 years of age and older. In 43 evaluable patients, 16% had erythroid response, 36% had increase in weight, and 44% had an increase in linear growth velocity.

Spontaneous remission of anemia with independence from steroid or red cell transfusion therapy has been reported. The likelihood of remission is 25% by age 25 years, with most of these patients experiencing remission during the first decade. Mild macrocytic anemia and increased erythrocyte ADA levels persist in these circumstances.

Hematopoietic stem cell transplantation (HSCT) can be curative. Indications for HSCT include steroid resistance or unacceptable toxicity and transfusion dependence as well as significant complications of chronic red cell transfusions including iron overload and alloimmunizations. HLA-matched sibling HSCT is recommended for transfusion-dependent children with DBA. One recommendation is for HSCT between ages 3 and 9 years, and some advocate HSCT at a younger age to avoid iron overload and allosensitization from chronic red cell transfusions. It is important that sibling donors be carefully screened, including genotype if known, to ensure that the donor does not carry the pathologic genetic variant. Overall, outcomes are improving for matched-sibling and alternative donor HSCT.

PROGNOSIS

DBA has been identified as a **cancer predisposition syndrome** because of the higher risk of myelodysplastic syndrome, acute myeloid leukemia, colon carcinoma, osteogenic sarcoma, and female genital cancers. Patients are at risk for iron overload-related endocrine abnormalities (diabetes, hypogonadism), especially if transfused. Patients who have undergone HSCT are at risk of associated late effects (see Chapters 179, 180, and 181). The overall actuarial survival of all patients with DBA is approximately 75% at age 40 years, with approximately 87% for those maintained on corticosteroids and approximately 57% for transfusion-dependent patients. Of reported deaths, 67% were treatment related and 22% were DBA related (malignancy and severe aplastic anemia).

Treatment outcome and survival data are collected through the Diamond-Blackfan Anemia Registry (https://www.dbar.org).

Chapter 498

Pearson Syndrome

Courtney D. Thornburg

Pearson syndrome (PS) is a rare multisystem mitochondrial disorder that presents with a hypoplastic anemia that may be initially confused with Diamond-Blackfan syndrome (anemia) or transient erythroblastopenia of childhood (see Chapter 499). The marrow failure usually appears in the neonatal period and is characterized by a *sideroblastic macrocytic anemia* and, occasionally, neutropenia and thrombocytopenia. There are vacuolated erythroblasts and myeloblasts in the bone marrow (Fig. 498.1). PS is considered a unique variant of congenital sideroblastic anemia because the marrow also contains ringed sideroblasts. The hemoglobin F level is elevated. There is multiorgan involvement manifested by failure to thrive and symptoms of exocrine pancreas dysfunction, liver and renal tubular defects, malabsorption, and myopathy. Endocrine dysfunction (type 1 diabetes, adrenal insufficiency, hypoparathyroidism, and hypothyroidism) has also been reported. Children that survive early childhood typically develop **Kearns-Sayre syndrome**, an early-onset, mitochondrial disorder with lactic acidosis, progressive external ophthalmoplegia (impaired eye movement and ptosis), pigmentary retinitis, deafness, cerebellar ataxia, and heart block. Pearson syndrome is caused by a large heteroplasmic **mitochondrial DNA (mtDNA) deletion** (see Chapter 108) that predominates in the hematopoietic lineage. Subsequently, there is heterogeneity in different tissues and between patients, accounting for the variable clinical picture. The proportion of deleted mtDNA in the bone marrow correlates with the severity of the hematologic disease, and a reduction in the percentage of deleted mtDNA over time may be associated with spontaneous improvement of red blood cell hypoproliferation. PS may be misdiagnosed as Diamond-Blackfan anemia (DBA) based on the overlapping features, including severe anemia starting at a young age. Evaluation for mtDNA deletion differentiates PS from DBA (see Chapter 497).

Therapy for the hematologic manifestations of the disease includes red cell transfusions to correct anemia and granulocyte colony-stimulating factor in the setting of severe neutropenia. The hematologic manifestations may spontaneously resolve within the first few years of life and stem cell transplantation may be considered for persistent cytopenias.

Hematopoietic stem cell transplantation (HSCT) can be curative. Indications for HSCT include steroid resistance or unacceptable toxicity and transfusion dependence as well as significant complications of chronic red cell transfusions including iron overload and alloimmunizations. HLA-matched sibling HSCT is recommended for transfusion-dependent children with DBA. One recommendation is for HSCT between ages 3 and 9 years, and some advocate HSCT at a younger age to avoid iron overload and allosensitization from chronic red cell transfusions. It is important that sibling donors be carefully screened, including genotype if known, to ensure that the donor does not carry the pathologic genetic variant. Overall, outcomes are improving for matched-sibling and alternative donor HSCT.

PROGNOSIS

DBA has been identified as a **cancer predisposition syndrome** because of the higher risk of myelodysplastic syndrome, acute myeloid leukemia, colon carcinoma, osteogenic sarcoma, and female genital cancers. Patients are at risk for iron overload-related endocrine abnormalities (diabetes, hypogonadism), especially if transfused. Patients who have undergone HSCT are at risk of associated late effects (see Chapters 179, 180, and 181). The overall actuarial survival of all patients with DBA is approximately 75% at age 40 years, with approximately 87% for those maintained on corticosteroids and approximately 57% for transfusion-dependent patients. Of reported deaths, 67% were treatment related and 22% were DBA related (malignancy and severe aplastic anemia).

Treatment outcome and survival data are collected through the Diamond-Blackfan Anemia Registry (https://www.dbar.org).

Chapter 498

Pearson Syndrome

Courtney D. Thornburg

Pearson syndrome (PS) is a rare multisystem mitochondrial disorder that presents with a hypoplastic anemia that may be initially confused with Diamond-Blackfan syndrome (anemia) or transient erythroblastopenia of childhood (see Chapter 499). The marrow failure usually appears in the neonatal period and is characterized by a *sideroblastic macrocytic anemia* and, occasionally, neutropenia and thrombocytopenia. There are vacuolated erythroblasts and myeloblasts in the bone marrow (Fig. 498.1). PS is considered a unique variant of congenital sideroblastic anemia because the marrow also contains ringed sideroblasts. The hemoglobin F level is elevated. There is multiorgan involvement manifested by failure to thrive and symptoms of exocrine pancreas dysfunction, liver and renal tubular defects, malabsorption, and myopathy. Endocrine dysfunction (type 1 diabetes, adrenal insufficiency, hypoparathyroidism, and hypothyroidism) has also been reported. Children that survive early childhood typically develop **Kearns-Sayre syndrome**, an early-onset, mitochondrial disorder with lactic acidosis, progressive external ophthalmoplegia (impaired eye movement and ptosis), pigmentary retinitis, deafness, cerebellar ataxia, and heart block. Pearson syndrome is caused by a large heteroplasmic **mitochondrial DNA (mtDNA) deletion** (see Chapter 108) that predominates in the hematopoietic lineage. Subsequently, there is heterogeneity in different tissues and between patients, accounting for the variable clinical picture. The proportion of deleted mtDNA in the bone marrow correlates with the severity of the hematologic disease, and a reduction in the percentage of deleted mtDNA over time may be associated with spontaneous improvement of red blood cell hypoproliferation. PS may be misdiagnosed as Diamond-Blackfan anemia (DBA) based on the overlapping features, including severe anemia starting at a young age. Evaluation for mtDNA deletion differentiates PS from DBA (see Chapter 497).

Therapy for the hematologic manifestations of the disease includes red cell transfusions to correct anemia and granulocyte colony-stimulating factor in the setting of severe neutropenia. The hematologic manifestations may spontaneously resolve within the first few years of life and stem cell transplantation may be considered for persistent cytopenias.

Chapter 499

Acquired Pure Red Blood Cell Anemia

Courtney D. Thornburg

TRANSIENT ERYTHROBLASTOPENIA OF CHILDHOOD

Transient erythroblastopenia of childhood **(TEC)** is the most common *acquired red cell aplasia* occurring in children. It is more prevalent than congenital hypoplastic anemia (Diamond-Blackfan anemia [DBA]). This syndrome of severe *transient hypoplastic anemia* occurs mainly in previously healthy children between 6 months and 3 years of age. Most children are older than 12 months at onset. Only 10% of affected patients are more than 3 years of age. The annual incidence is estimated to be 4.3 cases per 100,000 children, although it is likely higher, because TEC often resolves spontaneously with many cases undiagnosed. The suppression of erythropoiesis has been linked to IgG, IgM, and cell-mediated mechanisms. Familial cases have been reported, suggesting a hereditary component. TEC often follows a viral illness, although no specific virus has been consistently implicated.

The temporary suppression of erythropoiesis results in reticulocytopenia and moderate to severe normocytic anemia. Some degree of neutropenia occurs in up to 20% of cases. Platelet numbers are normal or elevated. Like the situation observed in iron-deficiency anemia and other red blood cell (RBC) hypoplasias, thrombocytosis is presumably caused by increased erythropoietin (EPO), which has homology to thrombopoietin (TPO). Mean corpuscular volume (MCV) is characteristically normal for age, and fetal hemoglobin (HbF) levels are normal before the recovery phase. RBC adenosine deaminase levels are normal in TEC, thus contrasting with the elevation noted in most cases of congenital hypoplastic anemia (Table 499.1). Differentiation from DBA is sometimes difficult, but differences in age at onset and in age-related MCV, HbF, and adenosine deaminase are usually helpful. The peak occurrence of TEC coincides with that of iron-deficiency anemia in infants receiving milk as their main caloric source; differences in MCV should help to distinguish between TEC and DBA.

Virtually all children recover within 1-2 months. RBC transfusions may be necessary for severe anemia in the absence of signs of early recovery. The anemia develops slowly, and significant symptoms usually develop only with severe anemia. *Corticosteroid therapy is of no value in this disorder.* Any child with presumed TEC who requires more than one transfusion should be reevaluated for another possible diagnosis. In rare instances, a prolonged case of apparent TEC may be caused by parvovirus-induced RBC aplasia, occurring in children with *hemolytic anemia* or *congenital* or *acquired immunodeficiencies.*

RED CELL APLASIA ASSOCIATED WITH PARVOVIRUS B19 INFECTION

Parvovirus B19 is a common infectious agent that causes **erythema infectiosum** (fifth disease) (see Chapter 298). It is also the most clearly documented viral cause of RBC aplasia in patients with chronic hemolytic anemia or an immunocompromised state. This single-stranded virus is cytotoxic to marrow erythroid progenitor cells, interacting specifically by binding to the red cell P antigen. In addition to decreased or absent erythroid precursors, characteristic nuclear inclusions in erythroblasts and giant pronormoblasts may be seen under light microscopy in bone marrow specimens. The virus does not cause significant anemia in immunocompetent individuals with a normal RBC life span.

Because parvovirus infection usually lasts less than 2 weeks, anemia may not develop or be appreciated in otherwise normal children whose peripheral RBC life span is 100-120 days. The RBC life span is much shorter in patients with **chronic hemolysis** secondary to conditions such as hereditary spherocytosis, immune hemolytic anemia, or sickle cell disease. In these children, a brief cessation of erythropoiesis can cause severe anemia, known as **aplastic crisis**. When a definitive diagnosis is required, the workup should include

Table 499.1 Comparison of Diamond-Blackfan Anemia and Transient Erythroblastopenia of Childhood

FEATURE	DBA	TEC
Male:female	1:1	1:3
AGE AT DIAGNOSIS, MALE (MO)		
Mean	10	26
Median	2	23
Range	0-408	1-120

serum parvovirus IgM and IgG titers. In young infants, a polymerase chain reaction (PCR) assay should be used since serologic testing may be inaccurate. Recovery from moderate to severe anemia is usually spontaneous, heralded by the appearance of nucleated RBCs and subsequent reticulocytosis in the peripheral blood. Nonetheless the parvovirus PCR may remain positive for months after recovery. An RBC transfusion may be necessary if the anemia is associated with significant symptoms. Parvovirus-induced aplastic crisis usually occurs only once in children with chronic hemolysis. In families with more than one child with a hemolytic disorder, parents should be warned that a similar aplastic episode can occur in the other children if they have not been previously infected. During the episode of aplastic crisis, the child is potentially contagious and should be isolated from at-risk patients.

Persistent parvovirus infection may occur in children with congenital immunodeficiency diseases, lymphoproliferative disorders, those being treated with immunosuppressive agents, and those with HIV/AIDS, because these children may be unable to mount an adequate antibody response. The resultant pure RBC aplasia may be severe, and affected children may be thought to have TEC. This type of RBC aplasia differs from TEC in that there is no spontaneous recovery, and more than one transfusion is often needed. The diagnosis of parvovirus infection is made by PCR of peripheral blood or bone marrow DNA because the usual serologic responses, reflected by parvovirus serum IgM or IgG titers, are impaired in immunodeficient children. In chronically infected patients, the disease may be treated with high doses of intravenous immunoglobulin, which contains neutralizing antibody to parvovirus and is effective in the short term.

Parvovirus infection and destruction of erythroid precursors can also occur in utero. Such events are associated with increased rates of fetal loss in the first and second trimesters. Infants may be born with **hydrops fetalis** and anemia (see Chapter 138). The presence of persistent congenital parvovirus infection is detected by PCR of peripheral blood and/or bone marrow DNA because immunologic tolerance to the virus can prevent the usual development of specific antibodies.

OTHER RED CELL APLASIAS IN CHILDREN

Acquired red cell aplasia in adults is usually mediated by a chronic antibody and often associated with disorders such as chronic lymphocytic leukemia, lymphoma, thymoma, lymphoproliferative disorders, and systemic lupus erythematosus. This chronic antibody-mediated type of RBC aplasia, often responsive to immunosuppressive therapy, is quite rare in childhood. Cases of acquired pure RBC aplasia attributable to T-cell suppression have also been described.

Infections other than parvovirus, such as cytomegalovirus, Epstein-Barr virus, and human herpes virus-6, may cause pure RBC aplasia. Certain drugs, such as chloramphenicol, also can inhibit erythropoiesis in a dose-dependent manner. Reticulocytopenia, erythroid hypoplasia, and vacuolated pronormoblasts in the bone marrow are reversible effects of this drug. These effects are distinct from the idiosyncratic and rare development of severe aplastic anemia in chloramphenicol recipients. Acquired antibody-mediated (to erythropoietin) pure RBC aplasia is a rare complication in chronic kidney disease patients treated with erythropoietin. In addition to discontinuing erythropoiesis-stimulating agents, therapy and addressing anemia with red cell transfusions, further treatment may require immunosuppression and eventually renal transplantation.

Chapter 500

Anemia of Chronic Disease and Renal Disease

500.1 Anemia of Chronic Disease

Courtney D. Thornburg

The anemia of chronic disease **(ACD)**, also referred to as **anemia of inflammation**, is found in conditions where there is ongoing immune activation. It occurs in a wide range of disorders, including infections, malignancies, chronic disease, autoimmunity, and graft-versus-host disease. A similar anemia is associated with chronic kidney disease. ACD is typically a mild to moderate normocytic, normochromic, hypoproliferative anemia associated with a decreased serum iron and low transferrin saturation.

ETIOLOGY

Decreased red cell life span, impaired erythropoiesis, and an increased uptake of iron in the reticuloendothelial system are important mechanisms contributing to ACD.

ACD-associated alterations in iron recycling are characterized by an accumulation of iron in reticuloendothelial macrophages despite low levels of serum iron. The diversion of iron from the circulation into the reticuloendothelial system results in *functional* iron deficiency, which causes the impaired heme synthesis and iron-restricted erythropoiesis that contribute to anemia. These alterations in iron metabolism have been attributed to inflammation-associated excess synthesis of hepcidin, a key regulatory protein that controls intestinal iron absorption and tissue distribution. Hepcidin, although mainly synthesized by hepatocytes, is expressed in other cells, including monocytes and macrophages. It functions by binding to and initiating the degradation of the iron exporter, ferroportin (Fig. 500.1).

CLINICAL MANIFESTATIONS

Although the important symptoms and signs associated with ACD are those of the underlying disease, the mild to moderate anemia can affect the patient's quality of life.

LABORATORY FINDINGS

Hemoglobin concentrations are generally 6-9 g/dL. The anemia is usually normochromic and normocytic, although some patients have modest hypochromia and microcytosis, particularly if there is concomitant iron deficiency. Absolute reticulocyte counts are normal or low, and leukocytosis is common. The serum iron level is low, without the increase in serum transferrin (the iron transport protein) that occurs in iron deficiency. This pattern of low serum iron and low-to-normal serum transferrin is a valuable diagnostic feature. *However, note that the serum ferritin level may be elevated secondary to inflammation*. Soluble transferrin receptor (sTfR) is a useful diagnostic test to distinguish ACD from iron-deficiency anemia (IDA) because sTfR levels are high in IDA and normal in ACD. A bone marrow biopsy typically shows normal cellularity with decreased or adequate red blood cell precursors; marrow hemosiderin may be increased and granulocytic hyperplasia may be present.

serum parvovirus IgM and IgG titers. In young infants, a polymerase chain reaction (PCR) assay should be used since serologic testing may be inaccurate. Recovery from moderate to severe anemia is usually spontaneous, heralded by the appearance of nucleated RBCs and subsequent reticulocytosis in the peripheral blood. Nonetheless the parvovirus PCR may remain positive for months after recovery. An RBC transfusion may be necessary if the anemia is associated with significant symptoms. Parvovirus-induced aplastic crisis usually occurs only once in children with chronic hemolysis. In families with more than one child with a hemolytic disorder, parents should be warned that a similar aplastic episode can occur in the other children if they have not been previously infected. During the episode of aplastic crisis, the child is potentially contagious and should be isolated from at-risk patients.

Persistent parvovirus infection may occur in children with congenital immunodeficiency diseases, lymphoproliferative disorders, those being treated with immunosuppressive agents, and those with HIV/AIDS, because these children may be unable to mount an adequate antibody response. The resultant pure RBC aplasia may be severe, and affected children may be thought to have TEC. This type of RBC aplasia differs from TEC in that there is no spontaneous recovery, and more than one transfusion is often needed. The diagnosis of parvovirus infection is made by PCR of peripheral blood or bone marrow DNA because the usual serologic responses, reflected by parvovirus serum IgM or IgG titers, are impaired in immunodeficient children. In chronically infected patients, the disease may be treated with high doses of intravenous immunoglobulin, which contains neutralizing antibody to parvovirus and is effective in the short term.

Parvovirus infection and destruction of erythroid precursors can also occur in utero. Such events are associated with increased rates of fetal loss in the first and second trimesters. Infants may be born with **hydrops fetalis** and anemia (see Chapter 138). The presence of persistent congenital parvovirus infection is detected by PCR of peripheral blood and/or bone marrow DNA because immunologic tolerance to the virus can prevent the usual development of specific antibodies.

OTHER RED CELL APLASIAS IN CHILDREN

Acquired red cell aplasia in adults is usually mediated by a chronic antibody and often associated with disorders such as chronic lymphocytic leukemia, lymphoma, thymoma, lymphoproliferative disorders, and systemic lupus erythematosus. This chronic antibody-mediated type of RBC aplasia, often responsive to immunosuppressive therapy, is quite rare in childhood. Chapter 500

Anemia of Chronic Disease and Renal Disease

500.1 Anemia of Chronic Disease

Courtney D. Thornburg

The anemia of chronic disease **(ACD)**, also referred to as **anemia of inflammation**, is found in conditions where there is ongoing immune activation. It occurs in a wide range of disorders, including infections, malignancies, chronic disease, autoimmunity, and graft-versus-host disease. A similar anemia is associated with chronic kidney disease. ACD is typically a mild to moderate normocytic, normochromic, hypoproliferative anemia associated with a decreased serum iron and low transferrin saturation.

ETIOLOGY

Decreased red cell life span, impaired erythropoiesis, and an increased uptake of iron in the reticuloendothelial system are important mechanisms contributing to ACD.

ACD-associated alterations in iron recycling are characterized by an accumulation of iron in reticuloendothelial macrophages despite low levels of serum iron. The diversion of iron from the circulation into the reticuloendothelial system results in *functional* iron deficiency, which causes the impaired heme synthesis and iron-restricted erythropoiesis that contribute to anemia. These alterations in iron metabolism have been attributed to inflammation-associated excess synthesis of hepcidin, a key regulatory protein that controls intestinal iron absorption and tissue distribution. Hepcidin, although mainly synthesized by hepatocytes, is expressed in other cells, including monocytes and macrophages. It functions by binding to and initiating the degradation of the iron exporter, ferroportin (Fig. 500.1).

CLINICAL MANIFESTATIONS

Although the important symptoms and signs associated with ACD are those of the underlying disease, the mild to moderate anemia can affect the patient's quality of life.

LABORATORY FINDINGS

Hemoglobin concentrations are generally 6-9 g/dL. The anemia is usually normochromic and normocytic, although some patients have modest hypochromia and microcytosis, particularly if there is concomitant iron deficiency. Absolute reticulocyte counts are normal or low, and leukocytosis is common. The serum iron level is low, without the increase in serum transferrin (the iron transport protein) that occurs in iron deficiency. This pattern of low serum iron and low-to-normal serum transferrin is a valuable diagnostic feature. *However, note that the serum ferritin level may be elevated secondary to inflammation*. Soluble transferrin receptor (sTfR) is a useful diagnostic test to distinguish ACD from iron-deficiency anemia (IDA) because sTfR levels are high in IDA and normal in ACD. A bone marrow biopsy typically shows normal cellularity with decreased or adequate red blood cell precursors; marrow hemosiderin may be increased and granulocytic hyperplasia may be present.

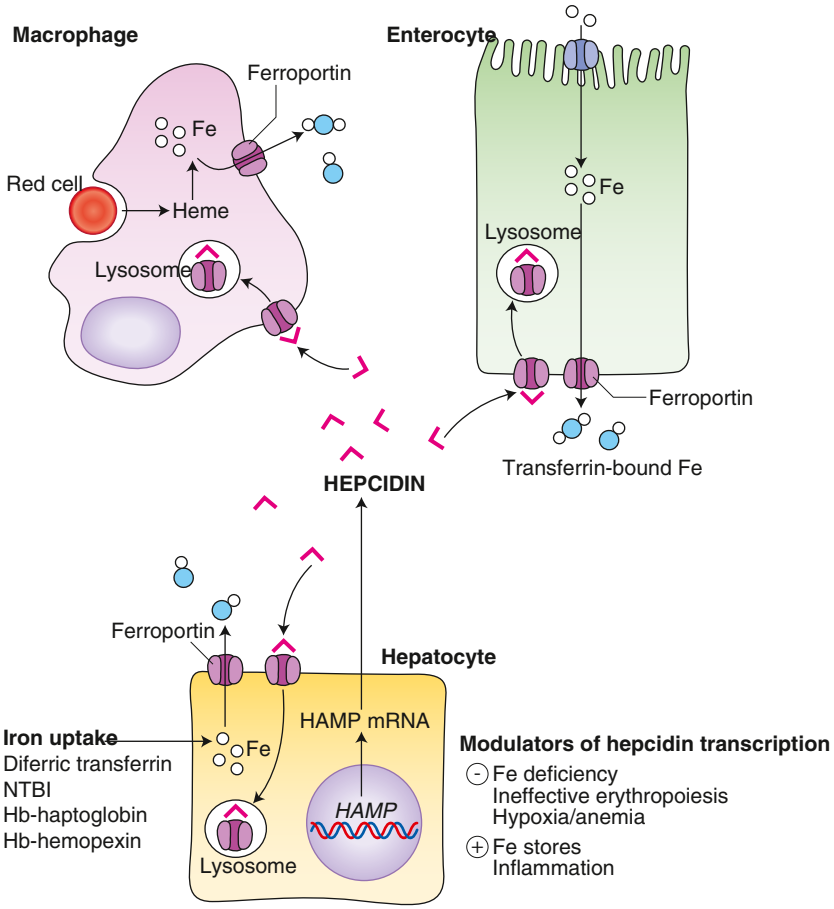

Fig. 500.1 Central role of hepcidin in iron metabolism. Hepcidin, produced by hepatocytes, downregulates iron export to circulating transferrin from iron "donor" cells (hepatocytes, macrophages, and duodenal enterocytes) by promoting the internalization and lysosomal degradation of ferroportin. Hepatocytes take up iron in several forms, whereas enterocytes obtain their iron predominantly from the gut lumen, and macrophages are specialized to deal with the high throughput of iron from senescent red cells. (*From Pippard M. Iron deficiency anemia, anemia of chronic disorders and iron overload. In Porwit A, McCullough J, Erber WN, eds. Blood and Bone Marrow Pathology, 2nd ed. London: Elsevier, 2011; Fig 11-5.*)

TREATMENT

Where possible, the best approach to ACD is the treatment of the underlying disorder. If the associated systemic disease can be controlled, the anemia typically improves or resolves. Transfusions raise the hemoglobin concentration temporarily but are rarely indicated. Erythropoiesis-stimulating agents (ESAs), such as recombinant human erythropoietin (EPO) or related extended half-life formulations, increase the hemoglobin level and improve activity and the sense of well-being. When using ESAs, *treatment with iron* is usually necessary to produce optimal effect. Response to these agents is highly variable, and poorly responsive patients may require high doses to reach target hemoglobin levels. In adults, high doses are associated with a higher incidence of adverse events, such as stroke, cardiovascular events, cancer progression, and death, leading the U.S. Food and Drug Administration (FDA) to require a "black box" warning on labels.

ACD does not respond to iron alone unless there is concomitant deficiency. Unfortunately, it is a common clinical challenge to identify iron deficiency in patients with an inflammatory disease (see Chapters 496 and 504). In this circumstance, a trial of iron therapy might be helpful, although there may be no response because persistent inflammation impairs iron absorption and utilization; intravenous iron may further increase hepcidin production.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

500.2 Anemia of Renal Disease

Courtney D. Thornburg

Anemia is common in children with chronic kidney disease (CKD). The anemia is usually normocytic, and the absolute reticulocyte count is normal or low. Although most patients with end-stage renal disease (ESRD) are anemic, earlier stages of CKD are also associated with a lower prevalence of anemia. In adults, a lower glomerular filtration rate (GFR) has been correlated with lower hemoglobin concentration, and hemoglobin has been reported to decline below a GFR threshold of 40-60 mL/min/1.73 m^2. In children with CKD, hemoglobin levels decline as the GFR decreases below 43 mL/min/1.73 m^2.

Decreased hemoglobin values are linked to increased incidence of left ventricular hypertrophy, impaired physical activity, and a reduced quality of life in pediatric patients with CKD. In those with ESRD on dialysis, anemia is also associated with increased risk of hospitalization and mortality.

ETIOLOGY

Although the anemia of CKD shares many features with anemia of chronic disease, its predominant cause is decreased erythropoietin (EPO) production by diseased kidneys. Other important causes include absolute and/or functional iron deficiency because of chronic blood loss (from blood sampling, surgeries, and dialysis) and disturbances in iron metabolism. Higher hepcidin levels have also been implicated in the anemia of CKD. Hepcidin is filtered by the glomerulus and excreted by the kidney; serum concentrations are increased in patients with decreased GFR. Inflammation may also be a contributing factor in pediatric dialysis patients who have elevated levels of proinflammatory cytokines. Hyperparathyroidism and deficiencies of vitamin B_{12}, folate, and carnitine may also have a role in anemia of CKD.

LABORATORY FINDINGS

Anemia in children with CKD is defined by age: hemoglobin <11.0 g/dL (0.5-5 years), <11.5 g/dL (5-12 years), <12 g/dL (12-15 years), <13.0 g/dL (males >15 years), and <12.0 g/dL (females >15 years). The anemia of CKD is hypoproliferative and usually normocytic and normochromic, unless there is concomitant iron deficiency or vitamin deficiency. The EPO level and absolute reticulocyte count are usually

low. White cell and platelet counts are generally normal. Ferritin will be low if there is accompanying iron deficiency and high if there is associated inflammation.

TREATMENT

Oral iron therapy is recommended for all pediatric CKD patients with anemia. Intravenous (IV) iron therapy may be considered for those receiving maintenance hemodialysis and those who to do not respond to oral iron. Current IV iron preparations (iron-gluconate, iron-sucrose, iron-carboxymaltose, iron-isomaltoside, ferumoxytol) have iron as a core within a carbohydrate stabilizer shell, thus preventing the uncontrolled release of free iron and thus reducing serious side effects.

Erythropoiesis-stimulating agents (ESAs) are the mainstay of therapy and, particularly for children with ESRD, have greatly reduced the need for frequent transfusions, decreasing the incidence of associated iron overload and alloimmunization.

Hemoglobin levels at which ESAs are initiated may be guided by individual patient characteristics, with a goal of 11-12 g/dL for children on maintenance ESA therapy. Dosing varies with age and dialysis modality. Darbepoetin, a synthetic form of EPO, appears to be equally effective as recombinant human EPO and has the benefit of less frequent dosing because of a longer half-life. Iron therapy should be prescribed when using ESAs because treatment demands additional iron for erythropoiesis. Infants and children require higher doses of ESAs.

In the rare case in which anti-EPO antibody-mediated pure red cell aplasia develops, ESA therapy should be stopped, and immunomodulatory therapy may be indicated to suppress the antibody response.

Chapter 501

Congenital Dyserythropoietic Anemias

Courtney D. Thornburg

The congenital dyserythropoietic anemias **(CDAs)** are a heterogeneous class of inherited disorders resulting from abnormalities of late erythropoiesis. These rare conditions are characterized by variable degrees of anemia, ineffective erythropoiesis, hyperbilirubinemia, gallstones, splenomegaly, and secondary hemochromatosis (iron overload). They may be misdiagnosed as other congenital anemias, such as hereditary spherocytosis or thalassemia. **Dyserythropoiesis** is the major cause of anemia but a shortened half-life of circulating red blood cells (RBCs) may also contribute. The CDAs have been classified into four major types (I, II, III, and IV) and variants based on distinctive bone marrow morphology, clinical features, and genetic mutations. **Genetic testing** is now the key method for achieving a timely accurate diagnosis (Fig. 501.1).

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE I

Pathogenesis

Type I CDA **(CDA I)** is an autosomal recessive disorder. It is caused by pathogenic variants in *CDAN1,* the first gene to be implicated, which encodes Codanin-1, a cell-cycle regulated protein. Pathogenic variants in *CDIN1* (CDAN1-interacting nuclease 1, previously *C15orf41*) also cause CDA I. Proteins encoded by *CDAN1* and *CDIN1* likely contribute to DNA repair and/or chromatin reassembly after DNA replication.

Clinical Manifestations

CDA I may be diagnosed at any age, although most cases are recognized during childhood or adolescence in the setting of moderate to severe macrocytic anemia with relative reticulocytopenia. CDA I is rarely diagnosed in utero with severe anemia resulting in hydrops fetalis. Neonates with CDA 1 may have neonatal jaundice or pulmonary hypertension related to anemia. Type I CDA has been associated with **dysmorphic features** in 4–25% of patients, primarily involving the digits (syndactyly, absence of nails or curved toenails, supernumerary toes, skin pigmentation, café-au-lait spots, macrocephaly, dolichocephaly, spinal fusion, scoliosis, and short stature). Patients have progressive iron overload even in the absence of transfusions.

Laboratory Findings

Hemoglobin concentrations generally range between 7-11 g/dL. The anemia is usually macrocytic (mean corpuscular volume: 100-120 fL), but normocytic indices may be seen during childhood. **Anisopoikilocytosis** is appreciated on the peripheral blood smear. In some cases, normoblasts and basophilic stippling of RBCs may be seen. The reticulocyte count is inadequate for the degree of anemia **(reticulocytopenia)**. Elevated serum ferritin secondary to iron overload may be present. The bone marrow aspirate shows erythroid hyperplasia. Binucleate erythroblasts make up 2.5–10% of late erythroblasts. Incompletely divided cells with thin chromatin bridges between nuclei of pairs of erythrocytes are highly specific for type I CDA. Electron microscopy is the gold standard for clinical diagnosis, revealing erythroblasts with a characteristic "Swiss cheese" heterochromatin pattern.

Treatment

Treatment of this disorder includes transfusions, especially in the neonatal period and early childhood and in association with co-inherited disorders, such as thalassemia or RBC enzymopathy. However, adolescents and adults may require episodic transfusions only during aplastic crises, infection, or pregnancy. For patients with CDAN1 mutations, treatment with PEGylated interferon-α_2 can reduce transfusion requirements. Because of potential side effects of spastic diplegia and peripheral neuropathy, treatment initiation may be reserved for patients beyond early childhood requiring frequent transfusions. Patients do not respond to erythropoietin; splenectomy is generally not recommended. Cholecystectomy is often required for management of pigmented gallstones. Allogeneic stem cell transplantation may also be considered for severe cases.

The most important long-term complication is progressive **iron overload**, caused by increased intestinal absorption of iron and ineffective erythropoiesis and transfusion therapy. Regular phlebotomies is a treatment option as long as there is not significant anemia. If this approach is untenable, chelation therapy should be employed when repeated ferritin levels exceed 1,000 μg/L or liver iron is elevated as determined by hepatic magnetic resonance imaging T2*.

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE II

Pathogenesis

CDA type II **(CDA II)**, the most common type of CDA, is an autosomal recessive disorder caused by biallelic pathogenic variants in *SEC23B*. This gene encodes a component of the cytoplasmic coat protein II (COPII) complex that is involved in endoplasmic reticulum vesicle trafficking.

Clinical Manifestations

CDA II presents with varying degrees of normocytic anemia and no or mild reticulocytosis. Approximately 20% of patients are transfusion dependent. CDA II may be initially misdiagnosed as hereditary spherocytosis due to overlapping symptoms of anemia, jaundice, splenomegaly, or hepatomegaly. Extramedullary hematopoiesis may result in

low. White cell and platelet counts are generally normal. Ferritin will be low if there is accompanying iron deficiency and high if there is associated inflammation.

TREATMENT

Oral iron therapy is recommended for all pediatric CKD patients with anemia. Intravenous (IV) iron therapy may be considered for those receiving maintenance hemodialysis and those who to do not respond to oral iron. Current IV iron preparations (iron-gluconate, iron-sucrose, iron-carboxymaltose, iron-isomaltoside, ferumoxytol) have iron as a core within a carbohydrate stabilizer shell, thus preventing the uncontrolled release of free iron and thus reducing serious side effects.

Erythropoiesis-stimulating agents (ESAs) are the mainstay of therapy and, particularly for children with ESRD, have greatly reduced the need for frequent transfusions, decreasing the incidence of associated iron overload and alloimmunization.

Hemoglobin levels at which ESAs are initiated may be guided by individual patient characteristics, with a goal of 11-12 g/dL for children on maintenance ESA therapy. Dosing varies with age and dialysis modality. Darbepoetin, a synthetic form of EPO, appears to be equally effective as recombinant human EPO and has the benefit of less frequent dosing because of a longer half-life. Iron therapy should be prescribed when using ESAs because treatment demands additional iron for erythropoiesis. Infants and children require higher doses of ESAs.

In the rare case in which anti-EPO antibody-mediated pure red cell aplasia develops, ESA therapy should be stopped, and immunomodulatory therapy may be indicated to suppress the antibody response.

Chapter 501

Congenital Dyserythropoietic Anemias

Courtney D. Thornburg

The congenital dyserythropoietic anemias **(CDAs)** are a heterogeneous class of inherited disorders resulting from abnormalities of late erythropoiesis. These rare conditions are characterized by variable degrees of anemia, ineffective erythropoiesis, hyperbilirubinemia, gallstones, splenomegaly, and secondary hemochromatosis (iron overload). They may be misdiagnosed as other congenital anemias, such as hereditary spherocytosis or thalassemia. **Dyserythropoiesis** is the major cause of anemia but a shortened half-life of circulating red blood cells (RBCs) may also contribute. The CDAs have been classified into four major types (I, II, III, and IV) and variants based on distinctive bone marrow morphology, clinical features, and genetic mutations. **Genetic testing** is now the key method for achieving a timely accurate diagnosis (Fig. 501.1).

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE I

Pathogenesis

Type I CDA **(CDA I)** is an autosomal recessive disorder. It is caused by pathogenic variants in *CDAN1,* the first gene to be implicated, which encodes Codanin-1, a cell-cycle regulated protein. Pathogenic variants in *CDIN1* (CDAN1-interacting nuclease 1, previously *C15orf41*) also cause CDA I. Proteins encoded by *CDAN1* and *CDIN1* likely contribute to DNA repair and/or chromatin reassembly after DNA replication.

Clinical Manifestations

CDA I may be diagnosed at any age, although most cases are recognized during childhood or adolescence in the setting of moderate to severe macrocytic anemia with relative reticulocytopenia. CDA I is rarely diagnosed in utero with severe anemia resulting in hydrops fetalis. Neonates with CDA 1 may have neonatal jaundice or pulmonary hypertension related to anemia. Type I CDA has been associated with **dysmorphic features** in 4–25% of patients, primarily involving the digits (syndactyly, absence of nails or curved toenails, supernumerary toes, skin pigmentation, café-au-lait spots, macrocephaly, dolichocephaly, spinal fusion, scoliosis, and short stature). Patients have progressive iron overload even in the absence of transfusions.

Laboratory Findings

Hemoglobin concentrations generally range between 7-11 g/dL. The anemia is usually macrocytic (mean corpuscular volume: 100-120 fL), but normocytic indices may be seen during childhood. **Anisopoikilocytosis** is appreciated on the peripheral blood smear. In some cases, normoblasts and basophilic stippling of RBCs may be seen. The reticulocyte count is inadequate for the degree of anemia **(reticulocytopenia)**. Elevated serum ferritin secondary to iron overload may be present. The bone marrow aspirate shows erythroid hyperplasia. Binucleate erythroblasts make up 2.5–10% of late erythroblasts. Incompletely divided cells with thin chromatin bridges between nuclei of pairs of erythrocytes are highly specific for type I CDA. Electron microscopy is the gold standard for clinical diagnosis, revealing erythroblasts with a characteristic "Swiss cheese" heterochromatin pattern.

Treatment

Treatment of this disorder includes transfusions, especially in the neonatal period and early childhood and in association with co-inherited disorders, such as thalassemia or RBC enzymopathy. However, adolescents and adults may require episodic transfusions only during aplastic crises, infection, or pregnancy. For patients with CDAN1 mutations, treatment with PEGylated interferon-α_2 can reduce transfusion requirements. Because of potential side effects of spastic diplegia and peripheral neuropathy, treatment initiation may be reserved for patients beyond early childhood requiring frequent transfusions. Patients do not respond to erythropoietin; splenectomy is generally not recommended. Cholecystectomy is often required for management of pigmented gallstones. Allogeneic stem cell transplantation may also be considered for severe cases.

The most important long-term complication is progressive **iron overload**, caused by increased intestinal absorption of iron and ineffective erythropoiesis and transfusion therapy. Regular phlebotomies is a treatment option as long as there is not significant anemia. If this approach is untenable, chelation therapy should be employed when repeated ferritin levels exceed 1,000 μg/L or liver iron is elevated as determined by hepatic magnetic resonance imaging T2*.

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE II

Pathogenesis

CDA type II **(CDA II)**, the most common type of CDA, is an autosomal recessive disorder caused by biallelic pathogenic variants in *SEC23B*. This gene encodes a component of the cytoplasmic coat protein II (COPII) complex that is involved in endoplasmic reticulum vesicle trafficking.

Clinical Manifestations

CDA II presents with varying degrees of normocytic anemia and no or mild reticulocytosis. Approximately 20% of patients are transfusion dependent. CDA II may be initially misdiagnosed as hereditary spherocytosis due to overlapping symptoms of anemia, jaundice, splenomegaly, or hepatomegaly. Extramedullary hematopoiesis may result in

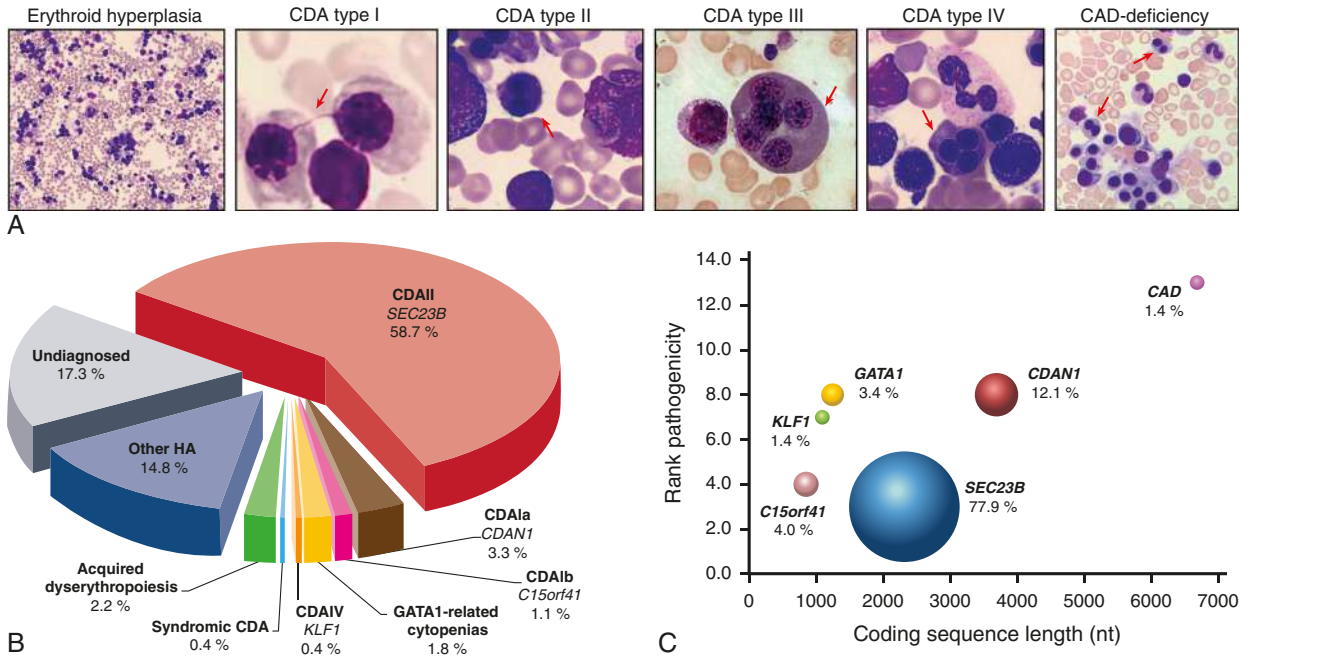

Fig. 501.1 Morphologic and molecular features of patients with congenital dyserythropoietic anemias (CDA). **A,** Light microscopy analysis of the bone marrow from patients with different CDA subtypes. CDA patients generally show erythroid hyperplasia. *Red arrows* indicate typical findings for each CDA subtype: CDAI, internuclear chromatin bridging; CDAII, binucleate erythroid precursors; CDAIII, giant multinucleated erythroblasts; CDAIV, multinucleate erythroblasts; and CAD deficiency, binucleate CDAII-like precursors. **B,** Pie chart showing the frequencies of the different CDA subtypes diagnosed after genetic testing in patients clinically suspected of having CDA. The frequency of each condition was calculated as the ratio between the number of patients in each CDA subtype and the overall count of patients tested (n = 218 patients [those included in our international registry of CDAs from 1995 to 2019]). Six patients originally suspected of CDA showed conclusive diagnosis of acquired dyserythropoiesis: two patients with liver failure, two with iron-deficiency anemia, one with erythrophagocytosis, and one with transient erythroblastopenia. Syndromic CDA refers to one patient with a mutation in the CAD gene. GATA1-related cytopenias include: X-linked thrombocytopenia with or without dyserythropoietic anemia; congenital erythropoietic porphyria; and idiopathic cytopenias of undetermined significance. Other hereditary anemias (HA) include: hereditary spherocytosis; hereditary dehydrated stomatocytosis; red cell enzymatic defects; and sideroblastic anemia. The undiagnosed cases were evaluated by analysis of the CDA gene panel, by extended targeted next-generation sequencing for hereditary anemias, or by whole-exome sequencing. **C,** Bubble chart defining the lengths of the coding sequences of each CDA-causative gene and their relative pathogenicity scores. These scores were calculated by combining the constraint metrics of each gene available at the ExAC database (http://exac.broadinstitute.org/). High pathogenicity scores identify increased constraints (intolerance to variation). The more intolerant to variation a gene is, the less likely it is to be mutated. The size of each bubble represents the frequency of the mutations in each gene, as calculated by the ratio of the number of mutated alleles for each gene and the overall count of disease alleles (n = 149, from 78 patients included in our international registry of CDAs from 2008 to 2019). (*From Iolascon A, Andolfo I, Russo R. Congenital dyserythropoietic anemias. Blood. 2020;136:1274–1281; Fig. 1.*)

posterior mediastinal or paravertebral masses. Iron overload occurs in both transfusion dependent and independent patients.

Laboratory Findings

The anemia is normocytic and is generally mild with inappropriately low reticulocytes. Hemoglobin levels are lower in children than adults and range from 8-11 g/dL. The peripheral blood smear shows anisopoikilocytosis, occasional basophilic stippling, as well as a few, sometimes binucleate, mature erythroblasts. The bone marrow aspirate is normoblastic but hypercellular, with erythroid hyperplasia. Binucleated and multinucleated erythroblasts with equal nuclei size (10–35%) and karyorrhexis (fragmentation of the nuclei) in >2% are characteristic. Electron micrographs demonstrate vesicles laden with endoplasmic reticulum proteins running beneath the plasma membrane (double membranes). Ninety-five percent of patients with CDA II have hypoglycosylated band 3, which has faster migration on the gel, and the diagnosis may be made by analyzing red blood cell membrane proteins with sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS PAGE).

Treatment

Most patients can lead a normal life and have a normal life expectancy if complications and consequences are managed appropriately. Approximately 10% of patients will require red cell transfusions in infancy and childhood but rarely during adulthood. Splenectomy may provide hematologic improvement and is currently recommended for patients with severe anemia and/or symptomatic splenomegaly. Splenectomy does not prevent further iron overloading, even in those patients whose hemoglobin is normalized, presumably because of persistent ineffective erythropoiesis in the bone marrow. Secondary iron overload is the most prominent long-term complication and should be approached as previously outlined.

Allogeneic stem cell transplantation may also be considered for severe cases.

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE III

CDA type III **(CDA III)** is an extremely rare, poorly defined entity characterized by mild to moderate macrocytic anemia. It is inherited in an autosomal dominant or de novo fashion, although there have been cases that might represent other inheritance patterns. CDA III is caused by pathogenic variants in *KIF23*, which encodes a ubiquitous protein, mitotic kinesin-like protein 1, which regulates daughter cell separation during mitosis. Iron overload is not clinically significant (likely due to hemolysis being predominantly intravascular), and spleen size is generally normal. Patients can present with angioid streaks with macular degeneration. An association with monoclonal gammopathy and multiple myeloma is also reported. The blood smear shows macrocytes, anisopoikilocytosis, and occasional basophilic stippling. The bone marrow is notable for giant erythroid precursors that are often multinucleated, containing up to 12 nuclei per cell. Such multinucleated erythroblasts can also be seen in myelodysplasia and erythroleukemia. Transfusions are usually not required.

TRANSCRIPTION FACTOR–RELATED CDA

Transcription factor–related CDA includes CDA type IV (CDA IV) and X-linked thrombocytopenia with or without dyserythropoietic anemia (XLTDA). CDA IV has an autosomal dominant inheritance due to pathogenic variants in *KLF1*, which encodes an erythroid transcription factor that regulates fetal hemoglobin switching and is necessary for terminal erythroid differentiation. Patients have severe hemolytic anemia with no or mild reticulocytosis and very high fetal hemoglobin. Bone marrow morphology consists of hypercellularity and binucleate or multinucleate erythroblasts. Electron micrographs show immature red cell progenitors that have atypical inclusions within the cytoplasm, nuclear membrane invaginations, and heterochromatin.

XLTDA is an X-linked condition due to pathogenic variants in *GATA1*, a DNA-binding protein with two zinc fingers and a transactivation domain that plays a key role in development and maintenance of red cell and platelet lineages. The laboratory features of this condition include mild to severe anemia and macrothrombocytopenia with poorly granulated platelets. Bone marrow morphology shows dyserythropoiesis and megakaryocytes that are abnormal and reduced in number. Patients present with bleeding and anemia, and management includes transfusion and supportive care.

Chapter 502

Physiologic Anemia of Infancy

Courtney D. Thornburg

At birth, normal full-term infants have higher hemoglobin (Hb) levels and larger red blood cells (RBCs) than do older children and adults. However, within the first week of life, a progressive decline in Hb level begins and then persists for 6-8 weeks. The resulting anemia is known as the **physiologic anemia of infancy**.

With the onset of respiration at birth, considerably more oxygen becomes available for binding to Hb, and as a result the Hb-oxygen saturation increases from 50–95% or more. There is also a gradual, normal developmental switch from fetal to adult Hb synthesis after birth that results in the replacement of high-oxygen-affinity fetal Hb with lower-affinity adult Hb, capable of delivering more oxygen to tissues. The increase in blood oxygen content and delivery results in the downregulation of erythropoietin (EPO) production, leading to suppression of erythropoiesis. Because there is no erythropoiesis, aged RBCs that are removed from the circulation are not replaced, and the Hb level decreases. The Hb concentration continues to decline until tissue oxygen needs become greater than oxygen delivery. Normally, this point is reached between 8-12 weeks of age, when the Hb concentration is about 11 g/dL. In healthy term infants, the nadir rarely falls below 10 g/dL. At this juncture, EPO production increases and erythropoiesis resumes. The supply of stored reticuloendothelial iron, derived from previously degraded RBCs, remains sufficient for this renewed Hb synthesis, even in the absence of dietary iron intake, until approximately 20 weeks of age. In all, this "anemia" should be viewed as a physiologic adaptation to extrauterine life, reflecting the excess oxygen delivery relative to tissue oxygen requirements. There is no hematologic problem, and no therapy is required unless physiologic anemia of infancy is exacerbated by other ongoing processes including nutritional deficiency and blood loss. The degree of anemia at birth is correlated with maternal hemoglobin.

A late **hyporegenerative anemia**, with reticulocytopenia, can occur in infants with **hemolytic disease of the newborn**. The persistence of maternally derived anti-RBC antibodies in the infant's circulation can lead to an ongoing low-grade hemolytic anemia that can exaggerate the physiologic anemia. Lower-than-expected Hb at the "physiologic" nadir has also been seen in infants after intrauterine or neonatal RBC transfusions. When infants are transfused with adult blood containing HbA, the associated shift of the oxygen dissociation curve facilitates oxygen delivery to the tissues. Accordingly, the definition of anemia and the need for transfusion should be based not only on the infant's Hb level, but also on oxygen requirements and the ability of circulating RBCs to release oxygen to the tissues.

Premature infants also develop a physiologic anemia, known as **anemia of prematurity**. The Hb decline is both more extreme and more rapid. Hb levels of 7-9 g/dL usually are reached by 3-6 weeks of age, and levels may be even lower in very small premature infants (see Chapter 139). The same physiologic factors at play in term infants are exaggerated in preterm infants. In premature infants, the physiologic Hb decline may be intensified by blood loss from repeated phlebotomies obtained to monitor ill neonates. Demands on erythropoiesis are further heightened by the premature infant's presumed shortened RBC life span (40-60 days) and the accelerated expansion of RBC mass that accompanies the premature baby's rapid rate of growth. Nonetheless, plasma EPO levels are lower than would be expected for the degree of anemia, resulting in a suboptimal erythropoietic response. The reason for diminished EPO levels is not fully understood. During fetal life, EPO synthesis is handled primarily by the liver, and the liver's oxygen sensor is less sensitive to hypoxia compared with that of the kidney. The developmental switch from liver to kidney EPO production is not accelerated by early birth, and thus the preterm infant must rely on the liver as the primary site for synthesis, leading to diminished responsiveness to anemia. An additional mechanism thought to contribute to diminished EPO levels may be accelerated EPO metabolism. Because the pronounced decline in Hb that occurs in many very low birthweight infants may be associated with abnormal clinical signs, this "anemia of prematurity" is not considered benign and usually requires transfusions when symptomatic.

TREATMENT

In the **full-term infant**, physiologic anemia requires no therapy beyond ensuring that the infant's diet contains essential nutrients for normal hematopoiesis. For infants who are exclusively breastfed, iron supplementation is indicated beginning at 4 months of age and continued until oral iron intake via food is sufficient. In **premature infants**, an optimal Hb has not been established and is usually dictated by the infant's overall clinical condition. Transfusions may be needed to maintain the Hb at what is considered safe for that child. Premature infants who are feeding well and growing normally rarely need transfusion unless iatrogenic blood loss has been significant. Although factors such as poor weight gain, respiratory difficulties, and abnormal heart rate have prompted transfusion, the beneficial effect has not been documented. Laboratory tests such as blood lactate, EPO, and mixed venous oxygen saturation have poor predictive value. A restrictive strategy does not increase infant morbidity or mortality. Long-term neurodevelopmental outcomes have been found to be poorer in liberally transfused neonates. Exposure to packed RBCs may be related to the development of necrotizing enterocolitis, and early transfusions may be associated with the risk of intraventricular hemorrhage. Iron supplementation is indicated starting at 2 to 6 weeks of age until 6 to 12 months of age; dosing depends on birth weight and infants with smaller birth weights require higher doses.

Strategies to decrease anemia include delayed cord clamping, avoiding unnecessary phlebotomy, and providing adequate iron supplementation. Delayed cord clamping at birth results in fewer transfusions and a reduction in both intraventricular hemorrhage and necrotizing enterocolitis in preterm infants. Given the impact of phlebotomy losses during monitoring in the neonatal intensive care unit, attention to reducing unnecessary blood draws also has been advocated. Iron therapy is indicated for all neonates with anemia of prematurity starting at 1 month of age and continuing until about 1 year of age. Iron is prescribed as mg of elemental iron per kg/day and depends on birthweight.

When transfusions are necessary, an RBC volume of 10-15 mL/kg is recommended. It is good practice to split units derived from a single donor to minimize donor exposure if sequential transfusions are indicated.

Chapter 503

Megaloblastic Anemias

Courtney D. Thornburg

Megaloblastic anemia describes a group of disorders that are caused by impaired DNA synthesis. Red blood cells (RBCs) are larger than normal at every developmental stage, and there is maturational asynchrony between the nucleus and cytoplasm of erythrocytes. The delayed nuclear development becomes increasingly evident as cell divisions proceed. Myeloid and platelet precursors are also affected, and giant metamyelocytes and neutrophil bands are often present in the bone marrow. *There is often an associated thrombocytopenia and leukopenia*. The peripheral blood smear is notable for large, often oval RBCs with increased mean corpuscular volume (Fig. 503.1). Neutrophils are characteristically hypersegmented, with many having more than five lobes (see Fig. 503.1). Most cases of childhood megaloblastic anemia result from a deficiency of folic acid or vitamin B_{12} (cobalamin), vitamins essential for DNA synthesis (Table 503.1). Rarely, these anemias may be caused by inborn errors of metabolism. Megaloblastic anemias resulting from malnutrition are relatively uncommon in the United States but are important worldwide (see Chapters 62, 64, and 496).

503.1 Folic Acid Deficiency

Courtney D. Thornburg

Folates are essential for DNA replication and cellular proliferation. Humans cannot synthesize folate and must depend on dietary sources, including green vegetables, fruits, and animal organs (e.g., liver, kidney). Folates are heat labile and water soluble; consequently, boiling or heating folate sources leads to decreased amounts of the vitamin. Naturally occurring folates are in a polyglutamated form that is less efficiently absorbed than the monoglutamate species (i.e., folic acid). Dietary folate polyglutamates are hydrolyzed to simple folates that are absorbed primarily in the proximal small intestine by a specific carrier-mediated system. Folates travel in the bloodstream and are taken up in cells, primarily in the form of unconjugated methyltetrahydrofolate, which is subsequently reconjugated (polyglutamated) in the cell. There is an active enterohepatic circulation. Although rare, megaloblastic anemia because of folate deficiency has its peak incidence at 4-7 months of age, somewhat earlier than iron-deficiency anemia, although both conditions may be present concomitantly in infants with poor nutrition.

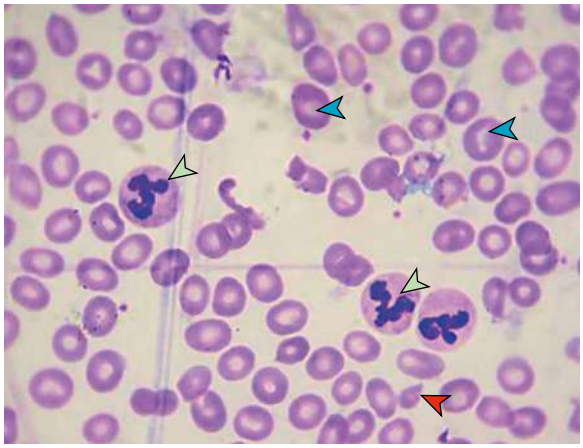

Fig. 503.1 Peripheral blood film shows hypersegmented neutrophils *(green arrowheads)*, macrocytes *(blue arrowheads)*, and a teardrop-shaped red blood cell *(red arrowhead)*. *(From Bawaskar HS, Bawaskar P, Bawaskar PH, Parekh PB. Tropical megaloblastic anemia. Lancet 2019;393:2261–2262.)*

ETIOLOGY

Folic acid deficiency can result from inadequate folate intake, decreased folate absorption, or acquired and congenital disorders of folate metabolism or transport (Table 503.2).

Inadequate Folate Intake

In the United States, anemia caused by insufficient folate intake usually occurs in the context of increased vitamin requirements associated with pregnancy, periods of accelerated growth, and chronic hemolysis (see Chapter 67.6). Folate requirements greatly increase during pregnancy, in part to meet fetal needs, and deficiencies are common in mothers, particularly those who are poor or malnourished. Folate supplementation is recommended from the start of pregnancy to prevent neural tube defects and to meet the needs of the developing fetus. Folate-deficient mothers generally do not give birth to infants with clinical folate deficiency because there is selective transfer of folate

Table 503.1 Causes of Red Blood Cell Macrocytosis

CAUSATIVE CONDITIONS	ACCOMPANYING HEMATOLOGIC FEATURES
MEGALOBLASTIC ANEMIA	
Cobalamin (vitamin B_{12}) deficiency	Megaloblastic changes, including hypersegmented neutrophils
Folate deficiency	Macrocytosis can become severe
Antifolate drugs (e.g., methotrexate)	Mild reticulocytopenia
Cytotoxic drugs (e.g., hydroxyurea, 5-FU)	Pancytopenia (when the megaloblastic process is severe)
Immunosuppressive drugs (e.g., azathioprine)	
Thiamine-responsive anemia	
Hereditary orotic aciduria	
DISORDERS OF ERYTHROID PRODUCTION	
Aplastic anemia, PRCA, Blackfan-Diamond anemia	Nonmegaloblastic
Some sideroblastic anemias	Some disorders feature dyserythropoiesis and sometimes hyposegmented neutrophils
CDA, non-CDA dyserythropoiesis, Fanconi anemia	
Myelodysplasia, myeloproliferative diseases	Macrocytosis can often be severe (e.g., aplastic processes)
	Reticulocytopenia (often severe)
RETICULOCYTOSIS	
Chronic hemolytic anemia	Nonmegaloblastic; no hypersegmented neutrophils
DRUGS AND TOXINS	
Alcohol abuse	Mechanism of macrocytosis is often unknown
Some antiviral drugs (e.g., nucleoside RT inhibitors)	No hypersegmented neutrophils
Some anticonvulsant drugs	
NONHEMATOLOGIC DISEASES	
Chronic liver diseases	Nonmegaloblastic; no hypersegmented neutrophils
Hypothyroidism	
Copper deficiency	Macrocytes are rarely oval
ARTIFACTS	
RBC clumping by cold agglutinins; some warm RBC antibodies	Nonmegaloblastic; no hypersegmented neutrophils
Severe hyperglycemia	Disparity between high MCV and normal morphologic examination
Hyponatremia	

CDA, Congenital dyserythropoietic anemia; MCV, mean corpuscular volume; PRCA, pure red cell aplasia; RBC, red blood cell; RT, reverse transcriptase; 5-FU, 5-fluorouracil.

Sulfasalazine§
Valproic acid§,#
Inherited defects
Methylenetetrahydrofolate reductase (MTHFR) deficiency
Disorders of intracellular cobalamin metabolism
Dihydrofolate reductase deficiency
Methylenetetrahydrofolate dehydrogenase, cyclohydrolase, and formyltetrahydrofolate synthetase 1 (MTHFD1) deficiency
Others
MULTIFACTORIAL OR UNCERTAIN MECHANISMS
Alcohol use disorder‡
Anticonvulsants§
Oral contraceptives§

*Folate deficiency is often multifactorial.
†Relative dietary insufficiency (i.e., intake that is adequate under usual circumstances) is a particularly important cofactor that can convert borderline folate deficiency to clinically overt deficiency when other conditions coexist, such as increased requirements for folate or mild malabsorption.
§Megaloblastic anemia rarely results unless other limitations of folate status coexist.
‖Neonatal stores are low in premature infants.
¶Cerebral folate deficiency can occur on a genetic basis or an autoimmune basis; megaloblastic anemia does not occur because folate deficiency appears not to exist outside the central nervous system.
#Disrupts mitochondrial folate metabolism in utero.
‡Poor intake is often associated with alcoholism in adults.
From Orkin SH, Fisher DE, Ginsburg D, et al., eds. *Nathan and Oski's Hematology and Oncology of Infancy and Childhood*, 8th ed. Philadelphia: Elsevier, 2015; Box 10-2.

to the fetus via placental folate receptors. Rapid growth after birth increases demands for folic acid, and infants who are premature or ill and those with certain hemolytic disorders will have particularly high folate requirements. Human breast milk, infant formulas, and pasteurized cow's milk provide adequate amounts of folic acid. *Goat's milk is folate deficient, and supplementation must be given when it is the child's main food source.* Unless supplemented, powdered milk may also be a poor source of folic acid.

Malnutrition is the most common cause of folate deficiency in older children. In addition, children with chronic hemolytic anemias, infections, or malabsorption are at increased risk due to increased demand. Because body stores of folate are limited, deficiency can develop quickly in malnourished individuals. On a folate-free diet, megaloblastic anemia will occur after 2-3 months.

Decreased Folate Absorption

Malabsorption caused by chronic diarrheal states or diffuse inflammatory disease can lead to folate deficiency. In both situations, some of the decreased folate absorption may be caused by impaired folate conjugase activity. Chronic diarrhea also interferes with the enterohepatic circulation of folate, thereby enhancing folate losses because of rapid intestinal passage. Megaloblastic anemia caused by folic acid deficiency can occur in celiac disease or chronic infectious enteritis and in association with enteroenteric fistulas. Previous intestinal surgery is another potential cause of decreased folate absorption.

Certain anticonvulsant drugs (e.g., phenytoin, phenobarbital) can impair folic acid absorption, and many patients treated with these drugs have low serum levels. Frank megaloblastic anemia is rare and readily responds to folic acid therapy, even when administration of the offending drug is continued. Alcohol overuse also is associated with folate malabsorption.

Congenital Abnormalities in Folate Transport and Metabolism

Inborn errors of folate transport or metabolism are rare but can be life threatening. Those associated with megaloblastic anemia include hereditary folate malabsorption and certain extremely uncommon enzyme deficiencies.

Hereditary folate malabsorption (HFM) is an autosomal recessive disorder caused by loss-of-function pathogenic variants in the *SLC46A1* gene encoding the protein-coupled folate transporter. HFM is associated with an inability to absorb folic acid, 5-tetrahydrofolate, 5-methyltetrahydrofolate, or 5-formyltetrahydrofolate (folinic acid). It can become apparent at 2-6 months of age with megaloblastic anemia and other deficits, including infections and diarrhea. Neurologic abnormalities attributable to folate deficiency in the central nervous system (CNS) include seizures, developmental delay, and intellectual disability. Folate transport is impaired both in the intestine and at the brain's choroid plexus. Serum and cerebrospinal fluid (CSF) folate levels are very low, with a loss of the normal 3:1 ratio of CSF to serum folate.

Treatment for HFM involves parenteral (intramuscular) folate or high-dose oral 5-formyltetrahydrofolate (5-formylTHF), folinic acid, leucovorin, or the active isomer of 5-formylTHF (Isovorin or Fusilev) targeting normal or near normal trough levels in the CSF to ameliorate both the megaloblastic anemia and neurologic complications of folate deficiency.

Functional methionine synthase deficiency may result from pathologic genetic variants affecting the function of methionine synthase reductase or methionine synthase. These disorders are autosomal recessive and characterized not only by megaloblastic anemia but also by cerebral atrophy, nystagmus, blindness, and altered muscle tone. Both respond to hydroxocobalamin (OHCbl) plus betaine with variable clinical success. **Dihydrofolate reductase (DHFR) deficiency** is extremely rare and is associated with homozygous pathologic genetic variants in the *DHFR* gene. Clinical symptoms include megaloblastic anemia and neurologic manifestations. Although **methylenetetrahydrofolate reductase (MTHFR) deficiency** is the most common inborn error of folate metabolism, and severe cases can produce several neurologic and vascular complications, there is *no* associated megaloblastic anemia.

Drug-Induced Abnormalities in Folate Metabolism

Several drugs have anti–folic acid activity as their primary pharmacologic effect and regularly produce megaloblastic anemia. *Methotrexate* binds to dihydrofolate reductase and prevents formation of tetrahydrofolate, the active form of folate. *Pyrimethamine,* used in the therapy of toxoplasmosis, and *trimethoprim,* used for treatment of various infections, can induce folic acid deficiency and occasionally megaloblastic anemia. Therapy with folinic acid (5-formyltetrahydrofolate) is usually beneficial.

CLINICAL MANIFESTATIONS

In addition to the clinical features associated with anemia, folate-deficient infants and children may manifest irritability, chronic diarrhea, and poor weight gain. Hemorrhages from thrombocytopenia may occur in advanced cases. HFM and other rare etiologies of folate deficiency may be further associated with hypogammaglobulinemia, severe infections, failure to thrive, neurologic abnormalities, and cognitive delays.

LABORATORY FINDINGS

The anemia is macrocytic (mean corpuscular volume >100 fL). Variations in RBC shape and size are common (see Chapter 496, Fig. 496.4B). The reticulocyte count is low, and nucleated RBCs with megaloblastic morphology are often seen in the peripheral blood. Neutropenia and thrombocytopenia may be present, particularly in patients with long-standing and severe deficiencies. The neutrophils are large, some with *hypersegmented nuclei* (see Fig. 503.1). The bone marrow is hypercellular because of erythroid hyperplasia, and megaloblastic changes are prominent. Large, abnormal neutrophilic forms (giant metamyelocytes) with cytoplasmic vacuolation are also seen.

Levels of RBC folate are a better indicator of chronic deficiency than serum folic acid levels. The normal RBC folate level is 150-600 ng/mL of packed cells. Levels of iron and vitamin B_{12} in serum usually are normal or elevated. Serum activity of lactate dehydrogenase, a marker of ineffective erythropoiesis, is markedly elevated.

TREATMENT

When the diagnosis of folate deficiency is established, folic acid may be administered orally or parenterally at 0.5-1.0 mg/day. If the specific diagnosis is in doubt, smaller doses of folate (0.1 mg/day) may be used for 1 week as a diagnostic test because a hematologic response can be expected within 72 hours. Doses of folate >0.1 mg can correct the anemia of vitamin B_{12} deficiency but might aggravate any associated neurologic abnormalities. In most medical settings in developed countries, this therapeutic trial to distinguish the different causes of megaloblastic anemia is rarely necessary because vitamin B_{12} and folate blood levels are usually readily available. Folic acid therapy (0.5-1.0 mg/day) should be continued for 3-4 weeks until a definite hematologic response has occurred. Maintenance therapy with a multivitamin (containing 0.2 mg of folate) is adequate. Parenteral or high doses of specific folate formulations are required in the setting of HFM. Transfusions are indicated only when the anemia is severe, or the child is very ill.

503.2 Vitamin B_{12} (Cobalamin) Deficiency

Courtney D. Thornburg

Vitamin B_{12}, a generic term encompassing all biologically active cobalamins, is a water-soluble vitamin with a central, functional cobalt atom and a planar corrin ring. Methylcobalamin and adenosyl cobalamin are the metabolically active derivatives, serving as cofactors in two essential metabolic reactions: methylation of homocysteine to methionine (via methionine synthase) and conversion of methyl-malonyl-coenzyme A (CoA) to succinyl CoA (via L-methyl-malonyl-CoA mutase). The products and by-products of these enzymatic reactions are critical to DNA, RNA, and protein synthesis.

Cobalamin (Cbl) is synthesized *exclusively* by microorganisms, and humans must rely on dietary sources (animal products, including meat, eggs, fish, and milk) for their needs (see Chapter 67.7). Unlike folate, older children and adults have sufficient vitamin B_{12} stores to last 3-5 years. In young infants born to mothers with low vitamin B_{12} stores, clinical signs of Cbl deficiency can become apparent in the first 6-18 months of life.

METABOLISM

Under normal circumstances, cobalamin is released from food protein in the stomach through peptic digestion. Cbl then binds to *haptocorrin* (HC), a salivary glycoprotein. This complex moves into the duodenum, where HC is digested by pancreatic proteases and Cbl is liberated. Cbl then binds to *intrinsic factor* (IF), another glycoprotein that is produced by gastric parietal cells. The Cbl-IF complex subsequently enters mucosal cells of the distal ileum by receptor-mediated endocytosis. Through a complex series of protein interactions, Cbl is taken up into the blood stream and taken up into cells. Cobalamins are processed in the cytoplasm to a common intermediate that can be allocated to the methylcobalamin and adenosylcobalamin synthesis pathways to meet cellular needs.

ETIOLOGY

Vitamin B_{12} deficiency can result from inadequate dietary intake of Cbl, lack of IF, impaired intestinal absorption of IF-Cbl, inactivation, or absence of vitamin B_{12} transport protein (see Table 503.1).

Inadequate Vitamin B_{12} Intake

Vitamin B_{12} deficiency in infants is most often nutritional, resulting from low Cbl levels in the breast milk of B_{12}-deficient mothers. Associated **megaloblastic anemia** often appears during the first year of life. Maternal deficiency may be caused by **pernicious anemia** or gastrointestinal disorders such as *Helicobacter pylori* infection, celiac disease, Crohn disease, or pancreatic insufficiency. Previous gastric bypass surgery, treatment with proton pump inhibitors, and inadequate intake from a strict unsupplemented vegetarian diet have also been implicated. Fortunately, because of active placental Cbl transport in utero, most children of B_{12}-deficient mothers maintain Cbl levels sufficient to support adequate prenatal development. Such infants are born with low B_{12} stores, the depletion of which is associated with a gradual onset of clinical manifestations. *Vitamin B_{12} replacement often results in rapid improvement, but the longer the deficient period, the greater the likelihood of permanent disabilities.* Neonatal screening programs may detect maternal-neonatal nutritional B_{12} deficiency because of an increase in propionyl carnitine, but there is higher sensitivity using a measurement of methylmalonic acid. In high-income countries, dietary deficiency during childhood or adolescence is infrequent but can result from strict vegetarian or vegan diet. Daily requirements range from 0.4-2.4 μg.

Impaired Vitamin B_{12} Absorption

Gastric surgery or medications that impair gastric acid secretion may result in IF deficiency, leading to decreased vitamin B_{12} absorption. Pancreatic insufficiency can also lead to Cbl deficiency because of impaired cleavage and IF complex formation. Patients with neonatal necrotizing enterocolitis, inflammatory bowel disease, celiac disease, or surgical removal of the terminal ileum may also have impaired absorption of vitamin B_{12}. An overgrowth of intestinal bacteria within diverticula or duplications of the small intestine can cause vitamin B_{12} deficiency by consumption of (or competition for) the vitamin or by splitting of its complex with IF. In these cases, *hematologic response can follow appropriate antibiotic therapy.* In endemic areas, when the fish tapeworm *Diphyllobothrium latum* infests the upper small intestine, similar mechanisms may be operative. When megaloblastic anemia occurs in such situations, the serum vitamin B_{12} level is low, and the gastric fluid contains IF.

Hereditary intrinsic factor deficiency (HIFD) is a rare autosomal recessive disorder caused by a variety of pathologic genetic variants in the *IF* gene that produce a lack of gastric IF or a functionally abnormal IF. HIFD differs from typical adult pernicious anemia in that gastric acid is secreted normally and the stomach is histologically normal. It is not associated with antibodies or endocrine abnormalities. Unlike Imerslund-Grasbeck syndrome, described next, HIFD is only occasionally associated with proteinuria. Symptoms become prominent at an early age (6-24 months), consistent with exhaustion of vitamin B_{12} stores acquired in utero. As the anemia becomes severe, weakness, irritability, anorexia, and listlessness occur. The tongue is smooth, red, and painful. Neurologic manifestations include ataxia, paresthesias, hyporeflexia, Babinski responses, and clonus. Oral vitamin B_{12} is usually *ineffective*, and lifelong intramuscular (IM) or intranasal Cbl should be used to bypass the absorption defect. The natural form, OHCbl, is believed to be more effective than the synthetic form, cyanocobalamin (CNCbl).

Imerslund-Grasbeck syndrome is a rare, recessively inherited pediatric disorder resulting in selective vitamin B_{12} malabsorption in the ileum and consequent vitamin B_{12} deficiency. It usually becomes clinically apparent within the first 6 years of life. In addition to megaloblastic anemia, the patient may also have neurologic defects (e.g., hypotonia, developmental delay, brain atrophy, movement disorders, dementia) and/or proteinuria. Patients carry pathologic variants in genes *CUBN* or *AMN*, which encode proteins that form the cubam receptor for the ileal IF-Cbl complex. Because CUBN is also a key receptor for protein reabsorption in the kidney, impaired expression at this site results in associated proteinuria. The disease can be fatal if it remains untreated. Early diagnosis and treatment with IM or intranasal Cbl will reverse the hematologic and neurologic abnormalities. Proteinuria does not respond to therapy.

Classic pernicious anemia (autoimmune gastritis) usually occurs in older adults but can rarely affect children. This disorder **(juvenile pernicious anemia)** usually presents during adolescence. In such cases, the disease is associated with various detectable antibodies, including those against IF and the hydrogen-potassium adenosine triphosphatase proton pump in gastric parietal cells. These children can have additional immunologic abnormalities, cutaneous candidiasis, hypoparathyroidism, and other endocrine deficiencies; atrophy of the gastric mucosa and achlorhydria may occur. IM or intranasal vitamin B_{12} should be administered regularly.

Absence of Vitamin B_{12} Transport Protein Transcobalamin

Transcobalamin (TC) deficiency is a rare cause of megaloblastic anemia. A congenital deficiency is inherited as an autosomal recessive condition resulting in a failure to absorb and transport vitamin B_{12}. Most patients lack TC, but some have functionally defective forms. This disorder usually manifests in the first weeks of life. Characteristically, there is failure to thrive, diarrhea, vomiting, glossitis, neurologic abnormalities, and megaloblastic anemia. The diagnosis can be difficult given that total serum vitamin B_{12} levels are often normal because approximately 80% of serum Cbl is bound to HC. The diagnosis is suggested by the presence of severe megaloblastic anemia in the face of normal folate levels and no evidence of another inborn error of metabolism. Plasma homocysteine and methylmalonic acid levels are elevated. A definitive diagnosis is made by measuring plasma TC. The serum vitamin B_{12} levels must be kept high to force enough Cbl into cells and allow normal function using high-dose oral supplementation or IM or intranasal treatment. Symptoms and laboratory studies should be monitored, and doses adjusted as needed.

Disorders of Intracellular Cobalamin Metabolism

Disorders of intracellular cobalamin metabolism are associated with pathologic genetic variants in genes associated with lettered complementation groups. These include *MMACHC (cblC)*, *MMADHC* (*cblD*-combined and *cblD* homocystinuria), *MTRR (cblE), LMBRD1 (cblF), MTR (cblG), ABCD4 (cblJ), THAP11* (*cblX*-like), *ZNF143* (*cblX*-like), or *HCFC1* (*cblX*, which can show a cblC complementation class). The disorders present at a range of ages starting in utero and have a variable clinical presentation including complications of methylmalonic acidemia, homocystinuria, and megaloblastic anemia. Patients require care with a metabolic specialist to guide treatment with OHCbl, avoidance of agents that can cause metabolic decompensation, and surveillance for complications.

Vitamin B_{12} deficiency may develop by inactivation of vitamin B_{12}. This most often occurs in adolescents who chronically use "Whippets," which contain nitrous oxide, as a recreational agent to get high. Conversely, patients with underlying vitamin B_{12} deficiency may have an exacerbation after nitrous oxide anesthesia.

CLINICAL MANIFESTATIONS

Children with Cbl deficiency often present with nonspecific manifestations such as weakness, lethargy, feeding difficulties, failure to thrive, and irritability. Other common findings include pallor, glossitis, vomiting, diarrhea, and icterus. Hyperpigmentation is another feature that may mimic Addison disease. Neurologic symptoms can include paresthesia, sensory deficits, hypotonia, seizures, developmental delay, developmental regression, neuropsychiatric changes, and brain/spine MRI changes. Neurologic problems from vitamin B_{12} deficiency may occur in the *absence* of any hematologic abnormalities. Thrombotic microangiopathy is a rare manifestation.

LABORATORY FINDINGS

The hematologic manifestations of folate and Cbl deficiency are identical. The anemia resulting from Cbl deficiency is macrocytic, with prominent macro-ovalocytosis of the RBCs (see Chapter 496, Fig. 496.2, and Fig. 503.1). The neutrophils may be large and hypersegmented (see Fig. 503.1). In advanced cases, neutropenia and thrombocytopenia can occur, simulating aplastic anemia or leukemia. Macrocytosis may not always be present. Serum vitamin B_{12} levels are low, and the serum concentrations of methylmalonic acid and homocysteine are elevated. Concentrations of serum iron and serum folic acid are normal or elevated. Serum lactate dehydrogenase activity is markedly increased, a reflection of ineffective erythropoiesis. Moderate elevations of serum bilirubin levels (2-3 mg/dL) also may be found. Excessive excretion of methylmalonic acid in the urine (normal: 0-3.5 mg/24 hr) is a reliable and sensitive index of vitamin B_{12} deficiency and is especially helpful when the serum vitamin B_{12} level is in the low-normal range.

DIAGNOSIS

A comprehensive medical history is essential to the clinical recognition of possible Cbl deficiency. Information regarding clinical symptoms, dietary history, diseases, surgeries, or medications and drugs is likely to provide important clues. The physical examination may reveal relevant findings such as irritability, pallor, pigmentation or specific neurologic symptoms. Screening laboratory findings offer important information, but more focused testing will be required to confirm a diagnosis of vitamin B_{12} deficiency and its cause. Cbl deficiency is usually identified by measuring total or TC-bound vitamin B_{12} in the blood. Although an extremely low level is generally diagnostic, this may not be the case because false negatives and false positives are reportedly common using currently available assays. As a result, it is wise not to discount vitamin B_{12} deficiency, particularly in the face of clinical symptoms, macrocytic anemia, an abnormal blood smear, and a normal folate level. In untreated patients, methylmalonic acid and total homocysteine levels are often helpful because they are greatly elevated in the majority of those with clinical signs of B_{12} deficiency. Excessive urinary methylmalonic acid excretion is also a sensitive test of B_{12} deficiency. Although modest increases occur with renal failure, elevated methylmalonic acid is otherwise quite specific for B_{12} deficiency. Notably, however, serum homocysteine is also elevated in folate deficiency, homocystinuria, and renal failure.

If vitamin B_{12} deficiency has been confirmed and there is no evidence of inadequate dietary intake or, in the case of an infant, inadequate maternal B_{12}, malabsorption should be investigated. Anti-IF antibodies and anti–parietal cell antibodies are useful for the diagnosis of pernicious anemia. Measurement of IF and testing from more specialized laboratories may be required for less common disorders.

TREATMENT

Treatment regimens in children have not been well studied. The cause of vitamin B_{12} deficiency should ultimately dictate treatment dosage and route of administration as well as the duration of therapy. Cyanocobalamin is available as a nasal spray as an alternative to parenteral injection. Dose adjustments should be made in response to clinical status and laboratory values. The physiologic requirement for vitamin B_{12} is about 1-3 µg/day. Hematologic responses have been observed with small doses, indicating that a mini-dose may be administered as a therapeutic test when the diagnosis of vitamin B_{12} deficiency is in doubt or in circumstances where the anemia is severe and higher initial doses might result in severe metabolic disturbances.

503.3 Other Rare Megaloblastic Anemias

Courtney D. Thornburg

Orotic aciduria is a rare autosomal recessive disorder that usually appears in the first year of life and is characterized by growth failure, developmental delay, megaloblastic anemia, and increased urinary excretion of orotic acid (see Chapter 110). Rarely, orotic aciduria occurs without megaloblastic anemia. This defect is the most common metabolic error in the de novo synthesis of pyrimidines and therefore affects nucleic acid synthesis. The usual form of hereditary orotic aciduria is caused by a deficiency (in all body tissues) of orotic phosphoribosyl transferase and orotidine-5-phosphate decarboxylase, two sequential enzymatic steps in pyrimidine nucleotide synthesis. The diagnosis is suggested by the presence of severe megaloblastic anemia with normal serum B_{12} and folate levels and no evidence of TC deficiency. A presumptive diagnosis is made by finding increased urinary orotic acid. However, confirmation of the diagnosis requires assay of the transferase and decarboxylase enzymes in the patient's erythrocytes. Failure to thrive and intellectual disability often accompany this condition. The anemia is refractory to vitamin B_{12} or folic acid, but the anemia responds promptly to administration of uridine.

Thiamine-responsive megaloblastic anemia (Rogers syndrome) is a very rare autosomal recessive disorder characterized by megaloblastic anemia, sensorineural deafness, and diabetes mellitus. Congenital heart defects, arrhythmias, visual problems, short stature, trilineage myelodysplasia, and strokes are also described. Thiamine-responsive megaloblastic anemia usually presents in infancy but may occasionally develop in childhood and adolescence and occurs in several ethnically distinct populations. The bone marrow is characterized not only by megaloblastic changes but also by ringed sideroblasts. The defect is caused by biallelic pathologic genetic variants in *SCL19A2*, which encodes a high-affinity plasma membrane thiamine transporter. Continuous thiamine supplementation usually reverses the anemia and diabetes, but not existing hearing defects.

Chapter 504
Iron-Deficiency Anemia

Jennifer A. Rothman

Iron deficiency is the most widespread and common nutritional disorder in the world. It is estimated that 30–50% of the global population has iron-deficiency anemia, and most of these individuals live in developing countries. In the United States, 8–14% of children ages 12-36 months are *iron deficient*, and 30% of this group progresses to *iron-deficiency anemia*.

A full-term newborn infant contains about 0.5 grams of iron, compared with 5 grams of iron in adults. This change in quantity of iron from birth to adulthood means that an average of 0.8 mg of iron must be absorbed each day during the first 15 years of life. A small additional amount is necessary to balance normal losses of iron by shedding of cells. It is therefore necessary to absorb approximately 1 mg daily to maintain positive iron balance in childhood. Because <10% of dietary iron is usually absorbed, a dietary intake of 8-10 mg of iron daily is necessary to maintain iron levels. During infancy, when growth is most rapid, the 1 mg/L of iron in cow's and breast milk makes it difficult to maintain body iron. Although breastfed infants have an advantage because they absorb iron 2-3 times more efficiently than infants fed cow's milk, breastfed infants nonetheless are at risk of developing iron deficiency without regular intake of iron-fortified foods by 6 months of age.

ETIOLOGY

Most iron in neonates resides in circulating hemoglobin. As the relatively high hemoglobin concentration of the newborn infant falls during the first 2-3 months of life, considerable iron is recycled. These iron stores are usually sufficient for blood formation in the first 6-9 months of life in term infants. Stores are depleted sooner in premature infants, low birthweight infants, or infants with perinatal blood loss, because their iron stores are smaller. Delayed (1-3 minute) clamping of the umbilical cord can improve iron status and reduce the risk of iron deficiency, whereas early clamping (<30 seconds) puts the infant at risk for iron deficiency. Dietary sources of iron are especially important in these infants. In term infants, anemia caused solely by inadequate dietary iron usually occurs at 9-24 months of age and is less common thereafter. The usual dietary pattern observed in infants and toddlers with nutritional iron-deficiency anemia in developed countries is excessive consumption of cow's milk (low iron content, blood loss from milk protein colitis) in a child who is often overweight or bottle feeding beyond 12 months of age. Worldwide, **undernutrition** is usually responsible for iron deficiency (Table 504.1).

Blood loss must be considered as a possible cause in every case of iron-deficiency anemia. Sources of blood loss, particularly in older children and adolescents, include menstrual losses, recurrent nosebleeds, or intravascular hemolysis with hemoglobinuria, as seen in diseases such as malaria or endurance athletics such as triathletes. Chronic iron-deficiency anemia from occult bleeding may be caused by a lesion of the gastrointestinal (GI) tract, such as peptic ulcer, Meckel diverticulum, polyp, hemangioma, or inflammatory bowel disease. Infants can have chronic intestinal blood loss induced by exposure to cow's milk protein. Involved infants characteristically develop anemia that is more severe and occurs earlier than would be expected simply from an inadequate intake of iron. The ongoing loss of blood in the stools can be prevented either by breastfeeding or by delaying the introduction of whole cow's milk in the first years of life and then limiting the quantity to <24 oz/24 hours. *Infants and toddlers who have excessive raw milk intake with no iron supplementation and limited iron containing foods are at high risk of iron deficiency.* Unrecognized blood loss also can be associated with chronic diarrhea and, rarely, with pulmonary hemosiderosis. In developing countries, infections with hookworm, *Trichuris trichiura,* and *Plasmodium* often contribute to iron deficiency. Since iron is absorbed in the proximal duodenum with the assistance of gastric acid, gastric bypass procedures or *Helicobacter pylori* infection may interfere with iron absorption. Similarly, inflammation of the bowel from celiac disease and giardiasis may also interfere with iron absorption.

Approximately 2% of adolescent females have iron-deficiency anemia, largely as a result of their adolescent growth spurt and menstrual blood loss. The highest risk of iron-deficiency anemia (>30%) is among teenagers who are or have been pregnant.

CLINICAL MANIFESTATIONS

Most children with iron-deficiency anemia are asymptomatic and are identified by routine laboratory screening at 9-12 months of age. Normal hemoglobin values vary according to age, gender, ethnicity, and method of testing, such as capillary versus venous blood. Pallor is the

Similarly, inflammation of the bowel from celiac disease and giardiasis may also interfere with iron absorption.

Approximately 2% of adolescent females have iron-deficiency anemia, largely as a result of their adolescent growth spurt and menstrual blood loss. The highest risk of iron-deficiency anemia (>30%) is among teenagers who are or have been pregnant.

CLINICAL MANIFESTATIONS

Most children with iron-deficiency anemia are asymptomatic and are identified by routine laboratory screening at 9-12 months of age. Normal hemoglobin values vary according to age, gender, ethnicity, and method of testing, such as capillary versus venous blood. Pallor is the

serum transferrin levels that are accompanied by the deposition of non–transferrin-bound iron in parenchymal tissues. Because hepcidin production is induced by inflammatory stimuli, hepcidin elevation is also a feature of the **anemia of chronic disease** (ACD). However, in contrast to patients with IRIDA, in whom the hepcidin dysregulation is congenital, patients with ACD generally retain normal to high iron stores because of the acquired nature of their hepcidin elevation (see Chapter 500.1). Rare medical causes that may mimic IRIDA include vascular malformations of the GI tract, Castleman disease (where IL-6 overproduction causes hepcidin elevation), autoimmune gastritis, and pathogenic germline variants in *KCNQ1* (which regulates gastric acid secretion).

TREATMENT

Because of the underlying pathophysiology of IRIDA, *parenteral iron supplementation* is required to correct the anemia. Although parenteral iron therapy raises body iron stores, the hematologic response is usually slow and not completely corrective. This likely results from insufficient export of the processed iron from macrophages into the circulation, an expected consequence of hepcidin elevation. Serum ferritin levels increase with parenteral iron therapy in a dose-dependent manner and may raise concerns for iron overload, which would be expected to exhibit a reticuloendothelial rather than a parenchymal pattern of iron loading. Given the limited number of IRIDA cases reported to date, the optimal formulation and dosing of parenteral iron have not yet been established. Although oral iron supplementation does not appear to have a significant role in treatment of IRIDA, the addition of ascorbic acid to a ferrous sulfate oral supplement has been associated with hematologic responses in isolated cases. Treatment with recombinant erythropoietin has not been found to produce significant clinical benefit in patients with IRIDA.

Chapter 505

Other Microcytic Anemias

Jennifer A. Rothman

A number of rare microcytic anemias need to be considered when children with microcytic anemia fail to respond to oral iron (Table 504.5). These anemias include thalassemia or thalassemia trait (see Chapter 511), infantile poikilocytosis and hereditary pyropoikilocytosis (Chapter 508), and anemia of chronic disease (Chapter 500.1). Additionally, rare nutritional disorders and disorders of iron metabolism can cause microcytosis.

INFANTILE POIKILOCYTOSIS AND HEREDITARY PYROPOIKILOCYTOSIS

Infants with common **hereditary elliptocytosis** (see Chapter 508) may initially present with hemolytic anemia characterized by marked poikilocytosis with budding and fragmentation of the red blood cells (RBCs). These small RBC fragments reduce the overall mean corpuscular volume (MCV), resulting in microcytosis. By 2 years of age, the findings become typical of hereditary elliptocytosis. **Hereditary pyropoikilocytosis** is a much less common variant of hereditary elliptocytosis, in which the hemolytic anemia and RBC changes are more severe.

COPPER DEFICIENCY

Copper deficiency is a rare cause of microcytic anemia and neurologic dysfunction. Copper is absorbed in the stomach and proximal duodenum. Deficiency is associated with malabsorption; severe malnutrition, often with feeding of milk alone; gastric surgery or feedings that bypass the stomach and duodenum; or parenteral nutrition with inadvertent omission of supplemental copper. Zinc and copper are competitively absorbed from the gastrointestinal (GI) tract, so zinc excess may inadvertently lead to copper deficiency. Diagnosis is made by measuring a serum copper level, serum ceruloplasmin, and possibly a zinc level. Treatment includes either oral or parenteral supplementation, depending on the underlying cause.

DEFECTS OF IRON METABOLISM

Rare microcytic anemias may be associated with defects in iron trafficking and regulation. Most are inherited and usually identified in childhood, including defects of iron absorption, transport, utilization, and recycling. A *defect of iron absorption* is **iron-refractory iron-deficiency anemia** (see Chapter 504.1). *Defects of iron recycling* include aceruloplasminemia and atransferrinemia. **Aceruloplasminemia** is an autosomal recessive disorder in the *CP* gene that encodes ceruloplasmin. Iron cannot be appropriately transported from macrophages to plasma to be available for RBC production but accumulates instead in the brain and visceral organs, which can lead to an adult-onset neurodegenerative disorder. The diagnosis is made by a combination of absence of serum ceruloplasmin, low serum copper and iron, elevated ferritin, and increased liver iron concentration. Hypotransferrinemia or **atransferrinemia** is also an autosomal recessive disorder caused by pathogenic variants in the transferrin *(TF)* gene. Diagnosis is made by low or absent serum transferrin and liver iron overload. Genetic testing can confirm the diagnosis for both disorders. Treatment includes iron chelation therapy, limiting iron supplementation and dietary iron, and possibly fresh-frozen plasma to replace ceruloplasmin and/or transferrin. Purified transferrin (apotransferrin) infusions are available.

Defects of mitochondrial iron utilization are a diverse group of acquired and inherited defects known as **sideroblastic anemias** (Table 505.1). Several genes associated with these disorders have been described. Impaired heme synthesis leads to retention of iron within the mitochondria of marrow RBCs. The perinuclear distribution of mitochondria results in a pattern of iron staining surrounding the nucleus. These are *ringed sideroblasts* (Fig. 505.1), which are distinct from the more diffuse cytoplasmic distribution of iron in normal RBC precursors. The anemia is characterized by hypochromic, microcytic RBCs mixed with normal RBCs, so the complete blood count indicates a very high RBC distribution width. The serum iron concentration usually is elevated, and the transferrin saturation of iron is increased.

Congenital sideroblastic anemia (CSA) can be *syndromic* or *nonsyndromic*. The most common type of nonsyndromic CSA is an X-linked disorder and is most often a result of pathogenic variants in *ALAS2* that encodes erythrocytic isozyme 5-aminolevulinic acid synthetase, the rate-limiting enzyme reaction in heme synthesis. An important cofactor for 5-ALA synthetase is *pyridoxal phosphate,* with several pathogenic variants occurring near its binding site. Severe anemia is recognized in infancy or early childhood, whereas milder cases might not become apparent until early adulthood or later. Clinical findings include pallor, icterus, and moderate splenomegaly and/or hepatomegaly. The severity of the anemia varies such that some patients require no therapy and others need regular RBC transfusions. A subset of patients with hereditary sideroblastic anemia manifest a hematologic response to pyridoxine doses of 50-200 mg/day. Iron overload, as manifested by elevated serum ferritin, elevated serum iron, and increased transferrin saturation, is a major complication of this disorder. Clinical evidence of iron overload (e.g., diabetes mellitus, liver dysfunction) may be found in some patients who have little or no anemia, which may require iron chelation therapy. Stem cell transplantation has been used to treat affected children who are dependent on RBC transfusions.

A unique variant of congenital sideroblastic anemia is **Pearson syndrome** (see Chapter 498), but the anemia is usually *macrocytic* and not microcytic. Another rare variant of sideroblastic anemia is caused by pathogenic variants in *TRNT1* and manifests with developmental

delay, periodic fevers, and B-cell immunodeficiency in addition to sideroblastic anemia.

Acquired sideroblastic anemias can be triggered by copper deficiency or drugs and toxins that disturb mitochondrial iron metabolism, including lead, chloramphenicol, penicillamine, ethanol, and isoniazid. The acquired neoplastic sideroblastic syndromes (myelodysplasias) seen in adults are very rare in children.

Section 3

Hemolytic Anemias

Chapter 506

Definitions and Classification of Hemolytic Anemias

Stephanie Prozora and Patrick G. Gallagher

Hemolysis is defined as the premature destruction of red blood cells (RBCs). Anemia results when the rate of destruction exceeds the capacity of the marrow to produce additional RBCs. Normal RBC survival time is 110-120 days (half-life: 55-60 days), and thus, approximately 0.85% of the most senescent RBCs are removed and replaced each day. During hemolysis, RBC survival is shortened, the RBC count falls, erythropoietin is increased, and marrow erythropoietic activity is stimulated. This leads to compensatory erythroid hyperplasia with increased RBC production, reflected by an increase in the reticulocyte count. The marrow can increase its output twofold to threefold acutely, with a maximum of sixfold to eightfold in chronic hemolysis. The reticulocyte percentage can be corrected to measure the magnitude of marrow production in response to hemolysis as follows:

$$\text{Reticulocyte index} = \text{reticulocyte } \% \times \frac{\text{Observed hematocrit}}{\text{Normal hematocrit}} \times \frac{1}{\mu}$$

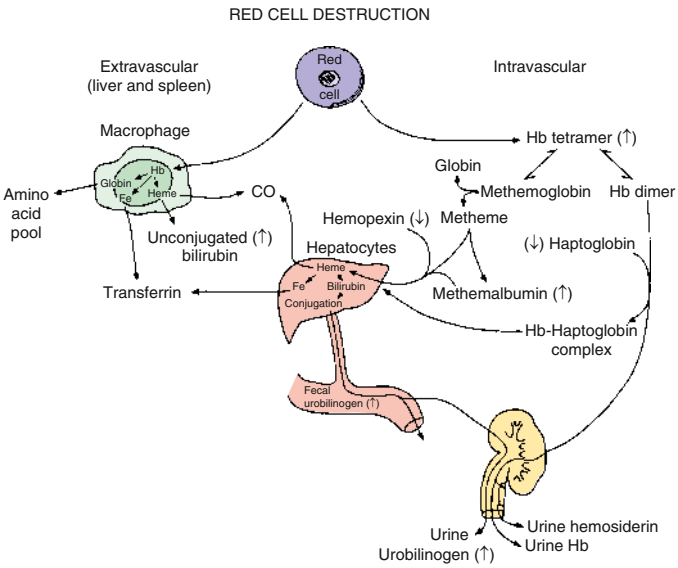

Fig. 506.2 Red cell destruction and catabolism of hemoglobin (Hb) based on the description by Hillman and Finch. Fe, Iron; CO, carbon monoxide. *(From Hillman RS, Finch CA. Red cell manual. Philadelphia: FA Davis, 1983.)*

where μ is a maturation factor of 1-3 related to the severity of the anemia (Fig. 506.1). The normal reticulocyte index is 1.0; therefore the index measures the fold increase in erythropoiesis (e.g., twofold, threefold). Because the reticulocyte index is essentially a measure of RBC production per day, the maturation factor μ provides this correction (see Fig. 506.1).

When hemolysis is chronic, compensatory erythroid hyperplasia may lead to significant expansion of the medullary spaces at the expense of cortical bone. This is particularly prominent in children with severe chronic hemolytic anemia such as thalassemia. These changes may be evident on physical examination or on radiographs of the skull and long bones. In severe cases, there is increased propensity for long bone fracture. Hemolysis also leads to increased degradation of hemoglobin. This process can result in indirect hyperbilirubinemia, increased biliary excretion of heme pigment derivatives, and formation of bilirubinate gallstones.

During hemolysis (Fig. 506.2), heme-binding proteins in the plasma are altered. Hemoglobin binds to haptoglobin and hemopexin, both of which are cleared more rapidly as heme-bound complexes. Oxidized heme binds to albumin to form methemalbumin, which is increased in the plasma during hemolysis. When the capacity of these heme-binding molecules is exceeded, free hemoglobin appears in the plasma. Free hemoglobin in the plasma is considered *prima facie* evidence of

serum transferrin levels that are accompanied by the deposition of non–transferrin-bound iron in parenchymal tissues. Because hepcidin production is induced by inflammatory stimuli, hepcidin elevation is also a feature of the **anemia of chronic disease** (ACD). However, in contrast to patients with IRIDA, in whom the hepcidin dysregulation is congenital, patients with ACD generally retain normal to high iron stores because of the acquired nature of their hepcidin elevation (see Chapter 500.1). Rare medical causes that may mimic IRIDA include vascular malformations of the GI tract, Castleman disease (where IL-6 overproduction causes hepcidin elevation), autoimmune gastritis, and pathogenic germline variants in *KCNQ1* (which regulates gastric acid secretion).

TREATMENT

Because of the underlying pathophysiology of IRIDA, *parenteral iron supplementation* is required to correct the anemia. Although parenteral iron therapy raises body iron stores, the hematologic response is usually slow and not completely corrective. This likely results from insufficient export of the processed iron from macrophages into the circulation, an expected consequence of hepcidin elevation. Serum ferritin levels increase with parenteral iron therapy in a dose-dependent manner and may raise concerns for iron overload, which would be expected to exhibit a reticuloendothelial rather than a parenchymal pattern of iron loading. Given the limited number of IRIDA cases reported to date, the optimal formulation and dosing of parenteral iron have not yet been established. Although oral iron supplementation does not appear to have a significant role in treatment of IRIDA, the addition of ascorbic acid to a ferrous sulfate oral supplement has been associated with hematologic responses in isolated cases. Treatment with recombinant erythropoietin has not been found to produce significant clinical benefit in patients with IRIDA.

Chapter 505

Other Microcytic Anemias

Jennifer A. Rothman

A number of rare microcytic anemias need to be considered when children with microcytic anemia fail to respond to oral iron (Table 504.5). These anemias include thalassemia or thalassemia trait (see Chapter 511), infantile poikilocytosis and hereditary pyropoikilocytosis (Chapter 508), and anemia of chronic disease (Chapter 500.1). Additionally, rare nutritional disorders and disorders of iron metabolism can cause microcytosis.

INFANTILE POIKILOCYTOSIS AND HEREDITARY PYROPOIKILOCYTOSIS

Infants with common **hereditary elliptocytosis** (see Chapter 508) may initially present with hemolytic anemia characterized by marked poikilocytosis with budding and fragmentation of the red blood cells (RBCs). These small RBC fragments reduce the overall mean corpuscular volume (MCV), resulting in microcytosis. By 2 years of age, the findings become typical of hereditary elliptocytosis. **Hereditary pyropoikilocytosis** is a much less common variant of hereditary elliptocytosis, in which the hemolytic anemia and RBC changes are more severe.

COPPER DEFICIENCY

Copper deficiency is a rare cause of microcytic anemia and neurologic dysfunction. Copper is absorbed in the stomach and proximal duodenum. Deficiency is associated with malabsorption; severe malnutrition, often with feeding of milk alone; gastric surgery or feedings that bypass the stomach and duodenum; or parenteral nutrition with inadvertent omission of supplemental copper. Zinc and copper are competitively absorbed from the gastrointestinal (GI) tract, so zinc excess may inadvertently lead to copper deficiency. Diagnosis is made by measuring a serum copper level, serum ceruloplasmin, and possibly a zinc level. Treatment includes either oral or parenteral supplementation, depending on the underlying cause.

DEFECTS OF IRON METABOLISM

Rare microcytic anemias may be associated with defects in iron trafficking and regulation. Most are inherited and usually identified in childhood, including defects of iron absorption, transport, utilization, and recycling. A *defect of iron absorption* is **iron-refractory iron-deficiency anemia** (see Chapter 504.1). *Defects of iron recycling* include aceruloplasminemia and atransferrinemia. **Aceruloplasminemia** is an autosomal recessive disorder in the *CP* gene that encodes ceruloplasmin. Iron cannot be appropriately transported from macrophages to plasma to be available for RBC production but accumulates instead in the brain and visceral organs, which can lead to an adult-onset neurodegenerative disorder. The diagnosis is made by a combination of absence of serum ceruloplasmin, low serum copper and iron, elevated ferritin, and increased liver iron concentration. Hypotransferrinemia or **atransferrinemia** is also an autosomal recessive disorder caused by pathogenic variants in the transferrin *(TF)* gene. Diagnosis is made by low or absent serum transferrin and liver iron overload. Genetic testing can confirm the diagnosis for both disorders. Treatment includes iron chelation therapy, limiting iron supplementation and dietary iron, and possibly fresh-frozen plasma to replace ceruloplasmin and/or transferrin. Purified transferrin (apotransferrin) infusions are available.

Defects of mitochondrial iron utilization are a diverse group of acquired and inherited defects known as **sideroblastic anemias** (Table 505.1). Several genes associated with these disorders have been described. Impaired heme synthesis leads to retention of iron within the mitochondria of marrow RBCs. The perinuclear distribution of mitochondria results in a pattern of iron staining surrounding the nucleus. These are *ringed sideroblasts* (Fig. 505.1), which are distinct from the more diffuse cytoplasmic distribution of iron in normal RBC precursors. The anemia is characterized by hypochromic, microcytic RBCs mixed with normal RBCs, so the complete blood count indicates a very high RBC distribution width. The serum iron concentration usually is elevated, and the transferrin saturation of iron is increased.

Congenital sideroblastic anemia (CSA) can be *syndromic* or *nonsyndromic*. The most common type of nonsyndromic CSA is an X-linked disorder and is most often a result of pathogenic variants in *ALAS2* that encodes erythrocytic isozyme 5-aminolevulinic acid synthetase, the rate-limiting enzyme reaction in heme synthesis. An important cofactor for 5-ALA synthetase is *pyridoxal phosphate,* with several pathogenic variants occurring near its binding site. Severe anemia is recognized in infancy or early childhood, whereas milder cases might not become apparent until early adulthood or later. Clinical findings include pallor, icterus, and moderate splenomegaly and/or hepatomegaly. The severity of the anemia varies such that some patients require no therapy and others need regular RBC transfusions. A subset of patients with hereditary sideroblastic anemia manifest a hematologic response to pyridoxine doses of 50-200 mg/day. Iron overload, as manifested by elevated serum ferritin, elevated serum iron, and increased transferrin saturation, is a major complication of this disorder. Clinical evidence of iron overload (e.g., diabetes mellitus, liver dysfunction) may be found in some patients who have little or no anemia, which may require iron chelation therapy. Stem cell transplantation has been used to treat affected children who are dependent on RBC transfusions.

A unique variant of congenital sideroblastic anemia is **Pearson syndrome** (see Chapter 498), but the anemia is usually *macrocytic* and not microcytic. Another rare variant of sideroblastic anemia is caused by pathogenic variants in *TRNT1* and manifests with developmental

Section 3

Hemolytic Anemias

Chapter 506

Definitions and Classification of Hemolytic Anemias

Stephanie Prozora and Patrick G. Gallagher

Hemolysis is defined as the premature destruction of red blood cells (RBCs). Anemia results when the rate of destruction exceeds the capacity of the marrow to produce additional RBCs. Normal RBC survival time is 110-120 days (half-life: 55-60 days), and thus, approximately 0.85% of the most senescent RBCs are removed and replaced each day. During hemolysis, RBC survival is shortened, the RBC count falls, erythropoietin is increased, and marrow erythropoietic activity is stimulated. This leads to compensatory erythroid hyperplasia with increased RBC production, reflected by an increase in the reticulocyte count. The marrow can increase its output twofold to threefold acutely, with a maximum of sixfold to eightfold in chronic hemolysis. The reticulocyte percentage can be corrected to measure the magnitude of marrow production in response to hemolysis as follows:

$$\text{Reticulocyte index} = \text{reticulocyte } \% \times \frac{\text{Observed hematocrit}}{\text{Normal hematocrit}} \times \frac{1}{\mu}$$

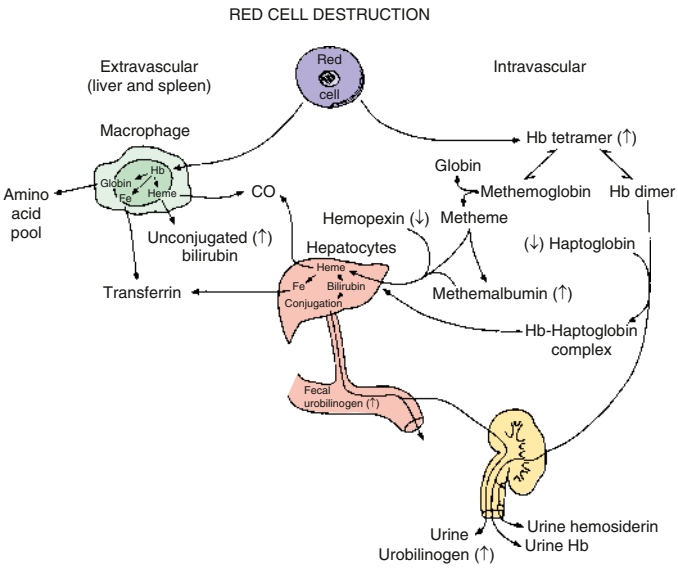

Fig. 506.2 Red cell destruction and catabolism of hemoglobin (Hb) based on the description by Hillman and Finch. Fe, Iron; CO, carbon monoxide. *(From Hillman RS, Finch CA. Red cell manual. Philadelphia: FA Davis, 1983.)*

where μ is a maturation factor of 1-3 related to the severity of the anemia (Fig. 506.1). The normal reticulocyte index is 1.0; therefore the index measures the fold increase in erythropoiesis (e.g., twofold, threefold). Because the reticulocyte index is essentially a measure of RBC production per day, the maturation factor μ provides this correction (see Fig. 506.1).

When hemolysis is chronic, compensatory erythroid hyperplasia may lead to significant expansion of the medullary spaces at the expense of cortical bone. This is particularly prominent in children with severe chronic hemolytic anemia such as thalassemia. These changes may be evident on physical examination or on radiographs of the skull and long bones. In severe cases, there is increased propensity for long bone fracture. Hemolysis also leads to increased degradation of hemoglobin. This process can result in indirect hyperbilirubinemia, increased biliary excretion of heme pigment derivatives, and formation of bilirubinate gallstones.

During hemolysis (Fig. 506.2), heme-binding proteins in the plasma are altered. Hemoglobin binds to haptoglobin and hemopexin, both of which are cleared more rapidly as heme-bound complexes. Oxidized heme binds to albumin to form methemalbumin, which is increased in the plasma during hemolysis. When the capacity of these heme-binding molecules is exceeded, free hemoglobin appears in the plasma. Free hemoglobin in the plasma is considered *prima facie* evidence of

Chapter 507

Hereditary Spherocytosis

Stephanie Prozora and Patrick G. Gallagher

Hereditary spherocytosis (HS) is a common cause of inherited hemolytic anemia, with a prevalence of approximately 1 in 2,000-5,000 persons. Described in patients of all ethnic groups, it is the most common inherited abnormality of the erythrocyte associated with inherited hemolytic anemia in persons of Northern European origin. HS is marked by wide variability in the associated clinical, laboratory, and genetic manifestations. Symptomatology ranges from asymptomatic patients with well-compensated anemia to severely affected patients with hemolytic anemia requiring regular blood transfusions.

ETIOLOGY

The pathophysiology underlying HS is twofold: an intrinsic defect of the erythrocyte membrane and an intact spleen that selectively retains, damages, and removes abnormal HS erythrocytes. Qualitative or quantitative defects of key membrane proteins lead to a multistep process of accelerated HS erythrocyte destruction. Abnormalities of ankyrin or spectrin are the most common molecular defects (Table 507.1). Defects in these membrane proteins result in uncoupling of the "vertical" interactions of the lipid bilayer with the underlying membrane skeleton with subsequent release of membrane microvesicles. The loss of membrane surface area without a proportional loss of cell volume causes decreased erythrocyte deformability. This impairs cell passage from the splenic cords to the splenic sinuses, leading to the trapping and premature destruction of HS erythrocytes by the spleen (Figs. 507.1 and 507.2). Splenectomy markedly improves erythrocyte life span and may be indicated in some patients with HS.

CLINICAL MANIFESTATIONS

Hereditary spherocytosis is usually transmitted as an autosomal dominant trait. However, as many as 25% of patients have no previous family history, representing either recessive inheritance or de novo gene variants.

In the neonatal period, HS is a significant cause of hemolysis and can manifest as anemia and/or hyperbilirubinemia severe enough to require phototherapy, transfusion, or exchange transfusions. Hemolysis may be more prominent in the newborn because hemoglobin F binds 2,3-diphosphoglycerate poorly, and the increased level of free 2,3-diphosphoglycerate destabilizes interactions among spectrin, actin, and protein 4.1 in the red blood cell (RBC) membrane (see Fig. 507.1). The need for transfusions in infancy is not indicative of more severe disease later in life because infants are typically slow to mount an adequate reticulocyte response for the first few months after birth.

Disease severity varies and can be used to clinically classify HS (Table 507.2). Mild cases (20–30% of all HS) are asymptomatic into adulthood and have well-compensated mild anemia where reticulocyte production and erythrocyte destruction are essentially balanced. Cases of moderate or "typical" HS (60–70%) have partially compensated hemolytic anemia with reticulocytosis, frequently with symptoms of fatigue, pallor, and intermittent jaundice. Splenomegaly is common after infancy, and it is present in almost all HS patients by young adulthood. Severe cases of HS (3–5%) have life-threatening anemia and are transfusion dependent.

Bilirubin gallstone formation is a function of age; they can form as early as 4-5 years of age and are present in most adult HS patients.

HS patients are susceptible to **aplastic crises** primarily as a result of parvovirus B19 infection, hypoplastic crises associated with other infections, and megaloblastic crises due to folate deficiency (Fig. 507.3). During these crises, high RBC turnover in the setting of erythroid marrow failure can result in profound anemia (hematocrit <10%), high-output heart failure, cardiovascular collapse, and death. Leukocyte and platelet counts may also fall.

Rare complications associated with HS include splenic sequestration crisis, gout, cardiomyopathy, priapism, leg ulcers, and neurologic or muscular abnormalities, including spinocerebellar degeneration.

Table 507.1 Common Gene Pathogenic Variants in Hereditary Spherocytosis

PROTEIN	GENE	COMMON PATHOGENIC VARIANTS	PREVALENCE	INHERITANCE	DISEASE SEVERITY
Ankyrin-1	*ANK1*	Frameshift Nonsense Splicing Missense Insertion/deletion Promoter region	50–67% 5–10% in Japan	Mostly dominant, rare recessive	Mild to moderate
Band 3	*AE1 (SLC4A1)*	Missense Nonsense	15–20%	Dominant	Mild to moderate
β-Spectrin	*SPTB*	Nonsense Missense Insertion/deletion	15–20%	Dominant	Mild to moderate
α-Spectrin	*SPTA1*	Splicing Nonsense Missense	<5%	Recessive	Severe
Protein 4.2	*EPB42*	Missense Nonsense Splicing Deletion	<5% 45–50% in Japan	Recessive	Mild to moderate

Hereditary spherocytosis. Lancet 2008;372:1411–1426.)*

DIAGNOSIS

Typically, there is evidence of hemolytic anemia with reticulocytosis and indirect hyperbilirubinemia. The mean corpuscular volume (MCV) of HS erythrocytes is low normal or even slightly decreased and the mean corpuscular hemoglobin concentration (MCHC) is usually increased (>35 g/dL). An MCHC > 35.4 g/dL combined with an RBC distribution width (RDW) <14% has been suggested as a screening test for HS. Erythroid cells on peripheral blood smear vary in size and include spherocytes and polychromatophilic reticulocytes. Spherocytes are smaller in diameter, hyperchromic due to elevated hemoglobin concentration from cellular dehydration, and lacking in central pallor (Fig. 507.4). Numbers of spherocytes are variable, with increased numbers likely reflecting the severity of disease. Other markers of hemolysis include decreased haptoglobin and elevated lactic dehydrogenase.

The diagnosis of HS can be established from a positive family history and the presence of typical clinical and laboratory features of the disease: splenomegaly, spherocytes on the blood smear,

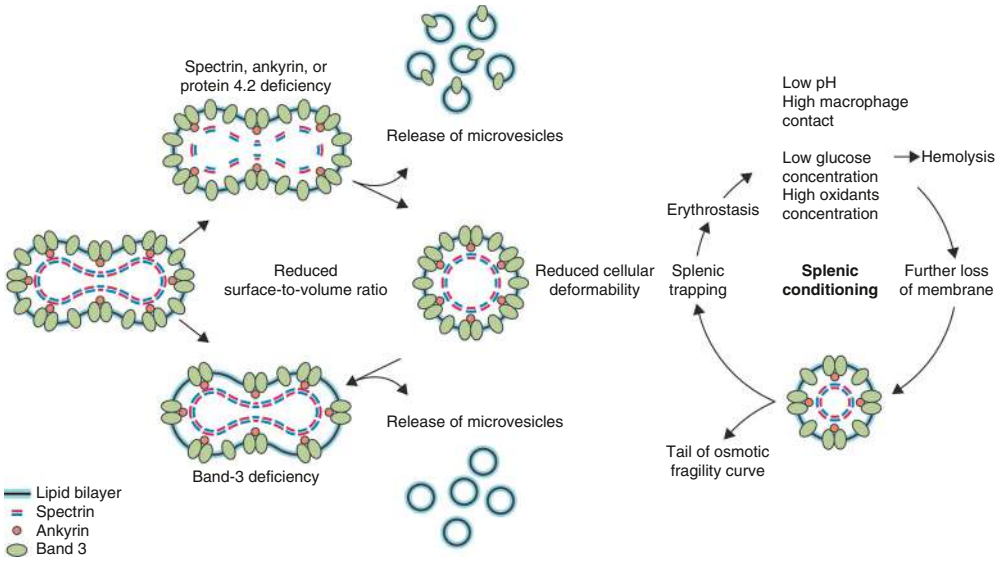

Fig. 507.2 Pathophysiologic effects of hereditary spherocytosis. *(From Perrotta S, Gallagher PG, Mohandas N. Hereditary spherocytosis. Lancet 2008;372:1411–1426.)*

reticulocytosis, and an elevated MCHC. If these are present, no additional testing is necessary to confirm the diagnosis clinically. If the diagnosis is less certain, additional testing can be performed. Binding of fluorescently labeled eosin-5-maleimide (EMA) to band 3 and other membrane proteins is decreased in HS erythrocytes. This flow cytometry–based screening test is easy to perform and has good diagnostic sensitivity and specificity. In the classic incubated osmotic fragility test, HS erythrocytes are incubated in progressive dilutions of sodium chloride causing the cells to swell and lyse, with spherocytes lysing at a lower dilution due to their lower surface area to volume ratio. This test detects the presence of spherocytes in the blood, but it is not specific to HS and may be abnormal in other anemias with prominent spherocytosis. Osmotic fragility testing has poor sensitivity and may miss cases of mild HS where the numbers of spherocytes are few. Other assays such as the cryohemolysis test, the acidified glycerol lysis test, and the osmotic gradient ektacytometry have been used for diagnosis of HS, but they are not available in many laboratories. Genetic diagnosis is widely available on a commercial basis. The precise role of molecular testing in HS diagnosis and management is evolving. Some experts suggest molecular testing before splenectomy to verify the diagnosis of HS.

Diagnosis in the neonatal period requires a high index of suspicion as the disease presents differently than in older children, particularly in de novo and recessively inherited cases where family history is not available for guidance. Jaundice is frequently observed, and kernicterus can occur. Hemolytic anemia may be severe enough to require blood transfusion. In fact, HS is the leading cause of Coombs-negative hemolytic anemia, requiring transfusion in the first months of life. Splenomegaly is uncommon in neonates.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for spherocytosis on peripheral blood smear includes isoimmune and autoimmune hemolysis. Isoimmune hemolytic disease of the newborn, particularly when there is a result of ABO incompatibility, closely mimics the appearance of HS. The detection of antibody on an infant's RBCs using a direct antiglobulin (Coombs) test should establish the diagnosis of immune hemolysis. Autoimmune hemolytic anemias also are characterized by spherocytosis, but there will typically be evidence of previously normal values for hemoglobin, hematocrit, and reticulocyte count. Rare causes of spherocytosis include thermal injury, hemolytic transfusion reaction, clostridial sepsis, severe hypophosphatemia, Wilson disease, and snake, bee, or wasp envenomation, which all may manifest as transient spherocytic hemolytic anemia.

TREATMENT

General Supportive Care

Infants born to a parent with known HS should be monitored carefully because hyperbilirubinemia may peak several days after birth. Parents should be advised of the risk of neonatal anemia and jaundice and the potential need for transfusion, phototherapy, and/or exchange transfusion to treat anemia or hyperbilirubinemia. A subset of infants will be transfusion-dependent until development of adequate erythropoiesis to compensate for the ongoing hemolysis, usually between 6-12 months of age. Transfusion dependence after this time is rare and is most likely due to recessive HS.

Once the baseline level of disease severity is reached, an annual visit to the hematologist usually is sufficient follow-up. Growth should be monitored, and exercise tolerance and spleen size documented. Vaccinations should be up to date. Screening for gallbladder disease should begin at ~4 years of age, repeated every 3-5 years, or as indicated clinically. Documentation of parvovirus B19 susceptibility or immunity should be obtained in newly diagnosed patients. Similarly, HIV and hepatitis serology should be documented in patients who have received transfusions. Folic acid supplementation is recommended in cases of moderate and severe HS due to the demands of brisk erythropoiesis. Parents should receive anticipatory guidance regarding the risk of aplastic crisis secondary to parvovirus infection and hypoplastic crises with other infections. Parents and patients should be informed of an increased risk for gallstone development.

Guidelines for Splenectomy

Because spherocytes are destroyed almost exclusively in the spleen, splenectomy is curative in most patients because hemolysis, anemia, hyperbilirubinemia, and the incidence of gallstones are significantly lessened, if not completely eradicated, after splenectomy. Thus splenectomy became routine in the care of HS patients. However, splenectomy is associated with *short-term* risks, related to the operative procedure itself, and *long-term* risks, particularly increased lifelong

Table 507.2 Clinical and Laboratory Classification of Hereditary Spherocytosis

	NORMAL	MILD SPHEROCYTOSIS	MODERATE SPHEROCYTOSIS	MODERATELY SEVERE SPHEROCYTOSIS	SEVERE SPHEROCYTOSIS*
Inheritance	—	Autosomal dominant	Autosomal dominant, de novo variant	Autosomal dominant, de novo variant	Autosomal recessive

risk for sepsis, often caused by encapsulated bacteria. This risk is not eliminated but reduced with the requisite preoperative and postoperative vaccination against pneumococcus, meningococcus, and *Haemophilus influenzae* type b. In addition, there are increasing concerns regarding the emergence of penicillin-resistant pneumococci, as well as increased risk for cardiovascular diseases including thrombosis, pulmonary hypertension, and atherosclerosis, which have tempered the practice of routine splenectomy in HS.

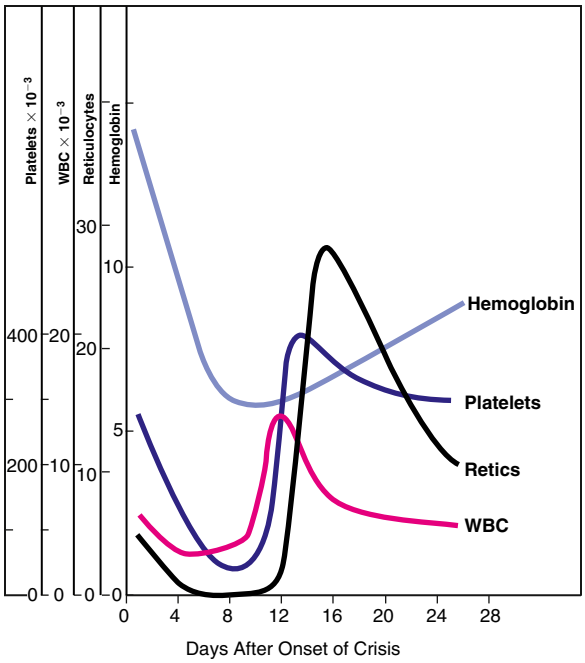

Fig. 507.3 Parvovirus-induced aplastic crisis. Progression of the changes in blood count is shown for a patient with hereditary spherocytosis and infection with parvovirus. Note that the fall in baseline reticulocytosis is associated with a rapid fall in hemoglobin. When considering splenectomy, the patient and the parents, together with their healthcare providers, should review and consider the risks and benefits. Individual-specific factors may confer additional risk after a splenectomy; time and distance from medical care in case of febrile illness and residence in or travel to areas where parasitic diseases such as malaria or babesiosis occur should be considered.

Most experts recommend splenectomy for patients with severe HS and believe it should be strongly considered for patients with moderate HS and frequent hypoplastic or aplastic crises, poor growth, or cardiomegaly. It is generally not recommended for patients with mild HS. When splenectomy is indicated, it should be performed after the age of 6 years, if possible, to avoid the heightened risk of postsplenectomy sepsis in younger children. The laparoscopic approach has less surgical morbidity and has become the technique of choice. Partial or subtotal splenectomy (removal of 85–95% of spleen volume) has been shown to decrease the hemolytic rate while preserving *some* splenic phagocytic function, although the decrease in hemolysis is less than that achievable with total splenectomy. Partial splenectomy is most attractive in children with severe HS requiring frequent transfusion early in childhood.

In children undergoing splenectomy, a concomitant cholecystectomy should be performed if there are gallstones. It is controversial whether to perform a concomitant splenectomy in less-severely ill patients who are undergoing cholecystectomy for gallstone disease. Postsplenectomy thrombocytosis is commonly observed but requires no treatment and usually resolves spontaneously. The patient should remain current on their vaccinations, as should household and frequent contacts. Prophylactic antibiotics are typically prescribed at least until the patient is 5 years of age or at least 2 years postsplenectomy. Folate supplementation should be continued if the hemoglobin level and reticulocyte count do not normalize.

Splenectomy failure may occur in cases of accessory spleen, accidental autotransplantation of splenic tissue into peritoneum at time of surgery, inaccurate diagnosis, or another co-inherited hemolytic anemia. Clues include return of hemolysis and disappearance of Howell-Jolly bodies on peripheral blood smear. The diagnosis can be made by radionucleotide studies.

Chapter 508

Hereditary Elliptocytosis, Hereditary Pyropoikilocytosis, and Related Disorders

Stephanie Prozora and Patrick G. Gallagher

Hereditary elliptocytosis (HE), hereditary pyropoikilocytosis (HPP), and related disorders are characterized by the finding of elliptocytes on peripheral blood smear (Table 508.1). Whereas hereditary spherocytosis is thought of as a disorder of the vertical interactions coupling the erythrocyte membrane skeleton to the lipid bilayer, the HE syndromes interfere with the horizontal interactions that link spectrin molecules to each other and to membrane skeleton junctional complexes (see Chapter 507, Fig. 507.1), leaving the cell vulnerable to shear stress.

HE is the prototypical member of the group, in which abnormal shear stress over time results in elliptical deformation of the cell. It is much more common than hereditary spherocytosis, but it is much less likely to cause significant clinical symptomatology. The severity of HE varies markedly, with most patients experiencing little or no symptomatology beyond the finding of elliptocytes on peripheral blood smear. About 10% of patients have hemolytic HE with ongoing hemolysis and anemia. HE is often worse during infancy, with hemolytic anemia and hyperbilirubinemia that evolves to a well-compensated state with anemia that is absent, sporadic, or chronic. Hereditary elliptocytosis occurs worldwide and in all ethnic groups, but it is more common in patients with ancestry linked to areas of endemic malaria.

HPP is a subtype of HE characterized by severe hemolytic anemia with findings on peripheral blood smear reminiscent of a thermal burn (*pyro*, fire). HE and HPP are seen co-segregating in the same families because they involve overlapping pathogenic variants in spectrin. HPP occurs predominantly in patients of African descent.

Table 508.1 Clinical Subtypes of Hereditary Elliptocytosis and Related Disorders

CLINICAL MANIFESTATIONS	LABORATORY MANIFESTATION
TYPICAL HETEROZYGOUS HE	
Asymptomatic Dominant inheritance: one parent with HE No splenomegaly *Variants:* Some neonates have moderately severe hemolytic anemia and HPP-like smear; converts to typical HE by "1 yr." Some patients with typical HE have mild to moderate chronic hemolysis and some poikilocytosis, caused by co-inheritance of the low-expression variant α-spectrin^{LELY}, coexistence of chronic disease producing splenomegaly, or unknown factors.	Blood smear: elliptocytes, rod forms, few or no poikilocytes No anemia, little or no hemolysis (reticulocytes, 1–3%) Normal osmotic fragility Usually a defect in α-spectrin or β-spectrin leading to decreased spectrin self-association, or a defect in protein 4.1 leading to partial deficiency or dysfunction
HOMOZYGOUS HE OR HPP	
Moderate to severe hemolytic anemia Splenomegaly Intermittent jaundice Aplastic crises Recessive inheritance: typically one parent with HE and one with α-spectrin mutation, or both parents with HE Good improvement after splenectomy	Blood smear: bizarre poikilocytes, fragments, ± spherocytes, ± elliptocytes Reticulocytosis Decreased MCV because of red cell fragmentation Increased osmotic fragility, positive EMA test *α-Spectrin defects:* Decreased red cell and spectrin heat stability Marked defect in spectrin self-association In the more severe variants, partial spectrin deficiency (indicated by more spherocytes on the blood smear)
SPHEROCYTIC HE	
Mild to moderate hemolytic anemia Splenomegaly Intermittent jaundice Aplastic crises Dominant inheritance pattern Excellent response to splenectomy	Blood smear: rounded elliptocytes, ± spherocytes; may see variable morphology within a kindred Reticulocytosis Increased osmotic fragility *Variable molecular defects:* C-terminal truncation of β-spectrin Protein 4.2 deficiency (some patients); variable morphology: spherocytes, ovalocytes, stomatocytes, or spiculated cells, sometimes resembling spherocytic HE Glycophorin C deficiency (rare)
SOUTHEAST ASIAN OVALOCYTOSIS	
Anemia and jaundice in neonatal period; then asymptomatic Dominant inheritance Lowland Aboriginal tribes, especially in Melanesia, Malaysia, and the Philippines Very rigid red cells that resist invasion by malarial parasites in vitro and protect against cerebral malaria in vivo	Blood smear: rounded elliptocytes, some with a transverse bar that divides the central clear space (theta cells) No hemolysis or anemia after neonatal period Normal osmotic fragility, positive EMA test Mutant band 3 that lacks anion exchange function and tends to aggregate, leading to a rigid membrane

EMA, Eosin-5′-maleimide; HE, hereditary elliptocytosis; HPP, hereditary pyropoikilocytosis; MCV, mean cell volume.
Adapted from Wilensky ID, Narla M, Lux SF. Disorders of the red cell membrane. In: Handin RI, Lux SF, Stossel TP, eds. *Blood: Principles and Practice of Hematology*. Philadelphia: Lippincott, 2003.

Southeast Asian ovalocytosis (SAO) is a disorder characterized by the presence of ovalocytes (less elongated and plumper than elliptocytes), some with one or two transverse ridges on peripheral smear. SAO is found in individuals from New Guinea, Malaysia, Indonesia, and the Philippines. Unlike HE and HPP, SAO is due to a variant in a transmembrane protein, band 3, affecting vertical skeletal interactions and leading to increased red cell rigidity. These changes may lead to protection from malaria, particularly cerebral malaria.

ETIOLOGY

Various molecular defects have been described in HE. HE is inherited as an autosomal dominant disorder with occasional de novo cases. Most commonly, there are missense pathogenic variants of α- or β-spectrin that interfere with the formation of spectrin heterodimers into tetramers, the primary structural unit of the membrane skeleton (see Fig. 507.1). Erythrocytes carrying many of these spectrin pathogenic variants are resistant to malaria in vitro, hypothesized to explain the increased prevalence of HE in malaria-endemic areas. Less commonly, elliptocytosis results from pathogenic variants in protein 4.1 or glycophorin C, proteins of the junctional complex that link spectrin tetramers to the actin cytoskeleton. These defects in horizontal membrane skeleton protein interactions leave the cell susceptible to shearing forces, leading to the characteristic elliptical deformation of the cell and potentially membrane fragmentation.

In HPP, two abnormal spectrin alleles are inherited. Frequently, an HPP patient inherits an abnormal spectrin allele carrying a self-association site missense variant from one parent, who has mild or asymptomatic HE, and a production-defective allele that leads to quantitative deficiency of spectrin from the other parent, who is otherwise clinically well.

SAO is an autosomal dominant disorder associated with an in-frame, nine amino acid deletion in band 3.

CLINICAL MANIFESTATIONS

Most HE patients do not have clinically significant hemolysis (see Fig. 507.4B). HE may be an incidental finding on a blood film examination for an unrelated indication. The diagnosis of HE is established by the findings on the peripheral blood smear, the autosomal dominant inheritance pattern, and the absence of other causes of elliptocytosis. The differential diagnosis for other causes of elliptocytosis includes deficiencies of iron, folic acid, and vitamin B_{12}, thalassemia, myelodysplastic syndromes, and pyruvate kinase deficiency.

Interestingly, elliptocytes are not always present on the peripheral blood smear in the first few months of life. Even in hemolytic HE, which may lead to neonatal jaundice and anemia, the peripheral blood smear typically shows bizarre poikilocytes and pyknocytes with rare to no elliptocytes. Hemolysis and anemia are aggravated in the newborn period because of the increased presence of hemoglobin F, which binds poorly to 2,3-diphosphoglycerate. The increased free 2,3-diphosphoglycerate tends to destabilize the spectrin–actin–protein 4.1 complex, leading to membrane instability (see Fig. 507.1). The usual features of a chronic hemolytic process due to hemolytic HE manifest as anemia, jaundice, and splenomegaly. Cholelithiasis may occur in later childhood and aplastic crises have been reported. HPP is characterized by extreme microcytosis (mean corpuscular volume [MCV], 50-65 fL/cell), extraordinary variation in cell size and shape, and microspherocytosis with occasional elliptocytosis (see Fig. 507.4C). Hemolysis is chronic and significant.

SAO is associated with neonatal hyperbilirubinemia, but it is associated with little to no hemolysis later in life.

LABORATORY FINDINGS

Examination of the peripheral blood smear is essential to establish the diagnosis of HE (see Fig. 507.4*B*). HE elliptocytes are normochromic and normocytic with varying degrees of elongation. Because some HE patients may present with relatively low numbers of elliptocytes, there is no cutoff percentage that is useful diagnostically. In hemolytic HE, other abnormal RBC shapes may be present, depending on the severity of hemolysis, including spherocytes, pyknocytes, and other poikilocytes. In HPP, microspherocytes, red cell fragments, and occasional elliptocytes are seen. SAO is suggested when ovalocytes, which in contrast to elliptocytes are less elongated, are observed.

Reticulocyte levels and other markers of hemolysis, such as total bilirubin, lactate dehydrogenase, and haptoglobin, are helpful in establishing the severity of hemolysis, if present. In hemolytic HE and HPP, additional testing may include the eosin-5-maleimide (EMA) binding test, which detects binding to band 3 by flow cytometry, or incubated osmotic fragility testing. In cases of chronic hemolysis, splenomegaly and cholelithiasis can be assessed with abdominal ultrasound.

TREATMENT

If the presentation is that of typical HE (i.e., an isolated peripheral blood smear abnormality without clinically evident hemolysis), no treatment is necessary. For chronic HE and HPP, red blood cell transfusions are occasionally required. Splenectomy decreases the hemolysis and should be considered using criteria similar to that of hereditary spherocytosis. If hemolysis continues after splenectomy, patients should receive folic acid to prevent secondary folic acid deficiency. SAO does not require treatment beyond the newborn period.

Chapter 509

Hereditary Stomatocytosis Syndromes

Stephanie Prozora and Patrick G. Gallagher

The hereditary stomatocytosis syndromes are a group of heterogeneous, dominantly inherited disorders in which alterations in red cell cation permeability lead to alterations in intracellular water content (Table 509.1). A net increase in sodium and potassium ions allows water to enter the erythrocyte, creating stomatocytes or hydrocytes, whereas a net loss of sodium and potassium ions leads to water loss, creating dehydrated red cells, or xerocytes (Fig. 509.1).

HEREDITARY XEROCYTOSIS

Pathophysiology

Hereditary xerocytosis, the most common type of the hereditary stomatocytosis syndromes, is a dominant disorder of erythrocyte dehydration. The underlying defect is most commonly a missense variant in *PIEZO1*, a mechanosensory transduction protein, associated with delayed channel inactivation. In a few patients, pathogenic variants in the Gardos channel, important in erythrocyte dehydration in sickle cell disease, have been observed. Typically, there is a net loss of intracellular potassium that is not accompanied by a compensatory increase in sodium. Subsequently, the gradual loss of intracellular water leads to erythrocyte dehydration. Hereditary xerocytosis may be associated with a syndrome of hydrops fetalis with perinatal anemia and ascites. These findings are transient and remain unexplained.

Clinical Features

Affected patients exhibit a mild compensated macrocytic hemolytic anemia with variable degrees of splenomegaly and intermittent jaundice. The mean corpuscular hemoglobin concentration (MCHC) and mean cell volume (MCV) are elevated, and erythrocyte osmotic fragility is decreased, as are potassium concentration and total monovalent cation content. There are small numbers of stomatocytes, target cells, and contracted red blood cells (RBCs) with hemoglobin puddled to the side on peripheral blood smear. Treatment is supportive, similar

Southeast Asian ovalocytosis (SAO) is a disorder characterized by the presence of ovalocytes (less elongated and plumper than elliptocytes), some with one or two transverse ridges on peripheral smear. SAO is found in individuals from New Guinea, Malaysia, Indonesia, and the Philippines. Unlike HE and HPP, SAO is due to a variant in a transmembrane protein, band 3, affecting vertical skeletal interactions and leading to increased red cell rigidity. These changes may lead to protection from malaria, particularly cerebral malaria.

ETIOLOGY

Various molecular defects have been described in HE. HE is inherited as an autosomal dominant disorder with occasional de novo cases. Most commonly, there are missense pathogenic variants of α- or β-spectrin that interfere with the formation of spectrin heterodimers into tetramers, the primary structural unit of the membrane skeleton (see Fig. 507.1). Erythrocytes carrying many of these spectrin pathogenic variants are resistant to malaria in vitro, hypothesized to explain the increased prevalence of HE in malaria-endemic areas. Less commonly, elliptocytosis results from pathogenic variants in protein 4.1 or glycophorin C, proteins of the junctional complex that link spectrin tetramers to the actin cytoskeleton. These defects in horizontal membrane skeleton protein interactions leave the cell susceptible to shearing forces, leading to the characteristic elliptical deformation of the cell and potentially membrane fragmentation.

In HPP, two abnormal spectrin alleles are inherited. Frequently, an HPP patient inherits an abnormal spectrin allele carrying a self-association site missense variant from one parent, who has mild or asymptomatic HE, and a production-defective allele that leads to quantitative deficiency of spectrin from the other parent, who is otherwise clinically well.

SAO is an autosomal dominant disorder associated with an in-frame, nine amino acid deletion in band 3.

CLINICAL MANIFESTATIONS

Most HE patients do not have clinically significant hemolysis (see Fig. 507.4B). HE may be an incidental finding on a blood film examination for an unrelated indication. The diagnosis of HE is established by the findings on the peripheral blood smear, the autosomal dominant inheritance pattern, and the absence of other causes of elliptocytosis. The differential diagnosis for other causes of elliptocytosis includes deficiencies of iron, folic acid, and vitamin B_{12}, thalassemia, myelodysplastic syndromes, and pyruvate kinase deficiency.

Interestingly, elliptocytes are not always present on the peripheral blood smear in the first few months of life. Even in hemolytic HE, which may lead to neonatal jaundice and anemia, the peripheral blood smear typically shows bizarre poikilocytes and pyknocytes with rare to no elliptocytes. Hemolysis and anemia are aggravated in the newborn period because of the increased presence of hemoglobin F, which binds poorly to 2,3-diphosphoglycerate. The increased free 2,3-diphosphoglycerate tends to destabilize the spectrin–actin–protein 4.1 complex, leading to membrane instability (see Fig. 507.1). The usual features of a chronic hemolytic process due to hemolytic HE manifest as anemia, jaundice, and splenomegaly. Cholelithiasis may occur in later childhood and aplastic crises have been reported. HPP is characterized by extreme microcytosis (mean corpuscular volume [MCV], 50-65 fL/cell), extraordinary variation in cell size and shape, and microspherocytosis with occasional elliptocytosis (see Fig. 507.4C). Hemolysis is chronic and significant.

SAO is associated with neonatal hyperbilirubinemia, but it is associated with little to no hemolysis later in life.

LABORATORY FINDINGS

Examination of the peripheral blood smear is essential to establish the diagnosis of HE (see Fig. 507.4*B*). HE elliptocytes are normochromic and normocytic with varying degrees of elongation. Because some HE patients may present with relatively low numbers of elliptocytes, there is no cutoff percentage that is useful diagnostically. In hemolytic HE, other abnormal RBC shapes may be present, depending on the severity of hemolysis, including spherocytes, pyknocytes, and other poikilocytes. In HPP, microspherocytes, red cell fragments, and occasional elliptocytes are seen. SAO is suggested when ovalocytes, which in contrast to elliptocytes are less elongated, are observed.

Reticulocyte levels and other markers of hemolysis, such as total bilirubin, lactate dehydrogenase, and haptoglobin, are helpful in establishing the severity of hemolysis, if present. In hemolytic HE and HPP, additional testing may include the eosin-5-maleimide (EMA) binding test, which detects binding to band 3 by flow cytometry, or incubated osmotic fragility testing. In cases of chronic hemolysis, splenomegaly and cholelithiasis can be assessed with abdominal ultrasound.

TREATMENT

If the presentation is that of typical HE (i.e., an isolated peripheral blood smear abnormality without clinically evident hemolysis), no treatment is necessary. For chronic HE and HPP, red blood cell transfusions are occasionally required. Splenectomy decreases the hemolysis and should be considered using criteria similar to that of hereditary spherocytosis. If hemolysis continues after splenectomy, patients should receive folic acid to prevent secondary folic acid deficiency. SAO does not require treatment beyond the newborn period.

Chapter 509

Hereditary Stomatocytosis Syndromes

Stephanie Prozora and Patrick G. Gallagher

The hereditary stomatocytosis syndromes are a group of heterogeneous, dominantly inherited disorders in which alterations in red cell cation permeability lead to alterations in intracellular water content (Table 509.1). A net increase in sodium and potassium ions allows water to enter the erythrocyte, creating stomatocytes or hydrocytes, whereas a net loss of sodium and potassium ions leads to water loss, creating dehydrated red cells, or xerocytes (Fig. 509.1).

HEREDITARY XEROCYTOSIS

Pathophysiology

Hereditary xerocytosis, the most common type of the hereditary stomatocytosis syndromes, is a dominant disorder of erythrocyte dehydration. The underlying defect is most commonly a missense variant in *PIEZO1*, a mechanosensory transduction protein, associated with delayed channel inactivation. In a few patients, pathogenic variants in the Gardos channel, important in erythrocyte dehydration in sickle cell disease, have been observed. Typically, there is a net loss of intracellular potassium that is not accompanied by a compensatory increase in sodium. Subsequently, the gradual loss of intracellular water leads to erythrocyte dehydration. Hereditary xerocytosis may be associated with a syndrome of hydrops fetalis with perinatal anemia and ascites. These findings are transient and remain unexplained.

Clinical Features

Affected patients exhibit a mild compensated macrocytic hemolytic anemia with variable degrees of splenomegaly and intermittent jaundice. The mean corpuscular hemoglobin concentration (MCHC) and mean cell volume (MCV) are elevated, and erythrocyte osmotic fragility is decreased, as are potassium concentration and total monovalent cation content. There are small numbers of stomatocytes, target cells, and contracted red blood cells (RBCs) with hemoglobin puddled to the side on peripheral blood smear. Treatment is supportive, similar

to other disorders with congenital hemolytic anemia. Because of the apparent predisposition to major thromboses postsplenectomy, *splenectomy is not recommended in hereditary xerocytosis and related disorders.* Another unusual manifestation of hereditary xerocytosis is the propensity for iron overload, independent of transfusion history. Thus iron indices should be monitored at regular intervals.

HEREDITARY HYDROCYTOSIS

Pathophysiology

Hereditary hydrocytosis is a very rare, dominant disorder associated with large, swollen stomatocytic erythrocytes. The principal defect is an increase in Na^+ and K^+ permeability, leading to markedly increased intracellular sodium and water content. The molecular defect is unknown in most cases. In a subset of cases, missense variants in the Rh-associated glycoprotein (RhAG) have been identified.

Clinical Features

Hereditary hydrocytosis is the most clinically severe disorder of altered erythrocyte volume regulation. It is characterized by moderate to severe hemolysis and macrocytosis (110-150 fL), with a low MCHC (24–30%), elevated erythrocyte sodium concentration, reduced potassium concentration, increased total Na^+ and K^+ content, and increased erythrocyte osmotic fragility. There are large numbers (10–30%) of stomatocytes on peripheral blood smear. Patients typically develop jaundice, splenomegaly, and cholelithiasis.

Treatment is supportive. RBC transfusions are occasionally required. Patients should be followed for evidence of hematologic decompensation during acute illness. Interval ultrasonography to detect cholelithiasis should be obtained. When there is significant hemolysis, folate should be prescribed daily. Similar to hereditary xerocytosis, significant postsplenectomy major thromboses have been observed; thus splenectomy is not recommended in hereditary hydrocytosis.

INTERMEDIATE SYNDROMES AND OTHER VARIANTS

Hereditary xerocytosis and hereditary hydrocytosis are at the extremes of disorders with alterations in erythrocyte permeability. Patients with intermediate defects have been described with varying degrees of hemolysis and anemia. One of these intermediate syndromes is **cryohydrocytosis** in which affected patients typically suffer from mild anemia associated with stomatocytes, spherocytes, and sphero-stomatocytes on peripheral blood smear. Cryohydrocytosis erythrocytes are deficient in band 3 and demonstrate a significant cation leak upon cooling to low temperature (*kyros* = cold). This disorder is due to missense variants in band 3 that likely convert band 3 from an anion exchanger to a nonselective cation leak channel.

Rh deficiency syndrome, also known as Rh_{null} syndrome, is mild to moderate hemolytic anemia associated with markedly decreased (Rh_{mod}) or absent (Rh_{null}) Rh antigens on the erythrocyte membrane. Rh_{null} erythrocytes, which lack all Rh antigens, LW, and Fy5 antigens and have decreased reduced expression of Ss, U, and Duclos antigens, are dehydrated with decreased cell cation and water content. Findings on blood smear include reticulocytes, stomatocytes, and spherocytes. In response to immunization during pregnancy or after blood transfusion, Rh_{null} patients produce antibodies varying in specificity from reacting to anti-e or anti-C to reacting with all erythrocytes tested, an antibody called "anti-total Rh."

Familial deficiency of high-density lipoproteins (Tangier disease) is a rare recessive disorder that results from pathogenic variants in the cholesterol and phospholipid transport protein ABCA1, which lead to perturbations of cellular cholesterol transport and result in the accumulation of cholesterol esters in many tissues. Hematologic manifestations include a mild to moderate stomatocytic hemolytic anemia and thrombocytopenia. Affected patients can also have large orange tonsils, hepatosplenomegaly, lymphadenopathy, cloudy corneas, peripheral neuropathy, and premature atherosclerosis.

Sitosterolemia, also known as phytosterolemia, is a recessive disorder in which the absorption of sterols, both cholesterol and its plant-derived relatives (e.g., sitosterol), is unlimited and unselective. Clinical manifestations include early-onset xanthomatosis, short stature, and premature coronary artery disease. Hematologic abnormalities include macrothrombocytopenia and stomatocytic hemolytic anemia. The plasma cholesterol may or may not be abnormal, but mass spectrometry always shows a massive increase in plant sterol levels in the plasma and in the membranes of platelets and erythrocytes. Pathogenic variants in *ABCG5* or *ABCG8*, transporters that actively pump plant sterols out of intestinal cells back into the intestine and out of liver cells into bile ducts, lead to gastrointestinal hyperabsorption and decreased biliary elimination of plant sterols, as well as altered cholesterol metabolism. Treatment involves dietary restriction of cholesterol and plant sterols and prescription of ezetimibe, a sterol absorption inhibitor, and cholestyramine and other related bile acid–sequestering agents.

OTHER DISORDERS ASSOCIATED WITH STOMATOCYTOSIS

Acquired stomatocytosis may be seen with liver disease, alcoholism, malignancy, and cardiovascular disease and after vinca alkaloid administration. Stomatocytes can be seen as a blood smear–processing artifact.

Chapter 510

Paroxysmal Nocturnal Hemoglobinuria and Acanthocytosis

Stephanie Prozora and Patrick G. Gallagher

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Etiology

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired disorder of the cell membranes of multipotent bone marrow stem cells. The underlying somatic pathogenic variant propagates into a clonal population of stem cells so that all blood cells derived from these variant clonal progenitors, especially red blood cells (RBCs), are susceptible to complement-mediated destruction (Fig. 510.1). The pathogenic variant causes cell membranes to be deficient (either partially or completely) in proteins that impede complement-mediated lysis via the constitutively active alternative pathway. These complement regulating proteins include decay-accelerating factor (CD55), the membrane inhibitor of reactive lysis (CD59), and the C8 binding protein. The underlying defect involves the glycolipid anchor that maintains these protective proteins on the cell surface. Various pathogenic variants in the *PIGA* gene that encodes the glycosylphosphatidylinositol anchor protein have been identified in patients with PNH.

Clinical Manifestations

PNH is a rare disorder in children. Approximately 60% of pediatric patients have marrow failure, and the remainder have either intermittent or chronic anemia, often with prominent intravascular hemolysis (Tables 510.1 and 510.2). Nocturnal and morning hemoglobinuria is the classic finding in adults, but only a minority of PNH patients experience this. Most patients experience chronic hemolysis, often with thrombocytopenia and leukopenia. Hemoglobinuria is rarely seen in children compared with adults with PNH. *Thrombosis and thromboembolic phenomena* are serious complications that may be related to altered glycoproteins on the platelet surface and resultant platelet activation and production of procoagulant microparticles. Abdominal venous thrombosis presents as recurrent episodes of abdominal pain, Budd-Chiari syndrome (hepatic veins), or splenomegaly (splenic vein). Released free hemoglobin results in depletion of nitric oxide, fostering vasoconstriction, thrombosis, and pain. Back and head pain may also be prominent. Hypoplastic or aplastic pancytopenia can precede or follow the diagnosis of PNH; rarely, PNH may progress to acute myelogenous leukemia. At the time of presentation, more than 90% of patients with PNH have some blood abnormality (including ~35% with anemia alone, ~15% with anemia and thrombocytopenia, ~7% with anemia and neutropenia, and ~30% with pancytopenia), >10% have abdominal pain, and >5% have thrombosis. The mortality in PNH is related primarily to the development of aplastic anemia or thrombotic complications. The predicted survival rate for children before the development of eculizumab was 80% at 5 years, 60% at 10 years, and 28% at 20 years.

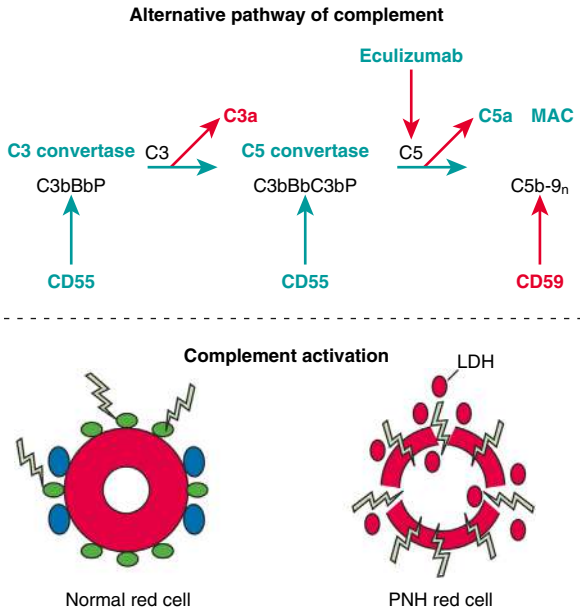

Fig. 510.1 Complement-mediated lysis in paroxysmal nocturnal hemoglobinuria (PNH). *Red circles* are hemoglobin. *Blue circles* are decay accelerating factor (CD55). *Green circles* are membrane inhibitor of reactive lysis (CD59). Bb, activated factor B; C3b, activated C3; C5b, activated C5; MAC, membrane attack complex (consisting of C5b, C6, C7, C8, and several molecules of C9 [9n]). *(From Parker C. Eculizumab for paroxysmal nocturnal haemoglobinuria. Lancet 2009;373:759–767.)*

Laboratory Findings

Hemoglobin levels can range from normal to markedly decreased. Common findings reflect chronic intravascular hemolysis and include hemosiderinuria, an elevated reticulocyte percentage, a low serum haptoglobin, and increased lactic dehydrogenase. Initially, the anemia is normocytic, but if iron deficiency develops, it becomes microcytic. On the blood smear, poikilocytosis and anisocytosis may be present. Markedly reduced levels of RBC acetylcholinesterase activity and decay-accelerating factor are also found. *Flow cytometry is the diagnostic test of choice for PNH*. With the use of anti-CD59 for RBCs and anti-CD55 and anti-CD59 for granulocytes, flow cytometry is more sensitive than the classic RBC lysis (Ham or sucrose) tests in detecting these reduced glycolipid-bound membrane proteins. Fluorescently labeled aerolysin testing can heighten the sensitivity of detection by binding selectively to glycosylphosphatidylinositol anchors.

Treatment

Eculizumab therapy has resulted in sustained survival in the majority of patients. Eculizumab is a monoclonal antibody against complement component C5 that interrupts formation of the membrane attack complex, blocking downstream complement destruction of RBCs and activation of platelets. It decreases the rate of hemolysis, stabilizes hemoglobin levels, reduces the number of transfusions, reduces the risk of thrombosis, and improves quality of life. Eculizumab is an approved and effective treatment for PNH in adults. A recent phase I/II trial demonstrated safety and efficacy in patients 11-17 years of age. Because of the cost and duration of treatment (i.e., lifelong) required, particularly in children, it may be most useful in preventing thrombosis, anemia, and other symptoms while stem cell transplant is considered. Survival in adults with PNH treated with eculizumab may not be different from sex- and age-matched control patients from the general population. However, the medication does not improve the hematopoietic clonal expansion or prevent marrow failure. Before beginning eculizumab, it is recommended to immunize patients with the meningococcal vaccine if the patient hasn't already received this vaccine because a very serious risk of complement inhibition is increased susceptibility to *Neisseria* infections. If eculizumab therapy is desired to begin immediately for clinical reasons, the vaccine can be given at the same time, and prophylactic antibiotics can be given for a 2-week bridge. Headache is a common adverse effect after the first few doses but disappears subsequently. A poor response to eculizumab may be due to polymorphisms in the C5 gene that produce resistance to

Table 510.1 Suggested Criteria as Indications for PNH Testing

CATCH CRITERION	INDICATIONS FOR TESTING	SUPPORTING INFORMATION
Cytopenias	Patients for whom a bone marrow examination is considered for otherwise unexplained cytopenia(s)	Additional features such as elevated LDH, DAT-negative hemolysis, history of unexplained TE, and hemoglobinuria
AA/MDS	All patients with a diagnosis or suspicion of AA Testing should be done at diagnosis and monitored at least q6 months Low or intermediate-1 risk MDS, and especially if hypoplastic	Additional features such as elevated LDH, DAT-negative hemolysis, history of unexplained TE, and hemoglobinuria
Thrombosis	Unprovoked and/or unusual site TE (e.g.,, splenic, hepatic, CNS), especially if recurrent and/or despite anticoagulation	Additional features such as elevated LDH, DAT-negative hemolysis, otherwise-unexplained cytopenias, especially including anemia
Coombs-negative hemolysis	Hemolysis or hemolytic anemia (i.e., elevated LDH and indirect bilirubin, reduced haptoglobin, DAT/Coombs test negative) without other clear cause	Test in all patients unless a clear alternate explanation exists Supportive information may be helpful but is not necessary
Hemoglobinuria	Otherwise-unexplained hemoglobinuria or cases where "hematuria" has been identified without evidence of erythrocytes on microscopy	Test in all patients unless a clear alternate explanation exists Supportive information may be helpful but is not necessary

AA, Aplastic anemia; CNS, central nervous system; DAT, direct antiglobulin test (aka Coombs test); LDH, lactate dehydrogenase; MDS, myelodysplastic syndromes; TE, thromboembolic event.

Table 510.2 Classification of Paroxysmal Nocturnal Hemoglobinuria

CATEGORY	RATE OF INTRAVASCULAR HEMOLYSIS*	BONE MARROW	FLOW CYTOMETRY	BENEFIT FROM ECULIZUMAB
Classic clinical PNH	Florid (markedly abnormal LDH, often with episodic macroscopic hemoglobinuria)	Cellular marrow caused by erythroid hyperplasia and normal or near-normal morphology†	Large population (>50%) of GPI-AP– PMNs§	Yes
Clinical PNH in the setting of another bone marrow failure syndrome‡	Mild (often with minimal abnormalities of biochemical markers of hemolysis)	Evidence of a concomitant bone marrow failure syndrome‡	Although variable, the percentage of GPI-AP– PMNs is usually relatively small (<50%)	Typically no, but some patients have relatively large clones and clinically significant hemolysis and may benefit from treatment
Subclinical PNH	No clinical or biochemical evidence of intravascular hemolysis	Evidence of a concomitant bone marrow failure syndrome‡	Small (<1%) population of GPI-AP– PMNs detected by high-resolution flow cytometry	No

*Based on macroscopic hemoglobinuria, serum LDH concentration and reticulocyte count.
†Karyotypic abnormalities are uncommon.
‡Aplastic anemia or low-risk myelodysplastic syndrome.
§Analysis of PMNs is more informative than analysis of red blood cells because of selective destruction GPI-AP– RBCs.
GPI-AP–, Glycosylphosphatidylinositol–anchored protein–deficient; LDH, lactate dehydrogenase; PMNs, polymorphonuclear leukocytes.
From Parker CJ, Ware RE. Paroxysmal nocturnal hemoglobinuria. In: Orkin SH, Fisher DE, Ginsburg D, et al., eds. *Nathan and Oski's Hematology and Oncology of Infancy and Childhood*, 8th ed. Philadelphia: Elsevier, 2015: Table 14-1.

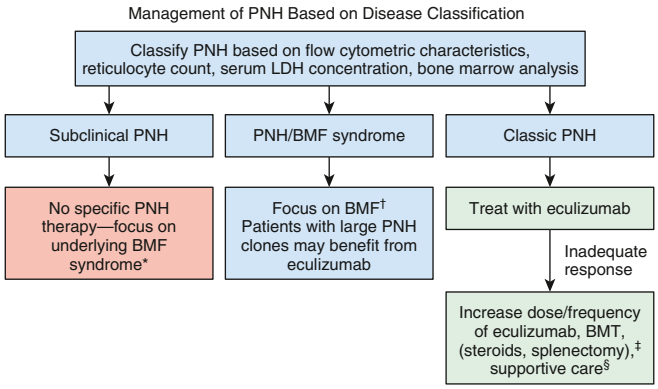
eculizumab blockades. Patients on eculizumab therapy require regular monitoring, including complete blood counts with reticulocytes, lactate dehydrogenase, total bilirubin, and repeat flow cytometry every 6-12 months.

Hematopoietic stem cell transplantation (HSCT) is a key therapeutic consideration if a suitable donor exists, particularly in children. Severe aplastic anemia is a strong indication for transplant in PNH (Fig. 510.2). HSCT is the only potentially curative therapy available for PNH. Nonmyeloablative transplantation (with reduced intensity conditioning regimens) are often used to reduce transplant-related mortality and morbidity; because eradication of only the PNH clones is sought, total myeloablation is not necessary.

Glucocorticoids such as prednisone can be used for acute hemolytic episodes; the dosage should be tapered as soon as the hemolysis abates. Prolonged anticoagulation (heparin or low molecular weight heparin) therapy may be of benefit when thromboses occur. Because of chronic urinary loss of iron as hemosiderin, iron therapy may be necessary. Androgens (e.g., fluoxymesterone), antithymocyte globulin, cyclosporine, and growth factors (e.g., erythropoietin and granulocyte colony-stimulating factor) have been used to treat marrow failure.

ACANTHOCYTOSIS

Acanthocytosis is characterized by RBCs with irregular circumferential pointed projections (also known as spur cells) (see Fig. 507.4E).



*Some, but not all, studies suggest a favorable response to immunosuppressive therapy (IST).
† BMT eradicates the PNH clone, and typically, treatment with IST does not affect PNH clone size.
‡ Consider for patients with clinically significant extravascular hemolysis.
§ Transfusion.

Fig. 510.2 Management algorithm for paroxysmal nocturnal hemoglobinuria (PNH). A management scheme based on classification of PNH into two categories: subclinical, PNH in the setting of another bone marrow failure syndrome (PNH/BMF), and classic PNH (see Table 510.2 for characteristics of each category.) *LDH*, Lactic dehydrogenase; *BMF*, bone marrow failure (aplastic anemia and low risk MDS); *BMT*, bone marrow transplant. *(From Orkin SH, Fisher DE, Ginsburg D, et al., eds. Nathan and Oski's Hematology and Oncology of Infancy and Childhood, 8th ed. Philadelphia: Elsevier, 2015. Fig 14-9.)*

Table 510.3 Hereditary Acanthocytosis Syndromes

SYNDROME	INHERITANCE	GENES
Chorea-acanthocytosis	Autosomal recessive	*VPS13A*
McLeod syndrome	X-linked recessive	*XK*
Huntington disease–like 2	Autosomal dominant	*JPH3*
Pantothenate kinase-associated neurodegeneration	Autosomal recessive	*PANK2*
Abetalipoproteinemia	Autosomal recessive	*MTTP*
Hereditary hypobetalipoproteinemia	Autosomal recessive	*APOB, MTP, PCSK9*
Aceruloplasminemia	Autosomal recessive	*CP*

This morphologic finding results from alterations in the membrane ratio of cholesterol to phospholipid, with the morphology attributed to an excess of lipid in the outer layer relative to the inner layer of the membrane bilayer. In liver disease, acanthocytes develop because of increased abundance of free cholesterol, as patients develop splenic congestion, hemolytic anemia, and jaundice. **Abetalipoproteinemia** is an inherited autosomal recessive disease in which acanthocytosis is associated with fat malabsorption, progressive ataxia, and retinitis pigmentosa. The fat malabsorption may become apparent in the first year of life, whereas the ataxia develops at school-age. The anemia is usually mild. **Hypobetalipoproteinemia** is a recessive familial disease that has a similar clinical spectrum, but with milder findings. Aceruloplasminemia leads to anemia, diabetes, ocular problems, tremors, chorea, ataxia, and facial abnormalities due to increased iron in the brain and other organs.

There are four genetically diverse **neuroacanthocytosis syndromes** (Table 510.3). *Chorea-acanthocytosis* is an adult-onset disease without anemia, variable numbers of acanthocytes on peripheral blood smear, with multiple neurologic findings such as limb chorea, tics, and hypotonia. The rare *X-linked McLeod syndrome* (marked by absence of the Kell antigen) presents with mild hemolytic anemia, late-onset myopathy, peripheral neuropathy, chorea, and splenomegaly. There are usually >3% acanthocytes on peripheral smear and caudate atrophy noted on MRI. McLeod syndrome is the only neuroacanthocytosis syndrome likely to present in childhood. Acanthocytes also are seen in *pantothenate kinase-associated neurodegeneration* (with dystonia, rigidity, chorea, dysarthria, spasticity, retinopathy) and *Huntington disease–like 2*.

In contrast to acanthocytes, echinocytes or "burr cells" have a more regular distribution of projections or serrations along the surface of the RBCs and will tend to a more spheroidal cell contour as they age. They are seen often as artifacts (e.g., due to elevated pH, contact with glass, or blood storage) and infrequently in end-stage renal disease, liver disease, uremia, pyruvate-kinase deficiency, long-distance runners, and patients with hypomagnesemia and hypophosphatemia.

Chapter 511

Hemoglobinopathies

Kim Smith-Whitley and Janet L. Kwiatkowski

HEMOGLOBIN DISORDERS

Hemoglobin is a tetramer consisting of two pairs of globin chains. Abnormalities in these proteins are referred to as **hemoglobinopathies**.

More than 800 variant hemoglobins have been described. The most common and useful clinical classification of hemoglobinopathies is based on nomenclature associated with alteration of the involved *globin chain*. Two hemoglobin (Hb) gene clusters are involved in Hb production and are located at the end of the short arms of chromosomes 16 and 11. Their control is complex, including an upstream locus control region on each respective chromosome and an X-linked control site. On chromosome 16, there are three genes within the alpha (α) gene cluster: zeta (ζ), alpha 1 (α_1), and alpha 2 (α_2). On chromosome 11, there are five genes within the beta (β) gene cluster: epsilon (ε), gamma 1 (γ_1), gamma 2 (γ_2), delta (δ), and beta (β).

The order of gene expression within each cluster roughly follows the order of expression during the embryonic period, fetal period, and eventually childhood. After 8 weeks of fetal life, the embryonic hemoglobins, Gower-1 ($\zeta_2\varepsilon_2$), Gower-2 ($\alpha_2\varepsilon_2$), and Portland ($\zeta_2\gamma_2$), are formed. At 9 weeks of fetal life, the major hemoglobin is hemoglobin F (HbF; $\alpha_2\gamma_2$). Hemoglobin A (HbA; $\alpha_2\beta_2$) first appears at approximately 1 month of fetal life but does not become the dominant hemoglobin until after birth, when HbF levels start to decline. HbA_2 ($\alpha_2\delta_2$) is a minor hemoglobin that appears shortly before birth and remains at a low level after birth. The final hemoglobin distribution pattern that occurs in childhood is not achieved until at least 6 months of age and sometimes later. The normal hemoglobin pattern is ≥95% HbA, ≤3.5% HbA_2, and <2.5% HbF.

511.1 Sickle Cell Disease

Kim Smith-Whitley and Janet L. Kwiatkowski

Children with sickle cell disease should be followed by experts in the management of this disease, most often by pediatric hematologists. Children who receive disease-specific care that focuses on prevention of infectious complications and end-organ damage should have a

higher likelihood of survival to adult age. Medical care provided by a pediatric hematologist is also associated with a decreased frequency of emergency department (ED) visits and length of hospitalization compared to patients who were not seen by a hematologist within the last year.

PATHOPHYSIOLOGY

Hemoglobin S (HbS) is the result of a single base-pair change, thymine for adenine, at the 6th codon of the β-globin gene. This change encodes valine instead of glutamine in the sixth residue in the β-globin molecule. Sickle cell anemia (HbSS), homozygous HbSS, occurs when both β-globin alleles have the sickle cell pathogenic variant (βs). Sickle cell disease refers not only to patients with sickle cell anemia but also to compound heterozygotes where one β-globin allele includes the sickle cell pathogenic variant and the second β-globin allele includes a gene pathogenic variant other than the sickle cell pathogenic variant, such as HbC, β-thalassemia, HbD, and HbO^{Arab}. In sickle cell anemia, HbS is typically as high as 90% of the total hemoglobin, whereas in sickle cell disease, HbS is >50% of all hemoglobin.

In red blood cells (RBCs), the hemoglobin molecule has a highly specified conformation allowing for the transport of oxygen in the body. In the absence of globin-chain pathogenic variants, hemoglobin molecules do not interact with one another. However, the presence of HbS results in a conformational change in the Hb tetramer, and in the deoxygenated state, HbS molecules interact with each other, forming rigid polymers that give the RBC its characteristic "sickled" shape. Intraerythrocytic changes lead to a shortened RBC life span and hemolysis. Hemolysis leads to multiple changes, including altered nitric oxide metabolism and oxidant stress, which contribute to endothelial dysfunction. Intravascular sickling primarily occurs in the postcapillary venules and is a function of both mechanical obstruction by sickled erythrocytes, platelets, and leukocytes and increased adhesion between these elements and the vascular endothelium. Sickle cell disease is also an inflammatory disease based on nonspecific markers of inflammation, including, but not limited to, elevated baseline white blood cell (WBC) count and cytokines.

DIAGNOSIS AND EPIDEMIOLOGY

Every state in the United States has instituted a mandatory newborn screening program for sickle cell disease. Such programs identify newborns with the disease and provide prompt diagnosis and referral to providers with expertise in sickle cell disease for anticipatory guidance and the initiation of penicillin prophylaxis before 4 months of age.

The most commonly used procedures for newborn diagnosis include thin-layer/isoelectric focusing (IEF) and high-performance liquid chromatography (HPLC). Some laboratories perform genetic testing on specimens demonstrating abnormal hemoglobins. A confirmatory step is recommended, with all patients who have initial abnormal screens being retested during the first clinical visit, which helps to account for potential administrative errors in specimen handling. In addition, a complete blood cell count (CBC) and Hb phenotype determination is recommended for both parents to provide an opportunity for genetic counseling and to better characterize disease genotype in the affected offspring if necessary. Infants who may have **HbS-hereditary persistence fetal hemoglobin (HbSHPFH)** but do not have full parental studies should have molecular testing for β-globin genotype before 12 months of age (or sooner if hydroxyurea is initiated). Table 511.1 correlates the initial hemoglobin phenotype at birth with the type of hemoglobinopathy.

In newborn screening programs, the hemoglobin with the greatest quantity is reported first, followed by other hemoglobins in order of decreasing quantity. Some states perform IEF initially on newborn blood samples, then use DNA probes to confirm abnormal hemoglobins found on IEF. In newborns with a hemoglobin analysis result of **HbFS**, the pattern supports HbSS, HbSHPFH, or $HbS\beta^0$-thalassemia. In certain situations, a newborn with a hemoglobin analysis of HbFS may have $HbS\beta^+$-thalassemia and the hemoglobin A may not be demonstrating on the electrophoresis in quantities high enough for detection. In a newborn with a hemoglobin analysis of **FSA**, the pattern is supportive of the diagnosis of $HbS\beta^+$-thalassemia. The diagnosis of $HbS\beta^+$-thalassemia is confirmed if at least 50% of the hemoglobin is HbS, HbA is present, and the amount of HbA_2 is elevated (typically >3.5%), although HbA_2 is not elevated in the newborn period. In newborns with a hemoglobin analysis of **FSC**, the pattern supports a diagnosis of HbSC. In newborns with a hemoglobin analysis of **FAS**, the pattern supports a diagnosis of HbAS (sickle cell trait); however, in this circumstance, care must be taken to confirm that the newborn has not received an RBC transfusion before testing.

A newborn with a hemoglobin analysis of **AFS** either has been transfused with RBCs before collection of the newborn screen to account for the greater amount of HbA than HbF, or there has been an error. The patient may have either sickle cell disease or sickle cell trait and

Table 511.1 Various Newborn Sickle Cell Disease Screening Results with Baseline Hemoglobin

NEWBORN SCREENING RESULTS: SICKLE CELL DISEASE*	POSSIBLE HEMOGLOBIN PHENOTYPE†	BASELINE HEMOGLOBIN RANGE AFTER AGE 5 YR

	SCD-S β^+ thal	6-9 g/dL
	SCD-S β^0 thal	7-13 g/dL variable

*Hemoglobins are reported in order of quantity.
†Requires confirmatory hemoglobin analysis after at least 6 mo of age and, if possible, β-globin gene testing or hemoglobin analysis from both parents for accurate diagnosis of hemoglobin phenotype.
‡Sickle cell trait is another possible diagnosis.
§Impossible to determine the diagnosis because the infant most likely received a blood transfusion before testing.
A, Normal hemoglobin A; C, hemoglobin C; F, fetal hemoglobin; HPFH, hereditary persistence of fetal hemoglobin; O^{Arab}, hemoglobin O^{Arab}; S, sickle hemoglobin; SC, sickle-hemoglobin C; SCD, sickle cell disease; SS, homozygous sickle cell disease; thal, thalassemia.

should be started on penicillin prophylaxis until the final diagnosis can be determined.

Given the implications of a diagnosis of sickle cell disease versus sickle cell trait in a newborn, the importance of repeating the Hb identification analysis in the patient and obtaining a Hb identification analysis and CBC to evaluate the peripheral blood smear and RBC parameters in the parents cannot be overemphasized. Unintended mistakes do occur in state newborn screening programs. Newborns who have the initial phenotype of HbFS but whose final true phenotype is HbSβ$^+$-thalassemia have been described as one of the more common errors identified in newborn screening hemoglobinopathy programs. Determining an accurate phenotype is important for appropriate genetic counseling for the parents. In addition, distinguishing HbSS from HbSHPFH in the newborn period usually requires parental or genetic testing. Infants who maintain HbF percentages above 25% after 12 months of age without evidence of hemolysis should have testing for β-globin gene deletions consistent with HPFH. These children have a much milder clinical course and do not require penicillin prophylaxis or hydroxyurea therapy.

If the parents are tested for sickle cell trait or hemoglobinopathy trait, full disclosure to the parent tested should be provided privately, and in some circumstances, the issue of paternity may be disclosed. For this reason and because of healthcare privacy, common practice is to always seek permission for the genetic testing and to report the hemoglobinopathy trait results back to each parent separately.

In the United States, sickle cell disease is the most common genetic disorder identified through the state-mandated newborn screening program, occurring in 1:2,647 births. The sickle hemoglobin gene is more prevalent in communities of color because descendants of people where malaria has been endemic are more likely to have been protected from the severe manifestations of malaria. Regarding ethnicity in the United States, sickle cell disease occurs in Black persons at a rate of 1:396 births and in Hispanics at a rate of 1:36,000 births. In the United States, an estimated 100,000 people have sickle cell disease, with an ethnic distribution of 90% Black and 10% Hispanic. The U.S. sickle cell disease population represents a fraction of the worldwide burden of the disease, with global estimates of 312,000 neonates born annually with HbSS disease.

CLINICAL MANIFESTATIONS AND TREATMENT OF SICKLE CELL ANEMIA

For a comprehensive discussion of the clinical management of children and adolescents with sickle cell disease, refer to the National Heart, Lung, and Blood Institute (NHLBI) 2014 Expert Panel Report on the Evidence-Based Management of Sickle Cell Disease (https://www.nhlbi.nih.gov/sites/www.nhlbi.nih.gov/files/sickle-cell-disease-report.pdf).

Fever and Bacteremia

Fever in a child with sickle cell anemia is a medical emergency, requiring prompt medical evaluation and delivery of antibiotics because of the increased risk of serious bacterial infection and subsequent high mortality rate. As early as 6 months of age, infants with sickle cell anemia develop abnormal immune function because of splenic dysfunction. By 5 years of age, most children with sickle cell anemia have complete functional asplenia. Regardless of age, all patients with sickle cell anemia are at increased risk of infection and death from bacterial infection, particularly encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, and *Neisseria meningitidis,* as well as *Salmonella* spp.

Several clinical strategies have been developed to manage children with sickle cell disease who present with fever. These strategies range from hospital admission for intravenous (IV) antimicrobial therapy to administering a third-generation cephalosporin in an ED or outpatient setting to patients without established risk factors for occult bacteremia (Table 511.2). Given the observation that the average time for a positive blood culture is <20 hours in children with sickle cell anemia, admission for 24 hours is probably the most prudent strategy for children and families who live out of town or who are identified as high risk for poor follow-up.

Table 511.2 Clinical Factors Associated with Increased Risk of Acute Complications in Febrile Children with Sickle Cell Disease

Seriously ill appearance
Hypotension: systolic blood pressure <70 mm Hg at 1 yr of age or <70 mm Hg + 2 × age (yr) for older children
Poor perfusion: capillary refill time >4 sec
Temperature >40.0°C (104°F)
Hypoxia
Corrected white blood cell count >30,000/mm^3 or <5,000/mm^3
Platelet count <100,000/mm^3
History of pneumococcal sepsis*
Severe pain
Dehydration: poor skin turgor, dry mucous membranes, history of poor fluid intake, or decreased output of urine
Presence of acute chest syndrome (new infiltrate on chest radiograph)
Hemoglobin level <5.0 g/dL
No prophylactic antibiotics
Not immunized

*Or other serious infection requiring hospital admission.
Adapted from Williams JA, Flynn PM, Harris S et al. A randomized study of outpatient treatment with ceftriaxone for selected febrile children with sickle cell disease. *N Engl J Med* 1993;329:472–476.

Outpatient management of fever without a source should be considered in children with the lowest risk of bacteremia and after appropriate cultures are obtained and IV ceftriaxone or another cephalosporin is given. Observation after antibiotic administration is important because children treated with ceftriaxone can develop severe, rapid, and life-threatening immune hemolysis. In the event that *Salmonella* spp. or *Staphylococcus aureus* bacteremia occurs, strong consideration should be given to an evaluation for osteomyelitis with an MRI, given the increased risk of osteomyelitis in children with sickle cell anemia compared to the general population. Screening laboratory and radiologic studies are strongly recommended to identify those at risk for transient red cell aplasia, acute splenic sequestration, and acute chest syndrome (ACS), because many children with these diagnoses present to acute care settings with isolated fever. Screening children and caregivers for psychosocial factors that could impede their return to the hospital in the case of a positive blood culture is essential.

Aplastic Crisis

Human parvovirus B19 infection poses a unique threat for patients with sickle cell disease because this infection results in temporary **red cell aplasia**, limiting the production of reticulocytes and causing profound anemia (see Fig. 507.3 in Chapter 507). Any child with sickle cell disease, fever, and *reticulocytopenia* should be presumed to have parvovirus B19 infection until proven otherwise. However, reticulocytopenia is not a requirement for the diagnosis of a recent parvovirus B19 infection because reticulocytosis and increased nucleated RBCs may be seen in the recovery phase. Diagnostic testing for the presence of human parvovirus B19 with polymerase chain reaction (PCR) testing is superior to using immunoglobulin M (IgM) and IgG titers. The acute exacerbation of anemia is treated conservatively using red cell transfusion when the patient becomes hemodynamically symptomatic or has a concurrent illness, such as ACS or acute splenic sequestration. Children with suspected aplastic crisis should be closely monitored because acute infection with parvovirus B19 is associated with pain, splenic sequestration, ACS, glomerulonephritis, arthropathy, and stroke. Patients with parvovirus-associated aplastic crisis are contagious, and infection precautions should be taken to avoid nosocomial spread of the infection and to avoid exposure of pregnant caregivers who may be at risk for adverse fetal outcomes with acute infection.

Splenic Sequestration

Acute splenic sequestration is a life-threatening complication occurring primarily in infants and young children with sickle cell anemia.

The incidence of splenic sequestration has declined from an estimated 30% to 12.6% with early identification by newborn screening and improved parental education. Sequestration can occur as early as 5 weeks of age but most often occurs in children between ages 6 months and 2 years. Patients with the SC and Sβ$^+$-thalassemia types of sickle cell disease can have acute splenic sequestration events throughout adolescence and adulthood.

Splenic sequestration is associated with rapid spleen enlargement causing left-sided abdominal pain and Hb decline from the patient's baseline. Sequestration may lead to signs of hypovolemia as a result of the trapping of blood in the spleen and profound anemia, with total Hb falling below 3 g/dL. A decrease in WBC and platelet count may also be present. Sequestration may be spontaneous or triggered by fever, bacteremia, or viral infections.

Treatment includes early intervention and maintenance of hemodynamic stability using isotonic fluid or transfusions. Careful blood transfusions with RBCs are recommended to treat both the sequestration and the resultant anemia. Blood transfusion aborts the RBC trapping in the spleen and allows release of the patient's blood cells that have become sequestered, often raising Hb above baseline values. A reasonable approach is to provide only 5 mL/kg of RBCs and/or a posttransfusion Hb target of 8 g/dL, keeping in mind that the goal of transfusion is to prevent hypovolemia. Blood transfusion that results in Hb levels >10 g/dL may put the patient at risk for **hyperviscosity syndrome** because RBCs may be released from the spleen after transfusion.

Repeated episodes of splenic sequestration are common, occurring in 65% of patients. Most recurrent episodes develop within 6 months of the previous episode. Prophylactic splenectomy performed after an acute episode has resolved is the only effective strategy for preventing future life-threatening episodes. Although blood transfusion therapy has been used with the goal of preventing subsequent episodes, evidence strongly suggests that this strategy does not reduce the risk of recurrent splenic sequestration compared to no transfusion therapy. However, a short course of regular RBC transfusions can be used until splenectomy is arranged. Children should be appropriately immunized with meningococcal and pneumococcal vaccines before surgery. Penicillin prophylaxis should be prescribed after splenectomy.

Hepatic and Gallbladder Involvement

See Chapters 408 and 414.

Sickle Cell Pain

Dactylitis, referred to as **hand-foot syndrome**, is often the first manifestation of pain in infants and young children with sickle cell anemia, occurring in 50% of children by their second year of life (Fig. 511.1). Dactylitis often manifests with symmetric or less often unilateral swelling of the hands and/or feet. Unilateral dactylitis can be confused with osteomyelitis, and careful evaluation to distinguish the two is important because treatment differs significantly. Dactylitis requires palliation with pain medications, whereas osteomyelitis requires at least 4-6 weeks of IV antibiotics. Feedback from the parents is needed to determine if pain therapy is successful in relieving pain.

The cardinal clinical feature of sickle cell disease is **acute vasoocclusive pain**. Acute sickle cell pain is characterized as unremitting discomfort that can occur in any part of the body but most often occurs in the chest, abdomen, or extremities. These painful episodes are often abrupt and cause disruption of daily life activities and significant stress for children and their caregivers. A patient with sickle cell anemia has approximately one painful episode per year that requires medical attention, but the frequency is extremely variable. The pattern of symptoms with subsequent episodes may resemble that of previous episodes.

The exact etiology of pain is unknown, but the pathogenesis may be initiated when blood flow is disrupted in the microvasculature by sickled RBCs and other cellular elements, resulting in tissue ischemia. Acute sickle cell pain may be precipitated by physical stress, infection, dehydration, hypoxia, local or systemic acidosis, exposure to cold, and swimming for prolonged periods. However, most pain episodes occur without an identifiable trigger. Successful treatment of these episodes requires education of both caregivers and patients regarding the recognition of symptoms and the optimal management strategy. Given the absence of any reliable objective laboratory or clinical parameter associated with pain, trust between the patient and the treating physician is paramount to successful clinical management. Specific therapy for pain varies greatly but generally includes the use of acetaminophen or a nonsteroidal antiinflammatory drug (NSAID) early in the course of pain, followed by escalation to a combination analgesic regimen using a single-agent short-acting oral opioid, long-acting oral opioid, and continued nonopioid agent.

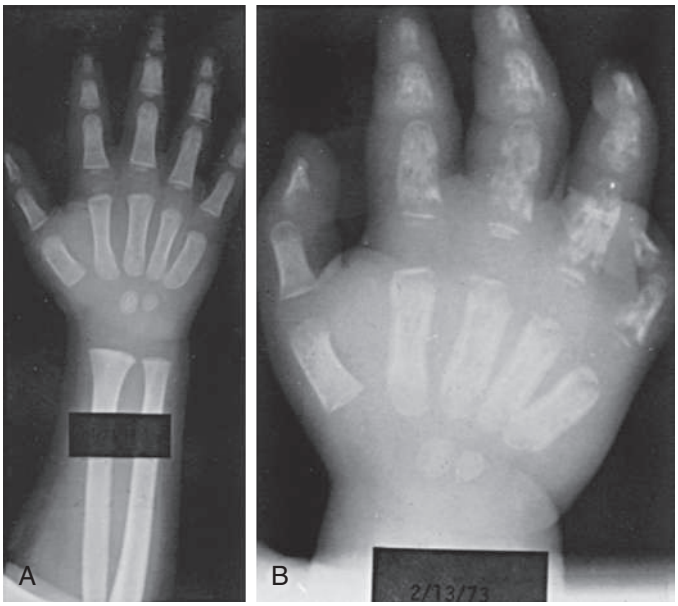

Fig. 511.1 Radiographs of an infant with sickle cell anemia and acute dactylitis. **A**, The bones appear normal at the onset of the episode. **B**, Destructive changes and periosteal reaction are evident 2 weeks later.

The majority of painful episodes in patients with sickle cell disease are managed at home with comfort measures, such as heating pad, relaxation techniques, massage, and oral pain medication. Some patients require treatment in an acute care setting with IV morphine or derivatives of morphine. The primary goal of treatment in these settings is timely administration of analgesics to provide relief of pain. The incremental increase and decrease in the use of the medication to relieve pain roughly parallels the eight phases associated with a chronology of pain and comfort in children (Table 511.3). When pain requires continued parenteral analgesic administration, hospitalization or prolonged stays in day hospitals are required. The average hospital length of stay for children admitted in pain is 4.4 days. The American Society of Hematology and NHLBI clinical guidelines for treating acute and chronic pain in children and adults with sickle cell disease are comprehensive and represent a starting point for treating pain.

The only measure for degree of pain is the patient. Healthcare providers working with children in pain should use a consistent, validated pain scale (e.g., Wong-Baker FACES Scale) for assessing pain. Although pain scales have proved useful for some children, other forms of pain assessment may be required to determine when opioid therapy should be initiated and decreased. Individualized pain plans provide important information for assessment and treatment that address patient preferences.

Several myths have been propagated regarding the treatment of pain in sickle cell disease. The concept that all painful episodes in children should be managed without opioids is without foundation and results in unwarranted suffering on the part of the patient. Blood transfusion therapy during an existing painful episode does not decrease the intensity or duration of the painful episode. Aggressive IV hydration does

Table 511.3 Phases of a Painful Episode in Patients with Sickle Cell Disease

PHASE	DESCRIPTION AND COMFORT MEASURES
DATA FROM CHILDREN	
I	*Baseline* No pain and no comfort measures
II	*Prepain phase* No evidence of pain Child begins to display some prodromal signs and symptoms of VOE (yellow eyes, fatigue) No comfort measures used Caregivers encouraged child to increase fluids to prevent the pain event from occurring
III	*Pain starting point* Child complained of mild "ache-ish" pain in one specific area, which gradually or rapidly increased or "waxed" Mild analgesics (ibuprofen and acetaminophen) given Child maintained normal activities and continued to attend school Caregivers hoped to prevent an increase in pain intensity
IV	*Pain acceleration* Pain continued to escalate; intensity increased from mild to moderate; pain appeared in more areas of the body; child was kept home from school; decreased level of activity; differences in behaviors, appearance, and mood Stronger oral analgesics may be combined with rest, rubbing, heat, distraction, and psychologic comfort
V	*Peak pain experience* Pain continued to escalate Some children were incapacitated and unable to obtain pain relief Pain described as "stabbing," "drilling," "pounding," "banging," "excruciating," "unbearable," or "throbbing" Caregivers sometimes decide to seek help from ED for stronger analgesics and protection from complications such as fever or respiratory distress Caregivers may be exhausted from caring for the child for several days with little or no rest All methods of comfort were used around the clock to reduce the pain and avoid going to the hospital Pain increased despite all efforts Decision is made to take the child to ED
VI	*Pain decrease starting point* Pain begins to resolve after the use of IV fluids and analgesics Analgesics sedate the child and allow the child to sleep for longer periods Pain described as "slowly decreasing" Pain is still sharp and throbbing
VII	*Steady pain decline* Pain decreased slowly or rapidly Child takes more interest in surroundings, roommates, and visitors Child is less irritable Level of activity increased—child may be taken to tub room for warm bath, may watch television, may play games with other children or hospital volunteers Mobility has improved Pain levels reported as "just a little" More animation in behaviors evident
VIII	*Pain resolution* Pain is at a tolerable level Child may be discharged from the hospital on mild oral analgesics; child is at or close to baseline conditions, with behavior, appearance, and mood more normal Caregiver and child attempt to regain, recapture, and catch up with life as it was before the pain event
DATA FROM ADULTS	
I	*Evolving/infarctive phase* 3 days ↓ RBC deformability ↓ Hemoglobin ↑ % of dense RBCs ↑ RDW, ↑ HDW S/S: fear, anorexia, anxiety, ↑ pain

Table 511.3 Phases of a Painful Episode in Patients with Sickle Cell Disease—cont'd

Red blood cell changes during the evolution of the sickle cell painful crisis. *Blood* 1992;79:2154–2163; and Beyer JE, Simmons L, Woods GM, Woods PM. A chronology of pain and comfort in children with sickle cell disease. *Arch Pediatr Adolesc Med* 1999;153:913–920.

not relieve or prevent pain and is appropriate when the patient is dehydrated or unable to drink as a result of the severe pain. *Opioid dependency in children with sickle cell disease is rare and should never be used as a reason to withhold pain medication.* However, patients with multiple painful episodes requiring hospitalization within 1 year or with pain episodes that require hospitalization for >7 days should be evaluated for comorbidities and environmental stressors that are contributing to the frequency or duration of pain. Children with chronic pain should be evaluated for other disease-related complications, including, but not limited to, presence of avascular necrosis, leg ulcers, and vertebral body compression fractures. A careful history is warranted to distinguish chronic pain that often is not relieved by opioids versus recurrent acute prolonged vasoocclusive pain episodes.

Skeletal pain (bone or bone marrow infarction) with or without fever must be differentiated from **osteomyelitis**. Both *Salmonella* spp. and *S. aureus* cause osteomyelitis in children with sickle cell disease, often involving the diaphysis of long bones (in contrast to children without sickle cell anemia, in whom osteomyelitis is in the metaphyseal region of the bone). Differentiating osteomyelitis from a vasoocclusive crisis is often difficult. Clinical signs and symptoms can be consistent with both osteomyelitis and vasoocclusive crises because low-grade fever pain, swelling of the affected area, high WBC counts, and elevated C-reactive protein levels can be present in both. Blood, fluid, and tissue cultures, when positive, are helpful. MRI may be useful for locating an area to obtain fluid for culture. Ultimately, aspiration with or with or without biopsy and culture will be needed to differentiate the two processes (see Chapter 725).

Avascular Necrosis

Avascular necrosis **(AVN)** occurs at a higher rate among children with sickle cell disease than in the general population and is a source of both acute and chronic pain. Most often, the femoral head is affected. AVN of the hip may cause limp and leg-length discrepancy. Other sites affected include the humeral head and mandible. Risk factors for AVN include HbSS disease with α-thalassemia trait, frequent vasoocclusive episodes, and elevated hematocrit (for patients with sickle cell anemia). Optimal treatment of AVN has not been determined, and individual management requires consultation with a sickle cell specialist, orthopedic surgeon, physical therapist, and primary care physician. Initial management should include referral to a pediatric orthopedist and a physical therapist to address strategies to increase strength and decrease weight-bearing daily activities that may exacerbate the pain associated with AVN as well as to determine whether surgical approaches may be beneficial. Opioids are often used but usually can be tapered after the acute pain has subsided. Regular blood transfusion therapy has not been demonstrated as an effective therapy to abate the acute and chronic pain associated with AVN.

Priapism

Priapism, defined as an unwanted painful erection of the penis, affects males of all sickle genotypes but most frequently affects males with sickle cell anemia. The mean age of first episode is 15 years, although priapism has been reported in children as young as 3 years. The actuarial probability of a patient experiencing priapism is approximately 90% by 20 years of age.

Priapism occurs in two patterns: *prolonged*, lasting >4 hours, or *stuttering*, with brief episodes that resolve spontaneously but may occur in clusters and herald a prolonged event. Both types occur from early childhood to adulthood. Most episodes occur between 3 AM and 9 AM. Priapism in sickle cell disease represents a low-flow state caused by venous stasis from RBC sickling in the corpora cavernosa. Recurrent prolonged episodes of priapism are associated with erectile dysfunction (impotence).

The optimal treatment for acute priapism is unknown. Supportive therapy, such as a hot shower, short aerobic exercise, or pain medication, is often used by patients at home. A prolonged episode lasting >4 hours should be treated by aspiration of blood from the corpora cavernosa, followed by irrigation with dilute epinephrine to produce immediate and sustained *detumescence.* Urology consultation is required to initiate this procedure, with appropriate input from a hematologist. Simple blood transfusion with exchange transfusion has been proposed for the acute treatment of priapism, but limited evidence supports this strategy as the initial management. If no benefit is obtained from surgical management, transfusion therapy should be considered. However, detumescence may not occur for up to 24 hours (much longer than with urologic aspiration) after transfusion, and transfusion for priapism has been associated with acute neurologic events. Consultation with a hematologist and urologist will help identify therapies to prevent recurrences.

Neurologic Complications

Neurologic complications associated with sickle cell disease are varied and complex, ranging from acute ischemic stroke with focal neurologic deficit to clinically *silent* abnormalities found on imaging. Before the development of transcranial Doppler ultrasonography to screen for stroke risk among children with sickle cell anemia, approximately 11% experienced an overt stroke before age 20. A functional definition of *overt stroke* is the presence of a focal neurologic deficit lasting for >24 hours and/or abnormal neuroimaging of the brain indicating a cerebral infarct on T2-weighted MRI corresponding to the focal neurologic deficit (Figs. 511.2 and 511.3). A *silent cerebral infarct* lacks focal neurologic findings and is diagnosed by abnormal imaging on T2-weighted MRI. The prevalence of silent infarct among children with HbSS is around 35%. Children with other types of sickle cell disease, such as HbSC or HbSβ$^+$-thalassemia, develop overt or silent cerebral infarcts as well, but at a lower frequency than children with HbSS and HbSβ^0-thalassemia. Other neurologic complications include transient ischemic attacks, headaches that may or may not correlate to degree of anemia, seizures, cerebral venous thrombosis, cerebral vasculopathy, and **posterior reversible encephalopathy syndrome (PRES)**. Chiari I malformations can occur in older children with sickle cell disease. **Fat embolism syndrome** (associated with bone marrow infarction) is a rapidly progressive, potentially fatal complication involving pain, respiratory distress, changes in mental status, and multiorgan system failure. When this syndrome is identified early, exchange transfusion therapy has improved patient survival in small case series. Skull infarction can lead to a subgaleal hematoma or epidural bleed, which may present as altered mental status.

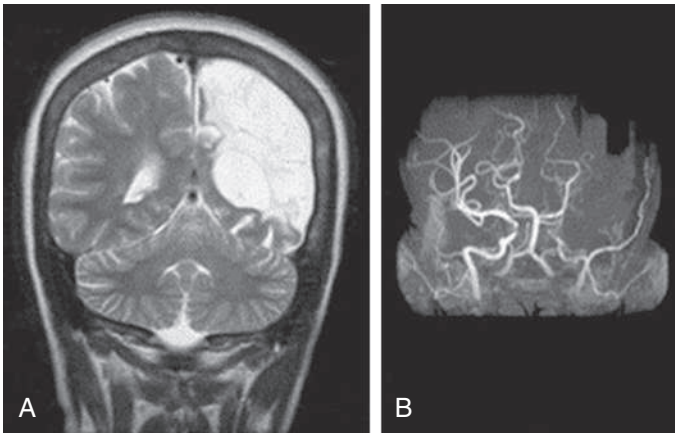

Fig. 511.2 MRI and magnetic resonance angiography (MRA) of the brain. **A**, T2-weighted MRI shows remote infarction of the territories of the left anterior cerebral artery and middle cerebral artery. **B**, MRA shows occlusion of the left internal carotid artery siphon distal to the takeoff of the ophthalmic artery.

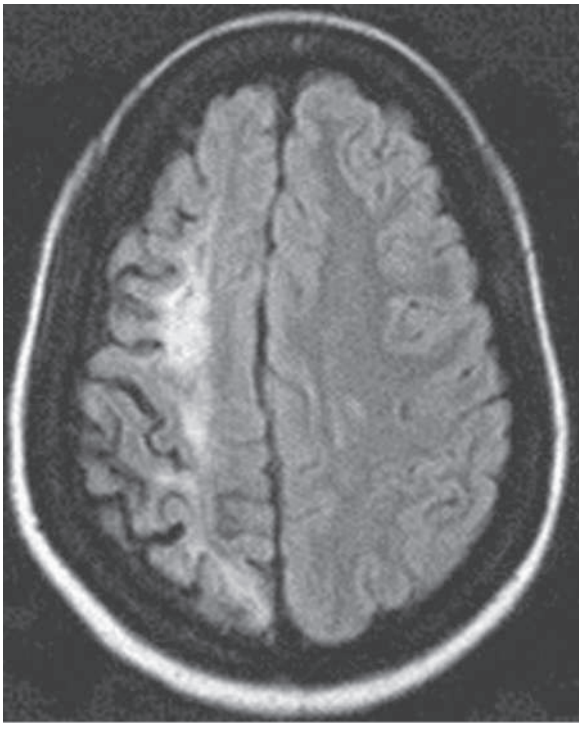

Fig. 511.3 Fast fluid-attenuated inversion recovery sequence MRI of the brain showing a right hemisphere border-zone cerebral infarction in a child with sickle cell anemia. *(From Switzer JA, Hess DC, Nichols F, et al. Pathophysiology and treatment of stroke in sickle-cell disease: present and future. Lancet Neurol 2006;5:501–512.)*

For patients presenting with acute focal neurologic deficit, a prompt pediatric neurologic evaluation and consultation with a pediatric hematologist is recommended. In addition, oxygen administration to keep oxygen saturation (So_2) >96% and blood transfusion within 2 hours of presentation, with a goal of increasing Hb to a maximum of 10 g/dL, is warranted. A timely simple blood transfusion is important because this is the most efficient strategy to dramatically increase oxygen content of the blood, particularly when exchange transfusion is not readily available. However, greatly exceeding this posttransfusion Hb limits oxygen delivery to the brain as a result of hyperviscosity by increasing the Hb significantly over the patient's baseline values. Subsequently, prompt treatment with an exchange transfusion is recommended, either manually or with automated erythrocytapheresis, to reduce the HbS percentage to <30%. Exchange transfusion at the time of acute stroke is associated with a decreased risk of second stroke compared to simple transfusion alone. CT of the head to exclude cerebral hemorrhage should be performed as soon as possible, and, if available, MRI of the brain with diffusion-weighted imaging to distinguish between ischemic infarcts and PRES. MR venography is useful to evaluate the possibility of **cerebral venous thrombosis**, a rare but potential cause of focal neurologic deficit in children with sickle cell disease. MR angiography may identify evidence of cerebral vasculopathy; these images are not critical in the initial time management of a child with sickle cell disease presenting with a focal neurologic deficit but are important for long-term management.

The clinical presentation of PRES or central venous thrombosis can mimic a stroke but would require a different treatment course. For both PRES and cerebral venous thrombosis, the optimal management has not been defined in patients with sickle cell disease, resulting in the need for consultation with both a pediatric neurologist and a pediatric hematologist. The primary approach for **prevention** of recurrent overt stroke is blood transfusion therapy aimed at keeping the maximum HbS concentration <30%. Despite regular blood transfusion therapy, approximately 20% of patients will have a second stroke and 30% of this group will have a third.

Transcranial Doppler Ultrasonography

Primary prevention of overt stroke can be accomplished using screening transcranial Doppler ultrasonography (TCD) assessment of the blood velocity in the terminal portion of the internal carotid and the proximal portion of the middle cerebral artery. Children with sickle cell anemia with an elevated *time-averaged mean maximum* (TAMM) blood flow velocity ≥200 cm/sec (abnormal study) are at increased risk for a cerebrovascular event. A repeat study should be performed within a week to confirm the result. However, a single value ≥220 cm/sec is concerning and does not require repeating before recommending an intervention. A TAMM measurement of <200 but ≥170 cm/sec represents a conditional threshold. A repeat measurement is suggested within a few months because of the high rate of conversion to a TCD velocity >200 cm/sec in this group of patients.

Two distinct methods of measuring TCD velocity are a nonimaging technique and an imaging technique. The *nonimaging* technique was the method used in the stroke prevention trial sponsored by the

National Institutes of Health, whereas most pediatric radiologists in practice use the *imaging* technique. When compared to each other, the imaging technique produces values that are 10–15% below those of the nonimaging technique. The imaging technique uses the *time-averaged mean of the maximum velocity* (TAMX), and this measure is believed to be equivalent to the nonimaging calculation of TAMM. A downward adjustment for the transfusion threshold is appropriate for centers using the imaging method to assess TCD velocity. The magnitude of the transfusion threshold in the imaging technique has not been settled, but a transfusion threshold of a TAMX of 185 cm/sec and a conditional threshold of TAMX of 165 cm/sec seem reasonable. Alternatively, some experts recommend using the same thresholds regardless of technique.

Children with abnormal TCD studies should begin chronic blood transfusion therapy to maintain HbS levels <30% to decrease the risk of first stroke. This strategy results in an over 90% reduction in the rate of overt strokes. Once transfusion therapy is initiated, a subset of patients at low risk for the development of increased TCD values, such as those without MRA-confirmed cerebral vasculopathy, may be able to transition from chronic transfusions to long-term hydroxyurea therapy. Acute stroke risk is decreased when hydroxyurea use and chronic transfusions overlap until a robust therapeutic response to hydroxyurea is achieved.

Pulmonary Complications

Lung disease in children with sickle cell disease is the second most common reason for hospital admission and is associated with significant mortality. **ACS** refers to a life-threatening pulmonary complication of sickle cell disease defined as a new radiodensity on chest radiography. Other clinical definitions include clinical features such as fever, respiratory distress, hypoxia, cough, and chest pain (Fig. 511.4). Even in the absence of respiratory symptoms, very young children with fever should receive a chest radiograph to identify evolving ACS because clinical examination alone is insufficient to identify patients with a new radiographic density. Early detection of ACS may alter clinical management. The radiographic findings in ACS are variable but may include single-lobe involvement, predominantly left lower lobe; multiple lobes, most often both lower lobes; and pleural effusions, either unilateral or bilateral. *ACS may progress rapidly from a simple infiltrate to extensive infiltrates and a pleural effusion.* Therefore continuous pulse oximetry and frequent clinical exams are required, and repeat chest x-ray films may be indicated for progressive hypoxia, dyspnea, tachypnea, and other signs of respiratory distress.

Most patients with ACS do not have a single identifiable cause. Infection is the most well-known etiology, yet only 30% of ACS episodes will have positive sputum or bronchoalveolar culture, and the most common bacterial pathogens are *S. pneumoniae*, *Mycoplasma pneumoniae,* and *Chlamydia* spp. The most frequent event preceding ACS is a painful episode requiring systemic opioid treatment. **Fat emboli** have also been implicated as a cause of ACS, arising from infarcted bone marrow, and can be life-threatening if large amounts are released to the lungs. Fat emboli can be difficult to diagnose but should be considered in any patient with sickle cell disease presenting with rapid onset of respiratory distress and altered mental status changes. Petechial rash may also occur but may be difficult to detect if not carefully sought.

Given that the causes of ACS are varied, recommended management is also multimodal (Table 511.4). The type of opioid, with overuse of morphine being more likely to cause ACS than nalbuphine

Table 511.4 Overall Strategies for the Management of Acute Chest Syndrome

PREVENTION
Incentive spirometry and periodic ambulation in patients admitted for sickle cell pain, surgery, or febrile episodes
Watchful waiting in any hospitalized child or adult with sickle cell disease (pulse oximetry monitoring and frequent respiratory assessments)
Cautious use of intravenous fluids
Intense education and optimum care of patients who have sickle cell anemia and asthma
DIAGNOSTIC TESTING AND LABORATORY MONITORING
Blood cultures, if febrile
Nasopharyngeal samples for viral culture (respiratory syncytial virus, influenza), depending on clinical setting
Complete blood counts every day and appropriate chemistries
Continuous pulse oximetry
Chest radiographs, for persistent or progressive illness
TREATMENT
Blood transfusion (simple or exchange), depending on clinical features; consider maintaining an active type and cross match
Supplemental O_2 for drop in pulse oximetry by 4% over baseline, or values <90%
Empirical antibiotics (third-generation cephalosporin and macrolide)
Continued respiratory therapy (incentive spirometry and chest physiotherapy as necessary)
Bronchodilators and corticosteroids for patients with asthma
Optimum pain control and fluid management

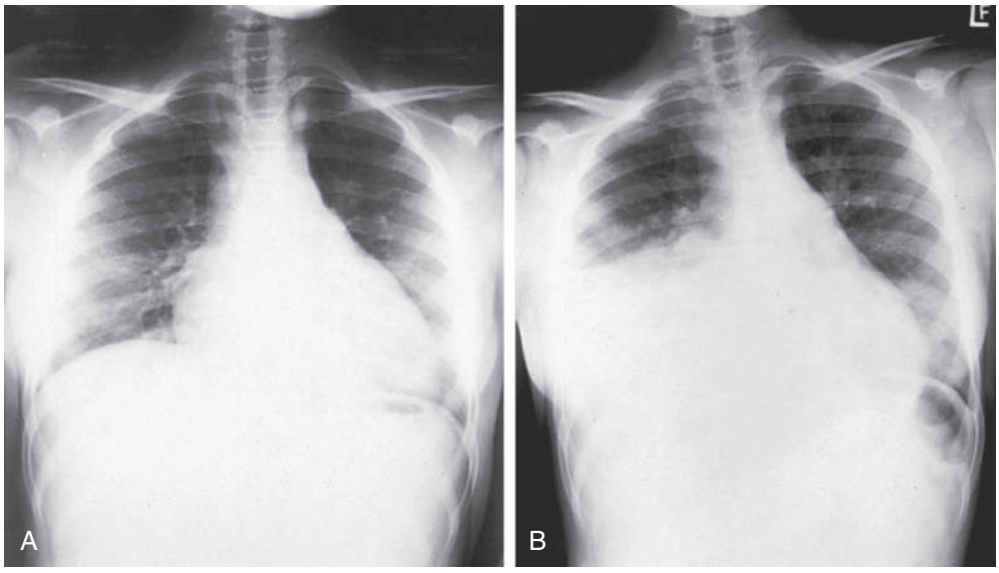

Fig. 511.4 Probable pulmonary infarction in a 15-year-old patient with HbSS. **A,** Frontal radiograph shows consolidation and a small pleural effusion posteriorly in the right lower lobe. **B,** Radiograph obtained <24 hr later shows massive right middle and lower lobe consolidation and effusion. No organisms could be cultured. The diagnosis of "probably pulmonary infarction" was established clinically. *(Courtesy Dr. Thomas L. Stovis, Children's Hospital of Michigan, Detroit. From Kuhn JP, Stovis TL, Haller JO: Caffey's Pediatric Diagnostic Imaging, 10th ed. Philadelphia: Mosby, 2004. p. 1087.)*

hydrochloride, is associated with an increase in the risk of ACS, in part because of sedation and hypoventilation. However, under no circumstance should opioid administration be limited to prevent ACS; rather, other measures must be taken to prevent ACS from developing. In patients with pain, regular use of an **incentive spirometer** at 10-12 breaths every 2 hours can significantly reduce the frequency of subsequent ACS episodes. Because of the clinical overlap between pneumonia and ACS, all episodes should be treated promptly with antimicrobial therapy, including at least a macrolide and a third-generation cephalosporin. A previous diagnosis of asthma or wheezing with ACS should prompt treatment following standard of care for an asthma exacerbation with bronchodilators. The diagnosis of ACS does not negate the recommended management of a patient with asthma exacerbation. Oxygen should be administered for patients who demonstrate hypoxia. Blood transfusion therapy using either simple or exchange (manual or automated) transfusion is the only method to abort a rapidly progressing ACS episode. The decision when to give blood and whether the transfusion should be a simple or exchange transfusion is less clearly defined. Usually, blood transfusions are given when at least one of the following clinical features are present: decreasing So_2, increasing work of breathing, rapidly changing respiratory effort either with or without a worsening chest radiograph, a dropping Hb of 2 g/dL below the patient's baseline, or previous history of severe ACS requiring admission to the intensive care unit.

Pulmonary hypertension has been identified as a major long time risk factor for death in adults with sickle cell anemia. The natural history of pulmonary hypertension in children with sickle cell anemia is unknown. Asymptomatic patients do not require screening for pulmonary hypertension. The initial diagnostic test is an echocardiogram and, depending on the severity of those findings, the echocardiogram should be followed by right-sided heart catheterization. Clinical findings suggestive of pulmonary hypertension include hypoxia or dyspnea at rest or with exertion, comorbid vascular complications (leg ulcers, priapism), elevated N-terminal, pro-B-type natriuretic peptide, or an abnormal 6-minute walk distance.

Renal Disease and Enuresis

Renal disease among patients with sickle cell disease is a major comorbid condition that can lead to premature death. Seven sickle cell disease nephropathies have been identified: gross hematuria, papillary necrosis, nephrotic syndrome, renal infarction, hyposthenuria, pyelonephritis, and renal medullary carcinoma. The presentation of these entities is varied but may include hematuria, proteinuria, renal insufficiency, concentrating defects, or hypertension.

The common presence of **nocturnal enuresis** occurring in children with sickle cell disease is not well defined but is troublesome for affected children and their parents. The overall prevalence of enuresis was 33% in the Cooperative Study of Sickle Cell Disease, with the highest prevalence (42%) among children 6-8 years old. Furthermore, enuresis may still occur in approximately 9% of older adolescents. Patients with sickle cell disease and nocturnal enuresis should have a systematic evaluation for recurrent urinary tract infections, kidney function, and possibly obstructive sleep apnea syndrome. Unfortunately, most children with nocturnal enuresis do not have an etiology, and targeted therapeutic interventions have been of limited success.

Cognitive and Psychologic Complications

Ongoing evaluation of the family unit and identification of the resources available to cope with a chronic illness are critical for optimal management. Children and adolescents with sickle cell disease have decreased quality of life, as measured on standardized assessments, compared to their siblings and children with other chronic diseases. Furthermore, children with sickle cell disease are at great risk for academic failure and have a 20% high school graduation rate, possibly because, among other reasons, approximately one third of children with sickle cell anemia have had a cerebral infarct, either silent or an overt stroke. Early school-age children with sickle cell anemia should have MRI without sedation to screen for silent cerebral ischemia. Children with cerebral infarcts require ongoing cognitive and school performance assessment so that education resources can be focused to optimize educational attainment. Participation in relevant support groups and group activities, such as camps for children with sickle cell disease, may be of direct benefit by improving self-esteem and establishing peer relationships.

Other Complications

In addition to the previous organ dysfunctions, patients with sickle cell disease can have other significant complications. These complications include, but are not limited to, sickle cell retinopathy, delayed onset of puberty, leg ulcers, and complications associated with pregnancy. Optimal treatment for each of these entities has not been determined, and individual management requires consultation with the hematologist and primary care physician. Reproductive health issues are prevalent in children and adolescents with sickle cell disease; therefore hematologists, adolescent medicine teams, and obstetrics/gynecology teams should co-manage patients to provide optimal care.

THERAPEUTIC CONSIDERATIONS

Hydroxyurea

Hydroxyurea is a well-established drug proven effective in reducing the frequency of acute pain episodes. In adults with sickle cell anemia, hydroxyurea decreases the rate of hospitalization for painful episodes by 50% and the rate of ACS and blood transfusion by almost 50%. In addition, adults taking hydroxyurea have shorter hospitalizations and require less analgesic medication during hospitalization.

In children with sickle cell anemia, hydroxyurea is safe and well tolerated. The primary toxicities are limited to myelosuppression that reverses on cessation of the drug. Infants treated with hydroxyurea experience fewer episodes of pain, dactylitis, and ACS; are hospitalized less frequently; and less often require a blood transfusion. Infants treated with hydroxyurea do not experience increased rates of bacteremia or serious infection.

Current recommendations are that all children with sickle cell anemia should be offered hydroxyurea beginning at 9 months of age. Hydroxyurea may be indicated for other sickle cell–related complications, especially in patients who are unable to tolerate other treatments. For patients who either will not or cannot continue blood transfusion therapy to prevent recurrent stroke, hydroxyurea therapy may be a reasonable alternative. The trial assessing the efficacy of hydroxyurea as an alternative to transfusions to prevent a *second* stroke was terminated early after the data safety and monitoring process found an increased stroke rate in the hydroxyurea arm compared to the transfusion arm. Hydroxyurea alone is inferior to transfusion therapy for secondary stroke prevention in patients who do not have contraindications to ongoing transfusions.

The long-term toxicity associated with initiating hydroxyurea in very young children has not yet been established. However, all evidence to date suggests that the benefits far outweigh the risks. For these reasons, very young children starting hydroxyurea require well-informed parents and medical care by pediatric hematologists, or at least co-management by a physician with expertise in immunosuppressive medications. The typical starting dose of hydroxyurea is 15-20 mg/kg once daily, with an incremental dosage increase every 8 weeks of 5 mg/kg, and if no toxicities occur, up to a maximum of 35 mg/kg per day. The infant hydroxyurea study found young children could safely be started at 20 mg/kg/day without increased toxicity. Achievement of the therapeutic effect of hydroxyurea can require several months, and for this reason, initiating hydroxyurea to address short-term symptom relief is not optimal. We prefer to introduce the concept to parents within the first year of life, preferably by 9 months; provide literature that describes both the pros and cons of starting hydroxyurea in children with severe symptoms of sickle cell disease; and educate parents on starting hydroxyurea in asymptomatic children as a preventive therapy for repetitive pain and ACS events. Other effects of hydroxyurea that may vary include an increase in the total Hb level and a decrease in the TCD velocity.

Other medications are available for long-term use in children and adults with sickle cell disease. **Oral L-glutamine** reduces hospitalizations and sickle cell crisis in children age 5 years and older. In addition, **crizanlizumab**, a humanized P-selectin inhibitor administered

monthly IV, is indicated for reducing acute pain in adults and children age 16 years and older. **Voxelotor**, a sickle hemoglobin polymerization inhibitor, is FDA-approved for adults and children 4 years and older. In clinical trials, Voxelotor demonstrated reduced hemolysis in patients with sickle cell disease.

Gene Therapy

The FDA (2023) has approved two different gene therapy approaches to ex vivo gene modification of autologous hematopoietic stem and progenitor cells following myeloablative conditioning. Both therapies are approved for patients ≥12 years of age with recurrent vasoocclusive crises.

Casgevy (exagamglogene autotemcel: exa-cel), involves *gene editing* with CRISPR/Cas9 (clustered regularly interspaced short palindromic repeats / CRISPR associated nuclease 9). Exa-cel specifically targets and inactivates the red cell precursor *BCL11A* gene (a suppressor of fetal hemoglobin expression), which results in increased production of fetal hemoglobin (which does not sickle), resulting in decreased polymerization of sickle hemoglobin.

Lyfgenia (lovotibeglogene autotemcel: lovo-cel) is a *gene addition* approach using a lentiviral vector carrying a modified beta globin gene (beta-A-T87Q globin), thus increasing the levels of hemoglobin A.

Both have been successful in reducing or eliminating vasoocclusive crises after therapy. Lyfgenia has a black box warning for the risk of off target editing /insertional mutagenesis and the possibility of acute myeloid leukemia.

Hematopoietic Stem Cell Transplantation

The only currently approved cure for sickle cell anemia is transplantation with human leukocyte antigen (HLA)–matched hematopoietic stem cells from a sibling donor (allogenic) without sickle cell disease. Because of the limited availability of appropriate sibling donors, research is exploring a wide variety of curative regimens. Clinical trials are underway to explore unrelated and partially matched related donor stem cell transplants.

The most common indications for allogenic transplant are recurrent ACS, stroke, and abnormal TCD. Sibling-matched stem cell transplantation has a lower risk for graft-versus-host disease than unrelated donors. Surveys suggest that younger children may have lower morbidity and mortality. The decision to consider unrelated transplantation should involve appropriate consultation and counseling from physicians with expertise in sickle cell transplantation.

Stem cell transplantation for children with sickle cell disease who have a genetically matched sibling and *few complications* is less commonly performed. The use of hydroxyurea has dramatically decreased the disease burden for the patient and family, with far fewer hospitalizations for pain or ACS episodes and less use of blood transfusions. The field of stem cell transplantation is also progressing such that larger studies involving nonsibling donor and haploidentical donor transplantation. Transplant-related complications caused by conditioning regimens may be decreased by using low-intensity, nonmyeloablative HLA-matched sibling, allogenic stem cell transplantation.

Red Blood Cell Transfusions

RBC transfusions are used frequently both in the treatment of acute complications and to prevent acute or recurrent complications. Typically, short-term transfusions are used to prevent progression of acute complications such as ACS, aplastic crisis, splenic sequestration, and acute stroke, as well as to prevent surgery-related ACS. RBC transfusions are not recommended for uncomplicated acute pain events. Select RBC volumes judiciously to avoid high posttransfusion Hb levels and hyperviscosity. Long-term or chronic transfusion therapy is used to prevent first stroke in patients with abnormal TCD or MRI findings (silent stroke), recurrent stroke, or recurrent ACS. Patients with sickle cell disease are at increased risk of developing *alloantibodies* to less common RBC surface antigens after receiving even a single transfusion. In addition to standard cross matching for major blood group antigens (A, B, O, RhD), more *extended matching* should be performed to identify donor units that are C-, E-, and Kell-antigen matched. Full RBC antigen phenotyping or genotyping for all patients with sickle cell disease should be performed before RBC transfusion whenever possible to have the RBC units least likely to result in alloimmunization available for these patients.

Three methods of **blood transfusion therapy** are used in the management of acute and chronic complications associated with sickle cell disease: automated erythrocytapheresis, manual exchange transfusion (phlebotomy of a set amount of patient's blood followed by rapid administration of donated packed RBCs), and simple transfusion. The decision on which method to use depends on the patient's pretransfusion Hb level, the clinical indication, RBC alloimmunization, and transfusional iron overload. Exchange transfusion, manual or automated, is preferable for patients with new neurologic symptoms. *Automated erythrocytapheresis* is the preferred method for patients requiring chronic blood transfusion therapy because there is a minimum net iron balance after the procedure, followed by manual exchange transfusion. However, this method requires technical expertise, special machines, and good patient venous access. *Manual exchange* is more accessible. However, both methods may expose the patient to more RBC units and possible alloimmunization. *Simple transfusion* therapy may lower donor exposure and be more readily available but may result in higher net iron burden when compared to erythrocytapheresis or exchange transfusion.

Preparation for surgery for children with sickle cell disease requires a coordinated effort from the hematologist, surgeon, anesthesiologist, and primary care provider. Historically, ACS was associated with general anesthesia in patients with sickle cell disease. Blood transfusion before surgery for children with sickle cell disease is recommended to raise Hb level preoperatively to no more than 10 g/dL, to avoid ACS development. Because of better general perioperative care and the use of long-term therapies such as hydroxyurea and chronic transfusions, the decision to transfuse before general anesthesia should be made in conjunction with the medical team who provides sickle cell disease–related care for the patient. When preparing a child with sickle cell disease for surgery with a simple blood transfusion, caution must be used not to elevate Hb level beyond 10 g/dL because of the risk of hyperviscosity syndrome. For children with milder forms of sickle cell disease, such as HbSC or HbSβ-thalassemia, a decision must be made on a case-by-case basis as to whether an exchange transfusion is warranted because a simple transfusion may raise the hemoglobin to an unacceptable level.

Iron Overload

The primary toxic effect of blood transfusion therapy relates to excessive iron stores or iron overload, which can result in organ damage and premature death. Excessive iron stores develop after 100 mL/kg of RBC transfusion, or about 10 transfusions. The assessment of iron overload in children receiving regular blood transfusions is difficult. *The most common and least invasive method of estimating total body iron involves serum ferritin levels.* Ferritin measurements have significant limitations in their ability to estimate iron stores for several reasons, including, but not limited to, elevation during acute inflammation and poor correlation with excessive iron in specific organs, such as the heart and endocrine glands. MRI of the liver has proved to the most effective approach for assessment of iron stores. MRI T2* and MRI R2 and R2* sequences are used to estimate iron levels in the heart and liver. These imaging strategies are more accurate than serum ferritin in estimating heart and liver iron content. The standard for iron assessment previously was liver biopsy, which is an invasive procedure exposing children to the risk of general anesthesia, bleeding, and pain. Liver biopsy alone does not accurately estimate total body iron because iron deposition in the liver is not homogeneous and does not always correlate with iron levels in the heart and other organs. The major advantage of a liver biopsy is that histologic assessment of the parenchyma can be ascertained along with appropriate staging of suspected pathology, particularly cirrhosis.

The primary **treatment** of transfusion-related iron overload requires iron chelation using medical therapy. In the United States, three chelating agents are approved for use in transfusional iron overload. *Deferoxamine* is administered subcutaneously 5 of 7 nights/week over 8 to 12 hours a night. *Deferasirox* is taken by mouth daily, and *deferiprone* is available in tablet forms taken orally twice or three times a day and an oral solution taken three times a day. The FDA approved *deferasirox* for use in patients

age ≥2 years. A pill formulation of deferasirox is available that does not require mixing before oral administration. A sprinkle formulation that is mixed with a soft food such as applesauce also is available for young children who are unable to swallow pills. *Deferiprone* is an older oral chelator that has been widely used outside the United States for many years and was also approved as a first-line agent (see Table 511.8). Because of a 1–2% risk of agranulocytosis, weekly CBC monitoring is recommended, particularly in the first 6 months of treatment and with any febrile illness. Transfusion-related excessive iron stores in children with sickle cell disease should be managed by a physician with expertise in chelation therapy because of the need for close monitoring and due to the risk of significant toxicity from available chelation therapies.

OTHER SICKLE CELL SYNDROMES

The most common sickle cell syndromes besides HbSS are HbSC, HbSβ^0-thalassemia, and HbSβ^+-thalassemia. The other syndromes—HbSD, HbSO^{Arab}, HbSHPFH, HbSE, and other variants—are much less common. Patients with HbSβ^0-thalassemia have a clinical phenotype similar to those with HbSS. In the RBCs of patients with HbSC, crystals of HbC interact with membrane ion transport, dehydrating RBCs and inducing sickling. Children who have HbSC disease can experience the same symptoms and complications as those with severe HbSS disease, but less frequently. Children with HbSC have increased incidence of retinopathy, chronic hypersplenism, and acute splenic sequestration over the life span. The natural history of the other sickle cell syndromes is variable and difficult to predict because of the lack of systematic evaluation.

There is no validated model that can predict the clinical course of an individual with sickle cell disease. A patient with HbSC can have a more severe clinical course than a patient with HbSS. Management of end-organ dysfunction in children with sickle cell syndromes requires the same general principles as managing patients with sickle cell anemia; however, each situation should be managed on a case-by-case basis and requires consultation with a pediatric hematologist.

ANTICIPATORY GUIDANCE

Children with sickle cell disease should receive general health maintenance as recommended for all children, with special attention to disease-specific guidance and infection prevention education. In addition to counseling regarding adherence to penicillin and a vaccination schedule, patients, parents, and caregivers should be instructed to seek immediate medical attention for all febrile illness. In addition, early detection of acute splenic sequestration has been shown to decrease mortality. Therefore parents and caregivers should be educated early and repeatedly about the importance of daily penicillin administration and correct palpation of the spleen.

Prophylactic Penicillin

Children with sickle cell anemia should receive prophylactic oral penicillin VK until at least 5 years of age (125 mg twice daily up to age 3 years, then 250 mg twice daily thereafter). No established guidelines exist for penicillin prophylaxis beyond 5 years of age; some clinicians continue penicillin prophylaxis, and others recommend discontinuation. Penicillin prophylaxis should be continued beyond 5 years in children with a history of pneumococcal infection because of the increased risk of a recurrent infection. An alternative for children who are allergic to penicillin is erythromycin ethylsuccinate.

Immunizations

In addition to penicillin prophylaxis, routine childhood immunizations, as well as the annual administration of influenza vaccine, are highly recommended. Children with sickle cell disease develop functional asplenia and also require immunizations to protect against encapsulated organisms, including additional pneumococcal and meningococcal vaccinations. The U.S. Centers for Disease Control and Prevention (CDC) provides vaccination guidelines at https://www.cdc.gov/vaccines/hcp/acip-recs/index.html.

Spleen Palpation

Splenomegaly is a common complication of sickle cell disease, and splenic sequestration can be life threatening. Parents and primary caregivers should be taught how to palpate the spleen to determine if the spleen is enlarging starting at the first visit, with reinforcement at subsequent visits. Parents should also demonstrate spleen palpation to the provider.

Transcranial Doppler Ultrasound

Primary stroke prevention using TCD has resulted in a decrease in the prevalence of overt stroke among children with sickle cell anemia. Children with HbSS or HbSβ^0-thalassemia should be screened annually with TCD starting at age 2 years. TCD is best performed when the child is quietly awake and in their usual state of health. TCD measurements may be falsely elevated or decreased in the settings of acute anemia, sedation, pain, fever, or immediately after blood transfusions. Screening should occur annually from ages 2-16 years. Abnormal values should be repeated within a week to identify patients at greatest risk of overt stroke. Conditional values should be repeated within at least 3 months, and normal values should be repeated annually. Routine neuroimaging with MRI in asymptomatic patients requires consultation with a pediatric hematologist or neurologist with expertise in sickle cell disease.

Hydroxyurea

Recommendations include offering hydroxyurea therapy to all children with sickle cell anemia starting at 9 months of age regardless of clinical symptoms. Monitoring children receiving hydroxyurea is labor intensive. Hydroxyurea is a chemotherapeutic agent, and patients receiving this agent require the same level of nursing and physician oversight as any child with cancer receiving chemotherapy. The parents must be educated about the consequences of therapy, and when ill, children should be promptly evaluated. Starting doses should be approximately 20 mg/kg/day. CBC with differential and reticulocyte count should be checked within 4 weeks after initiation of therapy or any dose change to monitor for hematologic toxicity, then every 8-12 weeks. Dose escalation should be based on clinical and laboratory parameters. If appropriate, dose increases should be in 5 mg/kg/day increments to a maximum of 35 mg/kg/day.

While receiving hydroxyurea, steady-state absolute neutrophil count should be approximately 2,000/μL or higher and platelet count should be 80,000/μL or higher. However, children may tolerate lower absolute neutrophil counts while receiving hydroxyurea. Holding hydroxyurea and adjusting to lower doses may be required for neutropenia and thrombocytopenia. Hydroxyurea is a pregnancy class D medication, and adolescents should be counseled regarding methods to prevent pregnancy while taking this medication. Close monitoring of the patient requires a commitment by the parents and the patient as well as diligence by a physician to identify toxicity early. Information is scarce regarding the impact of hydroxyurea on fertility, although hydroxyurea has been shown to further reduce sperm count in males with sickle cell disease in several case reports; this effect may be reversible once hydroxyurea is discontinued.

Red Cell Transfusion Therapy

At the initiation of blood transfusion therapy, children with sickle cell disease should have testing to identify the presence of alloantibodies and RBC phenotyping or genotyping, which is performed to identify the best matched blood. RBC units selected should be extended antigen-matched for C, E, and K, when feasible. Goals of transfusion for acute events should be established before initiating therapy, including target posttransfusion Hb level and HbS percentage, or both. For children receiving chronic transfusion therapy, pretransfusion HbS goals should be defined; the most common goal is <30%. Posttransfusion Hb values should be targeted to avoid hyperviscosity. Children, parents, and caregivers should be educated about the symptoms of delayed hemolytic transfusion reactions. Any child with sickle cell disease with a recent history of RBC transfusion who presents with pain, dark urine, increased scleral icterus, or symptoms of worsening anemia should be screened for a delayed hemolytic transfusion reaction after consultation with the blood bank. Children meeting criteria for chronic transfusion therapy should receive annual evaluation for transfusion-transmitted infections, including hepatitis B, hepatitis C, and HIV. After receiving 100 mL/kg RBC transfusions, regular assessments of iron overload should begin, usually including measurements of serum ferritin and MRI assessments for hepatic iron every 1-2 years. Cardiac iron assessments should be

performed in children over 10 years old, especially if there is a history of poor adherence with iron chelation and/or liver iron concentration of 15 mg/g dry weight or higher. For children requiring chelation therapy, audiology and ophthalmology exams should be performed annually and monitoring of liver function and pituitary function performed regularly because of iron deposition.

Pulmonary and Asthma Screening

Pulmonary complications of sickle cell disease are common and life threatening. Asthma is common in children with sickle cell disease, and thus evaluation for asthma symptoms and asthma risk factors should be performed routinely, particularly given the high morbidity and mortality. All children should receive annual screening for signs and symptoms of lower airway disease, such as nighttime cough and exercise-induced cough. In children with symptoms consistent with lower airway disease, consultation with an asthma specialist should be considered. Pulse oximetry readings should be performed during well visits to identify children with abnormally low daytime oxygen saturation. For children with snoring, daytime somnolence, and symptoms associated with obstructive sleep apnea syndrome (OSAS), sleep studies should be performed as necessary.

Retinopathy

Effective therapy is available for retinopathy associated with sickle cell disease. Although all patients are at risk for development of retinopathy, those with sickle cell disease, type SC, are at very high risk. Patients should receive annual screening by an ophthalmologist to identify vascular changes that would benefit from laser therapy. Although changes may occur earlier, children with sickle cell disease should begin annual screenings no later than age 10 years.

Renal Disease

Sickle cell–associated renal disease starts in infancy and may not become clinically evident until adulthood. Chronic kidney disease is common in adults with sickle cell disease, with high morbidity and mortality. Screening protocols for early signs of sickle nephropathy in children have not been adopted due to lack of data. However, when creatinine elevation, microalbuminuria, or macroalbuminuria is detected, a nephrologist should be consulted to determine next steps for further evaluation and possible treatment. The age to begin screening for proteinuria has not been defined, but some experts recommend screening annually after at least 10 years, if not sooner. If proteinuria is detected, urine studies should be repeated with an early-morning urine collection; if the protein remains elevated, the patient should be referred to a pediatric nephrologist. Males with sickle cell disease should also receive counseling regarding the diagnosis and treatment of priapism. Because of the high frequency of enuresis beyond early childhood, approximately 9% between 18 and 20 years of age, parents and caregivers should be educated about the prolonged nature of enuresis in this disease. OSAS is associated with an increased prevalence of enuresis in sickle cell disease. Unfortunately, no evidence-based therapies have been developed to treat enuresis in children and young adults with sickle cell disease. In children with enuresis who have symptoms and clinical features of OSAS, referral to specialists for evaluation is recommended.

Echocardiography

Echocardiography is a screening tool to identify individuals with sickle cell disease who have pulmonary artery hypertension (see the section on "Pulmonary Hypertension"). Studies in adults with sickle cell disease have found that echocardiography is insensitive at identifying individuals truly at risk for pulmonary hypertension, although an elevated tricuspid velocity measurement may still be a risk factor for premature death in adults with sickle cell disease. Routine echocardiograms for pulmonary hypertension screening are not recommended in asymptomatic children; however, they are recommended in patients with leg ulcers, priapism, and connective tissue disease, as well as referral to a pulmonary hypertension specialist for patients with new steady-state cardiorespiratory symptoms, heart failure, or pulmonary embolus.

Additional Screening

Patients with sickle cell disease are at increased risk for behavioral health issues, including anxiety and depression. Screening should be performed at routine and acute visits. AVN of the hips and shoulders is increased in patients with sickle cell disease and may be identified early on routine physical exam. Plain radiographs may not detect early disease; thus, when AVN is suspected and plain films are normal, MRI should be obtained. When AVN is confirmed, patients should be referred promptly to orthopedics and physical therapy.

511.2 Sickle Cell Trait (Hemoglobin AS)

Kim Smith-Whitley and Janet L. Kwiatkowski

The prevalence of sickle cell trait varies throughout the world; in the United States, the incidence is 7–10% of the Black population. Because all state newborn screening programs include sickle cell disease, for most children, sickle cell trait is first identified on their newborn screen. Communication of sickle cell trait status from infancy to young adulthood for the affected individual, family, and healthcare providers is often inconsistent, and many young adults are unaware of their sickle cell trait status.

By definition, among individuals with sickle cell trait, the HbS level is <50%. The life span of people with sickle cell trait is normal, and serious complications are extremely rare. The CBC is within the normal range (Fig. 511.5B). Hemoglobin analysis is diagnostic, revealing a predominance of HbA, typically >50%, and HbS <50%. Rare complications of sickle cell trait may exist. Sickle cell trait is reported to be associated with exertional rhabdomyolysis in military recruits, and possibly with sudden death during rigorous exercise. However, whether these reports establish sickle cell trait as a risk factor that is nonmodifiable by other genetic factors remains unclear. Other complications reported with sickle cell trait include splenic infarction at high altitude, hematuria, hyposthenuria, deep vein thrombosis, and susceptibility to progressive eye injury after hyphema (Table 511.5). Renal medullary carcinoma has been reported almost exclusively in individuals with sickle cell trait and occurs predominantly in young people.

Children with sickle cell trait do not require limitations on physical activities as long as provisions are made for frequent rest and oral hydration, particularly when participating in physical conditioning or competitive sports. **Sudden death** in persons with sickle cell trait while exercising under extreme conditions is most likely associated with a second genetic factor and/or environmental factors and not the presence of sickle cell trait itself. However, if **exertional rhabdomyolysis** is identified, evaluation by neurology and cardiology should be considered. No causal pathway has been implicated for the presence of sickle cell trait and sudden death. All patients with sickle cell trait who participate in rigorous athletic activities should receive maximum hydration and appropriate rest during exertion, as would be the precautionary steps for all athletes, particularly when participating in hot, humid conditions. The presence of sickle cell trait should never be a reason to exclude a person from athletic participation but rather should serve as an indication that prudent surveillance is necessary to ensure appropriate hydration and prevention of exhaustion from heat or other strenuous exercise. If athletes are to be screened for sickle cell trait, the appropriate procedure is testing using a hemoglobin electrophoresis followed by genetic counseling, along with the knowledge that genetic information may provide opportunities to challenge paternity. Such situations are typically handled by a pediatrician or hematologist accustomed to providing both a balanced approach to genetic counseling and addressing the challenges about paternity.

511.3 Other Hemoglobinopathies

Kim Smith-Whitley and Janet L. Kwiatkowski

HEMOGLOBIN C

The pathogenic variant for HbC is at the same site as in HbS, with substitution of lysine instead of valine for glutamine. In the United States, hemoglobin C trait **(HbAC)** occurs in 1:40 and homozygous hemoglobin C disease **(HbCC)** occurs in 1:5,000 of the Black population. HbAC is asymptomatic. HbCC can result in mild anemia, splenomegaly, and cholelithiasis; rare cases of spontaneous splenic rupture have been reported. Splenic dysfunction does not occur. This condition is usually diagnosed through newborn screening programs. HbC crystallizes, disrupting the red cell membrane, and HbC crystals may be visible on peripheral smear (see Fig. 511.5C).

HEMOGLOBIN E

Hemoglobin E is an abnormal hemoglobin resulting from a qualitative pathogenic variant in the β-globin gene and is the second most common globin pathogenic variant worldwide. Patients may have asymptomatic hemoglobin E trait **(HbAE)** or benign homozygous hemoglobin E disease **(HbEE)**. Compound heterozygous hemoglobin E/β-thalassemia produces clinical phenotypes ranging from moderate to severe anemia, depending on the β-thalassemia pathogenic variant. In California, HbE/β-thalassemia is found almost exclusively in persons of Southeast Asian descent, with a prevalence of 1:2,600 births.

HEMOGLOBIN D

At least 16 variants of hemoglobin exist. HbD-Punjab (Los Angeles) is a rare hemoglobin that is seen in 1–3% of Western Indians and in some Europeans with Asian-Indian ancestry and produces symptoms of sickle cell disease when present in combination with HbS. Heterozygous HbD or hemoglobin D trait **(HbAD)** is clinically silent. Homozygous hemoglobin D disease **(HbDD)** produces a mild to moderate anemia with splenomegaly.

511.4 Unstable Hemoglobin Disorders

Kim Smith-Whitley and Janet L. Kwiatkowski

At least 200 rare unstable hemoglobins have been identified; the most common is **Hb Köln**. Most patients seem to have de novo pathogenic variants rather than inherited hemoglobin disorders. The best-studied unstable hemoglobins are the ones leading to hemoglobin denaturation from pathogenic variants affecting heme binding. The denatured hemoglobin can be visualized during severe hemolysis or after splenectomy as **Heinz bodies**. Unlike the Heinz bodies seen after toxic exposure, in unstable hemoglobins, Heinz bodies are present in reticulocytes and older RBCs (see Fig. 511.5D). Heterozygotes are asymptomatic.

Children with homozygous gene pathogenic variants can present in early childhood with anemia and splenomegaly or with unexplained hemolytic anemia. Hemolysis is increased with febrile illness and with the ingestion of oxidant medications (similar to glucose-6-phosphate dehydrogenase [G6PD] deficiency [see Chapter 512.3]) with some unstable hemoglobins. If the spleen is functional, the blood smear can appear almost normal or have only hypochromasia and basophilic stippling. A diagnosis may be made by demonstrating Heinz bodies, Hb instability, or an abnormal Hb analysis (although some unstable hemoglobins have normal mobility and are not detected on Hb analysis).

Treatment is supportive. Transfusion may be required during hemolytic episodes in severe cases. Oxidative drugs should be avoided, and folate supplementation may be helpful if dietary deficiency is a concern. Splenectomy may be considered in patients requiring recurrent transfusion or demonstrating poor growth, but the complications of splenectomy, including bacterial sepsis, risk of thrombosis, and risk of developing pulmonary hypertension, should be considered before surgery.

511.5 Abnormal Hemoglobins with Increased Oxygen Affinity

Kim Smith-Whitley and Janet L. Kwiatkowski

More than 110 high-affinity hemoglobins have been characterized. These pathogenic variants affect the state of Hb configuration during oxygenation and deoxygenation. Hemoglobin changes structure when in the oxygenated versus the deoxygenated state. The deoxygenated state is termed the **T (tense) state** and is stabilized by 2,3-diphosphoglycerate. When fully oxygenated, hemoglobin assumes the **R (relaxed) state**. The exact molecular interactions between these two states are unknown. High-affinity hemoglobins contain pathogenic variants that either stabilize the R form or destabilize the T form. The interactions between the R and T forms are complex, and the mechanisms of the pathogenic variants are not known. In most cases, the high-affinity hemoglobins can be identified by Hb analysis; approximately 20% must be characterized under controlled conditions where measurements are obtained with the P_{50} lowered to 9-21 mm Hg (normal: 23-29 mm Hg). The decreased P_{50} in these hemoglobins leads to an erythrocytosis with Hb levels of 17-20 g/dL. Levels of erythropoietin and 2,3-DPG are normal. Patients are usually asymptomatic and do not need phlebotomy. If phlebotomy is performed, oxygen delivery could be problematic because of the reduced number of Hb molecules to carry oxygen.

511.6 Abnormal Hemoglobins Causing Cyanosis

Kim Smith-Whitley

Abnormal hemoglobins causing cyanosis, also called **structural methemoglobinemias**, are rare. They are referred to as **M hemoglobins** and represent a group of hemoglobin variants that result from point pathogenic variants in one of the globin chains, α, β, or γ, located in the heme pocket; 13 known variants exist. These unstable hemoglobins lead to hemolytic anemia, most pronounced when the β-globin gene is affected. Clinically, these children are cyanotic from birth, without other signs or symptoms of disease, if the pathogenic variant is in the α-**globin** gene (HbM Boston, HbM Iwate, Hb Auckland). Infants with β-**globin** pathogenic variants become cyanotic later in infancy after the fetal hemoglobin switch (HbM Saskatoon, HbM Chile, HbM Milwaukee 1 and 2). The γ-**chain** pathogenic variants (HbF-M Fort Ripley, HbF-M Osaka, HbF Cincinnati, HbF Circleville, HbF Toms River, HbF Viseu) are all transient, presenting with cyanosis at birth, which resolves during the neonatal period after HbF production discontinues.

The abnormal M hemoglobins exhibit autosomal dominant inheritance and are diagnosed by Hb analysis. HbM variants may not be isolated reliably using Hb analysis (HPLC or IEF); consequently, diagnostic confirmation may require DNA sequencing or mass spectrometry. There is no specific treatment and affected patients do not respond to treatments used for *enzyme-deficient methemoglobinemia*. Beyond cyanosis, individuals are otherwise asymptomatic and do not require additional monitoring. Children with the β-globin form should avoid oxidant drugs. Individuals with all forms have a normal life expectancy and pregnancy course.

Low-affinity hemoglobins have less cyanosis than the M hemoglobins. The amino acid substitutions destabilize the oxyhemoglobin and lead to decreased oxygen saturation. The best characterized are Hb Kansas, Hb Beth Israel, and Hb Denver. Hb analysis (IEF and HPLC techniques) may be normal in affected individuals. When clinically suspected, oxygen affinity studies reveal a right-shifted dissociation curve, and heat testing demonstrates unstable hemoglobin. Children present with mild cyanosis only.

511.7 Hereditary Methemoglobinemia

Kim Smith-Whitley and Janet L. Kwiatkowski

Hereditary methemoglobinemia is a clinical syndrome caused by an increase in the serum concentration of methemoglobin either because of congenital changes in hemoglobin synthesis or of metabolism leading to imbalances in reduction and oxidation of hemoglobin. The iron molecule in hemoglobin is normally in the ferrous state (Fe^{2+}), which is essential for oxygen transport. Under physiologic conditions, there is a slow, constant loss of electrons to released oxygen, and the ferric (Fe^{3+}) form combines with water, producing **methemoglobin (MetHb)**. The newly formed MetHb has a reduced ability to bind oxygen.

Two pathways for MetHb reduction exist. The physiologic and predominant pathway is a reduced form of nicotinamide adenine dinucleotide (NADH)–dependent reaction catalyzed by cytochrome b5 reductase. This mechanism is >100-fold more efficient than the production of MetHb. The alternate pathway uses NAD phosphate generated by G6PD in the hexose monophosphate shunt and requires an extrinsic electron acceptor to be activated (i.e., methylene blue, ascorbic acid, riboflavin). In normal individuals, oxidation of hemoglobin to MetHb occurs at a slow rate, 0.5–3%, which is countered by MetHb reduction to maintain a steady state of 1% MetHb.

MetHb may be increased in the RBC because of exposure to toxic substances or to absence of reductive pathways, such as NADH-cytochrome b5 reductase deficiency. **Toxic methemoglobinemia** is much more common than hereditary methemoglobinemia (Table 511.6). Infants are exceptionally vulnerable to hemoglobin oxidation because their erythrocytes have half the amount of cytochrome b5 reductase seen in adults, hemoglobin F is more susceptible to oxidation than hemoglobin A, and the more alkaline infant gastrointestinal (GI) tract promotes the growth of nitrite-producing gram-negative bacteria. When MetHb levels are >1.5 g/24 hours, cyanosis is visible (15% MetHb); a level of 70% MetHb is lethal. The MetHb level is usually reported as a percentage of normal hemoglobin, and the toxic level is lower at a lower Hb level. Methemoglobinemia has been described in infants who ingested foods and water high in **nitrates**, who were exposed to aniline teething gels or other chemicals, and in some infants with severe gastroenteritis and acidosis. Methemoglobin can color the blood brown (Fig. 511.6). A patient with significant methemoglobinemia is cyanotic and does not respond to 100% oxygen. Arterial oxygen tension will be normal or elevated (if on high FiO_2) despite cyanosis, but blood oxygen saturation determined by multiwavelength co-oximetry will be low. Oxygen saturation calculated from arterial blood gas or pulse oximetry is misleading and inaccurate. Although pulse oximetry is usually lower than normal, it does not reflect the true degree of desaturation.

511.8 Hereditary Methemoglobinemia with Deficiency of NADH Cytochrome b5 Reductase

Kim Smith-Whitley

The first reported inherited disorder causing methemoglobinemia resulted from an enzymatic deficiency of NADH cytochrome b5

Sulfonamides
MEDICAL CONDITIONS
Pediatric gastrointestinal infection, sepsis
Recreational drug overdose with amyl nitrate ("poppers")
Sickle cell disease–related painful episode
MISCELLANEOUS
Aniline dyes
Fume inhalation (automobile exhaust, burning of wood and plastics)
Herbicides
Industrial chemicals: nitrobenzene, nitroethane (found in nail polish, resins, rubber adhesives)
Pesticides
Gasoline octane booster
Nitrate rich vegetables (beets, borage, chard)
Well water

From Ash-Bernal R, Wise R, Wright SM. Acquired methemoglobinemia. *Medicine (Baltimore)* 2004;83:265–273.

Fig. 511.6 Normal arterial blood vs methemoglobinemia. Arterial whole blood with 1% methemoglobin *(left)* vs arterial whole blood with 72% methemoglobin *(right)*. Note the characteristic chocolate-brown color of the sample with an elevated methemoglobin level. Both samples were briefly exposed to 100% oxygen and shaken. This quick analysis is a good bedside test for methemoglobinemia. The sample on the *left* turned bright red, whereas the sample on the *right* remained chocolate-brown. *Methods:* Whole blood samples were drawn at the same time from the same person. The measured hemoglobin concentration was 11.7 g/dL. Calculated concentration of methemoglobin: 11.7 g/dL × 0.01 = 0.117 g/dL *(left)* and 11.7 g/dL × 0.72 = 8.42 g/dL *(right)*. An elevated methemoglobin level was made in vitro by adding 0.1 mL of a 0.144 molar solution of sodium nitrate *(right),* and 0.1 mL of normal saline was added as a control *(left)*. Co-oximetry measurements were taken on both samples shortly after the blood was drawn and 20 min after the addition of sodium nitrate solution. Both blood samples were exposed to 100% oxygen before the second measurement. *(Protocol based on personal communication with Dr. Ali Mansouri, December 2002.)*

reductase, which was classified into two distinct phenotypes. **In type I**, the most common form, the deficiency of NADH cytochrome b5 activity is found only in erythrocytes, with other cell types unaffected. In **type II,** the enzyme deficiency is present in all tissues and results in more significant symptoms beginning in infancy with encephalopathy, intellectual impairment, spasticity, microcephaly, and growth retardation, with death most often by 2 years of age. Both types exhibit an autosomal recessive inheritance pattern.

Cyanosis varies in intensity with season and diet. The time of cyanosis onset also varies, appearing in some patients at birth and others as late as adolescence. Although as much as 50% of the total circulating hemoglobin may be in the form of nonfunctional MetHb, little or no cardiorespiratory distress occurs in these patients, except on exertion.

Daily oral treatment with *ascorbic acid* (200-500 mg/day in divided doses) gradually reduces the MetHb to approximately 10% of the total pigment and alleviates the cyanosis as long as therapy is continued. Chronic high doses of ascorbic acid have been associated with hyperoxaluria and renal stone formation. Ascorbic acid should not be used to treat *acute toxic methemoglobinemia*. When immediately available, poison control should be contacted to verify the most up-to-date therapeutic strategies. As with ascorbic acid, *riboflavin* uses the alternate pathway of MetHb reduction and is most effective when given in high doses. *Methylene blue*, administered via IV (1-2 mg/kg initially), is used to treat toxic methemoglobinemia. An oral dose can be administered (100-300 mg/day) as maintenance therapy.

Methylene blue should not be used in patients with G6PD deficiency. This treatment is ineffective and can cause severe oxidative hemolysis. If methylene blue is given to a patient with G6PD deficiency, symptoms will not improve, and marked hemolysis can develop within 24 hours of administration. Because G6PD deficiency status is rarely known at the time of treatment, a careful history should be elicited. When the history is negative for symptoms of G6PD deficiency, treatment with methylene blue should be initiated judiciously, and the patient should be closely monitored for improvement.

511.9 Syndromes of Hereditary Persistence of Fetal Hemoglobin

Kim Smith-Whitley and Janet L. Kwiatkowski

Hereditary persistence of HbF **(HPFH)** syndromes are a form of thalassemia; pathogenic variants are associated with a decrease in the production of either or both β- and δ-globins. There is an imbalance in the α:non-α synthetic ratio characteristic of thalassemia. More than 20 variants of HPFH have been described. They are deletional, $\delta\beta^0$ (Black, Ghanaian, Italian), nondeletional (Tunisian, Japanese, Australian), linked to the β-globin–gene cluster (British, Italian-Chinese, Black), or unlinked to the β-globin–gene cluster (Atlanta, Czech, Seattle). The $\delta\beta^0$ forms have deletions of the entire δ- and β-globin gene sequences, and the most common form in the United States is the Black **(HPFH 1)** variant. As a result of the δ and β gene deletions, there is production only of γ-globin and formation of HbF. In the homozygous form, no manifestations of thalassemia are present. There is only HbF with very mild anemia and slight microcytosis. When inherited with other variant hemoglobins, HbF is elevated into the 20–30% range; when inherited with HbS, sickle cell disease is ameliorated, with fewer complications.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

511.10 Thalassemia Syndromes

Janet L. Kwiatkowski

Thalassemia refers to a group of genetic disorders of globin-chain production in which there is an imbalance between the α-globin and β-globin chain production. **β-thalassemia** syndromes result from a decrease in β-globin chains, which results in a relative excess of α-globin chains. There are >300 β-thalassemia pathogenic variants that have been characterized. These pathogenic variants can affect any step in the transcription of β-globin genes. **β^0-thalassemia** refers to the absence of production of the β-globin. When patients are homozygous for the β0-thalassemia gene, they cannot make any normal β-globin chains (HbA). **β+-thalassemia** indicates a pathogenic variant that makes decreased amounts of normal β-globin (HbA). Some β-thalassemia pathogenic variants have structural changes such as HbE. Others, such as δβ-thalassemia or HPFH, are variants of β-thalassemia that have decreased production of β-globin gene with increased compensatory production of HbF. β^0-thalassemia syndromes are generally more severe than β^+-thalassemia syndromes, but there is significant variability between the genotype and phenotype. β-thalassemia *major*, commonly called transfusion-dependent thalassemia, refers to severe β-thalassemia that requires early transfusion therapy. β-thalassemia *intermedia* (also known as non–transfusion-dependent thalassemia) is a clinical diagnosis of a patient with a less severe clinical phenotype that usually does not require regular transfusion therapy in childhood. Many of these patients have at least one β^+-thalassemia pathogenic variant. β-thalassemia syndromes usually require a β-thalassemia pathogenic variant in both β-globin genes. Carriers with a single β-globin pathogenic variant are generally asymptomatic, except for microcytosis and mild anemia.

In **α-thalassemia**, there is an absence or reduction in α-globin production usually due to deletions of α-globin genes. Normal individuals have four α-globin genes; the more genes affected, the more severe the disease. **α^0-thalassemia** indicates no α-chains produced from that chromosome (– –/). **α^+-thalassemia** produces a decreased amount of α-globin chain from that chromosome (-alpha/).

The primary pathology in the thalassemia syndromes stems from the *quantity* of globin produced, whereas the primary pathology in sickle cell disease is related to the *quality* of β-globin produced.

EPIDEMIOLOGY

There are >300 different pathogenic variants resulting in absent or decreased globin production. Although most are rare, the 20 most common abnormal alleles constitute 80% of the known thalassemias worldwide; 1.5% of the world's population carries alleles for β-thalassemia, and in Southeast Asia 5–10% of the population carry alleles for α-thalassemia. In the United States, an estimated 2,000 persons have β-thalassemia major.

PATHOPHYSIOLOGY

Two related features contribute to the sequelae of **β-thalassemia syndromes**: inadequate β-globin gene production leading to decreased levels of normal hemoglobin (HbA) and unbalanced α- and β-globin chain production leading to ineffective erythropoiesis. In β-thalassemia α-globin chains are in excess to non–α-globin chains, and α-globin tetramers (α_4) are formed and appear as RBC inclusions. The free α-globin chains and inclusions are very unstable, precipitate in RBC precursors, damage the RBC membrane, and shorten RBC survival, leading to anemia and increased erythroid production (Table 511.7). This results in a marked increase in erythropoiesis, with early erythroid precursor death in the bone marrow. Clinically, this is characterized by a lack of maturation of erythrocytes and an inappropriately low reticulocyte count. This ineffective erythropoiesis and the compensatory massive marrow expansion with erythroid hyperactivity characterize β-thalassemia. Because of the low or absent production of β-globin, the α-chains combine with γ-chains, resulting in HbF ($\alpha_2\gamma_2$) being the dominant hemoglobin. In addition to the natural survival effect, the γ-globin chains may be produced in increased amounts, regulated by genetic polymorphisms. The δ-chain synthesis is not usually affected in β-thalassemia or β-thalassemia trait, and therefore patients have a relative or absolute increase in HbA_2 production ($\alpha_2\delta_2$).

In the **α-thalassemia syndromes**, there is a reduction in α-globin production. Normally, there are four α-globin genes (two from each parent) that control α-globin production. α-thalassemia syndromes vary from complete absence (hydrops fetalis) to only slightly reduced (α-thalassemia silent carrier) α-globin production. In the α-thalassemia syndromes, an excess of β- and γ-globin chains are produced. These excess chains form **hemoglobin Bart's (γ_4)** in fetal life and **HbH** (β_4) after birth. These abnormal tetramers are nonfunctional hemoglobins with very high oxygen affinity. They do not transport oxygen and result in extravascular hemolysis. A fetus with the most severe form of α-thalassemia **(hydrops fetalis)** develops in utero anemia and, without therapeutic intervention, the pregnancy usually results in fetal loss because HbF production requires sufficient amounts of α-globin. In contrast, infants with β-thalassemia major become symptomatic only after birth when HbA predominates and insufficient β-globin production manifests in clinical symptoms.

HOMOZYGOUS β-THALASSEMIA (TRANSFUSION-DEPENDENT BETA THALASSEMIA, BETA THALASSEMIA MAJOR, COOLEY ANEMIA)

Clinical Manifestations

If not treated, children with homozygous β^0-thalassemia usually become symptomatic from progressive anemia, with weakness, poor growth, and cardiac decompensation during the second 6 months of life. Depending on the pathogenic variant and degree of HbF production, regular transfusions are necessary beginning in the second month to second year of life, but rarely later. The decision to transfuse is multifactorial but is not determined solely by the degree of anemia. Persistent hemoglobin level below 7 g/dL in the absence of acute illness is an indication to start transfusions. In addition, the presence of signs of ineffective erythropoiesis, such as growth failure, bone deformities secondary to marrow expansion, and hepatosplenomegaly, are important variables in determining transfusion initiation.

The classic presentation of children with severe disease includes *thalassemic facies* (maxilla hyperplasia, flat nasal bridge, frontal bossing), pathologic bone fractures, marked hepatosplenomegaly, and cachexia and is primarily seen in countries without access to chronic transfusion therapy. Occasionally, patients with moderate anemia develop these features because of severe compensatory, ineffective erythropoiesis.

In nontransfused patients with severe ineffective erythropoiesis, marked **splenomegaly** can develop with hypersplenism and abdominal symptoms. The features of ineffective erythropoiesis include expanded medullary spaces (with massive expansion of the marrow of the face and skull), extramedullary hematopoiesis, and higher metabolic needs (Fig. 511.7). The chronic anemia and increased erythroid drive produce an increase in iron absorption from the GI tract and secondary hemosiderosis-induced organ injury.

Chronic transfusion therapy dramatically improves the quality of life and reduces the complications of severe thalassemia. Transfusion-induced **hemosiderosis** becomes the major clinical complication of transfusion-dependent thalassemia. Each mL of pure packed RBCs contains approximately 1 mg of iron. Physiologically, there is no mechanism to eliminate excess body iron. Iron is initially deposited in the liver and is followed by deposition in the endocrine organs and the heart. This leads to a high rate of hypothyroidism, hypogonadotropic gonadism, growth hormone deficiency, hypoparathyroidism, and diabetes mellitus. Iron deposition in the heart causes heart failure and arrhythmias, and heart disease is the leading cause of death in inadequately chelated patients. Eventually, most patients not receiving adequate iron chelation therapy die from cardiac failure or cardiac arrhythmias secondary to hemosiderosis. Hemosiderosis-induced morbidity can be prevented by adequate iron chelation therapy.

Laboratory Findings

In the United States, some children with β-thalassemia major will be identified on newborn screening because of the detection of only HbF on hemoglobin electrophoresis. However, infants with β^+ pathogenic variants might be missed on newborn screen if small amounts of hemoglobin

Table 511.7 The Thalassemias

THALASSEMIA	GLOBIN GENOTYPE	RED BLOOD CELL FEATURES	CLINICAL FEATURES	HEMOGLOBIN ANALYSIS
α-THALASSEMIA				
1 Gene deletion	−,α/α,α	Normal	Normal	Newborn: Bart's: 1–2%
2 Gene deletion (α-thalassemia trait)	−,α/−,α −, −/α,α	Microcytosis, mild hypochromasia	Normal, mild anemia	Newborn: Bart's: 5–10%
3 Gene deletion hemoglobin H	−,−/−,α	Microcytosis, hypochromic	Mild anemia, transfusions not required	Newborn: Bart's: 20–30%
2 Gene deletion + Constant Spring	$-,-/\alpha,\alpha^{\text{Constant Spring}}$	Microcytosis, hypochromic	Moderate to severe anemia, transfusion, splenectomy.	2–3% Constant Spring, 10–15% HbH
4 Gene deletion	−,−/−,−	Anisocytosis, poikilocytosis	Hydrops fetalis	Newborn: 89–90% Bart's with Gower-1, Gower-2, and Portland
Nondeletional	$\alpha,\alpha/\alpha,\alpha^{\text{variant}}$	Microcytosis, mild anemia	Normal	1–2% variant hemoglobin
β-THALASSEMIA				
β^0 or β^+ heterozygote: trait	β^0/A, β^+/A	Variable microcytosis, mild anemia	Normal	Elevated A_2, variable elevation of F
β^0 or β^+- homozygote or compound heterozygote Thalassemia severe	β^0/β^0, β^+/β^0, $\beta^+\beta^+$, E/β^0, E/β^+	Microcytosis, nucleated RBC	Transfusion dependent	F 98% and A_2 2%, E 30–40% (E/β^0); variably low HbA with β^+
β^0 or β^+ homozygote or compound heterozygote Thalassemia intermedia	β^0/β^0, β^+/β^0, $\beta^+\beta^+$, E/β^0, E/β^+	Hypochromic, microcytosis	Mild to moderate anemia, intermittent transfusions	A_2 2–5%, F 10–30%, HbA variably low levels
Dominant (rare)	B^0/A	Microcytosis, abnormal RBCs	Moderately severe anemia, splenomegaly	Elevated F and A_2
δ-Thalassemia	A/A	Normal	Normal	A_2 absent
$(\delta\beta)^0$-Thalassemia	$(\delta\beta)^0$/A	Hypochromic	Mild anemia	F 5–20%
$(\delta\beta)^+$-Thalassemia Lepore	β^{Lepore}/A	Microcytosis	Mild anemia	Lepore 8–20%
Homozygous Hb Lepore	$\beta^{\text{Lepore}}/\beta^{\text{Lepore}}$	Microcytic, hypochromic	Thalassemia intermedia	F 80%, Lepore 20%
γδβ-Thalassemia	$(\gamma^A\delta\beta)^0$/A	Microcytosis, microcytic, hypochromic	Moderate anemia, splenomegaly, homozygote: thalassemia intermedia	Decreased F and A_2 compared with δβ-thalassemia
γ-Thalassemia	$(\gamma^A\gamma^G)^0$/A	Microcytosis	Insignificant unless homozygote	Decreased F

A are present. An HbFE pattern can be consistent with hemoglobin E β^0-thalassemia, or the more benign hemoglobin EE disease, and needs to be followed up. The lack of standardized neonatal diagnosis of thalassemia disorders requires close follow-up of newborns with unclear thalassemia pathogenic variants and babies from high-risk ethnic groups.

Infants with serious β-thalassemia disorders have a progressive anemia after the newborn period. Microcytosis, hypochromia, and targeting characterize the RBCs. Nucleated RBCs, marked anisopoikilocytosis, and a relative reticulocytopenia are typically seen (see Fig. 511.5E). The Hb level falls progressively often to <6 g/dL unless transfusions are given. The reticulocyte count is commonly <8% and is inappropriately low compared to the degree of anemia caused by ineffective erythropoiesis. The unconjugated serum bilirubin level is usually elevated, but other chemistries may be initially normal. Even if the child does not receive transfusions, iron eventually accumulates with elevated serum ferritin and transferrin saturation. Evidence of bone marrow hyperplasia can be seen on radiographs (see Fig. 511.7).

Early definitive diagnosis is recommended. Newborn screening techniques such as hemoglobin electrophoresis are not definitive. DNA diagnosis of the β-thalassemia pathogenic variants, along with testing for common genetic modifiers of the clinical phenotype, is recommended. Co-inheritance of one or more α-thalassemia deletions is common, and it decreases the severity of the β-thalassemia disease as it improves the α:β chain imbalance. Some patients' pathogenic variants cannot be diagnosed by standard electrophoresis or common DNA probes. Referral of the samples to a tertiary laboratory is indicated, along with parental and family testing. After the definitive diagnosis, families should undergo detailed counseling.

Management and Treatment of Thalassemia

See Figure 511.8.

Transfusion Therapy

β-thalassemia major is a clinical diagnosis that requires the integration of laboratory findings and clinical features. Of patients with homozygous β^0-thalassemia (the most severe pathogenic variants), 15–20% may have a clinical course that is phenotypically consistent with thalassemia intermedia. In contrast, 25% of patients with homozygous β^+-thalassemia, typically a more benign genotype, may have transfusion-dependent thalassemia. Transient clinical events, such as a sudden fall in hemoglobin secondary to an episode of parvovirus requiring transfusion, do not necessarily indicate a transfusion-dependent patient. The long-term observation of the clinical characteristics, such as growth, bony changes, and hemoglobin, are necessary to determine chronic transfusion therapy.

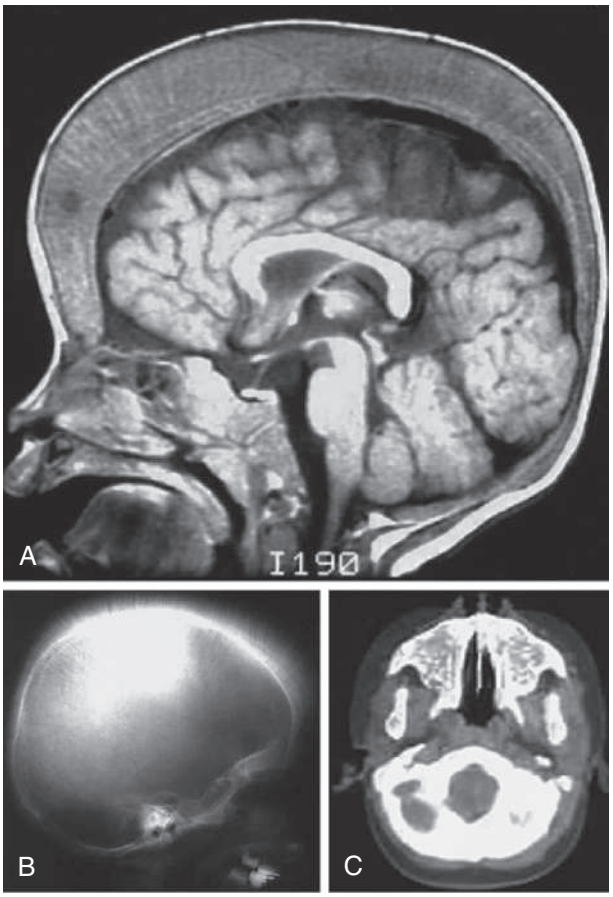

Fig. 511.7 Ineffective erythropoiesis in a 3-yr-old patient who has β-thalassemia major and has not received a transfusion. A, Massive widening of the diploic spaces of the skull as seen on MRI. B, Radiographic appearance of the trabeculae as seen on plain radiograph. C, Obliteration of the maxillary sinuses with hematopoietic tissue as seen on CT scan.

Guidelines for Transfusion Therapy. Patients who require transfusion therapy should have an extended RBC phenotype and/or genotype. Patients should receive RBCs depleted of leukocytes and matched for D, C, c, E, e, and Kell antigens at a minimum. Cytomegalovirus-safe units are indicated in stem cell transplantation candidates. Transfusions should generally be given at intervals of 3-4 weeks, with the goal being to maintain a pretransfusion Hb level of 9.5-10.5 g/dL. Ongoing monitoring for transfusion-associated transmitted infections (hepatitis A, B, and C, HIV), alloimmunization, annual blood transfusion requirements, and transfusion reactions is essential.

Iron Overload Monitoring

Excessive iron stores from transfusion cause many of the complications of β-thalassemia major. Accurate assessment of excessive iron stores is essential to optimal therapy. Serial serum ferritin levels provide a useful screening technique in assessing iron balance trends, but results may not accurately predict quantitative iron stores. Undertreatment or overtreatment of presumed excessive iron stores can occur in managing a patient based on serum ferritin alone. Quantitative measurements of liver iron and cardiac iron by MRI are standard noninvasive methods to assess tissue iron overload; estimation of pancreatic and gonadal iron is being studied. This technology, along with access to multiple chelators, enables targeted chelation therapy for patients with organ-specific hemosiderosis before the onset of overt organ failure. Integration of these imaging technologies with chelation therapy may prevent heart failure, diabetes, and other organ dysfunction.

Quantitative liver iron by approved R2 or R2* MRI is the best indicator of total body iron stores and should be obtained in patients after chronic transfusion therapy has been initiated. The liver iron results will help guide the chelation regimen. Cardiac iron estimation by T2* MRI, is usually obtained starting at 10 years old, but should be obtained earlier in the setting of severe iron overload or if the transfusion and chelation history is not known. There may be a discrepancy between the liver iron and the heart iron because of different rates of tissue loading and unloading and the differential effects of iron chelators on organ-specific iron removal.

Chelation Therapy

Iron-chelation therapy should start as soon as the patient becomes significantly iron-overloaded. In general, this occurs after 1 year of transfusion therapy and correlates with the serum ferritin >1,000 ng/mL and/or a liver iron concentration of >5,000 μg/g dry weight. Iron chelation is not currently labeled for use in children <2 years.

There are three available iron chelators (deferoxamine, deferasirox, and deferiprone); each varies in its route of administration, pharmacokinetics, adverse events, and efficacy (Table 511.8). Combination chelation therapy may be required for high iron burden. The overall goal is to prevent hemosiderosis-induced tissue injury and avoid chelation toxicity. This requires close monitoring of the patients. In general, chelation toxicity increases as iron stores decrease.

Deferoxamine (Desferal) is the most studied iron chelator; it has an excellent safety and efficacy profile. It requires subcutaneous or IV administration because of its poor oral bioavailability and short half-life of <30 minutes, necessitating administration as a continuous infusion over at least 8 hours daily, 5-7 days/week. Deferoxamine is initially started at 25 mg/kg and can be increased to 60 mg/kg in heavily iron-overloaded patients. The major problem with deferoxamine is poor adherence because of the difficult, time-consuming route of administration. Adverse side effects include local skin reactions, ototoxicity, retinal changes, and bone dysplasia with truncal shortening. Maintaining the therapeutic index (deferoxamine dose in mg/kg divided by the serum ferritin) below 0.025 limits these adverse effects.

The *oral* iron chelator **deferasirox** is commercially available in the United States. Of patients treated with deferoxamine, 70% have switched to deferasirox because it is orally available. Deferasirox has a half-life of >16 hours and requires once-daily administration. The drug was initially available as a dispersible tablet that is dissolved in water or juice. Subsequently, a film coated tablet that is swallowed whole and a granule form that is sprinkled on soft food and ingested became available. Dosing is different for the different deferasirox formulations. For the dispersible tablet form, the initial dose typically is 20 mg/kg/day and can be escalated to as high as 40 mg/kg/day based on the iron burden. The dosing for the film-coated tablet and granule forms is 30% lower than the dispersible tablet, with a starting dose of 14 mg/kg/day, which can be escalated to a maximum of 28 mg/kg/day. The most common side effects are GI symptoms, which may be lessened with the film-coated tablet and granule formulations because they do not contain lactose and sodium laureate, which are found in the dispersible tablet and are thought to be responsible for some of the GI symptoms. The most serious side effect of deferasirox is potential kidney damage. Up to 30% of patients have transient increases in creatinine that may require temporary modifications of dosing. This toxicity may occur more commonly in the setting of dehydration. Proteinuria also can develop and, less commonly, a renal Fanconi syndrome may occur. Long-term studies in thousands of patients have not demonstrated progressive renal dysfunction, but isolated cases of renal failure in patients have occurred. In addition, hepatic transaminitis may occur, with an increase to >5 times the upper limit of normal in approximately 8% of patients. All patients require monthly chemistry panels and ongoing monitoring for proteinuria.

Deferiprone, an oral iron chelator, is approved in the United States for use in individuals with transfusional iron overload 3 years and older. Deferiprone has a half-life of approximately 3 hours and requires dosing 3 times daily; a new longer-acting tablet form is available that is

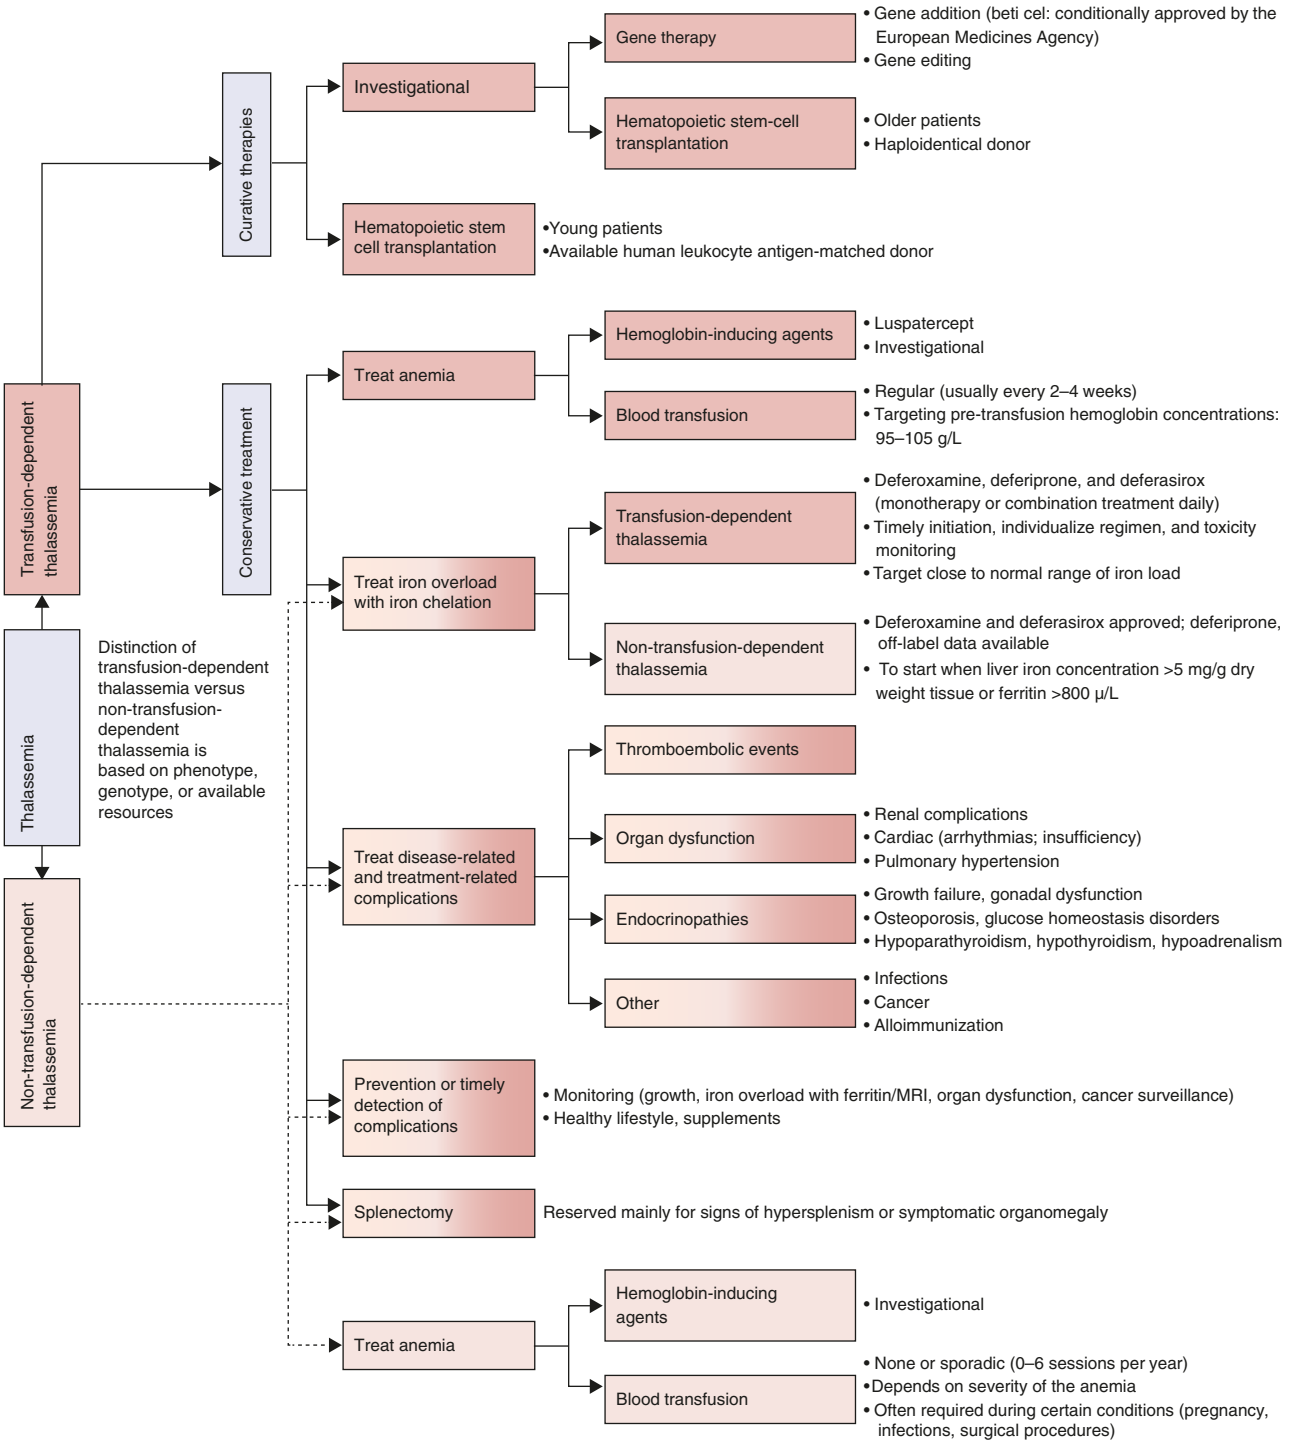

Fig. 511.8 Algorithm for the therapeutic management of thalassemia. *(From Kattamis A, Kwiatkowski JL, Aydinok Y. Thalassemia. Lancet. 2022;399:2310–2322; Fig. 3.)*

dosed twice daily. The starting dose is 75 mg/kg/day and can be escalated to 99 mg/kg/day based on the degree of iron overload. Deferiprone, a small molecule, effectively enters cardiac tissue and may be more effective than other chelators in reducing cardiac hemosiderosis. The most serious side effect of deferiprone is transient agranulocytosis, which occurs in 1-2% of patients and usually in the first year of treatment. It has been associated with rare deaths where patients were not adequately monitored. The use of deferiprone requires frequent CBC monitoring, typically weekly for at least the first 6 months of therapy. Most importantly, the drug should be held and the neutrophil count checked immediately with all febrile illnesses.

As thalassemia patients live longer, the iron chelation goals have changed. Aggressive treatment with combination chelation therapy is often used in heavily iron-overloaded patients to prevent or reverse organ dysfunction. Deferoxamine, in combination with deferiprone, is routinely used in patients with increased cardiac iron. Combination therapy of deferoxamine and deferasirox or with deferasirox and deferiprone may also be efficacious in patients with severe iron overload.

Luspatercept

Luspatercept is a recombinant fusion protein that binds TGFβ family ligands and thus blocks a signaling pathway involved in ineffective

Table 511.8 Properties of Iron Chelators

	DEFEROXAMINE	DEFERASIROX	DEFERIPRONE
Prototype trade name	Desferal	Exjade; Jadenu	Ferriprox
Route of administration	Subcutaneous; intravenous	Oral dispersible tablet; film-coated tablet; granules	Oral solution; oral tablet (3 times per day); oral tablet (twice per day)
Usual dose	Standard, 25–40 mg/kg per day over 8–12 h; low cardiac T2* or heart failure, 50–60 mg/kg per day over 12–24 h	Oral dispersible tablet, 20–40 mg/kg per day once daily; film-coated tablet and granules, 14–28 mg/kg per day once daily	75–100 mg/kg per day divided into 3 doses (oral solution or oral tablet, 3 times per day); 75–100 mg/kg per day divided into 2 doses (oral tablet, twice per day)
Excretion	Urinary (60%), defecation (40%)	Defecation (~90%)	Urinary (~75–90%)
Ability to remove liver iron	High	High	Moderate*
Ability to remove cardiac iron	Moderate†	Moderate‡	High
Adverse events	Local reactions, auditory, ophthalmologic, allergic reactions, bone defects, Yersinia or Klebsiella infections; high doses: pulmonary, neurologic, renal failure	Gastrointestinal, rash, renal impairment (increase in creatinine, proteinuria, proximal renal tubular dysfunction, renal insufficiency), elevated hepatic enzymes, gastrointestinal bleeding or ulcers, hepatic failure, auditory, ophthalmologic	Gastrointestinal, elevated hepatic enzymes, arthropathy, neutropenia or agranulocytosis
EU licensure	Licensed	Patients age 6 years and older with transfusion-dependent thalassemia; patients age 10 years and older with non-transfusion-dependent thalassemia (as a first-line treatment); patients age 2 years and older with transfusion-dependent thalassemia (as a second-line treatment)	Patients with thalassemia major when current chelation therapy is contraindicated or inadequate
USA licensure	Licensed	Patients age 2 years and older with transfusion-dependent thalassemia; patients age 10 years and older with nontransfusion-dependent thalassemia	Patients age 8 years and older with transfusional iron overload and thalassemia syndromes

*Reports of insufficient liver iron removal in some patients at doses of 75 mg/kg per day, but higher dosages, especially for patients with high transfusional iron burden, might be more effective.
†With continuous infusion.
‡Limited data show faster cardiac iron removal with modest hepatic iron loading, but this removal might be less effective in patients with more severe hepatic siderosis.
From Kattamis A, Kwiatkowski JL, Aydinok Y. Thalassemia. Lancet 2022;399:2310–2322; Table 1.

erythropoiesis and results in improved erythroid maturation. The drug is given by subcutaneous injection every 3 weeks at a starting dose of 1 mg/kg/dose, which can be escalated to 1.25 mg/kg/dose if no response after 6 weeks of treatment. In patients with transfusion-dependent β-thalassemia, use of luspatercept was associated with a reduction in RBC requirements in about 70% of treated patients. Luspatercept is approved by the FDA for use in adults with transfusion-dependent β-thalassemia. Adverse effects include bone pain, arthralgia, dizziness, hypertension, and hyperuricemia. The drug also is being studied in nontransfusion dependent thalassemia, where a 1 to 1.5 g/dL rise in hemoglobin has been seen.

Hydroxyurea

Hydroxyurea, a DNA antimetabolite, increases HbF production. It has been most successfully used in sickle cell disease and in some patients with β-thalassemia intermedia. Studies in β-thalassemia major are limited. In many parts of the world, hydroxyurea therapy is used in β-thalassemia intermedia patients. Even though increases in HbF levels are observed, they do not predictively correlate with increase in total Hb in these patients. In general, there appears to be a mean increase in Hb of 1 g/dL (range: 0.1-2.5 g/dL). Hydroxyurea therapy in thalassemia intermedia is associated with a reduced risk of leg ulcers, pulmonary hypertension, and extramedullary hematopoiesis. The initial starting dose for thalassemia intermedia is 10 mg/kg and may be escalated to 20 mg/kg/day. Patients with β-thalassemia are at increased risk of developing cytopenias with hydroxyurea use, which may prevent dose escalation. Close monitoring of the CBC with differential is required.

Hematopoietic Stem Cell Transplantation and Gene Therapy

Hematopoietic stem cell transplantation has cured >3,000 patients who had β-thalassemia major. In low-risk HLA-matched sibling patients, there is at least a 90% survival and an 80% event-free survival. In general, myeloablative conditioning regimens have been used to prevent graft rejection and thalassemia recurrence. Most success has been in children <14 years old without excessive iron stores and hepatomegaly who undergo sibling HLA-matched allogeneic transplantation. All children who have an HLA-matched sibling should be offered the option of bone marrow transplantation. Outcomes of hematopoietic stem cell transplantation with a matched *unrelated donor* using molecular techniques for HLA typing have significantly improved, approaching outcomes with matched sibling donors, but with an increased risk of graft versus host disease. Alternative transplantation regimens for patients without appropriate donors are experimental and have variable success.

Gene therapy using gene addition or gene editing approaches are FDA approved for transfusion-dependent patients with β-thalassemia. Results with gene addition using lentiviral vectors containing a functional β-globin gene have been promising. **Betibeglogene autotemcel** is a rare gene-based, FDA- approved therapy for adults and pediatric patients (≥4 years) with transfusion dependent β-thalassemia. This one-time therapy transduces harvested autologous CD34+ cells with a replicant incompetent vector containing a modified β-globin gene. Approximately 90% of treated patients achieve transfusion independence.

A second approved approach to gene therapy involves gene editing to increase hemoglobin F levels. The first patient treated with transfusion-dependent thalassemia treated with a CRISPR-Cas9 gene editing approach was able to discontinue RBC transfusions while maintaining a normal hemoglobin level, mostly consisting of HbF. This gene approach is indicated for transfusion-dependent β-thalassemia patients ≥12 years of age.

Splenectomy

Splenectomy may be required in thalassemia patients who develop hypersplenism. These patients have a falling steady-state Hb level and/or a rising transfusion requirement. However, splenectomy is less frequently used as a therapeutic option; serious adverse effects of splenectomy are increasingly recognized beyond infection risk. In thalassemia intermedia, splenectomized patients have a marked increased risk of venous thrombosis, pulmonary hypertension, leg ulcers, and silent cerebral infarction compared to nonsplenectomized patients. All patients should be fully immunized against encapsulated bacteria and receive appropriate instructions regarding fever management. Prophylactic penicillin should be administered after splenectomy to prevent sepsis, and families need to be educated on the risk of fever and sepsis.

Preventive Monitoring of Thalassemia Patients

See Table 511.9.

Cardiac Disease

Cardiac disease is the major cause of death in thalassemia. Serial echocardiograms should be monitored to evaluate cardiac function and pulmonary artery pressure. Pulmonary hypertension frequently occurs in nontransfusion dependent thalassemia patients and may be an indication for transfusion therapy. After approximately 8 years of chronic transfusion therapy, cardiac hemosiderosis may occur; consequently, cardiac T2* MRI imaging studies are recommended, typically beginning at 10 years of age. Patients with cardiac hemosiderosis and decreasing cardiac ejection fraction require intensive combination chelation therapy. Periodic electrocardiogram studies also are obtained after age 10 years because of the risk of arrhythmia from cardiac iron overload.

Endocrine Disease

Endocrine function progressively declines with age secondary to hemosiderosis and nutritional deficiencies. Iron deposition in the pituitary and endocrine organs can result in multiple endocrinopathies, including hypothyroidism, growth hormone deficiency, delayed puberty, hypoparathyroidism, diabetes mellitus, osteoporosis, and adrenal insufficiency. Monitoring for endocrine dysfunction starts early, about 5 years of age, or after at least 3 years of chronic transfusions. All children require monitoring of their height, weight, pubertal assessment, and sitting height semiannually. Bone density scans should be obtained starting in the second decade of life given the high rate of osteopenia. Nutritional assessments are required. Most patients need vitamin D, vitamin C, and zinc replacement. Fertility is a growing concern among patients and should be assessed routinely.

Psychosocial Support

Thalassemia imposes major disruption in the family unit and significant obstacles to normal development. Culturally sensitive anticipatory counseling is necessary, and the early use of child life services decreases psychologic trauma of therapy. Early social service consultation to address financial and social issues is mandatory.

OTHER β-THALASSEMIA SYNDROMES

Non–Transfusion-Dependent Thalassemia: β-Thalassemia Intermedia

Non–transfusion-dependent thalassemia (thalassemia intermedia) includes a spectrum of patients who initially are not chronically transfused in infancy but may be sporadically transfused throughout their lifetime. The major determining characteristic of these patients is less α-β–globin chain imbalance than observed in thalassemia major. Sometimes, genetic modifiers alter the primary pathogenic variant severity and improve the globin-chain imbalance. Co-inheritance of α-thalassemia trait or polymorphisms of globin promoters such as BCL11A may lessen disease severity and result in a nontransfusion dependent thalassemia. HbE β-thalassemia is a common cause of both transfusion-dependent and non–transfusion-dependent thalassemia. These secondary

Table 511.9 Risk Factors of Thalassemia Comorbidities

CARDIOVASCULAR	
Left ventricle dysfunction	Anemia; cardiac iron overload
Pulmonary hypertension	Chronic hypoxia; splenectomy hypercoagulability; advanced age; nontransfusion-dependent thalassemia
Arrhythmia	Anemia; cardiac iron overload; thyroid disturbances
Thromboembolic events	Splenectomy; hypercoagulability; iron-induced endothelial damage
HEPATOBILIARY	
Viral hepatitis	Red cell transfusions
Fibrosis or cirrhosis	Liver iron overload
Gallstones	Chronic hemolysis
ENDOCRINOPATHIES	
Growth retardation; delayed puberty; hypogonadism	Pituitary iron deposition (thyroid hormone, hypothalamus-pituitary-gonadal axis, growth hormone-insulin like growth factor disturbances); nutrition; anemia
Glucose intolerance; diabetes	Liver iron overload; pancreatic iron deposition; family predisposition
Thyroid dysfunction	Anemia; thyroid iron deposition; hypopituitarism
Adrenal insufficiency	Anemia; adrenal iron deposition; hypopituitarism
Bone disease	Ineffective erythropoiesis, iron predisposition and chelator toxicity; hypogonadism; hypoparathyroidism
NEOPLASIA	
Hepatocellular carcinoma	Chronic hepatitis B or hepatitis C virus infections; liver iron overload
Thyroid cancer; renal cancer; gastrointestinal cancer; breast cancer; hematologic malignancies	Iron toxicity; chronic anemia; advanced age
OTHER	
Renal dysfunction; tubular dysfunction; nephrolithiasis	Anemia; renal iron deposition; and chelator (especially deferasirox) toxicity
Extramedullary hematopoiesis	Ineffective erythropoiesis
Leg ulcers	Anemia; hypercoagulability
Auditory disturbances	Chelator toxicity
Ophthalmologic disturbances	Chelator toxicity
Infectious complications	Splenic dysfunction; transfusion-related infections; iron overload; use of iron chelation therapy (especially deferoxamine)
Spleen (splenomegaly, hypersplenism)	Ineffective erythropoiesis; extramedullary hematopoiesis

From Kattamis A, Kwiatkowski JL, Aydinok Y. *Thalassemia*. Lancet 2022;399:2310–2322. Table 2.

genetic modifiers play a role in altering the severity of this disorder. Occasionally, patients with a single β-thalassemia pathogenic variant or autosomal dominant β-thalassemia trait have clinical features of thalassemia intermedia, or non–transfusion-dependent thalassemia. Genetic studies of these patients often uncover coinheritance of genetic modifiers that worsens the condition, such as α-gene triplication or an unstable β-globin variant.

Individuals with thalassemia intermedia have significant ineffective erythropoiesis that leads to microcytic anemia with hemoglobin of approximately 7 g/dL (range: 6-10 g/dL). These patients have some of the complications characterized in untransfused thalassemia major patients, but the severity varies depending on the degree of ineffective erythropoiesis. They can develop medullary hyperplasia, hepatosplenomegaly, hematopoietic pseudotumors, pulmonary hypertension, leg ulcers, thrombotic events, and growth failure. Many patients develop hemosiderosis secondary to increased GI absorption of iron requiring chelation. Extramedullary hematopoiesis can occur in the vertebral canal, compressing the spinal cord and causing neurologic symptoms; the latter is a medical emergency requiring immediate local radiation therapy to halt erythropoiesis. Transfusions are indicated in thalassemia intermedia patients with significant clinical morbidity.

Thalassemia trait is often misdiagnosed as iron deficiency in children because the two diagnoses produce similar hematologic abnormalities on CBC. However, *iron deficiency is much more prevalent.* A short course of iron and reevaluation is all that is required to identify children who will need further evaluation. Children who have β-thalassemia trait have a persistently normal RBC distribution width and low mean corpuscular volume (MCV), whereas patients with iron deficiency develop an elevated red cell distribution width (RDW) with treatment. On Hb analysis, patients with β-thalassemia trait have elevated levels of HbA_2 and variably increased HbF. There are "silent" forms of β-thalassemia trait, and if the family history is suggestive, further studies may be indicated.

α-THALASSEMIA SYNDROMES

The same evolutionary pressures that produced β-thalassemia and sickle cell disease produced α-thalassemia. Infants are identified in the newborn period by the increased production of hemoglobin Bart's (γ_4) during fetal life and its presence at birth. The α-thalassemia syndromes occur most frequently in Southeast Asia. Deletions are most common in α-thalassemia. In addition to deletional pathogenic variants, there are nondeletional α-globin gene pathogenic variants, the most common being Constant Spring ($\alpha^{CS}\alpha$); these variants cause a more severe anemia and clinical course than the deletional variants. Normally, there are four α-globin genes. The different phenotypes in α-thalassemia largely result from whether one (α^{+}-thalassemia) or both (α^{0}-thalassemia) α-globin genes are deleted in each of the two loci.

The deletion of one α-globin gene (silent carrier) is not identifiable hematologically. Specifically, no alterations are noted in the MCV and mean corpuscular hemoglobin (MCH). Persons with this deletion are usually diagnosed after the birth of a child with a two-gene deletion or HbH (β_4), but some newborn screening programs report even low concentrations of Hb Bart's. During the newborn period, <3% Hb Bart's is observed. The deletion of one α-globin gene is common in Black persons.

The deletion of two α-globin genes results in α-thalassemia trait. The α-globin alleles can be lost in a *trans* (–α/–α) or *cis* (α,α^{-SEA}) configuration. The *trans* or *cis* pathogenic variants can combine with other pathogenic variants or deletions and lead to HbH or α-thalassemia major. In persons from Africa or of African descent, the most common α-globin deletions are in the *trans* configuration, whereas in persons from or descended from Asia or the Mediterranean region, *cis* deletions are most common.

α-Thalassemia trait (two missing α-globin genes) manifests as a microcytic anemia that can be mistaken for iron-deficiency anemia (see Fig. 511.5F). The Hb analysis is normal, except during the newborn period, when Hb Bart's is typically <8% but >3%. Children with a deletion of two α-globin genes are commonly mistaken to have iron deficiency, given the presence of both low MCV and MCH. The simplest approach to distinguish between iron deficiency and α-thalassemia trait is with a good dietary history. Children with iron-deficiency anemia often have a diet that is low in iron and drink a significant amount of cow's milk. Alternatively, a brief course of iron supplementation along with monitoring of erythrocyte parameters might confirm the diagnosis of iron deficiency. If both parents of a child diagnosed with α-thalassemia trait are carriers in the *cis* conformation, they are at risk for a future hydrops fetalis pregnancy. Thus family screening and genetic counseling are indicated.

The deletion of three α-globin genes leads to the diagnosis of HbH disease. A more severe form of HbH disease may be caused by a nondeletional α-globin pathogenic variant in combination with two gene deletions. HbH Constant Spring ($-\alpha/\alpha,\alpha^{CS}$) is the most common type of nondeletional HbH disease.

In California, where a large population of persons of Asian descent resides, approximately 1:10,000 of all newborns have HbH disease. The simplest manner of diagnosing HbH disease is during the newborn period, when excess in γ-tetramers are present and Hb Bart's is commonly >25%. Obtaining supporting evidence from the parents is helpful. Later in childhood, there is an excess of β-globin chain tetramers that results in HbH. A definitive diagnosis of HbH disease requires DNA analysis. Brilliant cresyl blue can stain HbH, but it is rarely used for diagnosis. Patients with HbH disease have a marked microcytosis, anemia, mild splenomegaly, and, occasionally, scleral icterus or cholelithiasis. Chronic transfusion is not usually required for therapy because the Hb range is 7-11 g/dL, with MCV 51-73 fL, but intermittent transfusions for worsening anemia, particularly in the setting of acute infection, may be needed. Individuals with nondeletional HbH disease are more likely to require transfusions than individuals with deletional HbH disease.

The deletion of all four α-globin gene alleles causes profound anemia during fetal life, resulting in **hydrops fetalis**; the ζ-globin gene must be present for fetal survival. There are no normal hemoglobins present at birth (primarily Hb Bart's, with Hb Gower-1, Gower-2, and Portland). Intrauterine transfusions may rescue the fetus, but congenital abnormalities and neurodevelopmental delay often result. Infants with severe α-thalassemia will have lifelong transfusion dependence, and hematopoietic stem cell transplantation is the only cure.

Treatment of HbH disease requires ongoing monitoring of growth and organ dysfunction. Dietary supplement with folate and multivitamins without iron is indicated. Older patients may develop decreased bone density with calcium and vitamin D deficiency. Vitamin D supplementation is indicated if the level is low, and adequate dietary calcium intake should be encouraged to promote bone health. Iron supplementation should be avoided as patients are at risk of developing iron overload. Intermittent transfusion requirements during intercurrent infection may occur, particularly in nondeletional HbH. Splenectomy is occasionally indicated, and because of the high risk of postsplenectomy thrombosis, aspirin or other anticoagulant therapy after splenectomy should be considered. Hemosiderosis, secondary to GI iron absorption or transfusion exposure, may develop in older patients and require chelation therapy. Because HbH is an unstable hemoglobin sensitive to oxidative injury, oxidative medications should be avoided. At-risk couples for hydrops fetalis should be identified and offered molecular diagnosis on fetal tissue obtained early in pregnancy. Later in pregnancy, intrauterine transfusion can improve fetal survival, but chronic transfusion therapy or bone marrow transplantation for survivors will be required.

Chapter 512

Enzymatic Defects

512.1 Pyruvate Kinase Deficiency

Allison S. Remiker and Amanda M. Brandow

Congenital nonspherocytic hemolytic anemia occurs in persons homozygous or compound heterozygous for autosomal recessive genes that cause either a marked reduction in red blood cell (RBC) pyruvate kinase (PK) or production of an abnormal enzyme with decreased catalytic activity resulting in impaired conversion of phosphoenolpyruvate to pyruvate. Generation of adenosine triphosphate (ATP) within RBCs at this step is impaired, and low levels of ATP, pyruvate, and the oxidized form of nicotinamide adenine dinucleotide (NAD^+) are found (Fig. 512.1). The concentration of 2,3-diphosphoglycerate is increased; this isomer is beneficial in facilitating oxygen release from hemoglobin but detrimental in inhibiting hexokinase and enzymes of the hexose monophosphate shunt. This decrease of hemoglobin oxygen affinity leads to a rightward shift of the hemoglobin-oxygen dissociation curve and therefore improved oxygen delivery manifesting as tolerance of anemia more than expected for the degree of severity. In addition, an unexplained decrease occurs in the sum of the adenine (ATP, adenosine diphosphate, and adenosine monophosphate) and pyridine (NAD^+ and reduced form of NAD) nucleotides, further impairing glycolysis. Because of decreased ATP, RBCs cannot maintain their potassium and water content; the cells become rigid, and their life span is considerably reduced with precipitous destruction in the liver and/or spleen. This is more pronounced in reticulocytes, which require higher levels of ATP.

ETIOLOGY

There are two mammalian PK genes, but only the *PKLR* gene is expressed in RBCs. More than 300 pathogenic variants are reported in this structural gene, which codes for a 574–amino acid protein that forms a functional tetramer. There is some correlation of the type, location, and amino acid substitution with disease severity. The majority of patients have at least one missense pathogenic variant. Most affected patients are compound heterozygotes for two different PK gene defects. The many possible combinations likely account for the variability in clinical severity. The pathogenic variants 1456 C to T and 1529 G to A are the most common pathogenic variants in the White population.

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

The clinical manifestations of **PK deficiency** vary from severe neonatal hemolytic anemia to mild, well-compensated hemolysis first noted in adulthood (Table 512.1). Perinatal complications include premature birth, prenatal anemia or fetal hydrops requiring transfusions, and preterm labor. Severe hyperbilirubinemia, anemia, and, in rare cases, hepatic failure may occur in the neonatal period, and kernicterus has been reported. The hemolysis in older children and adults varies in severity, with hemoglobin values ranging from 2-14 g/dL in various reports and associated pallor, jaundice, scleral icterus, splenomegaly, bone deformities due to extramedullary hematopoiesis, and hyperpigmentation. Reticulocyte counts are often extremely elevated, reflecting the severe ongoing hemolysis. Associated serum chemistries consistent with nonimmune hemolytic anemia are present, including an elevated indirect bilirubin, decreased haptoglobin, increased lactate dehydrogenase (LDH), negative direct antiglobulin test (DAT), and

negative indirect antiglobulin test. A severe form of the disease has a relatively high incidence among the Amish of the Midwestern United States (homozygous splicing pathogenic variant R479H). PK deficiency may possibly provide protection against falciparum malaria. There are long-term effects of chronic hemolysis, including folate deficiency, skin ulcers, gallstones, increased risk of bone fractures, and risk of transient bone marrow aplasia associated with certain viral infections.

Polychromatophilia and **mild macrocytosis** reflect the elevated reticulocyte count. Spherocytes are uncommon, but a few spiculated pyknocytes may be found. Diagnosis relies on demonstration of a marked reduction of RBC PK activity or an increase in the Michaelis-Menten dissociation constant (K_m) for its substrate, phosphoenolpyruvate (high K_m variant). Other RBC enzyme activity is normal or elevated, reflecting the reticulocytosis. No abnormalities of hemoglobin are noted. The white blood cells (WBCs) and platelets have normal PK activity and must be rigorously excluded from the RBC hemolysates used to measure PK activity. Fructose 1,6-disphosphate (FDP) must also be removed because it is an allosteric activator of PK. Heterozygous carriers usually have moderately reduced levels of PK activity. Molecular testing provides additional evidence for the disease. However, due to genotype-phenotype variability with unclear pathogenicity regarding variants, it is recommended to perform initial biochemical testing.

TREATMENT

Intrauterine RBC transfusions are performed in the setting of severe anemia associated with fetal hydrops. Phototherapy and exchange transfusions may be indicated for hyperbilirubinemia in newborns. Transfusions of packed RBCs are necessary for severe anemia or for aplastic crises. If the anemia is consistently severe and frequent transfusions are required, iron chelation may be necessary. Splenectomy should be considered after the child is 5-6 years of age to decrease the need for transfusions and minimize iron overload. Although not curative, splenectomy may be followed by higher Hb levels and by strikingly high (30–60%) reticulocyte counts. Death resulting from overwhelming pneumococcal sepsis has followed splenectomy; thus immunization with vaccines for encapsulated organisms should be given before splenectomy and prophylactic penicillin administered after the procedure. Splenectomy has also been associated with thrombosis and pulmonary hypertension. There is currently no standard curative therapy, although the role of gene therapy and hematopoietic cell transplant are actively being investigated. An oral allosteric PK activator (mitapivat) is being studied in clinical trials involving adults and is under review by the US Food and Drug Administration (FDA). The natural history of the disease is limited and is currently being studied through an international registry.

512.2 Other Glycolytic Enzyme Deficiencies

Allison S. Remiker and Amanda M. Brandow

Chronic nonspherocytic hemolytic anemias of varying severity have been associated with deficiencies of other enzymes in the glycolytic pathway, including hexokinase, glucose phosphate isomerase, and aldolase, which are inherited as autosomal recessive disorders. **Phosphofructokinase deficiency,** which occurs primarily in Ashkenazi Jews in the United States, results in hemolysis associated with a myopathy classified as **glycogen storage disease type VII** (see Chapter 107.1). Clinically, hemolytic anemia is complicated by

muscle weakness, exercise intolerance, cramps, and myoglobinuria. Erythrocyte production is increased to compensate for hemolysis. Enzyme assays for phosphofructokinase yield low values for RBCs and muscle.

Triose phosphate isomerase deficiency is an autosomal recessive disorder affecting many systems. Affected patients have hemolytic anemia, cardiac abnormalities, and lower motor neuron and pyramidal tract impairment, with or without evidence of cerebral impairment. They usually die in early childhood. The gene for triose phosphate isomerase has been cloned and sequenced and is located on chromosome 12.

Phosphoglycerate kinase (PGK) is the first ATP-generating step in glycolysis. At least 23 kindreds with PGK deficiency have been described. PGK is the only glycolytic enzyme inherited on the X chromosome. PGK is important in erythrocytes, the central nervous system (CNS), and skeletal muscle. The phenotype is quite variable and may affect one isolated tissue or a combination of all three. Affected males may present with dysfunction of the CNS with seizures, intellectual disability, and nonspherocytic hemolytic anemia; hemolytic anemia without CNS involvement; or myopathy, myoglobinuria, and progressive weakness. Some patients present with parkinsonism. Female heterozygotes have been shown to have partial symptoms depending on their degree of enzymatic activity, including signs of hemolysis. The gene for PGK is particularly large, spanning 23 kb, and various genetic abnormalities, including nucleotide substitutions, gene deletions, missense, and splicing pathogenic variants, result in PGK deficiency.

DEFICIENCIES OF ENZYMES OF HEXOSE MONOPHOSPHATE PATHWAY

The most important function of the hexose monophosphate pathway is to maintain glutathione in its reduced state (GSH) as protection against the oxidation of RBCs (see Fig. 512.1). Approximately 10% of the glucose taken up by RBCs passes through this pathway to provide the reduced form of NAD phosphate (NADPH) necessary for the conversion of oxidized glutathione to GSH. Maintenance of GSH is essential for the physiologic inactivation of oxidant compounds, such as hydrogen peroxide, that are generated within RBCs. If glutathione, or any compound or enzyme necessary for maintaining it in the reduced state, is decreased, the SH groups of the RBC membrane are oxidized, and the Hb becomes denatured and may precipitate into RBC inclusions called **Heinz bodies**. Once Heinz bodies have formed, an acute hemolytic process results from damage to the RBC membrane by the precipitated Hb, the oxidant agent, and the action of the spleen. The damaged RBCs then are rapidly removed from the circulation.

512.3 Glucose-6-Phosphate Dehydrogenase Deficiency and Related Deficiencies

Allison S. Remiker and Amanda M. Brandow

Glucose-6-phosphate dehydrogenase (G6PD) deficiency, the most frequent disease involving enzymes of the hexose monophosphate pathway, is responsible for two clinical syndromes: episodic *acute* hemolytic anemia and *chronic* nonspherocytic hemolytic anemia. The most common manifestations are neonatal jaundice and episodic acute hemolytic anemia, which is induced by infections, certain drugs, and, rarely, fava beans. This X-linked deficiency affects >400 million people worldwide, representing an overall 4.9% global prevalence. The global distribution of this disorder parallels that of malaria, representing an example of "balanced polymorphism," in which there is an evolutionary advantage of resistance to falciparum malaria in heterozygous females that outweighs the small negative effect of affected hemizygous males.

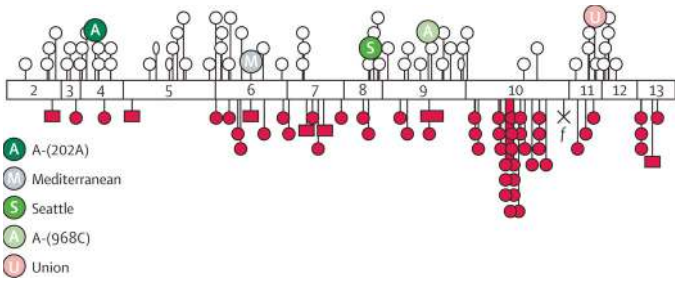

Fig. 512.2 Most common pathogenic variants along coding sequence of *G6PD* gene. Exons are shown as *open numbered boxes*. *Open circles* are pathogenic variants causing classes II and III variants. *Filled circles* represent sporadic pathogenic variants giving rise to severe variants (class I). *Open ellipses* are pathogenic variants causing class IV variants. X is a nonsense pathogenic variant; *f*, a splice site pathogenic variant; *filled squares*, small deletions. 202A and 968C are the two sites of base substitution in G6PD-A. *(From Cappellini MD, Fiorelli G. Glucose-6-phosphate dehydrogenase deficiency. Lancet. 2008;371:64–74.)*

The deficiency is caused by inheritance of any of a large number of abnormal alleles of the gene responsible for the synthesis of the G6PD protein. Over 200 pathogenic variants have been described in the gene responsible for the synthesis of the G6PD protein. Many of these pathogenic variants are missense point pathogenic variants leading to amino acid substitutions and destabilization of the G6PD enzyme. Figure 512.2 shows some of the pathogenic variants that cause episodic versus chronic hemolysis. Milder disease is associated with pathogenic variants near the *amino* terminus of the G6PD molecule, and chronic nonspherocytic hemolytic anemia is associated with pathogenic variants clustered near the *carboxyl* terminus near the G6P and NADP-binding sites. The normal enzyme found in most populations is designated G6PD B+. A normal variant, designated G6PD A+, is common in Americans of African descent.

EPISODIC OR INDUCED ACUTE HEMOLYTIC ANEMIA

Etiology

G6PD catalyzes the conversion of glucose 6-phosphate to 6-phosphogluconic acid. This reaction produces NADPH, which maintains GSH (glutathione in its reduced, functional state; see Fig. 512.1). GSH provides protection against **oxidant threats** from certain drugs and infections that would otherwise cause precipitation of hemoglobin (Heinz bodies) or damage the RBC membrane.

Synthesis of RBC G6PD is determined by a gene on the X chromosome. Thus heterozygous females have intermediate enzymatic activity and have two populations of RBCs: one is normal, and the other is deficient in G6PD activity. Because they have fewer susceptible cells, most heterozygous females do not have clinically evident hemolysis after exposure to oxidant drugs. Rarely, the majority of RBCs is G6PD deficient in heterozygous females because the inactivation of the normal X chromosome is random and sometimes exaggerated.

Disease involving this enzyme therefore occurs more frequently in males than in females. Approximately 13% of male Americans of African descent have a variant enzyme **(G6PD A–)** that results in a deficiency of RBC G6PD activity (5–15% of normal). Italians, Greeks, and other Mediterranean, Middle Eastern, African, and Asian ethnic groups also have a high incidence, ranging from 5–40%, of a variant designated **G6PD B– (G6PD Mediterranean)**. In these variants, the G6PD activity of homozygous females or hemizygous males is <5% of normal. Therefore the defect in Americans of African descent is *less severe* than that in Americans of European descent. A third variant enzyme with greatly reduced activity **(G6PD Canton)** occurs in approximately 5% of the Chinese population.

Clinical Manifestations

Most individuals with G6PD deficiency are asymptomatic, with no clinical manifestations of illness unless triggered by infection, drugs, or ingestion of fava beans. Typically, hemolysis ensues in about 24-96 hours after a patient has ingested a substance with **oxidant properties**. In severe cases, hemoglobinuria and jaundice result, and the Hb concentration may fall precipitously. Drugs that elicit hemolysis in these individuals include fluoroquinolones, methylene blue, sulfonylureas, rasburicase, and antimalarials, such as primaquine and dapsone (Table 512.2). There is mixed evidence regarding the safety data of aspirin and sulfa-containing medications, which are generally thought to be safe. Chemical exposures to henna compounds and naphthalene (e.g., mothballs and deodorant) have also been implicated. The degree of hemolysis varies with the inciting agent, amount ingested, and severity of the enzyme deficiency. In some individuals, ingestion of fava beans also produces an acute, severe hemolytic syndrome, known as **favism**. Fava beans contain divicine, isouramil, and convicine, which ultimately lead to production of hydrogen peroxide and other reactive oxygen products. Favism is thought to be more frequently associated with the G6PD Mediterranean and G6PD Canton variants.

In the G6PD A– variant, the stability of the folded protein dimer is impaired, and this defect is accentuated as the RBCs age. Thus hemolysis decreases as older RBCs are destroyed, even if administration of the drug is continued. This recovery results from the *age-labile enzyme*, which is abundant and more stable in younger RBCs (Fig. 512.3). The associated reticulocytosis produces a compensated hemolytic process in which the blood hemoglobin may be only slightly decreased, despite continued exposure to the offending agent.

G6PD deficiency can produce hemolysis in the neonatal period. In G6PD A–, spontaneous hemolysis and hyperbilirubinemia have been observed in preterm infants. In newborns with the G6PD B– and G6PD Canton varieties, hyperbilirubinemia and even kernicterus may occur. Neonates with co-inheritance of G6PD deficiency and a pathogenic variant of the promoter of uridine-diphosphate-glucuronyl transferase (UGT1A1), seen in **Gilbert syndrome**, have more severe neonatal jaundice. When a pregnant woman ingests oxidant drugs, they may be transmitted to her G6PD-deficient fetus, and hemolytic anemia and jaundice may be apparent at birth. Similarly, medications may be transmitted to a neonate through breast milk.

Laboratory Findings

The onset of acute hemolysis usually results in a precipitous fall in hemoglobin and hematocrit. If the episode is severe, the Hb-binding proteins, such as haptoglobin, are saturated, and free hemoglobin may appear in the plasma and subsequently in the urine. Hemolysis is intravascular and extravascular. Unstained or supravital preparations of RBCs reveal precipitated hemoglobin, or Heinz bodies. The RBC inclusions are not visible on the Wright-stained blood film. Cells that contain these inclusions are seen only within the first 3-4 days of illness because they are rapidly cleared from the blood. Also, the blood film may contain RBCs with what appears to be a bite taken from their periphery ("bite cells") and **polychromasia** (evidence of bluish, larger RBCs), representing reticulocytosis (Fig. 512.4).

Diagnosis

The diagnosis depends on direct or indirect demonstration of reduced G6PD activity in RBCs. By direct measurement, enzyme activity in affected persons is ≤10% of normal, and the reduction of enzyme activity is more extreme in Americans of European descent and in Asians than in Americans of African descent. Satisfactory screening tests are based on decolorization of methylene blue, reduction of methemoglobin, or fluorescence of NADPH. Confirmatory testing is available using quantitative NADPH formation measured spectrophotometrically. Immediately after a hemolytic episode, reticulocytes and young RBCs predominate. These young cells have significantly higher enzyme activity than do older cells in the A– variety (African). *Testing may therefore have to be deferred for a few weeks before a diagnostically low*

Table 512.2 Agents Precipitating Hemolysis in Glucose-6-Phosphate Dehydrogenase Deficiency

DEFINITE RISK OF AHA	"POSSIBLE" RISK OF AHA	POSSIBLE ASSOCIATION (LESS LIKELY)

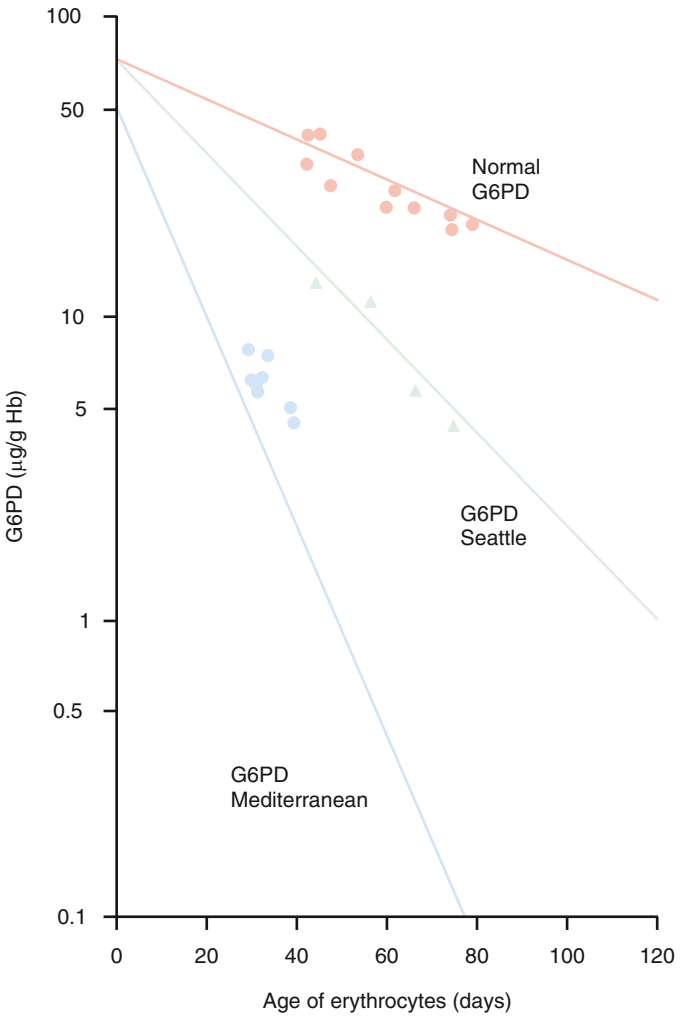

Fig. 512.3 Main mechanism of G6PD deficiency in RBCs is in vivo instability of mutant enzyme. For many G6PD variants, such as the two studied here, this is essentially acceleration of a process that takes place normally with the aging of RBCs in the circulation. Hb, Hemoglobin. *(Adapted from Morelli A, Benatti U, Gaetani GF, et al. Biochemical mechanisms of glucose-6-phosphate dehydrogenase deficiency. Proc Natl Acad Sci USA. 1978;75:1979–1983.)*

level of enzyme can be shown. The diagnosis can be suspected when G6PD activity is within the low-normal range in the presence of a high reticulocyte count. G6PD variants also can be detected by electrophoretic and molecular analysis. G6PD deficiency should be considered in any neonatal patients with hyperbilirubinemia and borderline low G6PD activity.

Prevention and Treatment

Prevention of hemolysis constitutes the most important therapeutic measure. When possible, males belonging to ethnic groups with a significant incidence of G6PD deficiency (e.g., Greeks, southern Italians, Sephardic Jews, Filipinos, southern Chinese, Black Americans, Thais) should be tested for the defect before known oxidant drugs are given.

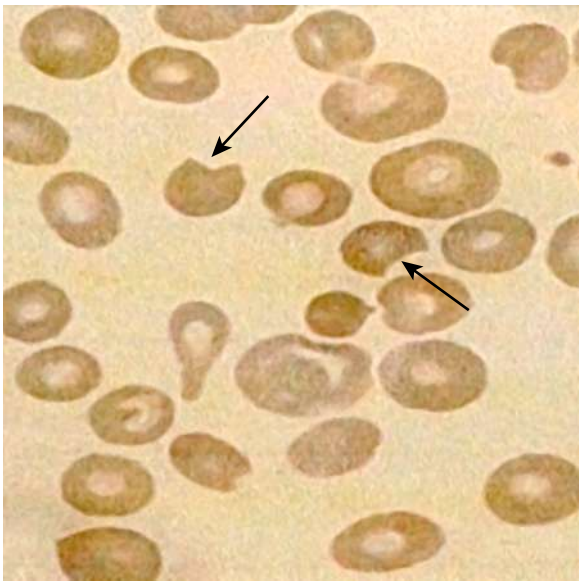

Fig. 512.4 Morphologic erythrocyte changes (anisopoikilocytosis, bite cells) during acute hemolysis in a G6PD-deficient patient. *Arrows* show bite cells. *Anisopoikilocytosis* is abnormality in the shape or size of erythrocytes. *(From Cappellini MD, Fiorelli G. Glucose-6-phosphate dehydrogenase deficiency. Lancet. 2008;371:64–74.)*

The usual doses of aspirin and trimethoprim-sulfamethoxazole do not cause clinically relevant hemolysis in the A– variety. Aspirin administered in doses used for acute rheumatic fever (50-100 mg/kg/24 hr) may produce a severe hemolytic episode. Infants with severe neonatal jaundice who belong to these ethnic groups also require testing for G6PD deficiency because of their heightened risk for this defect. If severe hemolysis has occurred, supportive therapy may require blood transfusions, although recovery is the rule when the oxidant agent is discontinued.

CHRONIC HEMOLYTIC ANEMIAS ASSOCIATED WITH DEFICIENCY OF G6PD OR RELATED FACTORS

Chronic **nonspherocytic hemolytic anemia** has been associated with profound deficiency of G6PD caused by enzyme variants, particularly those defective in quantity, activity, or stability. The gene defects leading to chronic hemolysis are located primarily in the region of the NADP-binding site near the carboxyl terminus of the protein (see Fig. 512.2). These include the Loma Linda, Tomah, Iowa, Beverly Hills, Nashville, Riverside, Santiago de Cuba, and Andalus variants. Persons with G6PD B– enzyme deficiency occasionally have chronic hemolysis, and the hemolytic process may worsen after ingestion of oxidant drugs. Splenectomy is of little value in these types of chronic hemolysis.

Other enzyme defects may impair the regeneration of GSH as an oxidant "sump" (see Fig. 512.1). Mild, chronic nonspherocytic anemia has been reported in association with decreased RBC GSH, resulting from γ-glutamylcysteine or GSH synthetase deficiencies. Deficiency of 6-phosphogluconate dehydrogenase has been associated primarily with drug-induced hemolysis, and hemolysis with hyperbilirubinemia has been related to a deficiency of GSH peroxidase in newborn infants.

Chapter 513

Hemolytic Anemias Resulting from Extracellular Factors—Immune Hemolytic Anemias

Allison S. Remiker and Amanda M. Brandow

IMMUNE HEMOLYTIC ANEMIAS

A number of extrinsic agents and disorders may lead to premature destruction of red blood cells (RBCs) at a rate where hemolysis exceeds hematopoietic replacement. Among the most clearly defined are antibodies associated with immune hemolytic anemias. The hallmark of this group of diseases is the positive result of the direct antiglobulin **(Coombs)** test (DAT), which detects a coating of immunoglobulin or components of complement on the RBC surface. The most important immune hemolytic disorder in pediatric practice is hemolytic disease of the newborn (erythroblastosis fetalis), caused by transplacental transfer of maternal antibody active against the RBCs of the fetus, that is, isoimmune hemolytic anemia (see Chapter 140).

Various other immune hemolytic anemias are **autoimmune** (Table 513.1). Often, no underlying cause can be found; this is the *primary* or idiopathic type. If the autoimmune hemolysis is associated with an underlying disease, including various infections (Epstein-Barr virus [EBV], rarely HIV, cytomegalovirus, and mycoplasma), autoimmune or inflammatory diseases (autoimmune lymphoproliferative disease [ALPS], systemic lupus erythematosus [SLE], rheumatoid arthritis, type 1 diabetes mellitus, ulcerative colitis), primary immunodeficiency diseases (common variable immunodeficiency [CVID], Wiskott-Aldrich syndrome), neoplasms (lymphoproliferative, solid tumors), or posttransplant (solid organ or allogeneic stem cell), it is considered *secondary* (Table 513.2). As many as 20% of episodes of autoimmune hemolysis are drug-induced (e.g.,

*Consider screening for these conditions in children with chronic single lineage autoimmune cytopenias or multi-lineage autoimmune cytopenias.

**Consider also screening for HIV in adolescents with chronic single lineage or multi-lineage autoimmune cytopenias. Other diseases should be considered if the history or physical are suggestive of the underlying condition. It is extremely rare for the other conditions to present with autoimmune cytopenias and no other signs or symptoms suggestive of the underlying disease. Thus, the utility of routine screening is low.

EBV, Epstein-Barr virus; CMV, cytomegalovirus; HCV, hepatitis C virus; ANA, antinuclear antibody; IPEX, immune dysregulation, polyendocrinopathy, enteropathy X-linked.

methyldopa, L-dopa, checkpoint inhibitors). Other drugs (penicillins, cephalosporins) cause hemolysis by means of "drug-dependent antibodies"—antibodies directed toward the drug and in some cases toward an RBC membrane antigen as well.

Etiology

Autoimmune hemolytic anemia (AIHA) is caused by the production of anti-RBC autoantibodies generated by tissue and self-reactive B lymphocytes circulating in the periphery supported by T helper lymphocytes. The complement system induces sequential activation of the membrane attack complex (MAC) leading to erythrocyte lysis typically in the liver and circulation. RBCs are opsonized by the autoantibodies or complement then phagocytosed primarily in the spleen and lymph tissue. Antibody-dependent cell-mediated cytotoxicity (ADCC) induced by cytotoxic $CD8^+$ T lymphocytes and natural killer (NK) cells are an additional important mechanism contributing to AIHA also predominantly in lymphoid organs and the spleen.

The underlying cause of autoimmunity is loss of central self-tolerance in the early stages of lymphocyte differentiation, as well as loss of peripheral self-tolerance driven by Tregs and $CD8^+$ suppressor T lymphocytes. Loss of tolerance allows for autoreactive cells to avoid negative selection, and/or suppression of autoantibodies fails to occur appropriately in the periphery. It is theorized patients who develop AIHA have an underlying predisposition to losing such self-tolerance, which is stimulated by environmental factors.

The autoantibody may be produced as an inappropriate immune response to an RBC antigen or to another antigenic epitope similar to an RBC antigen, known as *molecular mimicry.* Alternatively, an infectious agent may alter the RBC membrane so that it becomes "foreign" or antigenic to the host.

The autoantibodies that form in AIHA have antibody class, antigenic reactivity, and thermal characteristics associated with binding and/or destroying erythrocytes. The temperature predilection is associated with corresponding nomenclature, including warm (wAIHA), cold (cold agglutinin disease [CAD]), paroxysmal cold hemoglobinuria (PCH), and rare mixed forms.

AUTOIMMUNE HEMOLYTIC ANEMIAS ASSOCIATED WITH "WARM" ANTIBODIES

Etiology

Warm autoimmune hemolytic anemia (wAIHA) is the most common form in children found in as many as 90% of cases. Autoantibodies are "warm-reactive" meaning they preferentially bind to erythrocytes at 37°C. Extravascular hemolysis occurs in the spleen. Typically, the antibodies are immunoglobulin (Ig) G, and react to epitopes (antigens) that are "public" or common to all human RBCs, such as Rh proteins. When IgG is present in exceptional quantity, it can fix complement, which results in intravascular hemolysis.

Clinical Manifestations

Patients with wAIHA present with symptoms consistent with anemia and nonspecific signs of hemolysis. Onset may be acute, with pallor, jaundice, icterus, hemoglobinuria, abdominal pain, fever, shortness of breath, and dizziness, or more gradual with primarily fatigue and pallor. Cardiovascular compromise is rare. The spleen is usually enlarged and is the primary site of destruction of IgG-coated RBCs.

Laboratory Findings

In many cases, anemia is profound with hemoglobin (Hb) levels <6 g/dL. Considerable spherocytosis and polychromasia (reflecting the reticulocyte response) are present. More than 50% of the circulating RBCs may be reticulocytes, and nucleated RBCs usually are present. In some cases, a *low reticulocyte count* may be found, particularly early in the episode due to similar epitopes on RBC precursors in the marrow, marrow suppression if there is concurrent infection, and/or a "shocked" marrow after a severe hemolytic event. Leukocytosis is common. The platelet count is usually normal, but concomitant immune thrombocytopenic purpura sometimes occurs (**Evans syndrome**). Patients with Evans syndrome often have or eventually develop a chronic disease, including SLE, an immunodeficiency syndrome (common variable immunodeficiency), or autoimmune lymphoproliferative syndrome.

Results of the **DAT (Coombs test)** are strongly positive, and free antibody can sometimes be demonstrated in the serum **(indirect Coombs test)**. These antibodies are active at 35–40°C (95–104°F) ("warm" antibodies) and most often belong to the IgG class. They do not require complement for activity. Antibodies from the serum and those eluted from the RBCs react with the RBCs of many persons in addition to those of the patient. They often have been regarded as nonspecific panagglutinins, but careful studies have revealed specificity for RBC antigens of the Rh system in 70% of patients (50% of adult patients). Complement, particularly fragments of C3b, may be detected on the RBCs in conjunction with IgG. The Coombs test result is *rarely* negative because of the sensitivity of the Coombs reaction. A minimum of 260-400 molecules of IgG per cell is necessary on the RBC membrane to produce a positive reaction. Special tests are required to detect the antibody in cases of "Coombs-negative" autoimmune hemolytic anemia. In warm antibody hemolytic anemia, the direct Coombs test may detect IgG alone, both IgG and complement fragments, or solely complement fragments if the level of RBC-bound IgG is below the detection limit of the anti-IgG Coombs reagent.

Treatment

Transfusions may provide only transient benefit but may be lifesaving in cases of severe anemia until the effects of other treatments are observed. All tested units for transfusion are serologically incompatible. It is important to identify the patient's ABO blood group to avoid a hemolytic transfusion reaction mediated by anti-A or anti-B. The blood bank should also test for the presence of an underlying alloantibody, which could cause rapid hemolysis of transfused RBCs. Patients who have been neither previously transfused nor pregnant are unlikely to harbor an alloantibody. Early consultation between the clinician and the blood bank physician is essential. Failure to transfuse a profoundly anemic infant or child may lead to serious morbidity and even death.

Patients with mild disease and compensated hemolysis may not require treatment. *If the hemolysis is severe and results in significant anemia or symptoms, treatment with glucocorticoids is initiated.* Glucocorticoids decrease the rate of hemolysis by blocking macrophage function through downregulating Fcγ receptor expression, decreasing the production of the autoantibody, and perhaps enhancing the elution of antibody from the RBCs. Initial dosing is dependent on the degree of anemia and symptoms. In patients who present with Hb <6 to 7 g/dL or severe symptoms, initial treatment with intravenous (IV) methylprednisolone 0.5-1 mg/kg every 6 to 8 hours in the first 24-72 hours is typically indicated. With rapid deterioration or severity of anemia, high-dose methylprednisolone 30 mg/kg with maximum 1 g daily for 3 days may be required. When hemolytic anemia remains severe despite glucocorticoid therapy, or if very large doses are necessary to maintain a reasonable Hb level, intravenous immunoglobulin (IVIG) may be tried. Long-term use of IVIG has not been shown to be effective in the majority of children. In children who present with mild to moderate anemia with Hg ≥7 to 8 g/dL and an appropriate reticulocyte count, oral prednisone 2 mg/kg/day may be started. Response is typically seen within 2-4 weeks after initiation of steroids and considered adequate with Hb concentration >9 to 10 g/dL. Hb, reticulocyte count, lactate dehydrogenase, and DAT should be monitored for response. Treatment should be continued until the rate of hemolysis decreases, with the dose then gradually reduced, typically over at least 4 months. The Coombs test result may remain positive even after the Hb level returns to normal. It is usually safe to discontinue prednisone once the direct Coombs test result becomes negative.

The majority of patients (approximately 80%) have an initial response to glucocorticoids within the first month of treatment; however, it is common to require prolonged or multimodal therapies over time. If a patient is unable to taper prednisone effectively within 1-2 months after diagnosis, addition of a second-line therapy should be considered.

Relapse occurs in 15–40% of patients with wAIHA, typically within the first 6-12 months after initial response to treatment. If this occurs, resumption of the lowest dose of prednisone that was effective in treating the patient is recommended. Because of the adverse effects of long-term steroid use, alternative agents could be considered if relapse continues to occur.

There are limited data in second-line therapies for wAIHA in children. **Rituximab**, a monoclonal antibody that targets B lymphocytes, the source of antibody production, *is useful in chronic cases refractory to conventional therapy.* Plasmapheresis has been used in refractory cases but generally is not helpful because most hemolysis is in the extravascular space. Splenectomy may be beneficial but is complicated by a heightened risk of infection with encapsulated organisms, particularly in patients <6 years old. Prophylaxis is indicated with appropriate vaccines (pneumococcal, meningococcal, and *Haemophilus influenzae* type b) before splenectomy and with oral penicillin after splenectomy. Thrombosis and pulmonary hypertension are also increasingly recognized problems after splenectomy. In refractory disease, several immunomodulating agents have been used in small case series or reports including azathioprine, 6-mercaptopurine, cyclosporine, mycophenolate mofetil, tacrolimus, sirolimus, and monoclonal antibodies (e.g., obinutuzumab, daratumumab, alemtuzumab, bortezomib).

Prognosis

Acute idiopathic autoimmune hemolytic disease in childhood varies in severity but is self-limited; death from untreatable anemia is rare. Approximately 30% of patients have chronic hemolysis, often associated with an underlying disease, such as SLE, immunodeficiency, or lymphoma. The presence of antiphospholipid antibodies in adult patients with immune hemolysis predisposes to thrombosis. Mortality in chronic cases depends on the primary disorder.

AUTOIMMUNE HEMOLYTIC ANEMIAS ASSOCIATED WITH "COLD" ANTIBODIES OR COLD AGGLUTININ DISEASE

"Cold" antibodies agglutinate RBCs at temperatures <37°C (98.6°F). They are primarily of the IgM class and require complement for hemolytic activity. The highest temperature at which RBC agglutination occurs is called the thermal amplitude. A higher thermal amplitude antibody—that is, one that can bind to RBCs at temperatures achievable in the body—results in hemolysis with exposure to a cold environment. High antibody titers are associated with high thermal amplitude.

Cold antibodies usually have specificity for the oligosaccharide antigens of the I/i system. They may occur in primary or idiopathic cold agglutinin disease, secondary to infections such as those from *Mycoplasma pneumoniae* and EBV, or secondary to lymphoproliferative disorders. After *M. pneumoniae* infection, the anti-I levels may increase considerably, and occasionally, enormous increases may occur to titers ≥1/30,000. The antibody has specificity for the I antigen and thus reacts poorly with human cord RBCs, which possess the i antigen but exhibit low levels of I. Patients with infectious mononucleosis occasionally have CAD, and the antibodies in these patients often have anti-i specificity. This antibody causes less hemolysis in adults than in children because adults have fewer i molecules on their RBCs. Spontaneous RBC agglutination is observed in the cold and in vitro, and RBC aggregates are seen on the blood film (rouleaux formation). Mean corpuscular volume (MCV) may be spuriously elevated because of RBC agglutination and reticulocytosis. The severity of the hemolysis is related to the thermal amplitude of the antibody, which itself partly depends on the IgM antibody titer.

When very high titers of cold antibodies are present and active near body temperature, severe intravascular hemolysis with hemoglobinemia and hemoglobinuria may occur and may be heightened on a patient's exposure to cold (external temperature or ingested foods). Each IgM molecule has the potential to activate a C1 molecule, so that large amounts of complement are found on the RBCs in CAD. These sensitized RBCs may undergo intravascular complement-mediated lysis or may be destroyed in the liver and spleen. Only complement, not IgM, is detected on RBCs because the IgM is removed during the washing steps of the DAT.

CAD is less common in children than in adults and more frequently results in an acute, self-limited episode of hemolysis. RBC transfusion is indicated based on symptoms and severity of anemia. If transfusion is required, blood should be warmed before administration. Glucocorticoids are much less effective in CAD than in hemolytic disease with warm antibodies. Patients should avoid exposure to cold and should be treated for any underlying disease. In the uncommon patient with severe hemolytic disease, immunosuppression and plasmapheresis can be used. Successful treatment of CAD has been reported with rituximab, which effectively depletes B lymphocytes. Splenectomy is not useful in CAD.

Paroxysmal Cold Hemoglobinuria

Paroxysmal cold hemoglobinuria is mediated by the Donath-Landsteiner (D-L) hemolysin, which is an IgG cold-reactive autoantibody with anti-P specificity. In vitro, the D-L antibody binds to RBCs in the cold, and the RBCs are lysed by complement as the temperature is increased to 37°C. A similar sequence is thought to occur in vivo as RBCs move from the cooler extremities to warmer parts of the circulation. Most reported cases are self-limited; many patients experience only one paroxysm of hemolysis. Congenital or acquired syphilis was once the most common underlying cause of paroxysmal cold hemoglobinuria, but currently, most cases are associated with nonspecific viral infections. Treatment includes transfusion for severe anemia and avoidance of cold ambient temperatures.

Drug-Induced Hemolytic Anemia

Drugs (penicillin or sometimes cephalosporins) that cause hemolysis through the "hapten" mechanism (immune but not autoimmune) bind tightly to the RBC membrane. Antibodies to the drug, either newly or previously formed, bind to the drug molecules on RBCs, mediating their destruction in the spleen. In other cases, certain drugs, such as quinine and quinidine, do not bind to RBCs, but rather form part of a "ternary complex," consisting of the drug, an RBC membrane antigen, and an antibody that recognizes both (see Table 513.3). Methyldopa and sometimes cephalosporins may, by unknown mechanisms, incite true autoantibodies to RBC membrane antigens, so that the presence of the drug is not required to cause hemolysis. Cephalosporins are the most common cause of drug-induced immune hemolytic anemia.

Chapter 514

Hemolytic Anemias Secondary to Other Extracellular Factors

Allison S. Remiker and Amanda M. Brandow

FRAGMENTATION HEMOLYSIS

See Table 506.2 in Chapter 506.

Red blood cell (RBC) destruction may occur in hemolytic anemias because of **mechanical injury** as the cells traverse a damaged vascular bed. Damage may be microvascular when RBCs are sheared by fibrin in the capillaries during intravascular coagulation or when renovascular disease accompanies the **hemolytic-uremic syndrome (HUS)** (see Chapter 560.5) or **thrombotic thrombocytopenic purpura (TTP)** (see Chapter 533.5). Larger vessels may be involved in **Kasabach-Merritt syndrome** (giant hemangioma and thrombocytopenia; see Chapter 554) or when a replacement heart valve is poorly epithelialized. The blood film shows many *schistocytes*, or fragmented cells, as well as polychromatophilia, reflecting the reticulocytosis (see Fig. 507.4F in Chapter 507 on Castleman disease). Secondary iron deficiency may complicate the intravascular hemolysis because of urinary hemoglobin and hemosiderin iron loss (see Fig. 506.2 in Chapter 506). **Treatment should be directed toward the underlying condition**, and the prognosis depends on the effectiveness of this treatment. The benefit of transfusion may be transient because the transfused cells are destroyed as quickly as those produced by the patient.

It is critical to determine the precise etiology of the fragmentation hemolysis because the treatment depends on the underlying problem (Table 514.1). **Acquired TTP** results from an antibody to an enzyme (ADAMTS13) that regulates the size of von Willebrand multimers. The lack of this enzyme results in a marked increase in multimer size and a resultant *thrombotic microangiopathy*. **Congenital TTP** can result in the inability to produce adequate amounts of the enzyme ADAMTS13 and results in the same pathophysiology. The treatment for acquired TTP involves plasma exchange (PEX) to remove the antibody and replace the ADAMTS13, in addition to immunosuppressive therapy with glucocorticoids. Treatment should be initiated as soon as possible when there is a high index of suspicion, even before confirmation of the diagnosis because of high morbidity and mortality. Once diagnosis has been confirmed, rituximab is suggested. Use of caplacizumab, an anti-von Willebrand factor monoclonal antibody, is used in adult patients with severe disease, although it has not been approved by the US Food and Drug Administration (FDA) in children. The treatment for congenital TTP involves scheduled plasma infusions to replace the ADAMTS13. Recombinant ADAMTS13 is under investigation for use in acquired and congenital TTP. In contrast, HUS results from *Shiga* toxin produced by *Escherichia coli* 0157 and may not be helped by plasmapheresis, and treatment is largely based on supportive measures. **Atypical HUS** involves activation of the alternative complement pathway and can be treated with *eculizumab* (anti-C5), an inhibitor of the complement pathway. Plasmapheresis may reduce the RBC fragmentation and improve the platelet count but has little effect on the tissue (kidney) vasculopathy, and thus is not usually recommended. **Pneumococcal-induced HUS** results from neuraminidase produced by the bacteria, which damages the membranes of the RBCs and the kidney, exposing the **T-antigen**. Plasma contains natural antibody to the T-antigen, producing hemolysis, renal damage, and a thrombotic microangiopathy. Thus, patients with T-antigen activation from suspected pneumococcal-induced HUS should not be given plasma infusions because this will significantly exacerbate the RBC hemolysis and can lead to life-threatening anemia.

THERMAL INJURY

Extensive burns may directly damage the RBCs and cause hemolysis that results in the formation of *spherocytes*. Blood loss and marrow suppression may contribute to anemia and require blood transfusion. Erythropoietin (EPO) has been used as treatment for diminished RBC production. There may be a role of early use of propranolol, which has been shown to restore erythrocyte progenitors.

Table 514.1 Thrombotic Microangiopathies

DISEASE*	PATHOPHYSIOLOGY	LAB FINDINGS	MANAGEMENT
Thrombotic thrombocytopenic purpura (TTP)	*Acquired:* Ab to ADAMTS13 *Congenital:* Inadequate ADAMTS13 production	Ab to ADAMTS13 ADAMTS13 <10%	*Acquired:* Plasma exchange (PEX) Glucocorticoids +/- Rituximab *Congenital:* Scheduled plasma infusions, recombinant ADAMTS13
Hemolytic-uremic syndrome (HUS)	*Escherichia coli* 0157, *Shiga* toxin	*E. coli* 0157, *Shiga* toxin	Supportive ? Value of plasmapheresis
Atypical HUS	Complement-mediated alternative pathway	ADAMTS13 >10% Decreased factors H and I (inhibitors of complement)†	Eculizumab (Ab to C5) Plasmapheresis not indicated
Pneumococcal-induced HUS	Neuraminidase-induced RBC, platelet, and kidney damage Exposure of T-antigen on RBC and kidney	Pneumococcal infection ADAMTS13 >10%	Plasmapheresis with albumin for neuraminidase and endogenous T Ab removal Avoid plasma infusions, which will exacerbate RBC hemolysis
Disseminated intravascular coagulation (DIC)	Sepsis, shock, endotoxin	Decreased fibrinogen, increased fibrin split products, decreased clotting factors and platelets	Treat underlying condition; replace factors and platelets if bleeding

*All show fragmentation hemolytic anemia, thrombocytopenia, and potential renal and other organ damage. An elevated lactate dehydrogenase and reduced haptoglobin usually are present secondary to hemolysis.
†May be related to inherited defect in factor H or I.
Ab, Antibody; RBC, red blood cell.

RENAL DISEASE

The anemia of uremia is multifactorial in origin. EPO production may be decreased, and the marrow suppressed by toxic metabolites. Furthermore, the RBC life span often is shortened because of retention of metabolites and organic acidemia. The use of EPO in chronic renal disease can decrease the need for blood transfusion. Abnormalities in the hepcidin-ferroportin pathway provide an additional pathway contributing to anemia associated with chronic kidney disease. Investigative use of medications targeting this pathway are being evaluated in patients. Hemodialysis is also implicated in causing fragmentation of erythrocytes.

LIVER DISEASE

A change in the ratio of cholesterol to phospholipids in the plasma may result in changes in the composition of the RBC membrane and shortening of the RBC life span. Some patients with liver disease have many target RBCs on the blood film, whereas others have a preponderance of *spiculated cells.* These morphologic changes reflect the alterations in the plasma lipid composition.

TOXINS AND VENOMS

Bacterial sepsis caused by *Haemophilus influenzae,* staphylococci, or streptococci may be complicated by accompanying hemolysis. Particularly severe hemolytic anemia has been observed in clostridial infections and results from a hemolytic clostridial toxin. Large numbers of spherocytes may be seen on the blood film. **Spherocytic hemolysis** also may be noted after bites by various snakes, including cobras, vipers, and rattlesnakes, which have phospholipases in their venom. Large numbers of bites by insects, such as bees, wasps, and yellow jackets, also may cause spherocytic hemolysis by a similar mechanism (see Chapter 768).

WILSON DISEASE

See Chapter 405.2.

An acute and self-limited episode of hemolytic anemia may precede by years the onset of hepatic or neurologic symptoms in Wilson disease. This event appears to result from the toxic effects of free copper on the RBC membrane. The blood film often (but not always) shows large numbers of spherocytes, and the Coombs test result is negative. Because early diagnosis of Wilson disease permits prophylactic treatment with penicillamine and prevention of hepatic and neurologic disease, correct assessment of this rare type of hemolysis is important.

Section 4

Polycythemia (Erythrocytosis)

Chapter 515

Polycythemia

Allison S. Remiker and Amanda M. Brandow

Polycythemia exists when the hemoglobin concentration and/or hematocrit and total red blood cell (RBC) volume exceed the upper limits of normal in peripheral blood. In postpubertal individuals, an RBC mass >25% above the mean normal value (based on body surface area) or a hemoglobin level >16.5 g/dL (in males) or >16.0 g/dL (in females) and/or hematocrit >49% (in males) or >48% (in females) indicate **absolute erythrocytosis**. A decrease in plasma volume, such as occurs in acute dehydration and burns, may result in a high hemoglobin value. These situations are more accurately designated as **hemoconcentration** or **relative polycythemia** because the RBC mass is not increased, and normalization of the plasma volume restores hemoglobin to normal levels. Once the diagnosis of true polycythemia is made, sequential studies should be done to determine the underlying etiology (Fig. 515.1).

CLONAL POLYCYTHEMIA (POLYCYTHEMIA VERA)

Pathogenesis

Polycythemia vera is an acquired clonal myeloproliferative neoplastic disorder, which is rare in children and adolescents. The median age of diagnosis is >60 years. Although primarily manifesting as erythrocytosis, thrombocytosis and leukocytosis can also be seen. When isolated severe thrombocytosis exists in the absence of erythrocytosis, the myeloproliferative disorder is called **essential thrombocythemia**. A gain-of-function pathogenic variant involving exon 12 or 14 (V617F) of *JAK2,* a cytoplasmic tyrosine kinase, is found in >90% of adult patients with polycythemia vera, but in <30% of children with this condition. The erythropoietin receptor is normal, and serum erythropoietin levels are low. Patients without *JAK* pathogenic variants may have variants in the calreticulin or thrombopoietin receptor genes. Risk factors for development of polycythemia vera include a family history of polycythemia vera and presence of an autoimmune disorder.

Clinical Manifestations

Patients with polycythemia vera usually have splenomegaly. Erythrocytosis may cause hypertension, headache, early satiety, or neurologic symptoms and increases the risk of thrombosis. Granulocytosis may cause diarrhea or pruritus from histamine release. Thrombocytosis (with or without platelet dysfunction) may cause thrombosis or hemorrhage. Bleeding or acquired von Willebrand disease with extreme thrombocytosis, and complications of pregnancy may occur. Long-term effects include progression to myelofibrosis, myelodysplasia, and/or acute leukemia. These events are rare in children. Table 515.1 lists the diagnostic criteria for polycythemia vera.

Treatment

Phlebotomy and low-dose aspirin are the initial treatments of choice to alleviate symptoms of hyperviscosity and decrease the risk of thrombosis. Iron supplementation should be given to prevent viscosity problems from iron-deficient microcytosis or thrombocytosis. If these treatments are unsuccessful, the patient has progressive splenomegaly, thrombocytosis, or leukocytosis, or has high-risk features (i.e., age >60 or history of thrombosis), antiproliferative treatments (hydroxyurea, pegylated interferon, or busulfan) may be helpful. The use of ruxolitinib (a JAK2 inhibitor) is approved in hydroxyurea-resistant or hydroxyurea-intolerant adult patients, but the long-term effectiveness remains under investigation. There are limited data in the treatment of children, given the rarity of the condition. Often only phlebotomy is required. Transformation of the disease into myelofibrosis or acute leukemia is rare in children.

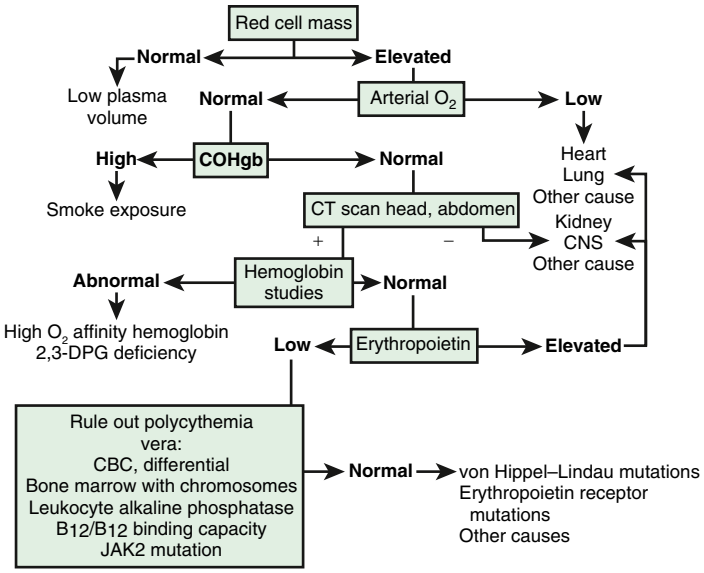

Fig. 515.1 Algorithm showing sequential studies in the evaluation of polycythemia. CBC, Complete blood count; CNS, central nervous system; COHgb, carboxyhemoglobin; 2,3-DPG, 2,3-diphosphoglycerate.

Table 515.1 World Health Organization (WHO) Diagnostic Criteria for Polycythemia Vera

MAJOR CRITERIA
1. Hb >16.5 g/dL (males) or Hb >16.0 g/dL (females)
   or
   Hct >49% (males) or >48% (females)
   or
   Elevated red cell mass >25% above mean normal predicted value
2. Bone marrow (BM) biopsy showing hypercellularity for age with trilineage growth (panmyelosis) including prominent erythroid, granulocytic, and megakaryocytic proliferation with pleomorphic mature megakaryocytes (difference in sizes)
3. Presence of *JAK2* or JAK2 exon 12 mutation

MINOR CRITERIA
1. Subnormal serum erythropoietin level

DIAGNOSIS
All three major criteria
or
First two major criteria and the minor criterion*

*Criterion number 2 (BM biopsy) may not be required in cases with sustained absolute erythrocytosis: hemoglobin levels >18.5 g/dL in males (hematocrit, 55.5%) or 16.5 g/dL in females (hematocrit >49.5%) if major criterion 3 and the minor criterion are present. However, initial myelofibrosis (present in up to 20% of patients) can only be detected by performing a BM biopsy; this finding may predict a more rapid progression to overt myelofibrosis (post-PV MF).

Hb, Hemoglobin; Hct, hematocrit.

Table 516.1 Differential Diagnosis of Polycythemia

CLONAL (PRIMARY)
Polycythemia vera

NONCLONAL
Congenital
High–oxygen affinity hemoglobinopathy (e.g., hemoglobin Chesapeake, Malmo, San Diego)
Erythropoietin receptor mutations (primary familial and congenital polycythemia [PFCP])
Methemoglobin reductase deficiency
Hemoglobin M disease
2,3-Diphosphoglycerate deficiency

Acquired
Hormonal
- Adrenal disease: virilizing hyperplasia, Cushing syndrome
- Athletic performance enhancing substances (e.g., anabolic steroids, androgens, recombinant erythropoiesis stimulating agents)
- Malignant tumors: adrenal, cerebellar, hepatic, other
- Renal disease: cysts, hydronephrosis, renal artery stenosis

Hypoxia
- Altitude
- Cardiac disease
- Lung disease
- Sleep apnea
- Central hypoventilation
- Chronic carbon monoxide exposure including smoking

Neonatal: delayed cord clamping (placental-fetal transfusion)
- Normal intrauterine environment
- Placental insufficiency (preeclampsia, maternal chronic hypertension, placental abruption)
- Twin-twin or maternal-fetal hemorrhage
- Perinatal asphyxia
- Infants of diabetic mothers
- Intrauterine growth restriction
- Trisomy 13, 18, or 21
- Adrenal hyperplasia
- Maternal-congenital hyperthyroidism

Spurious
Plasma volume decrease

Chapter 516

Nonclonal Polycythemia

Allison S. Remiker and Amanda M. Brandow

PATHOGENESIS

Nonclonal polycythemia is diagnosed when polycythemia is caused by a physiologic process that is not derived from a single cell (Table 516.1). Nonclonal polycythemia can be congenital or acquired (secondary).

Congenital Polycythemia

Lifelong or familial polycythemia should trigger a search for a congenital problem. These inherited conditions may be transmitted as dominant or recessive disorders instigating erythrocytosis

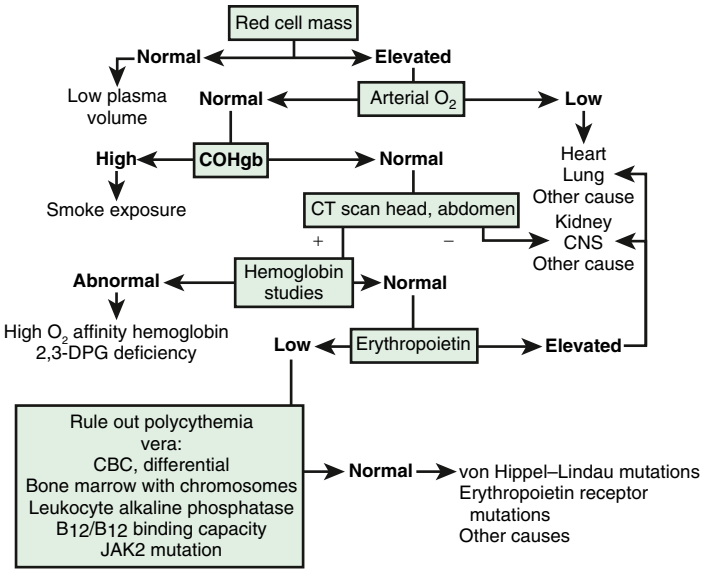

Fig. 515.1 Algorithm showing sequential studies in the evaluation of polycythemia. CBC, Complete blood count; CNS, central nervous system; COHgb, carboxyhemoglobin; 2,3-DPG, 2,3-diphosphoglycerate.

Chapter 516

Nonclonal Polycythemia

Allison S. Remiker and Amanda M. Brandow

PATHOGENESIS

Nonclonal polycythemia is diagnosed when polycythemia is caused by a physiologic process that is not derived from a single cell (Table 516.1). Nonclonal polycythemia can be congenital or acquired (secondary).

Congenital Polycythemia

Lifelong or familial polycythemia should trigger a search for a congenital problem. These inherited conditions may be transmitted as dominant or recessive disorders instigating erythrocytosis

by augmenting hypoxia sensing or abnormalities in oxygen sensing. Autosomal dominant causes include hemoglobins that have increased oxygen affinity (P_{50} [partial pressure of oxygen in the blood at which the hemoglobin is 50% saturated] <20 mm Hg), erythropoietin receptor pathogenic variants resulting in an enhanced effect of erythropoietin, or variants in the von Hippel–Lindau *(VHL), EGLN1*, or *EPAS1* genes that result in altered intracellular oxygen sensing. Another rare cause is autosomal recessive 2,3-diphosphoglyceric acid deficiency, which leads to a left shift of the oxygen dissociation curve, increased oxygen affinity, and consequent polycythemia.

Subtle decreases in oxygen delivery to tissues may cause polycythemia. Congenital **methemoglobinemia** resulting from an autosomal recessive deficiency of cytochrome b5 reductase may cause cyanosis and polycythemia (see Chapter 511.7). Most affected individuals are asymptomatic. Neurologic abnormalities may be present in patients whose enzyme deficits are not limited to hematopoietic cells. Hemoglobin M disease (autosomal dominant) causes methemoglobinemia and can lead to polycythemia. Cyanosis may occur in the presence of as little as 1.5 g/dL of methemoglobin but is uncommon in other hemoglobin variants unless hyperviscosity results in localized hypoxemia.

In rare cases, there is an undefined inherited lesion causing primary familial and congenital polycythemia (PFCP), which is described as an elevation of erythrocyte mass and hemoglobin, hypersensitivity to EPO, and low serum EPO in the setting of a normal hemoglobin-oxygen dissociation curve.

Acquired (Secondary) Polycythemia

Polycythemia may be present in clinical situations associated with chronic arterial oxygen desaturation. Cardiovascular defects involving right-to-left shunts and pulmonary diseases interfering with proper oxygenation are the most common causes of hypoxic polycythemia. Clinical findings usually include cyanosis, hyperemia of the sclerae and mucous membranes, and clubbing of the fingers. As the hematocrit rises to >65%, clinical manifestations of hyperviscosity, such as headache and hypertension, may require phlebotomy. Living at high altitudes also causes hypoxic polycythemia; the hemoglobin level increases approximately 4% for each rise of 1,000 m (~3,300 ft) in altitude. Smoking has been associated with polycythemia secondary to tissue hypoxia, elevation of carbon monoxide, and volume contraction. Partial obstruction of a renal artery rarely results in polycythemia. Polycythemia has also been associated with benign and malignant tumors that secrete paraneoplastic erythropoietin. Exogenous or endogenous excess of anabolic steroids also may cause polycythemia. A common spurious cause is a decrease in plasma volume, as occurs in moderate to severe dehydration.

DIAGNOSIS

See Chapter 515; Figure 515.1 outlines sequential studies to evaluate polycythemia.

TREATMENT

For mild disease, observation is sufficient. When the hematocrit is >65–70% (hemoglobin >23 g/dL), blood viscosity greatly increases. Periodic phlebotomy may prevent or decrease symptoms such as headache, dizziness, or exertional dyspnea. Apheresed blood should be replaced with plasma or saline to prevent hypovolemia in patients accustomed to a chronically elevated total blood volume. Increased demand for red blood cell production may cause iron deficiency. Iron-deficient microcytic red cells are more rigid, further increasing the risk of intracranial and other thromboses in patients with polycythemia. Periodic assessment of iron status should be performed, and iron deficiency should be treated.

Section 5

The Pancytopenias

Chapter 517

Inherited Bone Marrow Failure Syndromes with Pancytopenia

Yigal Dror and Michaela Cada

Pancytopenia refers to a reduction below normal values of all three peripheral blood lineages: leukocytes, platelets, and erythrocytes. Identifying the etiology of pancytopenia usually requires microscopic examination of the peripheral blood smear, as well as bone marrow biopsy and aspirate specimens to assess overall cellularity and morphology. The three general categories of pancytopenia are related to bone marrow pathologies and can frequently be differentiated based on bone marrow findings.

Pancytopenia with hypocellular bone marrow on biopsy is seen with *inherited bone marrow failure syndromes* (IBMFSs) with pancytopenia, *acquired* aplastic anemia of varied etiologies, and the *hypoplastic* variant of *myelodysplastic syndrome* (MDS). **Pancytopenia with cellular bone marrow** is seen with primary bone marrow disease (e.g., acute leukemia, myelodysplasia) and secondary to autoimmune disorders (e.g., autoimmune lymphoproliferative syndrome, systemic lupus erythematosus), vitamin B_{12} or folate deficiency, storage diseases (e.g., Gaucher, Niemann-Pick), overwhelming infection, sarcoidosis, and hypersplenism. **Pancytopenia with bone marrow infiltration** can be seen in metastatic solid tumors, myelofibrosis, hemophagocytic lymphohistiocytosis, and osteopetrosis. It is important to note that exceptions exist with regard to this classification; IBMFSs can manifest as normocellular or hypercellular bone marrow at early stages of presentation or in cases where MDS develops.

Inherited pancytopenias with hypocellular bone marrow are IBMFSs that feature decreased bone marrow production of the three major hematopoietic lineages occurring on an inherited basis and resulting in anemia, neutropenia, and thrombocytopenia. Patients may have single-lineage or bi-lineage cytopenia at presentation and gradually develop pancytopenia over time. All disorders for which a genetic basis has been deciphered have thus far been shown to be monogenic. Transmission of pathogenic variant genes is mendelian and in an autosomal dominant, autosomal recessive, or X-linked manner (Table 517.1). Modifying genes and acquired factors may also be operative. Inherited pancytopenias account for approximately 30% of cases of pediatric bone marrow failure. Clinical features may help differentiate the IBMFS disorders (Table 517.2), but whole exome sequencing (WES) or specific bone marrow failure syndrome gene panels help to confirm the diagnosis.

FANCONI ANEMIA

Etiology and Epidemiology

Fanconi anemia (FA) is a rare multisystem hereditary disorder resulting in the development of bone marrow failure in those affected and a predisposition to malignancy, including myelodysplasia (MDS), acute myeloid leukemia (AML), and epithelial cancers. Individuals with FA

Table 517.1 Inherited Bone Marrow Failure Syndromes with Multilineage Cytopenia and Familial MDS/AML: Inheritance, Variant Genes, and Affected Pathways

DISORDER	INHERITANCE	GENE	AFFECTED PATHWAYS
Fanconi anemia	AR	*FANCA, FANCC, FANCD1/BRCA2, FANCD2, FANCE, FANCF, FANCG/XRCC9, FANCI, FANCJ/BRIP1, FANCL/PHF9, FANCM, FANCN/PALB2, FANCO/RAD51C, FANCP/SLX4, FANCQ/ERCC4, FANCR/RAD51, FANCS/BRCA1, FANCT/UBE2T, FANCU/XRCC2, FANCV/REV7, FANCW/RFWD3*	DNA repair, homologous recombination, ribosome biogenesis *(FANCI)*

Table 517.2 Clinical Manifestations and Laboratory Findings in Inherited Bone Marrow Failure Syndrome

SYNDROME	NONHEMATOLOGICAL CLINICAL MANIFESTATIONS	LABORATORY FINDINGS
Fanconi anemia	Short stature, low birth weight, microcephaly, microphthalmia, hearing loss, triangular face, micrognathia, cardiac anomalies, tracheoesophageal fistula, esophageal atresia, kidney anomalies, hypoplastic thenar eminence, clinodactyly, café-au-lait spots	Pancytopenia, macrocytosis, elevated Hb F, increased chromosome breakage in clastogenic assay
Dyskeratosis congenita	Mucocutaneous triad (skin pigmentation, nail dysplasia, oral leukoplakia), short stature, low birth weight, failure to thrive, pulmonary fibrosis, stenosis of the esophagus, liver fibrosis	Pancytopenia, macrocytosis, elevated Hb F, very short telomeres
Diamond-Blackfan anemia	Low birth weight, short stature, developmental delay, anomalies in craniofacial skeleton, eyes, heart, visceral organs, and limbs	Anemia, elevated red blood cell adenosine deaminase, macrocytosis, elevated Hb F
Shwachman-Diamond syndrome	Exocrine pancreatic insufficiency, failure to thrive, malabsorption, short stature, neurodevelopment and skeletal abnormalities	Neutropenia, low serum isoamylase, low serum trypsinogen
Severe congenital neutropenia	Recurrent infection	Neutropenia
Congenital amegakaryocytic thrombocytopenia	Nonsyndromic (occasionally, growth retardation, cardiac anomalies, psychomotor developmental delay)	Thrombocytopenia, reduced megakaryocytes
GATA2 deficiency	Lymphedema, immunodeficiency, atypical mycobacterial infections	Neutropenia, anemia, thrombocytopenia
SAMD9/SAMD9L disorders	MIRAGE (SAMD9): MDS, infection, restriction of growth, adrenal hypoplasia, genital phenotypes, and enteropathy	Transient or permanent cytopenia
	Ataxia–pancytopenia syndrome (SAMD9L): cerebellar atrophy and white matter hyperintensities, gait disturbance, nystagmus	
MECOM-associated syndromes	Radioulnar synostosis, clinodactyly, hearing loss, cardiac/renal malformation	Thrombocytopenia
Pearson syndrome	Pancreatic insufficiency, failure to thrive, microcephaly, ptosis, Kearns-Sayre syndrome	Neutropenia, anemia, pancytopenia, lactic acidosis, hyperglycemia

Hb F, Hemoglobin F; MDS, myelodysplastic syndrome.
Modified from Park M. Overview of inherited bone marrow failure syndromes. *Blood Res.* 2022;57(S1):49–54. Table 1.

often have congenital malformations and high sensitivity to alkylating agents and radiation. The estimated frequency of FA is 1 in 200,000 in most populations but is higher in Ashkenazi Jews (1:30,000) and Afrikaners (1:22,000). Carrier frequency is approximately 1:200-300 in most populations. Pathogenic variants in 22 genes, designated *FANC* genes, have been reported to cause FA or FA-like disease. All pathogenic variants except for one are inherited in an autosomal recessive manner. One uncommon form of FA is X-linked recessive. FA occurs in all ethnic groups. At presentation, patients may have typical physical anomalies and abnormal hematologic findings (majority of patients), normal physical features but abnormal hematologic findings (about one third of patients), or physical anomalies and normal hematologic findings (unknown percentage of patients). There can be sibling discordance in clinical and hematologic manifestations, even in affected monozygotic twins.

Pathology

All FA genes code for proteins that play roles in various cellular pathways and most prominently in DNA cross linking and repair. Patients with FA have faulty DNA repair and increased chromosomal fragility caused by DNA interstrand cross-linking agents such as diepoxybutane (DEB) and mitomycin C (MMC). Cell fusion of FA cells with normal cells or with cells from some unrelated patients with FA produces a corrective effect on chromosomal fragility, a process called *complementation.* The classic FA phenotype that clearly defines the FA-associated genes *(FANCA, FANCB, FANCC, FANCD1/BRCA2, FANCD2, FANCE, FANCF, FANCG, FANCI, FANCJ/BACH1/BRIP1, FANCL, FANCM, FANCN/PALB2, FANCP/SLX4, FANCQ/ERCC4, UBE2T, REV7, RFWD3)* includes the triad of **bone marrow failure**, **congenital anomalies**, and **elevated chromosome fragility**. These genes can be mutated in patients who have one or all of the components of the triad. Genes that were found to be associated with one or two but not all three of the components are **FA-like genes** *(FANCO/RAD51C, RAD51, FANCS/BRCA1, FANCR/EXCC2). FANCA* accounts for approximately 64% of FA cases, *FANCC* for 14%, and *FANG* for 9%. *FANCB*, *FANCD1/BRCA2*, *FANCD2*, *FANCE,* and *FANCF* are collectively mutated in almost 13% of FA patients. The remaining genes are pathogenic variants in rare cases.

The proteins encoded by wild-type *FANC* genes are involved in the DNA damage recognition and repair biochemical pathway. Therefore aberrant proteins lead to genomic instability and chromosome fragility. FANC proteins are involved in other cellular activities, such as reactive oxygen species detoxification, energetic metabolism, and cytokine signaling. Thus FANC pathogenic variants likely affect several cellular and biochemical roles of the respective proteins, which eventually leads to the FA phenotype. The observed disease complexity and heterogeneity is likely caused by the involvement of multiple cellular and biochemical pathways both in unrelated individuals and in family members with the same genetic pathogenic variant.

Clinical Manifestations

The most common congenital anomalies in FA are skeletal and include absence of radii and/or thumbs that are hypoplastic, supernumerary, bifid, or absent. Anomalies of the feet, congenital hip dislocation, and leg abnormalities can also be seen (Fig. 517.1 and Table 517.3). Skin hyperpigmentation of the trunk, neck, and intertriginous areas;

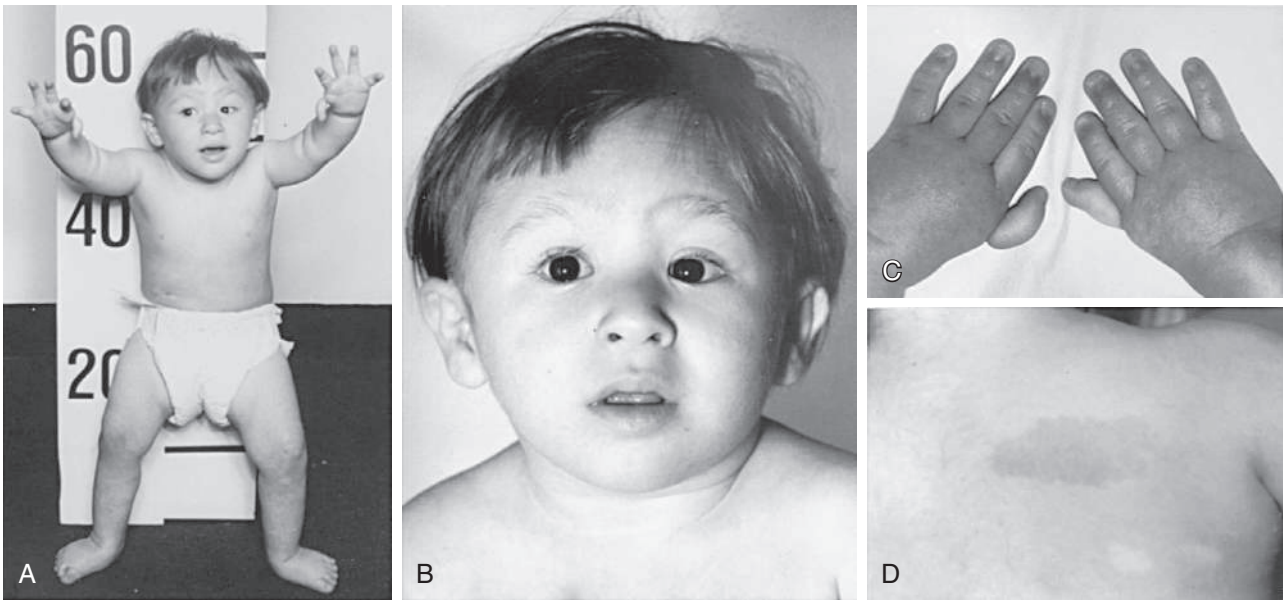

Fig. 517.1 A 3-year-old boy with Fanconi anemia who exhibits several classic phenotypic features. **A,** Front view. **B,** Face. **C,** Hands. **D,** Back right shoulder. The features to be noted include short stature, dislocated hips, microcephaly, a broad nasal base, epicanthal folds, micrognathia, thumbs attached by a thread, and café-au-lait spots with hypopigmented areas beneath. *(From Nathan DC, Orkin SH, Ginsburg D, et al, eds: Nathan and Oski's Hematology of Infancy and Childhood, 6th ed. Philadelphia: Saunders, 2003. p. 285.)*

Table 517.3 Specific Types of Anomalies in Fanconi Anemia

SKIN (40%) Generalized hyperpigmentation on the trunk, neck, and intertriginous areas; café-au-lait spots; hypopigmented areas	**EYES (20%)** Small eyes, strabismus, epicanthal folds, short or almond-shaped palpebral fissures, hypertelorism, ptosis, slanting, cataracts, astigmatism, blindness, epiphora, nystagmus, proptosis, small iris
BODY (40%) Short stature, delicate features, small size, underweight	**EARS (10%)** Deafness (usually conductive); abnormal shape; atresia; dysplasia; low set, large, or small; infections; abnormal middle ear; absent eardrum; dimples; rotated; canal stenosis
UPPER LIMBS (35%) *Thumbs (35%):* absent or hypoplastic; supernumerary, bifid, or duplicated; rudimentary; short, low set, attached by a thread; triphalangeal, tubular, stiff, hyperextensible *Radii (7%):* absent or hypoplastic (only with abnormal thumbs); absent or weak pulse *Hands (5%):* clinodactyly; hypoplastic thenar eminence; six fingers; absent first metacarpal; enlarged, abnormal fingers; short fingers; transverse crease *Ulnae (1%):* dysplastic or absent	**KIDNEY (20%)** Ectopic or pelvic; abnormal, horseshoe, hypoplastic, or dysplastic; absent; hydronephrosis or hydroureter; infections; duplicated; rotated; reflux; hyperplasia; no function; abnormal artery
LOWER LIMBS (5%) *Feet:* toe syndactyly, abnormal toes, flat feet, short toes, clubfeet, six toes, supernumerary toe *Legs:* congenital hip dislocation, Perthes disease, coxa vara, abnormal femur, thigh osteoma, abnormal legs	**GASTROINTESTINAL SYSTEM (5%)** High-arched palate, atresia (esophagus, duodenum, jejunum), imperforate anus, tracheoesophageal fistula, Meckel diverticulum, umbilical hernia, hypoplastic uvula, abnormal biliary ducts, megacolon, abdominal diastasis, Budd-Chiari syndrome
GONADS *Males (25%):* hypogenitalia, undescended testes, hypospadias, abnormal genitalia, absent testis, atrophic testes, azoospermia, phimosis, abnormal urethra, micropenis, delayed development *Females (2%):* hypogenitalia; bicornuate uterus; abnormal genitalia; aplasia of uterus and vagina; atresia of uterus, vagina, and ovary	**UROGENITAL** *Males (25%):* micropenis, penile-scrotal fusion, undescended or atrophic or absent testes, hypospadias, chordae, phimosis, azoospermia *Females (2%):* bicornuate uterus, aplasia or hypoplasia of vagina and uterus, atresia of vagina, hypoplastic uterus, hypoplastic or absent ovary, hypoplastic fused labia
OTHER SKELETAL ANOMALIES *Head (20%) and face (2%):* microcephaly, hydrocephalus, micrognathia, peculiar face, birdlike face, flat head, frontal bossing, scaphocephaly, sloped forehead, choanal atresia, dental abnormalities *Neck (1%):* Sprengel deformity; short, low hairline; webbed *Spine (2%):* spina bifida (thoracic, lumbar, cervical, occult sacral), scoliosis, abnormal ribs, sacral agenesis, sacrococcygeal sinus, Klippel-Feil syndrome, vertebral anomalies, extra vertebrae	**CARDIOPULMONARY SYSTEM (6%)** Patent ductus arteriosus, ventricular septal defect, abnormal heart, peripheral pulmonic stenosis, aortic stenosis, coarctation, absent lung lobes, vascular malformation, aortic atheromas, atrial septal defect, tetralogy of Fallot, pseudotruncus, hypoplastic aorta, abnormal pulmonary drainage, double aortic arch, cardiac myopathy
	CENTRAL NERVOUS SYSTEM (3%) Hyperreflexia, Bell palsy, central nervous system arterial malformation, moyamoya syndrome, Arnold-Chiari malformation, stenosis of internal carotid artery, small pituitary gland, absent corpus callosum Slow development (10%)

Abnormalities are listed in the approximate order of frequency within each category.
Adapted from Shimamura A, Alter BP. Pathophysiology and management of inherited bone marrow failure syndromes. *Blood Rev.* 2010;24:101–122.

café-au-lait spots; and vitiligo, alone or in combination, occur with similar frequency. Short stature is common and in some patients is aggravated by subnormal growth hormone (GH) secretion or hypothyroidism. Male patients with FA may have an underdeveloped penis; undescended, atrophic, or absent testes; and hypospadias or phimosis, and all are infertile. Females can have malformations of the vagina, uterus, and ovary, and all have reduced fertility. Many patients have characteristic facial dysmorphisms, including microcephaly, small eyes, epicanthal folds, and abnormal shape, size, or positioning of the ears (see Fig. 517.1). Kidneys may be ectopic, pelvic, horseshoe-shaped, hypoplastic, dysplastic, or absent. Cardiovascular (CV) and gastrointestinal (GI) malformations also occur. Approximately 10% of patients with FA are cognitively delayed. Neonates with FA usually have intrauterine growth restriction (IUGR) and low birthweight and may show malformations consistent with VACTERL/VACTERL-H association (vertebral anomalies, anal atresia, cardiac malformations, tracheoesophageal fistula with esophageal atresia, renal and limb structural abnormalities with hydrocephalus).

Bone marrow failure usually appears within the first decade of life. Thrombocytopenia, red blood cell (RBC) macrocytosis, and increased fetal hemoglobin (Hb F), as a result of bone marrow stress, often appear first. At these stages, bone marrow aspirate and biopsy often show a hypocellular specimen. Subsequently, patients develop neutropenia and then anemia. Severe aplasia develops in most cases, usually over a few years.

Cancer Risk and Other Complications

In addition to the low blood counts and physical anomalies, patients with FA have a high risk of developing cancer. The most frequent solid tumors are *squamous cell carcinomas* (SCCs) of the head and neck (600-fold higher risk than the general population) and carcinoma of the upper esophagus (2,000-fold higher risk), the vulva (3,000-fold higher risk), and/or anus, cervix, and lower esophagus. Onset of solid-tumor malignancy is much sooner than that seen in the general population, with median age of onset of SCC in the FA population occurring at 33 years vs 60–70 years in the general population. Human papillomavirus (HPV) is suspected in the pathogenesis of SCC. Benign and malignant liver tumors can occur (adenomas, hepatomas) and are usually associated with androgen therapy for aplastic anemia. Androgens are also implicated in the etiology of peliosis hepatis (blood-filled hepatic sinusoids), which is reversible when androgen therapy is discontinued. Clonal bone marrow cytogenetic abnormalities are common in FA and on follow-up can either be stable, intermittently detected, or progressive. The cumulative incidence of clonal and malignant myeloid transformation by age 18 years, which includes clonal cytogenetic marrow abnormalities, MDS, and AML, is approximately 75%. One study indicated that by age 40 years, the cumulative incidence of leukemia is 33%.

Diagnosis

FA should be considered in all children and young adults with unexplained cytopenias. Abnormal hematologic findings and characteristic physical anomalies suggest the diagnosis, which can be confirmed with a lymphocyte chromosomal breakage study done with and without the addition of cross-linking agents such as DEB and MMC. Increased chromosome fragility is indicated by spontaneously occurring chromatid breaks, rearrangements, gaps, endoreduplications, and chromatid exchanges in blood lymphocytes cultured with phytohemagglutinin, as well as in cultured skin fibroblasts, underscoring the constitutional nature of FA. With the addition of DEB or MMC, fragility is strikingly enhanced in lymphocyte cultures of patients with FA compared with those of controls. Abnormal chromosome breakage analysis and genetic testing for prenatal diagnosis can be performed on amniotic fluid cells or on tissue from a chorionic villus biopsy. No other inherited pancytopenia is associated with a prominent in vitro hypersensitivity to DEB or MMC by the chromosomal breakage study. However, 10–15% of patients with suspected FA have *somatic mosaicism* and may not show the characteristically high degree of chromosomal fragility in their lymphocytes, reflecting the presence of mixed populations of somatic cells, some with two abnormal alleles and some with only one. The latter population of lymphocytes derives from a portion of hematopoietic stem cells (HSCs) that underwent spontaneous somatic gene correction on one allele. Testing of skin fibroblasts should be performed if the suspicion of FA is high despite negative testing on peripheral blood lymphocytes.

Next-generation sequencing (NGS) gene panels and WES are the tests of choice for FA. NGS is an efficient and accurate method for diagnosing FA but can occasionally be limited by difficulties in interpreting previously unreported variants or in unraveling pathogenic variants due to reversion variants or technical matters. When no definite causative point pathogenic variants are found, high-resolution copy number variation analysis techniques are employed, followed by a genome-wide search for pathogenic variants in novel associated genes. Pathogenic variants in one of the 22 FA genes are found in over 95% of FA cases.

Extensive screening for potential medical problems is necessary after the diagnosis of FA is established. Imaging using radiation should be minimized as much as possible because of the carcinogenic risk inherent to this genetic instability disease; MRI should replace CT whenever possible. In addition to detailed review of the past medical history and thorough physical examination, the screen should include ultrasonographic examination of the abdomen and echocardiography to rule out internal congenital anomalies. Other imaging may be done as necessary and based on the initial screen. Subspecialty consultations for anomalies and disabilities that have been identified can be arranged during this interval. If growth velocity is below expectations, endocrine evaluation is needed to assess for GH and thyroid deficiency. Blood work should include evaluation of renal, liver, thyroid, metabolic, and immune systems.

Treatment

A hematologist, preferably one who specializes in IBMFSs, with a multidisciplinary team should manage patients with FA. At diagnosis, a detailed assessment of the patient's blood counts, bone marrow function, growth, development, and other organ function should be carried out.

If hematologic abnormalities are mild to moderate and stable and there is no transfusion requirement, patients can be observed closely with peripheral blood counts every 3 months and bone marrow aspiration surveillance every year for clonal cytogenetic abnormalities, MDS, and AML. Bone marrow biopsy might also be intermittently done during bone marrow testing to evaluate changes in percentage of cellularity and fibrosis. More frequent monitoring can be applied when deemed necessary, as when a decline in blood counts occurs. Glucose levels should be performed annually or biannually, depending on the degree of hyperglycemia found on initial testing. Screening for hypothyroidism should be performed yearly. Patients should be assessed for solid tumors at least annually, with a careful physical examination that includes comprehensive inspection of the skin, oral cavity, and other organs for unusual masses. After a certain age (e.g., 10 years) or after HSC transplant (HSCT), fluoroscopic examination of the orolaryngeal cavity and occult fecal blood testing are also recommended. Beginning at menarche, female patients should be screened annually for gynecologic cancer. Administration of HPV quadrivalent vaccine to decrease the risk of SCC is advised.

Chromosome fragility (and/or targeted genetic testing) should be offered to siblings and parents of affected patients for identification of other affected individuals. It is noteworthy that heterozygosity for several FA genes (e.g., *FANCN*, *FANCD1*, *FANCS*) is associated with cancer development. Human leukocyte antigen (HLA) typing of patients, biological parents, and full siblings for future HSCT should also occur early.

HSCT is the only curative therapy for the hematologic abnormalities observed in FA patients. Outcomes have improved because of modified reduced-intensity regimens that include fludarabine, low dose cyclophosphamide, and antithymocyte globulin with or without low-dose busulfan. Most regimens do not use radiation. These regimens have decreased the toxicities experienced by FA patients, who have high sensitivity to DNA-damaging agents such as alkylating drugs and irradiation. Those who undergo transplant using an HLA-identical sibling

donor without irradiation in the preparative regimen have an overall 3-5-year survival rate of >90%.

Traditionally, HSCT of FA patients with matched unrelated donors (MUD) or mismatched related donors have been a challenge because of the high degree of HSCT-related toxicity and death. However, major progress has been made in this regard. Several reports of radiation-free HSCT with in vivo or ex-vivo T-cell depleted, peripheral blood $CD34^+$ selected MUD graft and conditioning with fludarabine, rabbit antithymocyte globulin (ATG), low-dose cyclophosphamide, and low-dose busulfan demonstrated 80% or higher probabilities of overall and disease-free survival 1–5 years post HSCT. Improvement in high-resolution HLA typing contributes to better selection of unrelated-donor selection and a better outcome. Transplantation using haploidentical donors is on the rise and is showing promising outcomes, similar to those seen with unrelated donors.

Those transplanted before they receive multiple transfusions or develop clonal and malignant myeloid transformation (MDS or AML) do better. Survival rates are higher for patients who undergo transplant at <10 years of age. Molecular technology has led to preimplantation genetic diagnosis on parent-derived blastomeres, allowing for the unaffected ones to be implanted and resulting in the creation of an HLA-matched sibling donor without FA.

Androgens produce a response in approximately 70% of patients, heralded by reticulocytosis and a rise in hemoglobin within 1-2 months. White blood cell (WBC) counts may increase next, followed by platelet counts. After the initial response is seen, counts may continue to improve over many months until a maximum response is achieved. If a low dose is initially employed, the androgen dose can be increased every 3-4 weeks as long as no major side effects are seen and until the desired response is achieved. If a high dose is initially employed, androgen dosage can be slowly reduced to the minimum dose that maintains the required blood counts. Oral danazol and oxymetholone are currently the two most commonly used androgenic drugs. Patients typically stop responding to androgens after several months or years, as their bone marrow failure progresses or as they develop MDS or AML. Thus androgen therapy is not curative but is used rather as a bridge while waiting for a suitable donor for HSCT or while weighing the risks and benefits of transplant. Side effects of androgens include masculinization, increased linear growth, increased mood swings or aggressiveness, elevated hepatic enzymes, cholestasis, peliosis hepatis, and liver tumors. Screenings for these should be performed regularly.

The potential for recombinant growth factor (cytokine) therapy for FA has not been defined. Granulocyte colony-stimulating factor (G-CSF) can usually induce an increase in the absolute neutrophil count; however, there may be a heightened risk of expansion of bone marrow cells with clonal cytogenetic abnormalities such as monosomy 7. In one study, combination therapy consisting of G-CSF given subcutaneously daily or every 2 days along with erythropoietin given subcutaneously or intravenously 3 times per week resulted in improved neutrophil counts in most patients and a sustained rise in hemoglobin and platelet levels in approximately one third of patients. Most patients lost the response because of progression of bone marrow disease.

Prognosis

Improvements in supportive care, careful surveillance of known complications, prompt intervention, and improved transplant techniques have resulted in patients with FA surviving into their 30s. Unfortunately, there is an increased risk of solid tumors after HSCT. For example, head and neck cancer risk is increased 4.4-fold and is accelerated by approximately 15 years compared with nontransplanted patients. The cumulative incidence of malignancy 20 years after transplant is 35–40%. Some of the increased risk might be attributed to the use of DNA-damaging agents or the occurrence of graft-versus-host disease (GVHD).

SHWACHMAN-DIAMOND SYNDROME

Etiology and Epidemiology

Shwachman-Diamond syndrome (SDS) is an inherited disorder caused by pathogenic variants in one of four genes. It occurs in all racial and ethnic groups. SDS is a multisystem disorder. However, the nonhematologic manifestations of SDS are substantially different and usually include exocrine pancreatic insufficiency and skeletal abnormalities such as metaphyseal dysplasia (Table 517.4). SDS is a **ribosomopathy**, and the underlying defect is in ribosome assembly.

Table 517.4 Major Clinical Features of Shwachman-Diamond Syndrome

CLINICAL FEATURE	TOTAL/AVERAGE
Number of patients	225
Neutropenia	90%
Severe (≤500/μL)	46%
Anemia	46%
Thrombocytopenia	42%
Pancytopenia	21%
Exocrine pancreatic insufficiency	98%
Liver (elevated transaminases)	61%
Skeletal abnormalities	70%
Metaphyseal dysostosis	53%
Rib cage abnormalities	35%
Short stature (<3rd percentile)	66%

Data from Ginzberg H, Shin J, Ellis L, et al. Shwachman syndrome: phenotypic manifestations of sibling sets and isolated cases in a large patient cohort are similar. *J Pediatr*. 1999;135:81–88; Cipolli M, D'Orazio C, Delmarco A, et al. Shwachman's syndrome: pathomorphosis and long-term outcome. *J Pediatr Gastroenterol Nutr*. 1999;29:265–272; and Kuijpers TW, Alders M, Tool AT, et al. Hematologic abnormalities in Shwachman-Diamond syndrome: lack of genotype-phenotype relationship. *Blood*. 2005;106:356–361.

Pathology

Four genes have been linked to SDS. *SBDS* is the first gene that was described to have biallelic variants in SDS in 2003. *SBDS* maps to chromosome 7q11 and accounts for 80–90% of SDS cases. *SBDS* plays a role in the late stage of the pre-60S ribosome subunit maturation, binding to the *EFL1* GTPase and facilitating the release of eIF6 to enable 80S monosome formation. *DNAJC21* is the second reported SDS gene. The function of the human *DNAJC21* is required for the release and recycling of the Arx1/Alb1 heterodimer from the pre-60S biogenesis factors. The third SDS gene discovered is *EFL1*. *DNAJC21* and *EFL1*-associated SDS are autosomal recessive. Monoallelic pathogenic variants in *SRP54*, a protein involved in co-translational protein modification, mainly cause severe congenital neutropenia phenotype. Nevertheless, a small proportion of the patients have partial or classical SDS phenotype. The underlying genetic defects of SDS indicate that the last step in ribosome biogenesis is associated with pancytopenia (most often neutropenia) and a hypoplastic bone marrow. Defects in ribosomal proteins that are involved in earlier stages of ribosome subunit maturation and are structural components of the ribosome are associated with predominantly anemia and pure red cell aplasia.

Exocrine pancreatic insufficiency is caused by failure of exocrine pancreatic acinar development in SDS, and fatty replacement of pancreatic tissue is prominent. **Bone marrow failure** is characterized by dysfunctional HSCs, accelerated apoptosis of bone marrow progenitors, and a defective bone marrow microenvironment that does not support and maintain normal hematopoiesis.

Clinical Manifestations

Most patients with SDS have symptoms of fat malabsorption from birth that are caused by pancreatic insufficiency, but steatorrhea is not always obvious. Approximately 50% of patients appear to exhibit an improvement in pancreatic enzyme secretion as they age. The clinical picture can be dominated by complications from neutropenia, anemia,

or thrombocytopenia. Bacterial and fungal infections secondary to neutropenia, neutrophil dysfunction, and immunodeficiency can occur. A major concern is the development of MDS and acute leukemia, most often AML.

Short stature is a consistent feature of SDS. Most patients show normal growth velocity yet remain consistently below the 3rd percentile for height and weight. The occasional SDS adult achieves the 25th percentile for height. Although skeletal abnormalities are variable, classic findings are metaphyseal dysplasia, osteopenia, delayed appearance of secondary ossification centers, short or flared ribs, and thoracic dystrophy.

Some patients have hepatomegaly and elevations of liver enzymes. Most patients have dental abnormalities and poor oral health. Many have neurocognitive problems and poor social skills.

Laboratory Findings

Exocrine pancreatic insufficiency in SDS is associated with reduced age-adjusted serum trypsinogen and pancreatic isoamylase levels. Because serum pancreatic isoamylase is physiologically low in the first 3 years of life, and because reduced serum trypsinogen is typically seen in young infants and often improves with age, testing both enzymes is helpful. Fecal elastase is often reduced in SDS patients. Fat-soluble vitamin (A, D, E, and K) absorption is impaired, and thus measurement of vitamin A, D, and E levels, as well as prothrombin time (or international normalized ratio [INR]), is helpful to assess the consequences of fat malabsorption. Ultrasound or CT scan can visualize fatty replacement of pancreatic tissue. Fat malabsorption can be proven by assay on a 72-hour stool collection.

Neutropenia is observed in about 70% of patients with SDS at presentation and is seen in close to 100% of patients on follow-up. It is chronic but can be persistent or intermittent and mild, moderate, or severe. It has been identified in some neonates during an episode of sepsis. Neutrophils may have a defect in mobility, migration, and chemotaxis because of alterations in neutrophil cytoskeletal or microtubular function. Anemia, thrombocytopenia, and pancytopenia are seen in 40–66%, 40–60%, and 21–44% of cases, respectively. Pancytopenia can be severe as a result of full-blown aplastic anemia. Bone marrow aspirate and biopsy specimens show varying degrees of bone marrow hypoplasia and fat infiltration. However, at a young age or when patients develop MDS or leukemia, the bone marrow can be normocellular or even hypercellular.

Patients may also have B-cell defects with one or more of the following: low immunoglobulin G (IgG) or IgG subclasses, low percentage of circulating B lymphocytes, decreased in vitro B-cell proliferation, and lack of specific antibody production. Patients may have a low percentage of circulating T cells, subsets, or natural killer cells and decreased in vitro T-cell proliferation.

Diagnosis

The clinical diagnosis of SDS relies on having evidence of two of the following: bone marrow dysfunction, exocrine pancreatic insufficiency, and metaphyseal dysplasia. However, atypical presentations have been identified, such as MDS without previous documentation of low blood counts. Up to 20% of patients lack clear evidence of exocrine pancreatic defects at diagnosis. Furthermore, 20–60% lack metaphyseal dysplasia at diagnosis because this bony anomaly often develops with age. Therefore it is recommended that all patients with either hypoplastic/aplastic bone marrow or exocrine pancreatic insufficiency or metaphyseal dysplasia of unknown etiology be considered for SDS genetic testing. Genetic analysis for *SBDS*, *DNAJC21*, and *EFL1* are definitive in all or almost all cases of SDS. A patient with neutropenia and an *SRP54* pathogenic variant who does not have exocrine pancreatic insufficiency or metaphyseal dysplasia should be considered as having severe congenital neutropenia.

Pearson syndrome, consisting of refractory sideroblastic anemia, cytoplasmic vacuolization of bone marrow precursors, metabolic acidosis, exocrine pancreatic insufficiency, and a diagnostic mitochondrial DNA pathogenic variant, is similar to SDS, but the clinical course, morphologic features of the bone marrow, and gene pathogenic variant are different. Severe anemia requiring transfusion, rather than neutropenia, is present in Pearson syndrome from birth to 1 year of age. SDS shares some manifestations with **Fanconi anemia**, such as bone marrow dysfunction and growth failure, but patients with SDS are readily distinguished because of pancreatic insufficiency with fat malabsorption, fatty changes within the pancreatic body visualized by imaging, characteristic skeletal abnormalities not seen in FA, and a normal chromosomal breakage study with DEB and MMC. Distinguishing SDS from **dyskeratosis congenita (DC)** may not be possible based solely on clinical findings and pancreatic enzyme levels; telomere length measurement may facilitate a correct diagnosis. *In difficult cases of IBMFSs that cannot be easily classified, comprehensive genetic testing using an NGS panel of all known IBMFS genes or unbiased testing using WES/genome sequencing is likely to assist in establishing a diagnosis.*

Predisposition to Cancer

Patients with SDS are predisposed to MDS and leukemic transformation. Approximately 25% of patients develop clonal marrow cytogenetic abnormalities, MDS, or leukemia by age 18 years. About one third of patients have been reported to develop leukemia by age 30 years. Isochromosome 7q [i(7q)] is particularly common and is rarely seen in other conditions. i(7q) might be related to the presence of pathogenic variant *SBDS* on 7q11 and likely confers a compensatory effect by increasing *SBDS* transcribing alleles (although they remain variant). Other clonal chromosome abnormalities include monosomy 7, i(7q) combined with monosomy 7, deletions or translocations involving part of 7q, and deletions of 20q [Del(20q)]. The i(7q) and del(20q) are associated with relatively low risk and very slow progression to MDS or leukemic transformation.

Treatment

Fat malabsorption responds to oral pancreatic enzyme replacement and supplemental fat-soluble vitamins, administered according to guidelines similar to those for cystic fibrosis. A long-term plan should be initiated to periodically monitor changes in peripheral blood counts that require corrective action and to look for early evidence of malignant myeloid transformation. The latter also requires periodic bone marrow aspirations for smears and cytogenetic testing, as well as bone marrow biopsy. A common recommendation is to perform bone marrow testing every 1-3 years and complete blood counts every 3 months.

Daily *subcutaneous G-CSF* for profound neutropenia is effective in inducing a sustained increase in neutrophils. Some patients require transfusion support for management of severe anemia or thrombocytopenia. Experience with erythropoietin is limited. Androgens have been used in few published cases (with and without steroids); some patients showed response, and some did not.

The only curative option for severe bone marrow failure and advanced MDS or leukemia in SDS is allogeneic HSCT. Traditional myeloablative HSCT results in treatment-related mortality in 35–50% of patients. Reduced-intensity conditioning regimens that incorporate *fludarabine* appear to be safer and have been shown to be effective in SDS. Graft failure poses a challenge, possibly due to a stromal cell defect that is not corrected by HSCT. Results of treatment for advanced MDS and AML are generally limited, and outcome is typically poor.

Prognosis

The accurate life expectancy of SDS patients is unknown; analysis of published cases revealed a median survival of 35 years. Because the number of undiagnosed patients with mild or asymptomatic disease is unknown, the overall prognosis may be better than previously thought.

Although all patients have some degree of hematologic cytopenia at diagnosis, the changes in most patients are mild to moderate and do not require therapeutic intervention. Severe neutropenia responds well to G-CSF, but there is a concern that G-CSF may promote the growth of evolving MDS or leukemia clones because of the agent's powerful

growth stimulus on bone marrow cells. HSCT for severe bone marrow failure has produced a 50–70% survival rate, but safer protocols need to be introduced. Malignant bone marrow transformation remains ominous.

Approximately 50% of patients experience spontaneous conversion from exocrine pancreatic insufficiency to pancreatic sufficiency as a result of improvement in pancreatic enzyme secretion.

DYSKERATOSIS CONGENITA

Etiology and Epidemiology

DC is an inherited multisystem telomere disorder. A diagnostic triad of mucocutaneous features was proposed when the disorder was first described and included **dysplastic nails**, lacy **reticular pigmentation** of the upper chest and/or neck, and **oral leukoplakia** (Fig. 517.2). *However, this triad is not present in all individuals.* If it occurs, skin and nail findings usually become apparent in the first 10 years of life, whereas oral leukoplakia may be noticed later. Manifestations tend to progress as patients age. Hematological manifestations are actually the most common features in this disease. Varying degrees of bone marrow failure are seen in approximately 90% of patients. Severe aplastic anemia occurs in approximately 50% of cases, with the age of onset varying according to the genetic group. In some genetic groups, the disease usually starts in the first decade of life (e.g., *DKC1*, *TINF2, PARN*), whereas in others, it typically starts after the first decade (e.g., *TERT, TERC*). In addition to progressive bone marrow failure, patients with DC are also at high risk for pulmonary and hepatic fibrosis, other congenital anomalies, and a predisposition to solid tumors and MDS or AML. DC is rare, with an incidence in childhood of approximately 4 cases per 1 million population per year.

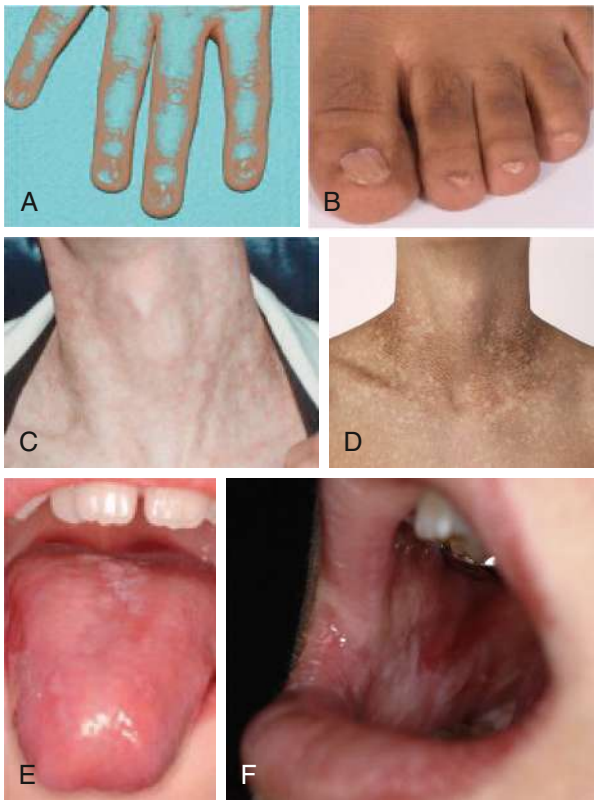

Fig. 517.2 Features of the diagnostic triad in dyskeratosis congenita. A and B, Dystrophic nails on hands and feet. C and D, Lacy reticular pigmentation on neck and upper thorax. E and F, Oral leukoplakia on tongue and buccal mucosa. *(A-C and E from Shimamura A, Alter BP. Pathophysiology and management of inherited bone marrow failure syndromes. Blood Rev. 2010;24:101–122, Fig. 8; D and F from Savage SA, Alter BP. Dyskeratosis congenital. Hematol Oncol Clin North Am. 2009;23:215–231)*

Pathology

DC is genetically heterogeneous, and patients have pathogenic variants in genes that encode components of the telomerase complex *(TERT, TERC)*, telomere-capping complex *(CTC1, STN1)*, T-loop unwinding and telomere replication *(RTEL1, RPA1)*, telomerase trafficking *(WRAP53*/TCAB1*)*, TERC-associated factors that stimulate telomerase activity *(DKC1, NOP10, NHP2, NAF1)*, TERC-maturation factors *(PARN)*, and telomere-shelterin complex *(TINF2, POT1, ACD)*.

All components are critical for telomere maintenance. The **X-linked recessive** form of DC maps to Xq28, and many pathogenic variants have been identified in the *DKC1* gene, which codes for the nuclear protein dyskerin. The **autosomal dominant** form of disease is caused by pathogenic variants in *TINF2, TERC, TERT, RTEL1, ACD, NAF1,* and *RPA1*. **Autosomal recessive** DC is linked to pathogenic variants in *NOP10, NHP2, TCAB1/WRAP53, CTC1,* and *STN1,* as well as *TERT, TERC, RTEL1, PARN*, and *ACD*. Because of impaired telomere maintenance in all three inherited forms of DC, extremely short telomeres (<1st percentile for age) are demonstrated in the peripheral blood cells of all patients. Finding extremely short telomeres in lymphocytes performed by automated multicolor flow fluorescence in situ hybridization (FISH) has 97% sensitivity and 91% specificity for DC. Approximately 70% of individuals who meet clinical diagnostic criteria of DC have a pathogenic variant in one of the known DC-related genes. Pathogenic variants in *DKC1* are most common (20–25% of individuals), followed by *TINF2* (12–20% of individuals), *TERC* (5–10% of individuals), *RTEL1*, *TERT,* and *CTC1*. The remainder of the genetic pathogenic variants have been described in only a few families. Bone marrow failure is likely caused by progressive attrition and depletion of HSCs because of premature senescence, apoptosis, or chromosome instability, which manifests as pancytopenia.

Clinical Manifestations

The clinical criteria for classic DC include the presence of at least two of the four major features—abnormal skin pigmentation, nail dystrophy, leukoplakia, and bone marrow failure—and two or more of the other somatic features known to occur in DC. However, making a diagnosis continues to be challenging because individuals develop clinical features of DC at variable rates and ages, even within the same family. Further, some of the patients have only one complication (e.g., isolated bone marrow failure or isolated pulmonary fibrosis). In about one quarter of individuals with DC, pathogenic variants in the known DC-related genes cannot be identified. The spectrum ranges from individuals who develop bone marrow failure first, then years later develop other classic findings such as nail abnormalities, to others who have severe nail problems and abnormalities of skin pigmentation at presentation but normal bone marrow function. In classic disease, skin pigmentation and nail changes typically appear first, usually in the first decade of life. Bone marrow failure usually develops within the first two decades, with 80% of patients developing bone marrow failure by age 30 years and almost 90% of patients having bone marrow failure at some point in their life.

Lacy reticulated **skin pigmentation** affecting the face, neck, chest, and arms is a common finding (89%). The degree of pigmentation increases with age and can involve the entire skin surface. There may also be a telangiectatic erythematous component. Nail dystrophy of both hands and feet is the next most common finding (88%). It usually starts with longitudinal ridging, splitting, or pterygium formation and may progress to complete nail loss. **Leukoplakia** usually involves the oral mucosa (78%), especially the tongue, but may also be seen in the conjunctiva and the anal, urethral, or genital mucosa. Excessive tearing **(epiphora)** secondary to nasolacrimal duct obstruction is common and observed in about 30% of individuals. Approximately 25% of individuals have learning difficulties and/or developmental delay. Hyperhidrosis of the palms and soles, hair loss and graying, dental caries or loss, esophageal stricture, pulmonary disease with reduced diffusion capacity and/or a restrictive defect due to pulmonary fibrosis and abnormalities in pulmonary vasculature, and short stature are each seen in approximately 15–20% of individuals.

Ocular abnormalities include conjunctivitis, blepharitis, loss of eyelashes, strabismus, cataracts, and optic atrophy. **Skeletal** abnormalities include osteoporosis, avascular necrosis of the hips or shoulders, abnormal bone trabeculation, scoliosis, and mandibular hypoplasia. **Genitourinary** abnormalities include hypoplastic testes, hypospadias, phimosis, urethral stenosis, and horseshoe kidney. **GI** findings, such as vascular lesions causing bleeding, hepatomegaly, peptic ulceration, and fibrosis, are seen in 10% of cases.

Laboratory Findings

The initial hematologic change in DC is usually thrombocytopenia, anemia, or both, followed by pancytopenia and aplastic anemia. The red cells are often macrocytic, and the Hb F is elevated. Initial bone marrow specimens may be normocellular or hypercellular, but with time, a symmetric depletion of all hematopoietic lineages ensues. Some patients have immunologic abnormalities, including reduced or elevated immunoglobulin values, decreased B- and/or T-lymphocyte counts, and reduction or absence of lymphocyte proliferative responses to phytohemagglutinin. This is particularly common and severe in the *DKC1*-associated disease. Primary skin fibroblasts in culture have abnormal morphologic features and doubling rate and show numerous unbalanced chromosome rearrangements, such as dicentrics, tricentrics, and translocations, in the absence of DEB or MMC. These findings provide evidence of a defect that predisposes patient cells to chromosomal rearrangements and possibly to DNA damage.

The hallmark of DC is very short telomeres, below the first percentile for age. However, some patients do not have short telomeres. Further, adult patients tend to have telomere length at the low range of normal rather than below the first percentile.

Diagnosis

The diagnosis of DC can often be made based on medical and family history and physical examination. The following abnormalities are seen in patients with DC but not in those with FA: nail dystrophy, early-onset leukoplakia, tooth abnormalities, hyperhidrosis of the palms and soles, and hair loss. There are several relatively more severe forms of DC. **Hoyeraal-Hreidarsson syndrome** is a multisystem disorder that presents in early childhood, which requires the features of DC along with **cerebellar hypoplasia** to establish the diagnosis. Patients have the classic diagnostic DC triad, in addition to developmental delay, IUGR, and bone marrow failure. Hoyeraal-Hreidarsson syndrome is genetically heterogeneous and caused by X-linked recessive pathogenic variants in *DKC1*. Some patients may also have severe immunodeficiency. **Revesz syndrome** has many of the features of DC and presents in early childhood. Bilateral exudative retinopathy is required to establish a diagnosis. Patients may also have intracranial calcifications, IUGR, developmental delay, and bone marrow failure. Pathogenic variants of *TINF2* are involved in Revesz syndrome, making it mostly an autosomal dominant condition, but a few patients have been described without an identified pathogenic variant. Individuals with these severe forms of DC have even shorter telomere lengths than those with classic DC. **Coats plus syndrome** is caused by compound heterozygous pathogenic variants in the *CTC1* gene or the *STN1* gene and has overlapping features with DC, including sparse and graying hair, dystrophic nails, and anemia. Telomeres can be very short, but patients display variable telomere length. Coats plus syndrome is characterized by retinal telangiectasia and exudates, intracranial calcification, leukodystrophy, brain cysts, osteopenia, GI bleeding, and portal hypertension caused by the development of vasculature ectasias in the stomach, small intestine, and liver.

Laboratory testing and imaging are an important part in establishing a diagnosis but also evaluate the spectrum of patient organ involvement. These tests include, but are not limited to, the laboratory tests described in the section "Laboratory Findings," as well as ultrasound of the abdomen, pulmonary function tests, liver enzymes, and nutritional elements (such as ferritin, folic acid, and vitamin B12). MRI of the head is useful when the patient has developmental delay and ataxia. Baseline bone marrow testing is critical. Annual evaluation of the bone marrow and complete blood counts every 3 months are common practice.

Because of genomic instability, imaging involving radiation should be limited to those that may affect management.

Cancer Risk and Other Complications

Patients with DC are predisposed to MDS and AML, as well as to solid tumors. Cancer usually develops in the third and fourth decades of life. The cumulative incidence of solid cancers and leukemia by the age of 65–70 years were estimated as 20% and 5–10%, respectively. The cumulative incidence of MDS was predicted to be 20% by the age of 50 years. The actuarial risk of clonal and malignant myeloid disease is 25% by age 18 years.

Forty percent of the cancers in such patients are SCCs of the head and neck (tongue, mouth, pharynx). SCCs of the skin and GI tract (esophagus, stomach, colon), as well as anorectal adenocarcinoma, are common. Patients may develop multiple separate primaries in different sites involving the tongue and nasopharynx.

Other life-threatening complications include pulmonary fibrosis, liver fibrosis, and severe GI bleeding.

Treatment

Androgens can induce improvement of bone marrow function in approximately 70% of patients, and in some, this treatment can result in normal trilineage blood counts for a number of years. Patients with DC become refractory to androgens as aplastic anemia progresses due to HSC depletion. They also tend to be more sensitive to the side effects of androgens than FA patients, making it important to start with lower doses and to monitor for side effects frequently. When the response is maximal, the androgen dose can be slowly reduced to the minimum dose required to maintain desired and safe blood cell counts but cannot be stopped.

Cytokine therapy with granulocyte-macrophage colony stimulating factor (GM-CSF) or with G-CSF alone or combined with erythropoietin appears to offer potential benefit, at least in the short term. Use of cytokines needs to be balanced with a potential growth-promoting effect of these medications on as-yet undetected MDS or AML cells.

Allogeneic HSCT is the only curative option for severe bone marrow failure, MDS, and AML. Long-term survival, even with sibling HLA-matched HSC donors, has traditionally been poor at about 50%. Morbidity and mortality result from transplant-related complications such as graft failure, GVHD, sepsis, or venoocclusive disease or from emergence of DC-related complications, such as pulmonary fibrosis and GI bleeding related to vascular anomalies. The high morbidity and mortality rate after HSCT is likely caused by ongoing tissue sensitivity and aging because of the telomere maintenance defect.

Prognosis

Considerable heterogeneity exists in DC, and some data about genotype-phenotype correlations are available. Patients with certain genetic groups (e.g., monoallelic *TERC, TERT*) may develop severe aplastic anemia or fibrosis of the liver and lungs, but these complications may appear later on in life and may not be accompanied by multisystem involvement. Patients with other genetic groups (e.g., monoallelic pathogenic variants in *DKC1* or *TINF2 and biallelic pathogenic variants in PARN, ACD, RTEL1, TERC or TERT*) appear to have more physical anomalies and a higher incidence and earlier onset of aplastic anemia and cancer. The mean age of death for patients with DC who are diagnosed in childhood is approximately 30 years. However, patients who are diagnosed during adulthood may have a mild disease or be completely asymptomatic. The main causes of death are bone marrow failure, complications of HSCT, cancer, fatal pulmonary problems, and GI bleeding.

CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA

Etiology and Epidemiology

Congenital amegakaryocytic thrombocytopenia **(CAMT)** is less common than FA, SDS, and DC. It is transmitted in an autosomal recessive manner. CAMT typically manifests in infancy as isolated thrombocytopenia caused by reduction or absence of bone marrow megakaryocytes

with initial preservation of granulopoietic and erythroid lineages. Pancytopenia due to aplastic anemia often ensues in the first few years of life. Development of MDS and AML was reported in patients with CAMT, as well as persistent aplastic anemia.

The defect in CAMT is directly related to pathogenic variants in *MPL*, the gene for the receptor of thrombopoietin (THPO). *THPO* is a growth factor that promotes HSC survival and stimulates megakaryocyte proliferation and maturation. Heterozygotes of the pathogenic variant gene have normal hematology, whereas affected individuals have pathogenic variants in both alleles. Genotype-phenotype correlations predict disease course and prognosis. **Nonsense pathogenic variants** cause a complete loss of function of the THPO receptor, resulting in persistently low platelet counts in early infancy due to absence of megakaryocytes and a fast progression to pancytopenia and aplastic anemia **(CAMT type I)**. Impaired stem cell survival with *MPL* nonsense pathogenic variants explains the evolution of CAMT into aplastic anemia because THPO also has an antiapoptotic and cell survival effect on HSCs. **Missense pathogenic variants** of *MPL* are associated with a milder disease course, a later presentation, a partial and transient increase in platelets during the first year of life after presentation, and a delayed onset, if any, of pancytopenia, indicating residual receptor function **(CAMT type II)**. Biologically active plasma THPO is consistently elevated in all patients with CAMT. A small proportion of patients with the clinical picture of CAMT have no pathogenic variants in *MPL*, but more recently have been found to have homozygous pathogenic variants in *THPO*.

Clinical Manifestations

Intracranial hemorrhage is a major risk; about 25% of the patients develop this complication either in utero (13%), at birth (4%), or within the first 4 weeks of life (7%). Patients with CAMT commonly have a petechial rash, bruising, or bleeding. Onset of symptoms may depend on the severity of pathogenic variants and ranges from birth to the first year of life. Most patients with CAMT have normal physical and imaging features. About 10–20% of published phenotypic CAMT cases involved physical anomalies. The most common anomalies are neurologic. Findings related to cerebellar and cerebral atrophy are frequent, and developmental delay is a prominent feature. Congenital heart disease is rare but includes atrial and ventricular septal defects, patent ductus arteriosus, tetralogy of Fallot, and coarctation of the aorta. Some of these occur in combinations. Other anomalies include abnormal hips or feet, kidney malformations, eye anomalies, and cleft or high-arched palate. Some patients have microcephaly and abnormal facies.

Laboratory Findings

Thrombocytopenia is the major laboratory finding in CAMT. At birth, most patients present with thrombocytopenia but not all. Typically, at first, thrombocytopenia appears with normal hemoglobin levels and WBC counts. Peripheral blood platelets are reduced or totally absent. As in other IBMFSs, RBCs may be macrocytic. Hemoglobin F may be elevated, and there may be increased expression of i antigen. Initial bone marrow aspirates and biopsy specimens show normal cellularity with marked reduction or absence of megakaryocytes. Most patients develop pancytopenia between 6 months to 2 years of age. In patients in whom aplastic anemia develops, bone marrow cellularity is decreased, with fatty replacement; erythropoietic and granulopoietic lineages are also symmetrically reduced.

Diagnosis

If thrombocytopenia persists beyond the neonatal period or is associated with adequate platelet transfusion response and no obvious precipitating cause such as infections or immunologic reactions, a bone marrow aspirate and biopsy are indicated. Deficient megakaryocytes in such cases suggest the diagnosis, and genetic analysis will confirm it. If CAMT occurs at birth or shortly after, it must be distinguished from other causes of inherited and acquired neonatal thrombocytopenia. Thrombocytopenia with absent radii **(TAR syndrome)** is distinguished from CAMT because radii are absent in TAR. The distinction from DC may be evident by a lack of mucocutaneous, neurologic, and immunologic findings that are characteristic of the early-onset forms of DC. Telomere lengths below the first percentile matched for age to healthy controls is characteristic of DC and not CAMT. CAMT blood lymphocytes do not show increased chromosomal breakage when exposed to DEB, distinguishing the disease from FA.

Cancer Predisposition

CAMT can evolve into MDS and AML, but the true risk cannot be defined because most patients undergo early transplantation. Typical course in patients with transformation includes thrombocytopenia, aplastic anemia, followed by MDS (e.g., with monosomy 7 or trisomy 8) and leukemia.

Therapy and Prognosis

The mortality rate from thrombocytopenic bleeding, complications of aplastic anemia, or leukemic transformation in patients with *MPL* **nonsense** pathogenic variants is close to 100% if bone marrow function is not improved. Patients with **missense** pathogenic variants have a milder course but may still have serious complications. HSCT is the only curative option. The majority of patients with CAMT who undergo HSCT are cured, especially if the procedure is performed with HLA-matched sibling donors. Before transplantation, platelet transfusion should be used carefully. Platelet count should not always be the sole indication for treatment, but symptoms such as clinical bleeding are an appropriate trigger. Single-donor, leuko-reduced platelets are preferred to minimize sensitization. In a patient who is a candidate for HSCT, all blood products should be irradiated and cytomegalovirus safe. The role of thrombomimetic agents such as eltrombopag or romiplostim might be suitable for some patients (CAMT type II) and need to be studied further. However, the promotion of fibrosis by these agents and the risk of MDS and leukemia in CAMT render HSCT the preferred treatment for patients with severe cytopenia. Romiplostim has shown good and sustained response in those with pathogenic variants in *THPO*, and there have been no reports of acute leukemia or MDS in this subgroup of CMPL patients, but the numbers of patients with pathogenic variants in *THPO* are small.

GATA2-RELATED DISORDERS

The *GATA2* gene codes for a hematopoietic transcription factor that is crucial for the proliferation and maintenance of early hematopoietic cells. Heterozygous germline pathogenic variants, inherited in an autosomal dominant fashion and that are spontaneous in the majority of cases, result in various phenotypes that range from mild cytopenia to severe immunodeficiency and myeloid neoplasia. Approximately two thirds of pathogenic variants in *GATA2* are null, and one third are missense substitutions. Germline pathogenic variants in *GATA2* have been recognized as a major MDS and AML predisposition syndrome. Approximately 150 unique *GATA2* germline pathogenic variants have been identified in about 550 patients.

Clinical manifestations include monocytopenia and *Mycobacterium avium* complex (MonoMAC syndrome) infections, MDS with lymphedema (Emberger syndrome), familial MDS/AML, primary MDS, and chronic neutropenia and dendritic cell, monocyte, and B and NK lymphoid deficiency (DCML deficiency). Hematologic presentation is variable. Some patients present with cytopenia, a hypocellular marrow and monocytopenia, whereas others have severe immunodeficiency, and others still present with MDS/AML and no preexisting relevant medical history or cytopenia. Immune deficiency results in HPV-related infections such as warts or generalized verrucosis, disseminated nontuberculous mycobacterial, and systemic bacterial and fungal infections. Recurrent respiratory tract infections can result in lung disease, such as pulmonary alveolar proteinosis. Few patients have autoimmune dysregulation manifesting as autoimmune cytopenia, arthritis, lupus, and others. Constitutional abnormalities, such as lymphedema, hydrocele, and congenital deafness, as well as abnormalities in pulmonary, CV, urogenital, and neurological systems have been observed in approximately 50% of patients (Fig. 517.3).

In children and adolescents with primary MDS, pathogenic variants in *GATA2* are a predominant germline predisposition accounting for 7% of all MDS cases, 15% of patients with advanced MDS, and 37% of patients

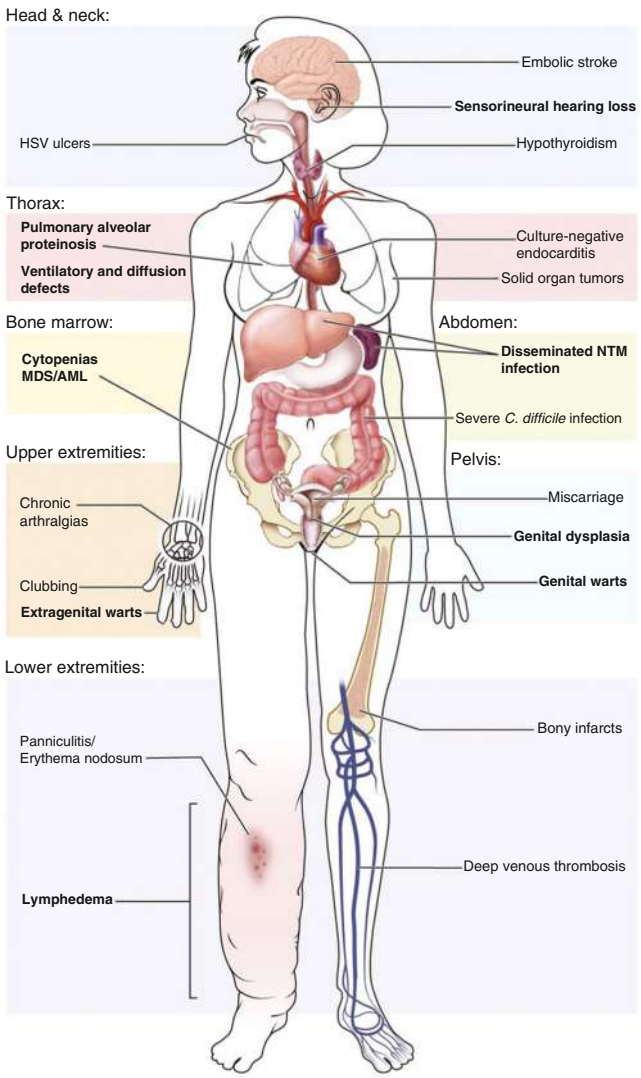

Fig. 517.3 Clinical features of GATA2 deficiency by organ system. Common clinical problems are indicated in bold. AML, acute myelogenous leukemia; MDS, myelodysplastic syndrome; NTM, non-tuberculous mycobacterium. *(From National Institute of Allergy and Infectious Diseases [NIAID] Health Information Fact Sheet.* https://www.niaid.nih.gov/sites/default/files/GATA2-Factsheet.pdf.*)*

with MDS and monosomy 7. Among children with MDS, the prevalence of *GATA2* pathogenic variants increases with age; 66% of adolescents with MDS and monosomy 7 carry germline *GATA2* pathogenic variants. Median age of diagnosis with *GATA2*-related MDS is approximately 10 years.

Patients should be followed by a hematologist with expertise in bone marrow failure/MDS and by an immunologist. Blood counts should be done every 3 months, and bone marrow aspirate and biopsy with cytogenetics should be carried out annually. HSCT is the only curative option for MDS and carries an overall survival ranging from 60–85% depending on donor type and MDS disease severity.

SAMD9/9L-RELATED DISORDER

Sterile alpha motif domain-containing protein 9 *(SAMD9)* and the paralogue gene *SAMD9*-like *(SAMD9L)* are located side-by-side on chromosome 7q21. They are interferon and tumor necrosis factor (TNF)-α responsive proteins that play a role in antiviral response, tumor suppression, inflammation, development, and endosomal fusion. Gain of function pathogenic variants, mostly missense, in these genes have variable penetrance. Thirty-eight pathogenic variants have been identified in approximately 110 patients.

Multiple organs can be affected in those with germline *SAMD9/9L* pathogenic variants, including the hematologic, immunologic, endocrine, and neurologic systems (see Table 517.2). The term **MIRAGE syndrome** was given to a constellation of abnormalities that include MDS, infection, restriction of growth (starting in utero), adrenal hypoplasia/insufficiency (with early onset), genital phenotypes (such as 46XY females and testicular dysgenesis), and enteropathy (often with reflux). Thrombocytopenia and anemia are often present at birth. In some patients, the anemia and thrombocytopenia resolve during infancy. Patients with *SAMD9L* pathogenic variants might show disease-specific neurological findings with very variable age of onset. Severe cerebellar ataxia is observed in some, whereas others have cerebellar atrophy, dysmetria, nystagmus, white matter abnormalities, and loss of Purkinje cells. The majority of patients in both syndromes have hematologic manifestations which range from single lineage cytopenia to pancytopenia with hypocellular marrow, MDS with monosomy 7, or deletion 7q. Some patients have nonsyndromic *SAMD9/9L* related MDS.

SAMD9/9L pathogenic variants are seen in 8–17% of pediatric MDS. The median age of presentation with SAMD9/9L related MDS is approximately 10 years. Ninety percent of children present in the early stage of MDS (refractory cytopenia of childhood), and another 10% present with advanced MDS. Transient monosomy 7 syndrome, the disappearance of monosomy 7 clones from the bone marrow, has been described in a few young children. It was hypothesized that pathogenic variants in the growth inhibitory genes, *SAMD9*/9L, confer gain of function that further suppress cell growth. Hence, monosomy 7, which depletes one allele of *SAMD9*/9L, reduces the growth inhibitory effect of the pathogenic variants. Somatic revertant mosaicism with expansion of benign, corrected hematopoiesis, has also been reported with normalization of blood counts and marrow cellularity for up to 20 years from diagnosis.

Monitoring and treatment depend on the degree of blood count abnormalities, the presence of MDS, and the presence of syndromic disease. Children who received HSCT for *SAMD9*/9L–related MDS showed an overall survival of 85% in one study.

OTHER INHERITED APLASTIC ANEMIAS

A substantial number of genes that are associated with bone marrow failure with pancytopenia have been identified with the emergence of whole genome screening methods (see Table 517.1). The specific gene-associated disorders may vary by phenotype but frequently include physical malformations, familial distribution, early age of disease onset, pancytopenia, and a risk of MDS and AML. Significant overlap exists between inherited pancytopenia syndromes and familial MDS and AML syndromes.

SRP72-Related Disorder

This autosomal dominant disorder is characterized by familial aplastic anemia and MDS. Some patients also have deafness. *SRP72* encodes for a signal recognition particle 72 protein. SRP72 is part of a ribonucleoprotein complex that mediates targeting of secretory proteins to the endoplasmic reticulum.

ERCC6L2-Related Disorder

This autosomal recessive disorder features multilineage cytopenia, MDS, and physical malformations. Neurological and cranial abnormalities are common in *ERCC6L2*-related disorder and include developmental delay, microcephaly, ataxia, dysmetria, generalized brain volume loss, retinal dystrophy, and low-set ears. ERCC6L2 regulates transcription by RNA Pol II through an interaction with DNA-PK; thereby, it promotes resolution of R loops and minimizes transcription-associated genome instability. The inherited BMF syndrome caused by biallelic pathogenic variants in ERCC6L2 is thus a primary transcription deficiency and may not cause a DNA repair defect.

Dubowitz Syndrome

Dubowitz syndrome is characterized by a peculiar facies, infantile eczema, small stature, and mild microcephaly. The face is small, with a shallow supraorbital ridge, a nasal bridge at the same level as the forehead, short palpebral fissures, variable ptosis, and micrognathia. There

is a predisposition to cancer in these patients. Approximately 10% of patients have hematopoietic disorders, including moderate pancytopenia, hypoplastic anemia, bone marrow hypoplasia, and full-blown aplastic anemia. Patients also have an increased risk of lymphoma and neuroblastoma. In about one third of patients, a genetic cause can be identified and includes biallelic pathogenic variants in *NSUN2* (an RNA methyltransferase), biallelic pathogenic variants in *LIG4* (a nuclear DNA ligase), or one copy deletion in several chromosome sites including 14q32, 17q24, -14q32, -17q24, and -19q13.

Seckel Syndrome

Seckel syndrome, sometimes called "bird-headed dwarfism," is a developmental disorder characterized by marked growth failure and mental deficiency, microcephaly, a hypoplastic face with a prominent nose, and low-set and/or malformed ears. Approximately 25% of patients have aplastic anemia or malignancies. The syndrome is genetically heterogeneous and is associated with biallelic pathogenic variants in *ATR*, *RBBP8*, *CENPJ*, *CEP152*, *CEP63*, *NIN,* or *ATRIP.* A deletion at the14q21-q22 locus has also been described.

Reticular Dysgenesis

Reticular dysgenesis is a severe form of immunodeficiency. It is mainly characterized by severe lymphopenia and neutropenia. Patients typically present with severe infections at birth or shortly thereafter. On physical examination, lymph nodes and tonsils are absent, and a thymic shadow on radiographs cannot be seen. Laboratory tests show absence of cellular and humoral immunity. Anemia, thrombocytopenia, and aplastic anemia may be evident. Bone marrow specimens show markedly reduced myeloid and lymphoid elements. Clonogenic assays of hematopoietic progenitors consistently show reduced to absent colony growth, suggesting that the disorder has its origins at the HSC level. The disease is inherited in an autosomal recessive fashion and is caused by biallelic pathogenic variants in mitochondrial *AK2*. The only curative therapy is HSCT.

Schimke Immunoosseous Dysplasia

Schimke immunoosseous dysplasia is an autosomal recessive disorder caused by pathogenic variants in the chromatin remodeling gene *SMARCAL1*. Patients have spondyloepiphyseal dysplasia with exaggerated lumbar lordosis and a protruding abdomen. There are pigmentary skin changes and abnormally discolored and configured teeth. T-cell immunodeficiency, progressive renal insufficiency, nephrotic syndrome, and early atherosclerosis are common causes of morbidity and mortality. Approximately 50% of patients have hypothyroidism; 50% have cerebral ischemia; 10% have bone marrow failure with neutropenia, thrombocytopenia, and anemia; and about 5% are predisposed to non-Hodgkin lymphoma. Eighty percent of patients have lymphopenia and altered cellular immunity. Bone marrow transplantation has been successfully applied to patients with bone marrow failure or immunodeficiency.

Cartilage Hair Hypoplasia

Cartilage-hair hypoplasia features metaphyseal dysostosis, short-limbed dwarfism, and fine sparse hair. Skeletal abnormalities may also include scoliosis, lordosis, chest deformity and varus lower limbs. GI abnormalities such as aganglionic megacolon have been reported. Most reported cases are of Finnish or Amish descent. In over 80% of patients, biallelic causal pathogenic variants in the noncoding RNA gene *RMRP* (RNA Component of Mitochondrial RNA Processing Endoribonuclease) can be found. Recently, biallelic pathogenic variants in *POP1* and in *NEPRO* have also been found to be associated with the disease. POP1 is a component of the RNAse-MRP endoribonuclease complex. NEPRO is a nucleolar and neural progenitor protein that interacts with multiple subunits of the RNase MRP complex. The complex plays a role in rRNA and in mitochondrial RNA processing by cleavage at a priming site during replication.

The hematological abnormalities include macrocytic anemia. In most cases the anemia is mild and self-limited, but a proportion of patients have severe and persistent anemia that requires regular RBC transfusions. Lymphopenia occurs in 65% of patients. Severe immunodeficiency can occur, often with severe anemia. Neutropenia has been reported in 25% of patients. HSCT has been used successfully to reconstitute the hemato/immunological system. Lymphomas and basal cell carcinoma occur at an increased frequency among these patients.

Pearson Syndrome

Pearson syndrome is a mitochondrial metabolic disorder with various bone marrow impairments. Insufficiency of the exocrine pancreas, caused by acinar cell atrophy and fibrosis, develops in 30% of cases. The syndrome is caused by a maternally inherited deletion of mitochondrial DNA (mtDNA) that encodes enzymes that are critical to oxidative phosphorylation. Severe macrocytic anemia requiring transfusions is commonly present within the first year of life, sometimes at birth. Bone marrow aspirate typically shows ringed sideroblasts and prominent vacuolization of erythroid and myeloid precursors. However, cases with pure red cell aplasia mimicking Diamond Blackfan anemia have been reported. Pancytopenia may occur alone or in association with hepatic failure, renal tubulopathy, and lactic acidosis. In such cases, platelet transfusions may also be required. Erythropoietin has been used for the anemia of renal failure. G-CSF is indicated to prevent infections in patients with severe neutropenia. HSCT is traditionally not recommended for the hematopoietic complications of Pearson syndrome due to their tendency to improve spontaneously in most cases; nonetheless, HSCT has been used in rare cases with Pearson syndrome, and engraftment was achieved. Interestingly, HSCT was associated not only with improved hematopoiesis but also with resolution of lactacidemia and acidosis. Patients may need pancreatic enzyme replacement if they develop malabsorption due to exocrine pancreatic insufficiency.

Immune-Related Pancytopenias

Primary immunodeficiency, autoimmune, lymphoproliferative, and hemophagocytic disorders can be associated with pancytopenia. Autoantibodies, hypersplenism, and bone marrow involvement are potential mechanisms. Recognizable disorders include common variable immunodeficiency syndrome (Chapter 165), hemophagocytic lymphohistiocytosis (Chapter 556.2), autoimmune lymphoproliferative syndrome (Chapter 174.7), and other lymphoproliferative disorders.

UNCLASSIFIED INHERITED BONE MARROW FAILURE SYNDROMES

Unclassified IBMFSs are heterogeneous disorders that in many cases were shown to present as new syndromes. In other cases, they may be atypical presentations of already characterized diseases. Unbiased approaches, such as study of comprehensive genetic panels of all known IBMFS genes regardless of the specific hematologic (e.g., isolated neutropenia or pancytopenia) or nonhematologic manifestations, or WES/genome sequencing, have proved this to be true. These disorders do not fit into classic genetic bone marrow failure diseases because all features of any one disease may not be evident at presentation. All are characterized by various cytopenias caused by underproductive bone marrow with or without physical manifestations. Compared with patients with classical disorders who present at a median age of 1 month, patients with unclassified disorders present later, at a median age of 9 months. Patients with unclassified IBMFSs can manifest single or multilineage cytopenia, aplastic anemia, MDS, or malignancy with variable expression of malformations. Table 517.5 lists criteria for the diagnosis, which include evidence of chronic bone marrow failure, in addition to factors that indicate a high likelihood of inherited disease (e.g., family history, congenital anomalies, young age at presentation).

When patients present later and without physical malformations, an acquired etiology cannot be ruled out. Detailed genetic testing for known IBMFS genes followed by approaches to discover novel genes and novel syndromes by WES/genome sequencing may identify an inherited etiology and define the disease.

Determining the actual genetic cause helps group patients according to diseases and guides counseling and proper medical care. Implementing a treatment plan is urgent in many cases. In such patients, the management should be according to the type of complications that the patient has at presentation and the lessons that can be learned from published experience on unclassified cases in the literature.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

Table 517.5 The Canadian Inherited Marrow Failure Registry Criteria for Unclassified Inherited Bone Marrow Failure Syndromes

FULFILLS CRITERIA 1 AND 2:
1. Does not fulfill criteria for any categorized inherited bone marrow failure syndrome*
2. Fulfills both of the following:
FULFILLS AT LEAST TWO OF THE FOLLOWING:
a. Chronic cytopenia(s) detected on at least two occasions over at least 3 months†
b. Reduced marrow progenitors or reduced clonogenic potential of hematopoietic progenitor cells or evidence of ineffective hematopoiesis‡
c. High fetal hemoglobin for age‡
d. Red blood cell macrocytosis (not caused by hemolysis or a nutritional deficiency)
FULFILLS AT LEAST ONE OF THE FOLLOWING:
a. Family history of bone marrow failure
b. Presentation at age <1 year
c. Anomalies involving multiple systems to suggest an inherited syndrome

*The criteria for most common syndromes are described in Tsangaris E, Klaasen R, Fernandez CV, et al. Genetic analysis of inherited bone marrow failure syndromes from one prospective, comprehensive, and population-based cohort and identification of novel mutations. *J Med Genet*. 2011;48:618–628.

†Cytopenia is defined according to the affected cell: neutropenia, neutrophil count of $<1.5 \times 10^9$/L; thrombocytopenia, platelet count of $<150 \times 10^9$/L; anemia, hemoglobin concentration of >2 standard deviations below mean, adjusted for age.

‡Hemoglobinopathies with ineffective erythropoiesis and high fetal hemoglobin should be excluded by clinical or laboratory testing.

Modified from Teo JT, Klaassen R, Fernandez CV, et al. Clinical and genetic analysis of unclassifiable inherited bone marrow failure syndromes. *Pediatrics*. 2008;22:e139–e148.

Table 518.1 Etiology of Acquired Aplastic Anemia

Radiation, Drug, and Chemicals
Predictable: chemotherapy, benzene
Idiosyncratic: chloramphenicol, antiepileptics, gold, 3,4-methylenedioxymethamphetamine, nonsteroidal antiinflammatory drugs (NSAIDs), antibiotics

Leishmaniasis

Chapter 518

Acquired Pancytopenias

John H. Fargo and Jeffrey D. Hord

ETIOLOGY AND EPIDEMIOLOGY

Therapeutic and recreational drugs, environmental toxins, infectious agents, radiation, and immune disorders can result in pancytopenia by direct destruction of hematopoietic progenitors, disruption of the marrow microenvironment, or immune-mediated suppression of marrow elements (Tables 518.1 and 518.2). A careful history of exposure to known risk factors should be obtained for every child presenting with pancytopenia. Even in the absence of the classic associated physical findings, the possibility of a genetic predisposition to bone marrow failure must also be considered (see Chapter 517). Many cases of acquired marrow failure in childhood are idiopathic, in that no causative agent is identified. Many are probably immune mediated through cytotoxic T lymphocytes and cytokine destruction of marrow stem and progenitor cells. Patients with an initial diagnosis of acquired aplastic anemia may have developed somatic pathogenic variants in genes associated with myelodysplastic syndromes (MDS) and acute myeloid leukemia (AML). Clonal hematopoiesis resulting from these acquired somatic genetic variants may over time lead to the development of MDS or AML. The overall incidence of **acquired aplastic anemia** is relatively low, with an approximate incidence in both children and adults in the United States and Europe of 2–6 cases per 1 million population per year. The incidence is higher in Asia, with as many as 14 cases per 1 million per year in Japan.

Severe bone marrow suppression can develop after exposure to many different therapeutic drugs and environmental chemicals, including certain chemotherapeutic agents, insecticides, antibiotics, anticonvulsants, nonsteroidal antiinflammatory drugs (NSAIDs), and recreational drugs. Some of the most notable agents are benzene, chloramphenicol, gold, and 3,4-methylenedioxymethamphetamine (MDMA, or "ecstasy").

A number of viruses can either directly or indirectly result in bone marrow failure. Parvovirus B19 is classically associated with isolated red blood cell (RBC) aplasia, but in patients with sickle cell disease or immunodeficiency, it can result in transient pancytopenia (see Chapter 298). Prolonged pancytopenia can occur after infection with many of the hepatitis viruses, herpesviruses, Epstein-Barr virus (see Chapter 301), cytomegalovirus (see Chapter 302), and HIV (see Chapter 322).

Immune-mediated acquired pancytopenia is also found to be prominent among acute, sporadic cases of aplastic anemia. Immunologic conditions, such as seronegative hepatitis, eosinophilic fasciitis, and thymoma, have been implicated in aplastic anemia.

Patients with evidence of bone marrow failure should also be evaluated for inherited forms of marrow failure, **paroxysmal nocturnal hemoglobinuria** (PNH; see Chapter 510), and collagen vascular diseases. Pancytopenia without peripheral blasts may be caused by bone marrow replacement by malignant cells including leukemia and solid tumor cells, such as neuroblastoma.

Table 518.2 Drugs and Toxins Associated with Aplastic Anemia

DOSE DEPENDENT
Antineoplastic Agents
Antimetabolites: fluorouracil, mercaptopurine, 6-thioguanine, methotrexate, cytosine arabinoside, gemcitabine, fludarabine, cladribine, pentostatin, hydroxyurea
Alkylating and cross-linking agents: busulfan, cyclophosphamide, chlorambucil, nitrogen mustard, melphalan, cisplatin, carboplatin, ifosfamide, nitrosoureas (BCNU and CCNU), mitomycin C
Cytotoxic antibiotics: daunorubicin, doxorubicin, mitoxantrone
Plant alkaloids: vinblastine, paclitaxel
Topoisomerase inhibitors: etoposide
Antimicrobial Agents
Chloramphenicol, dapsone, fluorocytosine
Antiinflammatory and Antirheumatic Agent
Colchicine
Insecticides
Chlordane, chlorophenothane (DDT), lindane, parathion
Other Chemicals
Benzene
Benzene-containing chemicals: kerosene, chlorophenols, carbon tetrachloride

DOSE INDEPENDENT*
Idiosyncratic, likely immune mediated
Antimicrobial Agents
Chloramphenicol, dapsone, sulfonamides, tetracycline, methicillin, amphotericin, quinacrine, chloroquine, pyrimethamine
Anticonvulsants
Hydantoins, carbamazepine, phenacemide, primidone, ethosuximide
Antiinflammatory Agents
Phenylbutazone, indomethacin, ibuprofen, oxyphenbutazone, sulindac, naproxen
Antiarrhythmic Drugs
Quinidine, tocainide, procainamide
Metals
Gold, arsenic, mercury, bismuth
Antihistamines
Cimetidine, ranitidine, chlorpheniramine, pyrilamine, tripelennamine
Diuretics
Acetazolamide, furosemide, chlorothiazide, methazolamide
Hypoglycemic Agents
Chlorpropamide, tolbutamide
Antithyroid Drugs
Propylthiouracil, potassium perchlorate, methylthiouracil, methimazole, carbimazole
Antihypertensive Agents
Methyldopa, enalapril, captopril
Sedatives
Chlordiazepoxide, chlorpromazine, meprobamate, prochlorperazine

*Most agents listed in this group should be considered to be possibly associated with aplastic anemia.
From Bagby GC. Aplastic anemia and related bone marrow failure states. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier, 2020: Table 156.2.

PATHOLOGY AND PATHOGENESIS

The hallmark of aplastic anemia is peripheral pancytopenia, coupled with hypoplastic or aplastic bone marrow. The severity of the clinical course is related to the degree of myelosuppression. **Severe aplastic anemia** is defined as a condition in which ≥2 cell components have become seriously compromised (absolute neutrophil count <500/mm^3, platelet count <20,000/mm^3, reticulocyte count <1% after correction for hematocrit) in a patient whose bone marrow biopsy material has <30% cellularity. Approximately 65% of patients who first present with **moderate aplastic anemia** (absolute neutrophil count 500–1,500/mm^3, platelet count 20,000–100,000/mm^3, reticulocyte count <1%) eventually progress to meet the criteria for severe disease if they are simply observed. Bone marrow failure may be a consequence of a direct cytotoxic effect on hematopoietic stem cells (HSCs) from a drug or chemical or may result from either cell-mediated or antibody-dependent cytotoxicity. There is strong evidence that many cases of idiopathic aplastic anemia are caused by an immune-mediated process, with increased circulating cytotoxic T lymphocytes producing cytokines (interferon-γ) that suppress hematopoiesis. Abnormal telomere length and telomerase activity in granulocytic precursors of patients with aplastic anemia suggest that early apoptosis of hematopoietic progenitors may play a role in the pathogenesis of this disease.

Cytogenetic abnormalities associated with aplastic anemia include uniparental disomy of 6p, monosomy 7/deletion of 7q, and trisomy 8, 6, or 15. Genes associated with aplastic anemia include telomere complex genes *(TERT, TERC)* and *BCOR/BCORL, PIGA, DNMT3A,* and *ASXL1*.

CLINICAL MANIFESTATIONS, LABORATORY FINDINGS, AND DIFFERENTIAL DIAGNOSIS

Pancytopenia results in increased risks of cardiac failure, fatigue, infection, and bleeding. Acquired pancytopenia is typically characterized by anemia, leukopenia, and thrombocytopenia in the setting of elevated serum cytokine values. Other treatable disorders, such as cancer, collagen vascular disorders, PNH, and infections, that may respond to specific therapies (IV immunoglobulin for parvovirus), should be considered in the differential diagnosis. Careful examination of the peripheral blood smear for RBC, leukocyte, and platelet morphologic features is important. A reticulocyte count should be performed to assess erythropoietic activity. In children, the possibility of *congenital* pancytopenia must always be considered, and chromosomal breakage analysis should be performed to evaluate for **Fanconi anemia** (see Chapter 517) and telomere length to evaluate for telomeropathies. The presence of fetal hemoglobin suggests congenital pancytopenia but is not diagnostic. To assess for possible PNH, flow cytometric analysis of erythrocytes and granulocytes for CD55 and CD59 is the most sensitive test. Bone marrow examination should include both aspiration and biopsy, and the marrow should be carefully evaluated for morphologic features, cellularity, and cytogenetic abnormalities.

TREATMENT

The treatment of children with acquired pancytopenia requires comprehensive supportive care coupled with an attempt to treat the underlying etiology for marrow failure. For patients with a human leukocyte antigen (HLA)–matched family member donor, **allogeneic hematopoietic stem cell transplantation (HSCT)** offers a 90% chance of long-term survival. Preparative regimens vary but typically consist of cyclophosphamide, fludarabine, and horse antithymocyte globulin (ATG). Preliminary data also suggest that children with severe aplastic anemia can be successfully transplanted using *alemtuzumab* (humanized monoclonal antibody against CD52 on lymphocytes)–based conditioning. The risks associated with bone marrow transplantation include the immediate complications of transplantation, graft failure, and graft-versus-host disease. Late adverse effects associated with transplantation may include secondary cancers, cataracts, short stature, hypothyroidism, and gonadal dysfunction (see Chapters 179 and 180). Only approximately 20% of patients have an HLA-matched family member donor, so matched-related HSCT is not an option for the majority of patients.

For patients without a sibling donor, the major form of therapy is **immunosuppression** with horse ATG and cyclosporine, with a response rate of 60–70%. The median time to response is 6 months. As many as 30–60% of patient responders experience relapse after discontinuation of immunosuppression, and some patients must continue cyclosporine for several years to maintain a hematologic

response. Among those who relapse after immunosuppression, approximately 50% show response to a second course of ATG and cyclosporine. To accelerate neutrophil recovery, a hematopoietic colony-stimulating factor (e.g., granulocyte CSF, granulocyte-macrophage CSF) is sometimes added to ATG and cyclosporine for treatment of patients with very severe neutropenia (absolute neutrophil count <200/mm^3), but there is no clear evidence that this treatment influences response rate or survival. Higher baseline reticulocyte count correlates with a higher probability of response to immunosuppression and survival. There is an inverse correlation between telomere length and the probability of relapse after immunosuppression.

For patients who show no response to immunosuppression or who experience relapse after immunosuppression, **matched-unrelated HSCT and T-cell–depleted haploidentical family member–donor HSCT** are treatment options, with a response rate approaching 90%. Cord blood transplants have been performed in this refractory group of pediatric patients, with survival approximating 90%. Ongoing studies using **eltrombopag** (an oral thrombopoietin mimetic agent) have shown promise in patients ≥15 years of age (mostly adults) with refractory disease. The use of eltrombopag resulted in a hematologic response with improvements in platelet and neutrophil counts and hemoglobin levels in over half the patients. In patients who responded, bone marrow biopsies demonstrated trilineage normalization of hematopoiesis, with some showing a durable response. **High-dose cyclophosphamide** has been used successfully in the treatment of patients who are not good candidates for HSCT and have not had an adequate response to immunosuppression. This therapy leads to prolonged severe pancytopenia, increasing the risk of life-threatening infection, especially fungal infections. Other therapies that have been used in the past with inconsistent results include androgens, corticosteroids, and plasmapheresis. **Alemtuzumab** as monotherapy in relapsed disease showed improved response rates and 3-year survival compared to additional courses of ATG and cyclosporine.

COMPLICATIONS

The major complications of severe pancytopenia are predominantly related to the risk of life-threatening bleeding from prolonged thrombocytopenia or to infection secondary to protracted neutropenia. Patients with protracted neutropenia as a result of bone marrow failure are at risk not only for serious bacterial infections but also for invasive mycoses. Patients who have been transfused with RBCs regularly over a long period are at increased risk of developing alloantibodies to RBC antigens and may require iron chelation therapy for transfusional iron overload. The general principles of supportive care that have evolved from the use of chemotherapy-related myelosuppression to treat patients with cancer should be fully extended to the care of patients with acquired pancytopenia.

PROGNOSIS

Spontaneous recovery from pancytopenia rarely occurs. If left untreated, severe pancytopenia has an overall mortality rate of approximately 50% within 6 months of diagnosis and of >75% overall, with infection and hemorrhage being the major causes of morbidity and mortality. The majority of children with acquired severe aplastic anemia show response to allogeneic marrow transplantation or immunosuppression, leaving them with normal or near-normal blood cell counts.

PANCYTOPENIA CAUSED BY MARROW REPLACEMENT

Processes that either infiltrate or replace the bone marrow can manifest as acquired pancytopenia. Infiltration can be caused by malignancy (classically, neuroblastoma or leukemia) or result from myelofibrosis, MDS, or osteopetrosis. Although uncommon, evidence of hypoplastic anemia can precede the onset of acute leukemia, generally by a few months. This relationship is important to appreciate in evaluating and monitoring children who present with what appears to be acquired aplastic anemia. Morphologic examination of the peripheral blood and bone marrow and marrow cytogenetic studies are critically important in making the diagnoses of leukemia, myelofibrosis, and MDS.

Myelodysplasia is very rare in children, but when it occurs, its clinical course is more aggressive than the same category of MDS in adults. Pediatric MDS can be subdivided into **refractory cytopenia of childhood** (peripheral blasts <2% and marrow blasts <5%) and **MDS with excess blasts** (peripheral blasts 2–19% and/or marrow blasts 5–19%). Disease in children with >20% blasts is usually defined as AML.

Myelodysplastic syndromes are a heterogeneous group of bone marrow failure disorders that have in common ineffective hematopoiesis that leads to pancytopenia over time. In one group, there are somatic variants (in >25 genes) leading to MDS. In another group, usually in younger patients (<55 years), there is autoimmune suppression of hematopoiesis by clonal expansion of T lymphocytes, particularly in those patients who look similar to patients with idiopathic aplastic anemia. In all patients, other causes of MDS (medications and vitamin B_{12}, folate, or copper deficiencies) must be ruled out.

A number of inherited conditions are associated with an increased risk for development of MDS, including Down syndrome, severe congenital neutropenia, Noonan syndrome, Fanconi anemia, trisomy 8 mosaicism, neurofibromatosis, Shwachman-Diamond syndrome, and some familial MDS syndromes caused by pathogenic variants in *ANKRD26, CEBPA, DDX41, ETV6, GATA2, RUNX1,* and *SRP72* genes. Significant clonal abnormalities are found within the marrow of approximately 50% of patients with MDS, with monosomy 7 being most common but prognostically neutral. Those with a structurally complex karyotype have a very poor outcome (see Chapter 517).

The transition time from pediatric MDS to acute leukemia is relatively short, 14–26 months, so aggressive treatment such as HSCT must be considered shortly after diagnosis. With allogeneic HSCT, the survival rate is approximately 60%. One exception to such an aggressive therapeutic approach is MDS and AML in children with Down syndrome because these diseases in this specific population are very responsive to conventional chemotherapy, with long-term survival rates >80%.

The decision on how to treat a child with MDS who lacks a suitable HSC donor should be made with the specific clonal abnormality found within the child's marrow taken into consideration. Lenalidomide produces the best responses among patients who have the chromosomal abnormality 5q−. Immunosuppressive therapy with ATG and cyclosporine is most effective in patients with trisomy 8, especially in the presence of a PNH clone. Imatinib mesylate targets mutations in the tyrosine kinase receptor family of genes found in patients with t(5;12) and del(4q12). The DNA hypomethylating agents azacitidine and decitabine have also been used in treating MDS without a known molecular target and have some effect.

Blood Component Transfusions

Chapter 519

Red Blood Cell Transfusions and Erythropoietin Therapy

Patricia E. Zerra and Cassandra D. Josephson

Red blood cells (RBCs) are transfused to increase the oxygen-carrying capacity of the blood, with the goal to increase or maintain satisfactory tissue oxygenation. This goal may not be achieved simply by increasing the hemoglobin (Hb) concentration or hematocrit (Hct) by an RBC transfusion because tissue oxygenation depends on several additional factors, including oxygen off-loading from RBCs, microvascular blood flow, and diffusion of oxygen into tissue cells. Although some attempts have been made to accurately relate posttransfusion Hb or Hct values to changes in posttransfusion tissue oxygenation (e.g., improvements in the ratio of cerebral vs mesenteric oxygenation patterns assessed by serial near-infrared spectroscopy measurements), decisions to transfuse RBCs per physiologic indications, rather than degree of anemia, remain investigational. This information can be applied to approaches for transfusion in both preterm infants/neonates and children/adolescents. However, neonates, especially extremely low birthweight infants (≤1,000 g), are not "small" children (i.e., RBC physiology and pathophysiology of anemia of prematurity are unique); thus RBC transfusions for neonates and children are considered separately.

RBC TRANSFUSION IN CHILDREN AND ADOLESCENTS

Guidelines for RBC transfusions in children and adolescents are based on maintaining a specified Hb or Hct level considered to be optimal (per the best evidence available) for the clinical condition present at the time of transfusion. The guidelines are similar to those for adults (Table 519.1). Transfusions may be given more stringently to children because normal Hb levels are lower in healthy children than in adults and, as is often the case, most children do not have the underlying multiorgan, cardiorespiratory, and vascular diseases that develop with aging in adults to suggest a need for RBC transfusions. As a result, children may compensate better for RBC loss than elderly adults, thus requiring less RBC transfusion support. In general, there is increasing enthusiasm for applying patient blood management strategies, encompassing conservative transfusion practices (i.e., accepting lower pretransfusion Hct values to "trigger" an RBC transfusion) to all patient ages with evidence-based support.

In the **perioperative period,** it is unnecessary for most children to maintain Hb of ≥8 g/dL, a level frequently desired for adults. Instead, Hb of ≥7 g/dL is an acceptable level, although the optimal value for individual patients is based on clinical and laboratory circumstances, as influenced by the following factors. The desired preoperative Hb level should consider the estimated blood loss for the surgical procedure planned and the rate of bleeding. There should be a compelling reason to prescribe any postoperative RBC transfusion, such as continued bleeding with hemodynamic instability because most children (without continued bleeding) can restore their RBC mass with iron therapy (in a relatively short time).

Table 519.1 Guidelines for Pediatric Red Blood Cell Transfusions*†

CHILDREN AND ADOLESCENTS
1. Maintain stable status with acute loss of >25% of circulating blood volume.
2. Maintain hemoglobin >7.0 g/dL† in the perioperative period.
3. Maintain hemoglobin >12.0 g/dL with *severe* cardiopulmonary disease.
4. Maintain hemoglobin >12.0 g/dL during extracorporeal membrane oxygenation.
5. Maintain hemoglobin >7.0 g/dL with *symptomatic* chronic anemia.
6. Maintain hemoglobin >7.0 g/dL with *marrow failure*.
INFANTS ≤4 MO OLD
1. Maintain hemoglobin >12.0 g/dL with *severe* pulmonary disease.
2. Maintain hemoglobin >12.0 g/dL during extracorporeal membrane oxygenation.
3. Maintain hemoglobin >10.0 g/dL with *moderate* pulmonary disease.
4. Maintain hemoglobin >12.0 g/dL with *severe* cardiac disease.
5. Maintain hemoglobin >10.0 g/dL preoperatively and during *major* surgery.
6. Maintain hemoglobin >7.0 g/dL postoperatively.
7. Maintain hemoglobin >7.0 g/dL with *symptomatic* anemia.

*Words in *italics* must be defined for local transfusion guidelines.
†Pretransfusion blood hemoglobin (Hb) level (convert to hematocrit values if preferred by multiplying Hb values by 3) "triggering" an RBC transfusion. Hb values to maintain vary among published reports, and the guideline values to maintain should be determined locally to fit the practices judged to be optimal by local physicians.

The most important measures in the treatment of **acute hemorrhage** are to control the hemorrhage and, if blood loss is modest, to restore the circulating blood volume and tissue perfusion with crystalloid or, less often, colloid solutions. If the estimated blood loss is >25% of the circulating blood volume (>15 mL/kg of an estimated 60 mL/kg total estimated blood volume) *and* the patient's condition is unstable despite initial intravenous (IV) fluids, RBC transfusions should be given without undue hesitation, along with plasma transfusions at a 1:1 ratio of RBC/plasma volumes. Some experts recommend transfusing platelets early if bleeding is sustained or "massive" (i.e., approximating one blood volume or 60 mL/kg, which may occur very quickly in infants and small pediatric patients). Details of combined RBC and plasma transfusions, the volume ratio transfused, and considerations for adding platelet transfusions to treat bleeding patients are controversial. Accordingly, each hospital should develop and follow a "massive transfusion" protocol to ensure consistent practices.

In critically ill children with severe cardiac or pulmonary disease requiring assisted ventilation, it is common practice to maintain the Hb level close to the normal range, although the efficacy of this practice has not been well documented. A similar approach is used for children with acute cardiac, pulmonary, or cardiopulmonary disorders managed with extracorporeal membrane oxygenation (ECMO).

The pretransfusion Hb level or Hct that should "trigger" an RBC transfusion remains controversial (i.e., restrictive or a low pretransfusion level vs liberal or a high pretransfusion level) despite a substantial amount of published information, including randomized clinical trials. The current trend in critical care settings is to transfuse RBCs conservatively, following restrictive guidelines, and to permit modest anemia because there appears to be no disadvantage to conservative/restrictive transfusion practices, and some patients with Hb levels maintained close to the normal range by RBC transfusions (i.e., liberal guidelines) have poorer outcomes. Studies in critically ill adults demonstrated better outcomes when Hb level was maintained at 7–9 g/dL vs 10–12 g/dL. Anemic adults with *significant cardiac disease* did better with Hb level maintained at 13 g/dL rather than 10 g/dL. A similar study in children admitted to intensive care units found no inferiority when RBC

transfusions were given by restrictive guidelines *(transfusion threshold of 7 g/dL)*. It must be remembered that the children studied were in stable clinical status and needed few transfusions. Therefore, results of the trial cannot be automatically generalized to all patients admitted to ICUs because unstable critically ill children (who were not included in the study) may need more liberal RBC transfusion approaches.

With **chronic anemia,** the decision to transfuse RBCs should not be based solely on blood Hb levels because children compensate well and may be asymptomatic despite low Hb levels. Patients with iron-deficiency anemia are often treated successfully with oral iron alone, even at Hb levels <5 g/dL. Factors other than Hb concentration to be considered in the decision to transfuse RBCs include (1) the patient's symptoms, signs, and compensatory capacities; (2) the presence of underlying cardiorespiratory, vascular, and central nervous system disease; (3) the cause and anticipated course of the anemia; and (4) alternative therapies, such as recombinant human erythropoietin (EPO) therapy, which is known to reduce the need for RBC transfusions and to improve the overall condition of children with chronic renal insufficiency (see Chapter 572.2). In anemias that are likely to be permanent, it is also important to balance the detrimental effects of the degree of long-standing anemia on growth and development against the potential toxicity associated with repeated transfusions (i.e., iron overload and risks of transfusion-transmitted diseases) given to maintain the Hb concentration at a specified level. RBC transfusions for disorders such as sickle cell anemia and thalassemia are discussed in Chapters 511.1 and 511.10.

RBC TRANSFUSION IN PRETERM INFANTS AND NEONATES

For neonates, almost all aspects of RBC transfusions remain controversial—the accepted indications for RBC transfusions, restrictive vs liberal pretransfusion Hb/Hct levels, optimal RBC product to be transfused, and fresh vs stored RBC units—and clinical practices vary greatly. Generally, RBCs are given to maintain an Hb value believed to be the most desirable for each neonate's clinical status. Restrictive guidelines (i.e., lower pretransfusion Hb/Hct levels) have been compared to more liberal transfusion practices, but both short-term and long-term results and outcomes have been inconsistent and controversial, particularly as to neurodevelopmental status. Two multicenter randomized controlled trials showed no difference in survival or neurodevelopmental outcome in premature infants receiving RBC transfusion based on liberal versus restrictive Hb thresholds. Importantly, a lower Hb threshold was *not inferior* to a higher threshold for RBC transfusion. However, these studies had limitations, and accordingly, conventional guidelines are recommended to avoid problems caused by undertransfusion or overtransfusion (see Table 519.1).

During the first few weeks of life, all neonates experience a decline in circulating RBC mass caused by physiologic factors and, in sick premature infants, by phlebotomy blood losses. In healthy term infants, the nadir Hb value rarely falls to <11 g/dL at age 10-12 weeks. This benign drop in Hb does not require transfusions. In contrast, the decline occurs earlier and is more pronounced in premature infants, in whom the mean Hb concentration falls to approximately 7 g/dL in infants weighing <1 kg at birth, resulting in the **anemia of prematurity**, for which there often is need for RBC transfusions, particularly when the anemia is worsened by blood draws for laboratory testing.

A key reason that the nadir Hb values of premature infants are lower than those of term infants is the premature infant's relatively diminished plasma EPO level in response to anemia (see Chapters 139 and 496). Another factor is the rapid disappearance of EPO from infant plasma (i.e., accelerated metabolism). Low plasma EPO levels provide a rationale for the possible use of recombinant EPO in the treatment of anemia of prematurity; treatment with EPO and iron effectively stimulate neonatal erythropoiesis. Recombinant EPO has not been widely accepted as a treatment for anemia of prematurity (see Chapter 139).

Many low birthweight preterm infants need RBC transfusions (see Table 519.1). Although the practice to maintain a very high Hb level >13 g/dL (or Hct >40%) was once widely recommended, currently more restrictive guidelines have been suggested. However, one prospective, observational, multisite, birth cohort study of very low birthweight infants (≤1500 g) found a sixfold increased risk of necrotizing enterocolitis (NEC) when an infant's hemoglobin was ≤8 g/dL. Importantly, RBC transfusion in a given week did not significantly increase the rate of NEC in this population. Consistent with the rationale for oxygen delivery in neonates with severe respiratory disease, it also seems appropriate to keep the Hb value relatively high in neonates with *severe cardiac disease* leading to either cyanosis or congestive heart failure, but convincing and consistent data are lacking.

The optimal Hb level for neonates facing major surgery has not been established. However, it seems reasonable to begin surgery in neonates with the Hb level no lower than 10 g/dL (hematocrit >30%) and to maintain that value during major surgery because even modest blood loss will have a relatively large effect on the small blood volume of the neonate. Neonates with underlying pulmonary problems have limited ability to compensate for anemia due to the inability to increase ventilation and the inferior off-loading of oxygen because of the diminished interaction between fetal Hb and 2,3-diphosphoglycerate. Postoperatively, a lower pretransfusion Hb value should be followed to "trigger" a transfusion.

Stable neonates do not require RBC transfusion, regardless of their blood Hb levels, unless they exhibit clinical symptoms attributable to anemia. Proponents of RBC transfusions for symptomatic anemia in preterm neonates believe that the low RBC mass contributes to tachypnea, dyspnea, tachycardia, apnea and bradycardia, feeding difficulties, and lethargy, which can be alleviated by transfusion of RBCs. However, anemia is only one of several possible causes of these problems, and RBC transfusions should only be given when clinical benefit seems likely.

RBC PRODUCT AND DOSE

The RBC product of choice to transfuse neonates, infants, children, and adolescents is prestorage *leukocyte-reduced* RBCs suspended in an anticoagulant/preservative storage solution at Hct of approximately 60–70% for storage up to 35–42 days. For those infants with birthweight <1,500 g, *irradiation* is recommended to prevent transfusion-associated graft-versus-host disease. Additionally, both leukoreduction and cytomegalovirus-seronegative RBC units have been recommended by some (estimated risk of *transfusion-transmission cytomegalovirus* [TT-CMV] infection: 0–0.3% per unit) as first-line therapy to prevent TT-CMV. However, given the low risks of TT-CMV with improvements in modern leukoreduction techniques, others have recommended use of leukoreduced blood without need for CMV antibody testing as an acceptably safe and low-risk alternative. RBC transfusion should not be delayed if CMV-negative blood is unavailable, and CMV-untested leukoreduced blood should be used because the risk of TT-CMV is relatively low, with possibly more harm to the patient if transfusion is withheld or delayed. The usual dose is 10–15 mL/kg, but transfusion volumes vary greatly depending on clinical circumstances (continued vs arrested bleeding, hemolysis). For neonates, some prefer a centrifuged RBC concentrate (Hct 70–90%). Unless transfusions are being given to treat rapid bleeding, RBCs are infused slowly (over 2–4 hours) at a dose of approximately 10–15 mL/kg. In this small-volume setting, because of the small quantity of extracellular fluid transfused and the slow rate of infusion, the type of RBC anticoagulant/preservative solution does not pose any risk for premature infants when the dose does not exceed 20 mL/kg. However, the additive solutions (e.g., AS-1, AS-3, AS-5) have not been studied by comparative randomized clinical trials in the setting of >20 mL/kg dosing or massive transfusion settings such as cardiopulmonary bypass, ECMO, or massive transfusion for trauma. Although a few anecdotal reports suggest RBCs in additive solutions are safe for large-volume transfusions while awaiting more definitive information, some hospitals that manage these complex neonates and children maintain separate inventories of different RBC products earmarked either for neonates and infants (e.g., citrate-phosphate-dextrose or citrate-phosphate-dextrose-adenine) or for older children (e.g., additive solutions).

STORAGE AGE OF RBC UNITS

The historical practice of transfusing fresh RBCs (<7 days of storage) for the small-volume (15 mL/kg) transfusions commonly given was supplanted several years ago in most centers by reserving a single unit of RBCs for an infant, from which multiple aliquots were obtained for transfusions as needed throughout the 42 days of storage. Concerns about high concentrations of extracellular potassium, loss of 2,3-diphosphoglycerate, altered RBC shape and deformability, and nitric oxide quenching were found not to pose clinically significant problems. Preterm neonates allocated to "fresh RBC" (<7 days' storage) transfusions vs "stored RBC" (up to 42 days' storage) transfusions have no advantage for fresh RBC transfusions in altering the composite clinical outcome of mortality, plus NEC, retinopathy of prematurity, bronchopulmonary dysplasia, and intraventricular hemorrhage, or of the individual disorders.

For children weighing >30 kg who are to undergo elective surgery for whom RBC transfusions are likely to be needed, autologous RBC transfusions offer an alternative to donor allogeneic RBCs. **Preoperative autologous** blood collections from the patient occur up to 6 weeks before the surgery and require careful considerations for the volume to be drawn, vascular access, and use of EPO and iron to help restore the donated RBCs. **Acute normovolemic hemodilution** occurs in the preoperative period, in which blood is withdrawn from the patient and replaced with saline, a task often difficult in centers without experience in the process. **Salvaged autologous blood** is collected from blood loss during the operation but is impractical unless the volume of blood salvaged is fairly large to permit washing and transfusion of a significant number of RBCs. Because of all these difficulties, plus the relative safety of the usual allogeneic blood supply, autologous RBC transfusions are not typically used in the pediatric setting.

Chapter 520

Platelet Transfusions

Patricia E. Zerra and Cassandra D. Josephson

CHILDREN AND ADOLESCENTS

Guidelines for platelet (PLT) support of children and adolescents with quantitative and qualitative PLT disorders are similar to those for adults, in whom the risk of life-threatening bleeding occurring after injury or spontaneously can be related to the severity of thrombocytopenia, although somewhat imprecisely (Table 520.1).

For children and adolescents with overt bleeding, therapeutic PLT transfusions should be given when the blood PLT count falls below 50×10^9/L and repeated as needed to maintain the PLT count $>50 \times 10^9$/L during bleeding and for 48 hours after bleeding ceases to allow the clot to "stabilize." Similarly, for a major invasive procedure (e.g., surgical), the PLT count should be maintained $>50 \times 10^9$/L until any bleeding that occurs ceases and the patient is stable. For minor invasive procedures (e.g., lumbar puncture, intravascular catheter placement), practices vary. It is reasonable to maintain the PLT count $>25 \times 10^9$/L, although these procedures often are performed in children with cancer or recent transplants, and it is important to be mindful of possible clotting abnormalities and anemia that may affect hemostasis beyond the effects of thrombocytopenia. Historical studies of patients with thrombocytopenia resulting from bone marrow failure suggest that the risk of spontaneous bleeding increases when blood PLT levels fall to $<20 \times 10^9$/L, particularly when hemorrhagic risk factors (infection, organ failure, clotting abnormalities, minor skin/mucosal bleeding, mucosal lesions, severe graft-versus-host disease [GVHD], anemia) are present. In this high-risk setting, prophylactic PLT transfusions are given to maintain a PLT count $>20 \times 10^9$/L. This threshold has been challenged by several studies of adult patients, who in many instances were carefully selected to be in relatively good clinical condition *without* hemorrhagic risk factors. Consequently, a lower PLT transfusion trigger of 10×10^9/L is recommended for stable (i.e., low-risk) patients.

Table 520.1 Guidelines for Pediatric Platelet (PLT) Transfusion*

CHILDREN AND ADOLESCENTS
1. Maintain PLT count $>50 \times 10^9$/L with bleeding.
2. Maintain PLT count $>50 \times 10^9$/L with *major invasive* procedure; $>25 \times 10^9$/L with minor.
3. Maintain PLT count $>20 \times 10^9$/L and *marrow failure* WITH hemorrhagic risk factors.
4. Maintain PLT count $>10 \times 10^9$/L and *marrow failure* WITHOUT hemorrhagic risk factors.
5. Maintain PLT count at any level with PLT dysfunction PLUS bleeding or invasive procedure.
INFANTS ≤4 MO OLD
1. Maintain PLT count $>100 \times 10^9$/L with bleeding or during extracorporeal membrane oxygenation.
2. Maintain PLT count $>50 \times 10^9$/L and an invasive procedure.
3. Maintain PLT count $>20 \times 10^9$/L and *clinically stable.*
4. Maintain PLT count $>50 \times 10^9$/L and *clinically unstable and/or bleeding or not when on indomethacin, nitric oxide, antibiotics, etc., affecting PLT function.*
5. Maintain PLT count at any level with PLT dysfunction PLUS bleeding invasive procedure.

*Words in *italics* must be defined for local transfusion guidelines.

In practice, severe thrombocytopenia that is prolonged beyond 1 week usually becomes complicated by the development of risk factors, including fever, antimicrobial therapy, GVHD, active bleeding, need for an invasive procedure, disseminated intravascular coagulation, and liver or kidney dysfunction with clotting abnormalities. In these situations, prophylactic PLT transfusions are given to maintain relatively high PLT counts (e.g., at least $>30 \times 10^9$/L). Despite the desire by some physicians to elevate the blood PLT count to 80×10^9/L or 100×10^9/L, there are no definitive data to justify a true benefit of PLT transfusions given at a PLT count $>50 \times 10^9$/L, unless bleeding is ongoing despite a PLT count between 50 and 100×10^9/L *and* thrombocytopenia seems to be the only cause for the bleeding.

Qualitative PLT disorders may be *inherited* or *acquired,* as in advanced hepatic or renal insufficiency or when blood flows through an extracorporeal circuit, such as during extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass. In patients with inherited disorders, PLT transfusions are justified only if the risk of significant bleeding is quite high or if bleeding is overt because inherited PLT dysfunction often is lifelong and repeated transfusions may lead to alloimmunization and refractoriness (i.e., poor response to PLT transfusions). Accordingly, prophylactic PLT transfusions are rarely justified unless an invasive procedure is planned, and therapeutic PLT transfusions must be given judiciously.

When managing patients with PLT dysfunction, it is important to remember that an abnormal test result with a modern PLT function device or, historically, a bleeding time more than twice the upper limit of normal provides diagnostic evidence of PLT dysfunction. However, an abnormal bleeding time or any other abnormal laboratory test is poorly predictive of hemorrhagic risk or the need to transfuse PLTs. Alternative therapies, particularly desmopressin acetate, should be considered to avoid PLT transfusions. Antiplatelet medications (nonsteroidal antiinflammatory drugs) should also be avoided.

INFANTS AND NEONATES

In neonates, thrombopoiesis and the risks of bleeding are substantially different from that in older children; the approach to thrombocytopenia and PLT transfusions likewise differs (see Table 520.1). **Thrombopoietin** (TPO) levels are higher in healthy neonates than in older individuals. Relative to adult PLT progenitors, *megakaryocyte* progenitors of neonates are more sensitive to TPO, have higher proliferative potential, and give rise to larger megakaryocyte colonies. Fetal/neonatal megakaryocytes are smaller in size and have lower ploidy than do their adult counterparts; this

information is important because small megakaryocytes of low ploidy produce fewer PLTs than do larger megakaryocytes of higher ploidy. Presumably, this allows the expanding marrow of the growing fetus and neonate to be supplied with sufficient numbers of megakaryocytes, yet not allowing blood PLT counts to become excessively high during proliferation because of the lower numbers of PLTs produced by each megakaryocyte.

An important contrasting point is that older children and adults respond to situations of increased demand for PLTs by first increasing megakaryocyte size and ploidy, which is followed in 3–5 days by increased megakaryocyte number. In thrombocytopenic neonates, megakaryocyte numbers but not size increase. Moreover, although cytoplasmic maturation is achieved per TPO stimulation, increases in ploidy are relatively diminished and actually appear to be inhibited by TPO, resulting in large numbers of small megakaryocytes that are cytoplasmically mature but with low ploidy and, consequently, lower PLT production.

PLT counts ≥150 × 10^9/L are present after 17 weeks' gestational age, and it is accepted that neonates have PLT counts in the same range as older children and adults (150,000–450,000/μL). However, other data suggest a lower limit of 120,000/μL for extremely small preterm infants. Approximately 1% of term infants demonstrate PLT counts <150 × 10^9/L, but bleeding in such infants is rare. In contrast, 18–35% of preterm neonates treated in intensive care units (ICUs) exhibit PLT counts <150 × 10^9/L at some time during admission, with approximately 4% overall receiving PLT transfusions. Notably, when only extremely low birthweight preterm infants (<1 kg) were considered in one report, 70% had PLT counts <150 × 10^9/L, and 5–9% of infants received platelet transfusions.

Debate continues in the United States as to the appropriate prophylactic platelet transfusion threshold for neonates, with a wide range in practice patterns. Multiple pathogenetic mechanisms underlie thrombocytopenia in these sick neonates, including predominantly accelerated PLT destruction plus diminished PLT production, as evidenced by decreased numbers of megakaryocyte progenitors and relatively low upregulation of TPO levels during thrombocytopenia, when compared with thrombocytopenic children and adults.

PLT counts <100 × 10^9/L pose significant clinical risks for premature neonates. Bleeding time may be prolonged at PLT counts <100 × 10^9/L in infants with birthweight <1,500 g, and PLT dysfunction is suggested by bleeding times (a test no longer performed) that are disproportionately long for the degree of thrombocytopenia. The risk of hemorrhage may be increased in thrombocytopenic infants. However, in a randomized trial, transfusing PLTs prophylactically whenever the PLT count fell to <150 × 10^9/L (i.e., at the lower limit of normal range) to maintain the average PLT count at >200 × 10^9/L, compared to not transfusing PLTs until the PLT count fell to <50 × 10^9/L to maintain the average PLT count at approximately 100 × 10^9/L, *did not result* in a lower incidence of intracranial hemorrhage (28% vs 26%, respectively). A U.S. multicenter observational study of very low birthweight infants in six neonatal ICUs found wide variation in PLT thresholds for transfusion, ranging from 10,000 to 139,000/μL in the first week of life and <10,000/μL to >50,000/μL after the first week. The most common thresholds were 80,000–89,000/μL in the first 7 days of life and 40,000–49,000/μL after the first 7 days. Furthermore, after controlling for severity of thrombocytopenia, the authors found PLT transfusions were not associated with a lower risk of intraventricular hemorrhage. Thus, there is no documented benefit for prophylactic PLT transfusions to maintain PLT counts within the normal range or to correct moderate thrombocytopenia (PLT count >50 × 10^9/L). As an exception, infants with inherited PLT dysfunction disorders *and* bleeding, as well as infants at high risk of bleeding because of acquired PLT dysfunction, such as during ECMO, typically receive transfusions to keep their PLT counts >100 × 10^9/L.

One randomized clinical trial reported a significantly higher rate of new major hemorrhage or death within 28 days of randomization in very low birthweight neonates given prophylactic PLT transfusions at a pretransfusion PLT count of 50,000/μL (26%) vs a pretransfusion PLT count of 25,000/μL (19%), irrespective of their baseline risk of bleeding. Results are too preliminary to permit changes in practice but support other published findings indicating no need to maintain normal PLT counts and add to the belief that a PLT count of 50,000/μL is too high to serve as the pretransfusion PLT count for transfusions in stable low birthweight neonates.

Table 520.1 lists pediatric PLT transfusion guidelines that are acceptable to many neonatologists. One particularly contentious issue is how to manage critically ill neonates receiving agents known to adversely affect PLT function (e.g., indomethacin, nitric oxide, antibiotics). Some reports suggest increased risk of bleeding for these neonates, but the efficacy of PLT transfusions has not been convincingly proven, particularly when given prophylactically. For optimal PLT transfusion practices, each hospital should modify their guidelines to comply with local practices, with audits and reviews done to avoid violations of the recommended practices.

PLATELET PRODUCTS AND DOSING

In the United States, two types/sources of PLT units are available, although any one blood bank or hospital may stock only one of these types. Whole blood–derived PLT units **(PLT concentrates)** and PLT units collected by apheresis **(apheresis PLTs)** differ in their PLT content and plasma volume. Although a PLT concentrate contains approximately 5.5-10 × 10^{10} PLTs in approximately 50 mL, and 1 apheresis PLT unit contains at least 3 × 10^{11} PLTs in 300–600 mL, the PLT content may vary considerably among different blood suppliers. Accordingly, it is prudent for hospital blood banks to confirm the composition of the PLT units they issue for transfusion, at the very least by contacting their blood supplier. It is often easier to use PLT concentrates for infants and small children because apheresis PLTs usually need to be prepared as *aliquots* to provide the correct dose (10–15 mL/kg). However, many blood centers exclusively provide only one type of PLT component. Platelet products generally have a 5-day expiration time, although 7-day storage has been approved for apheresis platelet units within certain stipulations to reduce the risk of bacterial contamination and are stored at room temperature with constant agitation.

The posttransfusion goal of most PLT transfusions is to raise the PLT count well above 50 × 10^9/L, hopefully to ≥100 × 10^9/L. These increases can be achieved consistently in children weighing up to 30 kg by infusion of 5–10 mL/kg of standard (unmodified) PLT concentrates, obtained either from PLT concentrates or apheresis PLTs. For larger children, the appropriate dose is 4-8 pooled PLT concentrates or 1 apheresis unit. Because PLT concentration/quantity varies in different PLT products made available for transfusion, each hospital should monitor posttransfusion PLT counts to determine the dose that works best locally. PLT concentrates may be transfused as rapidly as the patient's overall condition permits, certainly within 2 hours, but not longer than 4 hours. Neonates/infants requiring repeated PLT transfusions should receive leukocyte-reduced blood products to diminish HLA alloimmunization and PLT refractoriness and to reduce the risk of transfusion-transmission cytomegalovirus infection (TT-CMV). For those infants weighing <1,500 g at birth, *irradiation* is recommended to prevent transfusion associated GVHD. Additionally, some recommend both leukoreduction and CMV-seronegative RBC units (estimated risk of TT-CMV infection: 0–0.3% per unit) as first-line therapy to prevent TT-CMV. However, given the low risks of TT-CMV with improvements in modern leukoreduction techniques, others have recommended use of leukoreduced blood from CMV-untested donors as an acceptably safe and low-risk alternative. PLT transfusion should not be delayed if CMV-negative units are unavailable; CMV-untested leukoreduced units should be used because the risk of TT-CMV is relatively low and more harm may come to the patient if transfusion is withheld or delayed.

Routinely reducing the volume of PLT concentrates for infants and small children by additional centrifugation steps is both unnecessary and unwise. Transfusion of 10–15 mL/kg of an unmodified PLT concentrate is adequate because it adds approximately 10 × 10^9 PLTs to 70 mL of blood (estimated intravascular blood volume of 1 kg neonate), a dose/volume calculated to increase the PLT count by 100 × 10^9/L. This calculated increment is consistent with actual posttransfusion increment reported in patients. Moreover, 10–15 mL/kg is not an excessive transfusion volume, provided that the intake of other IV fluids, medications, and nutrients is monitored and adjusted.

It is important to select PLT units for transfusion with the donor ABO group identical to that of the neonate/infant and to avoid repeated transfusion of group O PLTs to group A or B recipients, because passive transfusion anti-A or anti-B in group O plasma can occasionally lead to intravascular hemolysis.

Chapter 521

Neutrophil (Granulocyte) Transfusions

Patricia E. Zerra and Cassandra D. Josephson

Table 521.1 lists guidelines for granulocyte transfusion (GTX). GTX has been used sparingly in older infants and children. The current ability to collect markedly higher numbers of neutrophils from donors stimulated with combined recombinant granulocyte colony-stimulating factor (G-CSF) plus dexamethasone has led to renewed interest for patients with neutropenic infections, particularly when severe neutropenia is prolonged (e.g., in the setting of placental/cord blood hematopoietic progenitor cell transplantation). As a result, higher neutrophil yields are collected with this approach, making the addition of GTX to antibiotics a therapeutic consideration. This is especially true at institutions where neutropenic patients continue to die of progressive bacterial and fungal infections or to suffer substantial morbidity despite optimal antiinfection measures, including antibiotics and recombinant myeloid growth factors.

GRANULOCYTE TRANSFUSIONS FOR CHILDREN

The use of GTX added to antibiotics for children with **severe neutropenia** (neutrophil count $<0.5 \times 10^9$/L) because of bone marrow failure is similar to that for adults. Unfortunately, two randomized clinical trials comparing antibiotics plus GTX from donors stimulated with G-CSF plus dexamethasone vs antibiotics without GTX to treat neutropenic infections in children have not provided definitive guidelines. However, in practice, neutropenic patients with bacterial infections usually show response to antibiotics alone, provided bone marrow function recovers within the first 7–10 days of infection onset, so that severe neutropenia is relatively brief. Children with newly diagnosed acute lymphoblastic leukemia show rapid response to induction chemotherapy and are rarely candidates for GTX. In contrast, infected children with more sustained bone marrow failure and consequent severe neutropenia (e.g., acute myeloblastic leukemia, malignant neoplasms resistant to treatment, severe aplastic anemia, placental/cord blood hematopoietic progenitor cell transplant recipients) may benefit when GTX is added to antibiotics.

Currently, the efficacy of GTX obtained from G-CSF plus dexamethasone–stimulated donors for bacterial sepsis unresponsive to antibiotics in patients with severe neutropenia (neutrophil count $<0.5 \times 10^9$/L) *is not well supported* by trials in children. Furthermore, GTX efficacy for yeast and fungal infections remains unproven, despite transfusing GTX with relatively large numbers of neutrophils.

Children with **qualitative neutrophil defects (neutrophil dysfunction)** usually have adequate or even increased numbers of blood neutrophils but develop serious infections because their neutrophils kill pathogenic microorganisms inefficiently. Neutrophil dysfunction syndromes are rare; accordingly, no definitive studies have established GTX efficacy. However, several patients with progressive life-threatening infections have shown striking improvement with the addition of GTX, often given for long periods, to antimicrobial therapy. These disorders are chronic and thus associated with an increased risk of alloimmunization to leukocyte antigens, specifically to Kell system antigens on the red blood cells in some patients with chronic granulomatous disease, and GTX is recommended only when serious infections are clearly unresponsive to antimicrobial drugs.

Table 521.1 Guidelines for Pediatric Granulocyte Transfusions*

CHILDREN AND ADOLESCENTS
1. Severe neutropenia (blood neutrophil count $<0.5 \times 10^9$/L) and infection (bacterial, yeast, or fungal) *unresponsive or progressive* despite appropriate antimicrobial therapy.
2. Qualitative neutrophil defect, neutropenia not required, and infection (bacterial or fungal) *unresponsive or progressive* to appropriate antimicrobial therapy.
INFANTS ≤4 MO OLD†
Blood neutrophil count $<3.0 \times 10^9$/L in first week of life or $<1.0 \times 10^9$/L thereafter and *fulminant* bacterial infection.

*Words in *italics* must be defined for local transfusion guidelines.
†No longer commonly used.

GRANULOCYTE TRANSFUSION FOR NEONATES

Neonates are unusually susceptible to severe bacterial infections, and a number of defects of neonatal defenses contribute to this susceptibility, including actual or "relative" neutropenia. Neonates with fulminant sepsis who exhibit *relative neutropenia* (blood neutrophil count $<3.0 \times 10^9$/L during the first week of life and $<1.0 \times 10^9$/L thereafter) and a severely diminished neutrophil marrow storage pool (with <10% of nucleated marrow cells being postmitotic neutrophils) are at risk of dying if treated only with antibiotics. Despite this risk, GTX has not provided the solution. GTX is rarely used in neonates because the results of clinical trials are mixed and not uniformly convincing, and it is difficult to obtain neutrophil apheresis concentrates in a timely fashion.

Current data are insufficient to conclude that recombinant myeloid growth factors have a role in treating septic neonates, despite demonstration that both G-CSF and granulocyte-macrophage CSF enhance myelopoiesis and raise neutrophil counts in infants. In contrast to the uncertain role of G-CSF and GM-CSF to treat infections in many clinical settings, it is important to remember that G-CSF is efficacious for the long-term treatment of several types of severe **congenital neutropenias**.

GRANULOCYTE PRODUCT

If the decision to provide a GTX has been made, an adequate dose of neutrophils/granulocytes collected by leukapheresis must be transfused as shortly after collection as possible. To facilitate this goal, experienced donors with recently performed negative testing for HIV and hepatitis (usually within the past 30 days) are selected. Granulocyte donors should be documented to be cytomegalovirus antibody negative (seronegative). These donors should also be ABO/Rh crossmatch compatible with the recipient because there is a large volume of red blood cells in the granulocyte product.

Granulocyte Product Dosing

Neonates and **infants** weighing <10 kg should receive $1\text{-}2 \times 10^9$/kg neutrophils per each GTX. **Larger infants** and **small children** should receive a minimal total dose of 1×10^{10} neutrophils per each GTX. The preferred dose for **adolescents** is $5\text{-}8 \times 10^{10}$ neutrophils per each GTX, a dose requiring donors to be stimulated with G-CSF plus dexamethasone. GTX should be given daily until either the infection resolves or the blood neutrophil count is sustained above 1.5×10^9/L for a few days. Because neutrophils transfused through the GTX often passively increase the blood neutrophil count, it may be necessary to skip 1-2 days of GTXs to accurately assess whether endogenous myelopoiesis and neutrophil production have recovered.

Chapter 522

Plasma Transfusions

Patricia E. Zerra and Cassandra D. Josephson

Guidelines for plasma transfusion in pediatric patients are similar to those for adults but with the understanding that plasma levels of coagulant and anticoagulant proteins can be developmentally low in preterm infants (Table 522.1). Therefore transfusions of plasma and plasma-derived commercial concentrates should be determined by actual bleeding or a significant risk of bleeding, not simply by prolonged clotting time results. Plasma is transfused to replace clinically significant congenital or acquired deficiencies of plasma proteins for which more highly purified protein concentrates, treated to reduce infectious disease risks, or recombinant products are not available. Plasma and plasma derivatives are required to provide clotting proteins when bleeding is actually occurring or in settings when prevention of bleeding is deemed critical.

PLASMA PRODUCTS AND PATIENT TESTING

Two interchangeable plasma products are available for transfusion, plasma frozen within 8 hours of collection **(fresh-frozen plasma [FFP])** and plasma frozen within 24 hours of collection **(F24)**. Although levels of factors V and VIII are modestly reduced in F24 (generally, not more than 25% lower), they are equally efficacious for all indications for which plasma is transfused in infants and children (see Table 522.1). Recommendations for the volume of plasma to be transfused vary with the specific protein being replaced and the severity of the deficiency, but a starting dose of 15 mL/kg is usually sufficient to elevate plasma levels satisfactorily.

Transfusion of plasma is efficacious for the treatment of deficiencies of clotting factors II, V, X, and XI. Deficiencies of factor XIII and fibrinogen are treated either with cryoprecipitate or specific commercial concentrates; for patients being given large doses of plasma (e.g., in massive transfusion settings or to treat bleeding in liver failure), however, additional sources of fibrinogen may not be necessary because plasma contains large amounts of fibrinogen. It is always useful to include a measurement of plasma fibrinogen (a separate test) when performing clotting assays, including prothrombin time (PT)/international normalized ratio (INR) and activated partial thromboplastin time (aPTT).

PLASMA TRANSFUSION IN CHILDREN

Transfusion of plasma is not recommended for the treatment of patients with severe hemophilia A or B, von Willebrand disease, or factor VII deficiency because safer plasma-derived and recombinant factor products for VII, VIII, IX, and von Willebrand factor are available. Moreover, mild to moderate hemophilia A and certain types of von Willebrand disease can be treated with intranasal or intravenous desmopressin (see Chapter 526). An important use of plasma is for rapid reversal of the effects of warfarin in patients who are actively bleeding or who require emergency surgery (in whom functional deficiencies of vitamin K–dependent factors II, VII, IX, and X cannot be rapidly reversed by vitamin K administration). Plasma-derived and virally inactivated prothrombin "complex" concentrates can also be used for this purpose.

Results of screening coagulation tests (PT/INR, aPTT, thrombin time, and plasma fibrinogen level) should not be assumed to reflect the integrity of the coagulation system or be regarded as indications for plasma transfusions. This is particularly true for neonates. To justify plasma transfusions, coagulation test results must be related to the patient's clinical condition in regard to bleeding and the risk of bleeding. Transfusion of plasma in patients with chronic liver disease and prolonged clotting times is not recommended unless bleeding is present, or an invasive procedure is planned because prophylactic correction of the clotting factor deficiencies is brief and of questionable benefit.

Plasma also contains several anticoagulant proteins (antithrombin III, protein C, and protein S) whose deficiencies have been associated with thrombosis. In select situations, plasma as replacement therapy along with anticoagulant treatment may be appropriate in patients with these disorders; when available, purified concentrates are preferred. Other indications for plasma include replacement fluid during plasma exchange in patients with **thrombotic thrombocytopenic purpura** (i.e., thrombotic microangiopathies) or other disorders for which plasma is likely to be beneficial. This includes plasma exchange in a patient with overt bleeding caused by the underlying disorder (e.g., Goodpasture syndrome, vasculitis) or disorders with significant severe coagulopathy that would substantially worsen with replacement by albumin solutions only. *Plasma is not indicated for correction of hypovolemia or as immunoglobulin replacement therapy because safer alternatives exist (albumin or crystalloid solutions and IV immunoglobulin, respectively).*

PLASMA TRANSFUSION IN NEONATES

In neonates, clotting times are "physiologically" prolonged because of developmental deficiency of clotting proteins; plasma should be transfused only after reference to normal values is adjusted for the birthweight and age of the infant (*not* to normal ranges for older children and adults). The indications for plasma in neonates include (1) reconstitution of red blood cell (RBC) concentrates to simulate whole blood for use in massive transfusions (exchange transfusion, cardiac bypass surgery, and extracorporeal membrane oxygenation), (2) hemorrhage secondary to vitamin K deficiency, (3) disseminated intravascular coagulation *with* bleeding, and (4) bleeding in congenital coagulation factor deficiency when more specific treatment is either unavailable or inappropriate. The use of prophylactic plasma transfusion to prevent intraventricular hemorrhage in premature infants is not recommended. Plasma should not be used as a suspending agent to adjust the hematocrit values of RBC concentrates before small-volume RBC transfusions to neonates because it offers no apparent medical benefit over the use of sterile solutions such as crystalloid and albumin. Similarly, the use of plasma in partial exchange transfusion for the treatment of neonatal hyperviscosity syndrome is unnecessary because safer crystalloid or colloid solutions are available.

In the treatment of bleeding infants, *cryoprecipitate* is often considered because of its small infusion volume. However, cryoprecipitate contains significant quantities of only fibrinogen, von Willebrand factor, and factors VIII and XIII. Thus it is not effective for treating the usual clinical situation in bleeding infants with multiple clotting factor deficiencies. However, cryoprecipitate is an excellent source of fibrinogen (much more concentrated than frozen plasma), and with a dose of 1–2 units/kg, the patient's fibrinogen level can be quickly raised by 60–100 mg/dL.

In preliminary studies, infusions of very small volumes of recombinant activated factor VII have been lifesaving in patients with hemorrhage caused by several mechanisms. Because the efficacy and toxicity of factor VIIa have not been fully defined in these "off-label" uses (not approved by the U.S. Food and Drug Administration), it must be considered "experimental" therapy at this time.

Table 522.1 Guidelines for Children and Infants for Plasma Transfusions*

1. *Severe* clotting factor deficiency AND bleeding.
2. *Severe* clotting factor deficiency AND an invasive procedure.
3. *Emergency reversal* of warfarin effects.
4. Dilutional coagulopathy and bleeding (e.g., massive transfusion).
5. Anticoagulant protein (antithrombin III, proteins C and S) replacement.
6. Plasma exchange replacement fluid for thrombotic thrombocytopenic purpura or for disorders with overt bleeding or in which there is risk of bleeding because of clotting protein abnormalities (e.g., liver failure).

*Words in *italics* must be defined for local transfusion guidelines.

Chapter 523

Risks of Blood Transfusions

Patricia E. Zerra and Cassandra D. Josephson

The greatest risk of a blood transfusion is mistakenly receiving a transfusion intended for another patient. *Misidentification* is usually a result of mistakes made in labeling the patient's blood sample sent to the blood bank or not accurately matching the unit with the patient at the bedside when the blood is transfused. This risk is particularly high for infants, especially if ABO type-specific or type-compatible blood is transfused, because (1) identification bands may not be attached directly to their bodies, (2) difficulties in drawing blood samples for pretransfusion compatibility testing may lead to deviations from usual policies, and (3) infants cannot speak to identify themselves. Thus particular care must be taken to ensure accurate patient and blood sample identification.

INFECTIOUS RISKS OF TRANSFUSION

Although the infectious disease risks of allogeneic blood transfusions are extremely low, transfusions must be given judiciously because "emerging infections," such as Ebola or Zika virus, when they first arise, pose a potential threat until they are studied definitively and, accordingly, are of constant concern, and testing is not done for every microorganism possibly transmitted by blood transfusions (Table 523.1 and Fig. 523.1). Taking nucleic acid amplification testing (NAT) and all other donor-screening activities (antibody and epidemiology screening) into account, a current estimate of the risk of transfusion-associated **HIV** infection is approximately 1 per every 2 million donor exposures. Similarly, with NAT, the risk of hepatitis C virus **(HCV)** infection is 1 per every 1.5-2 million donor exposures (see Table 523.1). NAT identifies circulating microbial nucleic acids that appear in the window before antibodies develop, and NAT is used routinely to detect HIV, HCV, West Nile virus, hepatitis B virus, *Trypanosoma cruzi, Babesia microti,* and Zika virus.

Transfusion-associated cytomegalovirus **(CMV)** has been nearly eliminated by transfusion of leukocyte-reduced cellular blood products or by selection of blood collected from donors who are seronegative for antibody to CMV. Although it is logical to hypothesize that first collecting blood components from CMV-seronegative donors and then removing the white blood cells (WBCs) might further improve safety, little data are available to document the superior efficacy of this combined approach. However, in a recent prospective birth cohort study of premature infants with birthweight ≤1,500 g, a combined approach of leukoreduction and CMV-seronegative cellular blood components yielded 0% transfusion transmission of CMV (15.3% cumulative incidence at 12 weeks of maternal breast milk transmission from CMV-seropositive mothers) in >300 transfused infants studied. Similar uncontrolled reports of hematopoietic stem cell transplant patients found 0% transmission of CMV from leukoreduced blood products from donors of unknown CMV antibody status. Therefore considerable care must be taken not to place children at risk of delayed or missed transfusions while awaiting/searching for blood from CMV-seronegative donors, then to leukoreduce (i.e., risks must not be taken for practices with no established benefits).

Further data on these two mitigation strategies revealed that large quantities of CMV viral material are present "free" in the plasma of healthy-appearing donors during the early phase of primary infection (while CMV antibodies are either absent ["window" phase] or are newly emerging and at low, inconsistently detected levels in plasma), rather than being leukocyte associated, as occurs with CMV as substantial quantities of IgG antibodies appear. As a result of this biology of CMV primary infection, plasma "free" virus will not be removed by leukoreduction during early infection, and CMV-seronegative donors who may be asymptomatic or deny symptoms of infection during blood donor screening will be misclassified as being CMV safe. They are not necessarily as safe because antibody is below the limits of detection, while plasma "free" CMV is plentiful during early infection. Because almost all plasma "free" CMV disappears and becomes almost exclusively cell associated, once donors are CMV seropositive with antibody present for several months, some propose that the best method to reduce CMV risk may be leukoreduction of blood from donors known to be CMV seropositive for at least 1 year. However, data to prove the efficacy of this proposal are lacking, and in practice, several studies have shown that the most efficacious method currently available to prevent transfusion-transmitted CMV is to perform leukoreduction in the

Table 523.1 Estimated Risks in Transfusion per Unit Transfused in the United States

ADVERSE EFFECT (INFECTIOUS)	ESTIMATED RISK
Human immunodeficiency virus (HIV)-1 and HIV-2	1:2 million
Hepatitis B	1:2 million
Hepatitis C	1:2 million
Human T-cell lymphotropic virus (HTLV) I and II	1:3 million
Bacterial contamination (usually platelets)	1:100,000
Malaria	<1:3 million
Hepatitis A	Unknown
Parvovirus	Unknown
Dengue fever	Unknown
Cytomegalovirus	<1:3 million
Babesiosis	Unknown
West Nile virus	<1:3 million
Trypanosoma cruzi	<1:3 million
Leishmania spp.	Unknown
Variant Creutzfeldt-Jakob prion disease	Unknown
Zika virus	<1:3 million
Syphilis	Unknown
ADVERSE EFFECT (NONINFECTIOUS)	**ESTIMATED RISK**
Febrile nonhemolytic reaction	1:800
Mild-moderate allergic reaction	1:1,000
Severe allergic reactions	1:40,000
Transfusion-associated circulatory overload (TACO)	1:8,500
Hypotensive	1:11,000
Acute hemolytic transfusion reaction	1:95,000
Transfusion-associated dyspnea	1:15,000
Transfusion-related acute lung injury (TRALI)	1:70,000
Delayed hemolytic transfusion reaction	1:20,000
Transfusion-associated graft-versus-host disease	Uncommon
Immunomodulation	Unknown
Posttransfusion purpura	1:30,000
Life-threatening reactions, requiring major medical intervention	1:20,000

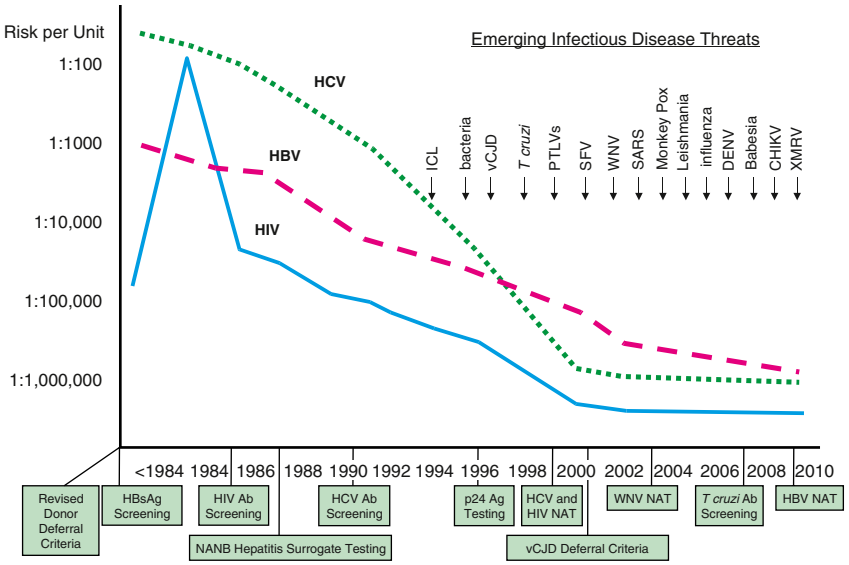

Fig. 523.1 Risks of major transfusion-transmitted viruses related to interventions and accelerating rate of emerging infectious diseases of concern to blood safety. Evolution of the risks of transmission by blood transfusion for human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV). Major interventions to reduce risks are shown below the timeline on the *x* axis. Emerging infectious disease threats in the past 20 years are shown above in the *top right quadrant* of the figure. Ab, Antibody; Ag, antigen; CHIKV, chikungunya virus; DENV, dengue virus; HBsAg, hepatitis B surface antigen; ICL, idiopathic CD4 T-lymphocytopenia; NANB, non-A, non-B hepatitis; NAT, nucleic acid amplification testing; PTLVs, primate T-lymphotropic viruses; SARS, severe acute respiratory syndrome; SFV, simian foamy virus; vCJD, variant Creutzfeldt-Jakob disease; WNV, West Nile virus; XMRV, xenotropic murine leukemia virus–related virus. *(From Busch MP. Transfusion-transmitted viral infections: Building bridges to transfusion medicine to reduce risks and understand epidemiology and pathogenesis. 2005 Emily Cooley Award Lecture. Transfusion. 2006;46:1624–1640.)*

blood center/bank without regard for the CMV antibody status of the donor/unit (i.e., leukoreduction alone performed by the blood center/bank, not at the bedside, is sufficient in most cases).

Additional infectious risks include other types of **hepatitis** (A, B, E) and **retroviruses** (human T-cell lymphotropic virus types I and II, HIV-2), syphilis, parvovirus B19, Epstein-Barr virus, human herpesvirus 8, West Nile virus, yellow fever vaccine virus, malaria, babesiosis, *Anaplasma phagocytophilum*, Chagas disease, and Zika virus. Variant Creutzfeldt-Jacob disease has also been transmitted by blood transfusions in humans. All are reported very infrequently, but nonetheless provide the rationale to transfuse only when true benefits are likely.

NONINFECTIOUS RISKS OF TRANSFUSION

Transfusion-associated risks of a noninfectious nature that may occur include hemolytic and nonhemolytic transfusion reactions, circulatory fluid overload, **graft-versus-host disease** (GVHD), electrolyte and acid-base imbalances, iron overload if repeated red blood cell (RBC) transfusions are needed long term, increased susceptibility to oxidant damage, exposure to plasticizers, hemolysis with T-antigen activation of RBCs, posttransfusion purpura, **transfusion-related acute lung injury** (TRALI), posttransfusion immunosuppression and immunomodulation, and alloimmunization (Fig. 523.2; see Table 523.1). The risk of TRALI may be reduced by avoiding transfusion of plasma or platelets from female donors, who were possibly alloimmunized to leukocyte antigens during pregnancy or by selecting donors (e.g., males) who are likely to be negative for human leukocyte antigen (HLA) antibodies.

Immunologic adverse effects, including immunosuppression, immunomodulation, and alloimmunization, may be reduced by leukoreduction. Transfusion reactions and alloimmunization to RBC and leukocyte antigens seem to be uncommon in infants, perhaps because of developmental immaturity of the immune system or deficient cytokine production. When they do occur, adverse effects are seen primarily in massive transfusion settings, such as exchange transfusions and trauma or surgery, in which relatively large quantities of blood components are needed but are rare when small-volume transfusions are usually given.

Premature infants are known to have immune dysfunction, but their relative risk of posttransfusion GVHD is controversial. The postnatal age of the infant, the number of immunocompetent lymphocytes in the transfusion product, the degree of HLA compatibility between donor and recipient, and other, poorly described phenomena determine which infants are truly at risk for GVHD. Regardless, many centers caring for preterm infants transfuse exclusively irradiated cellular products. As an alternative, pathogen-reduction technology has been documented to prevent GVHD and can substitute for irradiation. Directed donations with blood drawn from blood relatives must always be irradiated because of the risk of engraftment with transfused HLA-homozygous, haploidentical lymphocytes. Cellular blood products given as intrauterine or exchange transfusions should be irradiated, as should transfusions for patients with severe congenital immunodeficiency disorders (severe combined immunodeficiency syndrome and DiGeorge syndrome requiring heart surgery) and transfusions for recipients of hematopoietic progenitor cell transplants. Other groups who are potentially at risk but for whom no conclusive data are available include patients given T-cell antibody therapy (antithymocyte globulin or OKT3), those with organ allografts, those receiving immunosuppressive drug regimens, and those infected with HIV.

As an alternative, pathogen-reduction technology has been documented to prevent T-cell proliferation, and thus TA-GVHD may be used as a substitute for irradiation. Current practice uses **irradiation** from a cesium, cobalt, or linear acceleration source at doses ranging from 1,500 to 2,500 centigray (cGy); a maximum dose of 2,500 cGy is required to hit the center of the irradiation field and a minimum of 1,500 cGy delivered to any other portion of the cannister. All cellular blood components should be irradiated, except those frozen without a cryoprotectant agent and to be rendered as "acellular" products, such as plasma and cryoprecipitate, which do not require irradiation. Leukocyte reduction cannot be substituted for irradiation to prevent GVHD. However, as mentioned, pathogen-reduction technologies have been demonstrated to be efficacious.

Hemorrhagic and Thrombotic Diseases

Chapter 524

Hemostasis

Brian R. Branchford, Benjamin J. Samelson-Jones, Leslie J. Raffini, and Veronica H. Flood

Hemostasis is the biological process that limits hemorrhage after blood vessel injury. An initial platelet plug (primary hemostasis) is bolstered by the product of the coagulation cascade: a factor XIII-cross-linked fibrin clot (secondary hemostasis). Extraneous fibrin is lysed by plasmin (fibrinolysis), and normal blood flow is restored through the previously damaged vessel. If hemostasis is impaired, varying degrees of bleeding may occur depending on the hemostatic defect and the site of injury. Excess coagulation activity can lead to thrombotic complications. The hemostatic response therefore needs to be rapid and locally regulated, such that trauma neither results in hemorrhage nor triggers a systemic thrombotic reaction. When a platelet adheres to a site of vascular injury, the activated platelet surface provides a phospholipid reaction surface where clotting factors bind and create a "thrombin burst." Active clotting is controlled by negative feedback loops that inhibit the clotting process when procoagulant products come in contact with intact endothelium. The main components of the hemostatic process are the **vessel wall, platelets, coagulation factors, anticoagulant proteins,** and **fibrinolytic system.** Many components of the hemostasis system are multifunctional. Fibrinogen serves as the ligand between platelets during platelet aggregation and as the substrate for thrombin to produce fibrin. Platelets provide the reaction surface on which clotting reactions occur, form the plug at the site of vessel injury, release procoagulant compounds from their granules, and contract to constrict and limit clot size.

THE HEMOSTATIC PROCESS

The intact vascular endothelium is the primary barrier against hemorrhage and thrombosis. The endothelial cells that line the vessel wall normally inhibit coagulation and provide a smooth surface that permits rapid blood flow.

After vascular injury, vasoconstriction occurs, and flowing blood comes in contact with the subendothelial matrix. **Von Willebrand factor (VWF)** tethers platelets to the site of injury by binding subendothelial matrix components such as collagen and platelets, via the glycoprotein Ib complex on platelet membranes. Platelet binding of VWF initiates complex cellular signaling, activating the platelets and triggering secretion of storage granules containing adenosine diphosphate (ADP), serotonin, and stored plasma and platelet membrane proteins. On activation, the platelet receptor for fibrinogen, $\alpha IIb\beta_3$, is switched on ("inside out" signaling) to bind fibrinogen and triggers the aggregation and recruitment of other platelets to form the platelet plug. Multiple physiologic agonists can trigger platelet activation and aggregation, including ADP, collagen, thrombin, and arachidonic acid. Aggregation involves the interaction of specific receptors on the platelet surface with plasma hemostatic proteins, primarily fibrinogen.

One of the subendothelial matrix proteins that is exposed after vascular injury is *tissue factor*. Exposed tissue factor binds to factor VII and activates the *clotting cascade* (Fig. 524.1). The activated clotting factor then initiates the activation of the next sequential clotting factor in a systematic manner. During the process of platelet activation, internalized platelet phospholipids (primarily phosphatidylserine) become externalized supporting membrane binding of the principal enzyme complexes of coagulation: the extrinsic and intrinsic Xase complexes and the prothrombinase complex. These complexes are localized to the platelet surface and bring together the active proteolytic enzyme, an activated cofactor, and the zymogen substrate that will form the next active enzyme in the cascade. This sequence of the coagulation cascade serves as a biochemical amplifier where a small amount of activated proteolytic enzyme can rapidly produce a large amount of downstream components, in a temporally and spatially controlled manner. In vivo, small amounts of activated factor VII (VIIa) are present, so the system is always poised to act. Near the bottom of the cascade, the multipotent enzyme *thrombin* is formed. Thrombin converts fibrinogen into fibrin, activates factors V, VIII, and XI, and aggregates platelets. Activation of factor XI by thrombin amplifies further thrombin generation and contributes to inhibition of fibrinolysis. Thrombin also activates factor XIII. The stable fibrin-platelet plug is ultimately formed through clot retraction and cross linking of the fibrin clot by factor XIIIa.

Virtually all procoagulant proteins are balanced by anticoagulant proteins that regulate or inhibit procoagulant function. Four clinically important, naturally occurring anticoagulants regulate the extension of the clotting process: antithrombin **(AT)**, protein C, protein S, and tissue factor pathway inhibitor **(TFPI)**. AT is a serine protease inhibitor (SERPIN) that regulates primarily factor Xa and thrombin and to a lesser extent, factors IXa, XIa, and XIIa. When thrombin encounters intact endothelium, thrombin binds to *thrombomodulin,* its endothelial receptor. The thrombin-thrombomodulin complex then converts **protein C** into activated protein C. In the presence of the cofactor **protein S**, activated protein C proteolyzes and inactivates factor Va and factor VIIIa. Inactivated factor Va is also a functional anticoagulant that inhibits clotting. TFPI limits activation of factor X by factor VIIa and tissue factor and shifts the activation site of tissue factor and factor VIIa to that of factor IX (Fig. 524.2).

Once a stable fibrin-platelet plug is formed, the fibrinolytic system limits its extension and proteolyzes the clot **(fibrinolysis)** to reestablish vascular integrity. Plasmin, generated from plasminogen by either urokinase-like or tissue-type plasminogen activator, degrades the fibrin clot. In the process of dissolving the fibrin clot, fibrin degradation products are produced. The fibrinolytic pathway is regulated by plasminogen activator inhibitors and α_2-antiplasmin, as well as by the thrombin-activatable fibrinolysis inhibitor (TAFI).

PATHOLOGY

Congenital deficiency of an individual procoagulant protein leads to a bleeding disorder, whereas deficiency of an anticoagulant (clotting factor inhibitor) predisposes the patient to thrombosis. In acquired hemostatic disorders, there are frequently multiple problems with homeostasis that perturb and dysregulate hemostasis. A primary illness (sepsis) and its secondary effects (shock and acidosis) activate coagulation and fibrinolysis and impair the host's ability to restore normal hemostatic function. When sepsis triggers **disseminated intravascular coagulation,** platelets, procoagulant clotting factors, and anticoagulant proteins are consumed, leaving the hemostatic system unbalanced and prone to bleeding or clotting (see Chapter 532). Similarly, newborn infants and patients with severe liver disease have synthetic deficiencies of both procoagulant and anticoagulant proteins. Such dysregulation causes the patient to be predisposed to both hemorrhage and thrombosis with mild or moderate triggers that result in major alterations in the hemostatic process.

In the laboratory evaluation of hemostasis, parameters are manipulated to allow assessment of isolated aspects of hemostasis and limit the multifunctionality of some of its components. The coagulation process is studied in plasma anticoagulated with citrate to bind calcium, with added phospholipid to mimic the reaction surface normally provided by the platelet membrane and with a stimulus to trigger clotting. Calcium is added to restart the clotting process. This process does not necessarily reflect the in vivo pathways of clot formation.

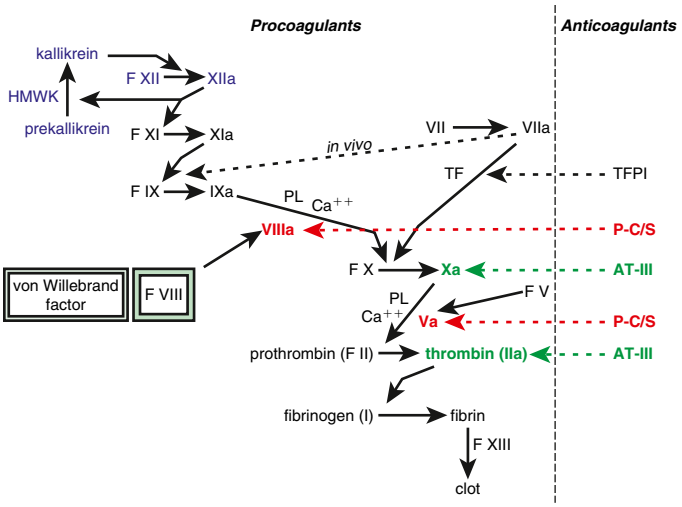

Fig. 524.1 The clotting cascade, with sequential activation and amplification of clot formation. Many of the factors (F) are activated by the clotting factors shown above them in the cascade. The activated factors are designated by the addition of an *a*. On the *right side*, the major anticoagulants and the sites that they regulate are shown. Tissue factor pathway inhibitor (TFPI) regulates tissue factor (TF); factor VIIa, protein C, and protein S (P-C/S) regulate factors VIII and V; and antithrombin III (AT-III) regulates factor Xa and thrombin (factor IIa). The *dotted line* shows that, in vivo, TF and factor VIIa activate both factors IX and X, but that, in vitro, only the activation of factor X is measured. Unactivated factor VIII, when bound to its carrier protein, von Willebrand factor (VWF), is protected from protein C inactivation. When thrombin, or factor Xa activates factor VIII, it becomes unbound from VWF, at which point it can participate with factor IXa in the activation of factor X in the presence of phospholipid (PL) and Ca^{++} (the "tenase" complex). Factor XIIIa cross-links the fibrin clot and thereby makes it more stable. Prekallikrein, high-molecular-weight kininogen (HMWK), and factor XII are shown in *purple* because they do not have a physiologic role in coagulation, although they contribute to the clotting time in partial thromboplastin time (PTT).

524.1 Clinical and Laboratory Evaluation of Hemostasis

Brian R. Branchford, Benjamin J. Samelson-Jones, Leslie J. Raffini, and Veronica H. Flood

CLINICAL HISTORY

For most hemostatic disorders, the clinical history provides the most useful information. To evaluate for a bleeding disorder, the history should determine the sites of bleeding, the severity and duration of hemorrhage, and the age at onset. Was the bleeding spontaneous, or did it occur after trauma? Was there a previous personal or family history of similar problems? Did the symptoms correlate with the degree of injury or trauma? Does bruising occur spontaneously? Are there lumps with bruises for which there is minimal trauma? If the patient had previous surgery or significant dental procedures, was there any increased bleeding? If a child or adolescent has had surgery that affects the mucosal surfaces, such as a tonsillectomy or major dental extractions, the absence of bleeding usually rules out a hereditary bleeding disorder. Delayed or slow healing of superficial injuries may suggest a hereditary bleeding disorder. In postpubertal females, it is important to take a careful menstrual history. Because some common bleeding disorders, such as **von Willebrand disease (VWD)**, have a fairly high prevalence, mothers and family members may have the same mild bleeding disorder and may not be cognizant that the child's menstrual history is abnormal. Females with mild VWD who have a moderate history of bruising frequently have a reduction in symptoms during pregnancy or after administration of oral contraceptives. Some medications, such as aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs), inhibit platelet function and increase bleeding symptoms in patients with a low platelet count or abnormal hemostasis. Standardized bleeding scores have been developed but have not been widely adopted in pediatrics.

Outside the neonatal period, thrombotic disorders are relatively rare until adulthood. In the neonate, physiologic deficiencies of procoagulants and anticoagulants place the hemostatic mechanism at greater risk for imbalance, and clinical events can lead to either hemorrhage or thrombosis. If a child or teenager presents with deep vein thrombosis

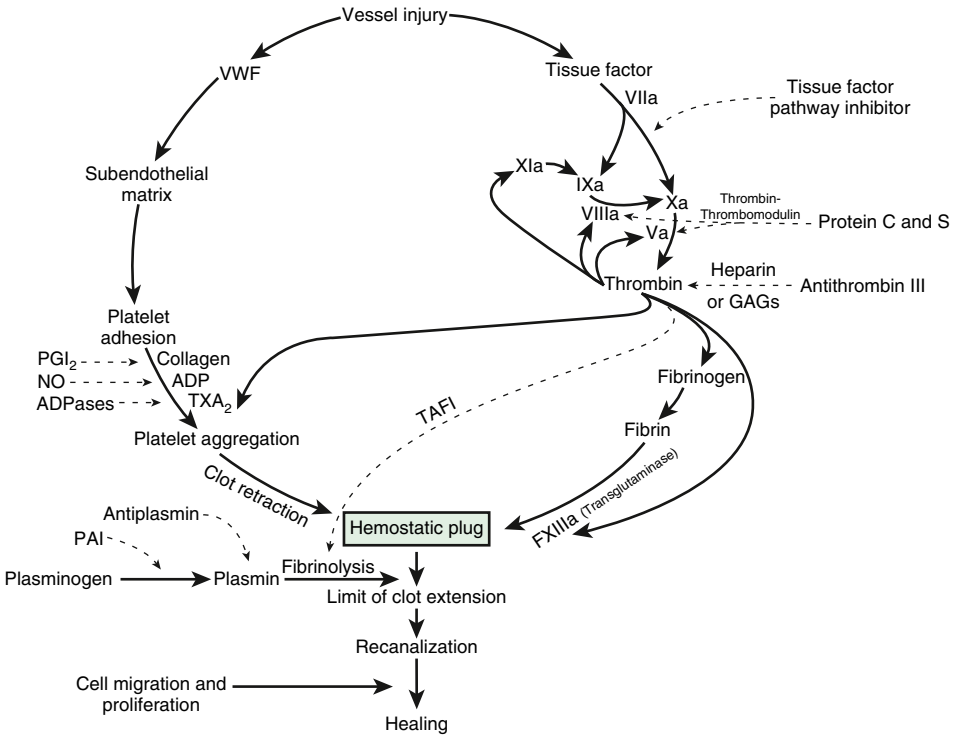

Fig. 524.2 The hemostatic mechanism. ADP, Adenosine diphosphate; GAGs, glycosaminoglycans; NO, nitric oxide; PGI_2, prostacyclin (prostaglandin I_2); PAI, plasminogen activator inhibitor; TAFI, thrombin-activated fibrinolytic inhibitor; TXA_2, thromboxane A_2; VWF, von Willebrand factor.

(DVT) or pulmonary embolism (PE), a detailed family history must be obtained to evaluate for DVT, PE, myocardial infarction (MI), or cerebrovascular accident (stroke) in other family members. The presence of **thrombosis**, especially in the absence of a provoking agent in the child or teenager, should induce the clinician to take a careful family history and consider an evaluation for a hereditary or acquired predisposition to thrombosis.

PHYSICAL EXAMINATION

The physical examination should focus on whether bleeding symptoms are associated primarily with the mucous membranes or skin (*mucocutaneous* bleeding) or with the muscles and joints (*deep* bleeding). The examination should determine the presence of petechiae, ecchymoses, hematomas, hemarthroses, or mucous membrane bleeding. Patients with defects in platelet–blood vessel wall interaction (VWD or platelet function defects) usually have mucocutaneous bleeding, which may include epistaxis, menorrhagia, petechiae, ecchymoses, occasional hematomas, and less frequently, hematuria and gastrointestinal bleeding. Individuals with a clotting deficiency of factor VIII or IX (hemophilia A or B) have symptoms of deep bleeding into muscles and joints, with much more extensive ecchymoses and hematoma formation. Patients with mild VWD or other mild bleeding disorders may have no abnormal findings on physical examination. Individuals with disorders of the collagen matrix and vessel wall may have loose joints and lax skin associated with easy bruising **(Ehlers-Danlos syndrome)**.

Patients undergoing evaluation for thrombotic disorders should be asked about swollen, warm, tender extremities (venous thrombosis), unexplained dyspnea or persistent "pneumonia," especially in the absence of fever (PE), and skin changes suggestive of chronic thrombosis (dilated collateral veins). Arterial thrombi usually cause an acute, dramatic impairment of organ function, such as stroke, MI, or a painful, white, cold extremity (Table 524.1).

LABORATORY TESTS

In patients who have a positive bleeding history or who are actively hemorrhaging, a platelet count, prothrombin time (PT), and partial thromboplastin time (PTT) should be performed as screening tests (Fig. 524.3). In individuals with abnormal screening tests, further evaluation should be based on those results (Table 524.2). In a patient with an abnormal bleeding history and a positive family history, normal screening tests should not preclude further laboratory evaluation, which may include a thrombin time, VWF testing, and platelet function studies. Historically, bleeding time and platelet function analysis **(PFA-100)** have been used as screening tests, but neither has proved to be useful in diagnosis of mild bleeding disorders.

There are no useful routine screening tests for *hereditary* thrombotic disorders. If the family history is positive or clinical thrombosis is unexplained, specific thrombophilia assays should be performed. Thrombosis is rare in children, and when it is present, the possibility of a hereditary predisposition should be considered (see Chapter 527).

Platelet Count

Platelet count is essential in the evaluation of the child with a positive bleeding history because thrombocytopenia is the most common acquired cause of a bleeding diathesis in children. Patients with a platelet count of $>50 \times 10^9$/L rarely have significant clinical bleeding. **Thrombocytosis** in children is usually reactive and is not associated with bleeding complications. Persistent, severe thrombocytosis in the absence of an underlying illness may require evaluation for the very rare pediatric presentation of essential thrombocythemia or polycythemia vera.

Prothrombin Time and Activated Partial Thromboplastin Time

Because clotting (coagulation) factors were named in the order of discovery, they do not necessarily reflect the sequential order of activation (Table 524.3; see also Table 524.2). Only two factors have commonly used names: fibrinogen (factor I) and prothrombin (factor II). The dual mechanisms of activating clotting have been termed the **intrinsic** (surface activation) and **extrinsic** (tissue factor–mediated) pathways. PT measures the activation of clotting by tissue factor (thromboplastin) in the presence of calcium. The tissue factor–factor VIIa complex activates factor X. Whether factor X is activated by the intrinsic or the extrinsic pathway, factor Xa on the platelet phospholipid surface complexes with factor Va and calcium (the "prothrombinase" complex) to activate prothrombin to thrombin (also referred to as *factor IIa*). Once thrombin is generated, fibrinogen is converted to a fibrin clot, the endpoint of the reaction (see Fig. 524.2). PT is not prolonged with deficiencies of factors VIII, IX, XI, and XII. In most laboratories, the normal PT value is 10-13 seconds. PT has been standardized using the international normalized ratio **(INR)** so that values can be compared from one laboratory or instrument to another. This ratio is used to determine similar degrees of anticoagulation with vitamin K antagonists, such as warfarin.

Partial Thromboplastin Time

The intrinsic pathway involves the initial activation of factor XII, which is accelerated by two other plasma proteins, prekallikrein and high-molecular-weight kininogen. In the clinical laboratory, factor XII is activated using a surface (silica or glass) or a contact activator, such as ellagic acid. Factor XIIa, in turn, activates factor XI to factor XIa, which then catalyzes factor IX to factor IXa. On the platelet phospholipid surface, factor IXa complexes with factor VIIIa and calcium to activate factor X ("tenase" complex).

This process is accelerated by interaction with phospholipid and calcium at the steps involving factors V and VIII. An isolated deficiency of

Table 524.1 Signs and Symptoms of Thrombosis

LOCATION OF CLOT	PRESENTING SYMPTOMS	RADIOGRAPHIC DIAGNOSIS
Venous thrombus in limbs	Swelling, pain, and/or redness	Venous ultrasonography with Doppler
Arterial thrombus in limbs	Cool limbs, diminished or absent pulse	Arterial ultrasonography with Doppler
Cerebral venous sinus thrombosis	Headache, nausea and/or vomiting, lethargy, change in mental status	CT venography or MR venography of head/brain
Pulmonary embolism	Chest pain, shortness of breath, pleuritis	CT angiography
Thrombus in the heart	Chest pain, shortness of breath, pleuritis	Echocardiogram
Portal vein thrombosis	Abdominal pain, nausea and/or vomiting, anorexia	Right upper quadrant ultrasonography with Doppler
Renal vein thrombosis	Hematuria, abdominal mass, abdominal pain, thrombocytopenia	Renal ultrasonography with Doppler or CT abdomen/pelvis with IV contrast

Modified from Han H, Hensch L, Hui SKR, Teruya J. Evaluation and management of coagulopathies and thrombophilias in pediatric patients. *Clin Lab Med.* 2021;41:83–100. Table 5.

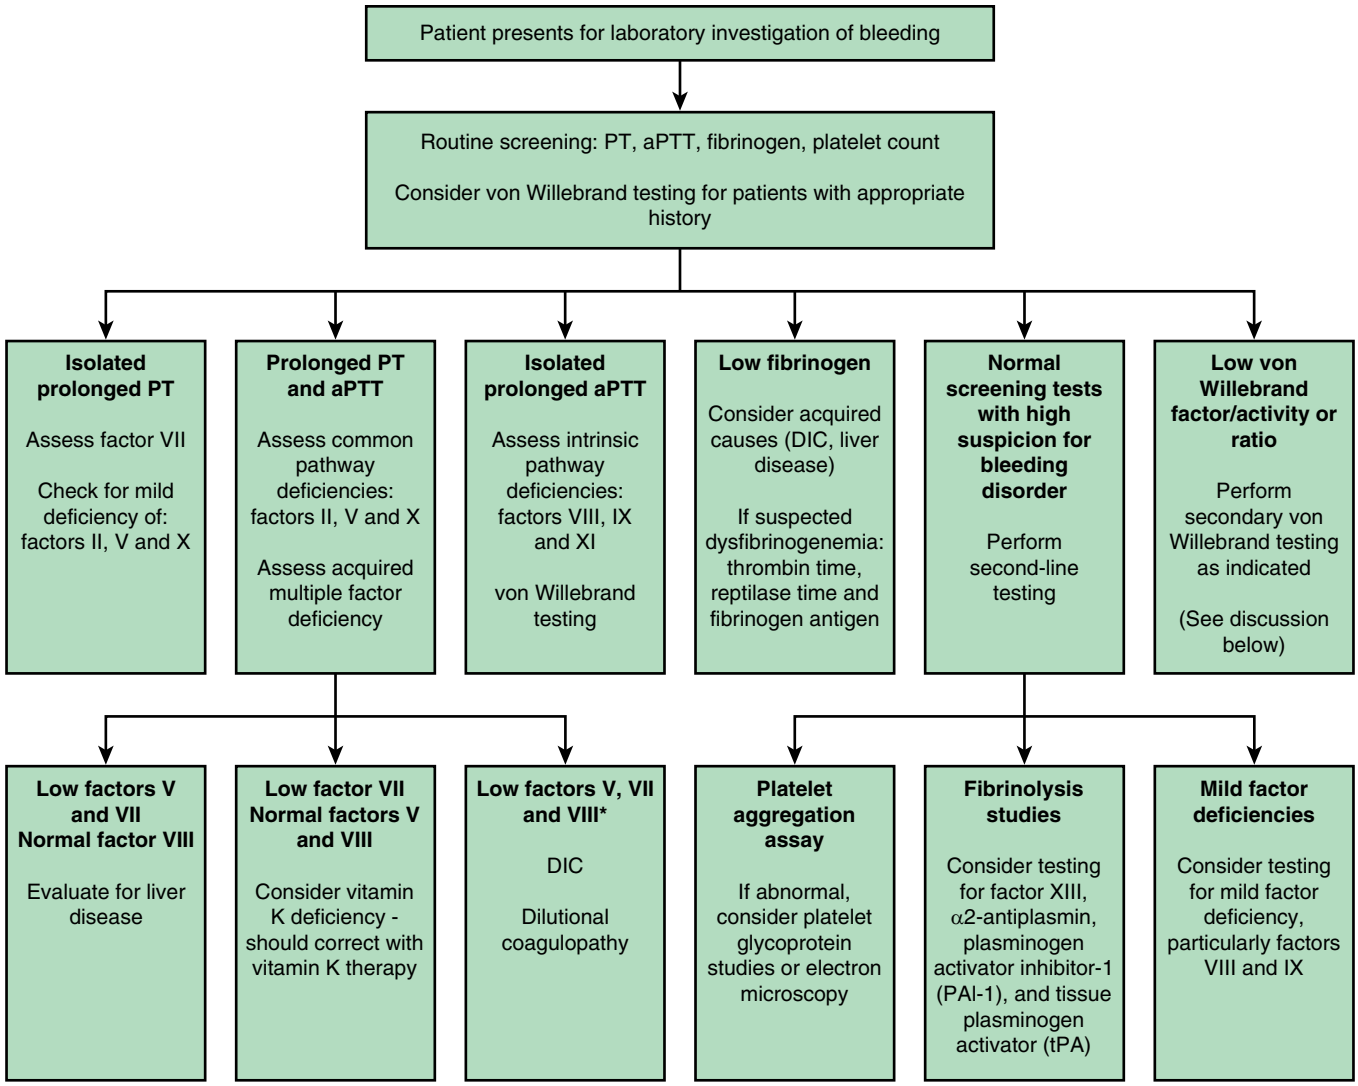

Fig. 524.3 Testing algorithm based on the screening tests (PT, aPTT, fibrinogen, and platelet count). DIC, disseminated intravascular coagulation. *Note: Factor VIII can be normal or increased in these settings secondary to the acute phase response. *(From Han H, Hensch L, Hui SKR, Teruya J. Evaluation and management of coagulopathies and thrombophilias in pediatric patients. Clin Lab Med. 2021;41:83–100. Fig. 1.)*

a single clotting factor may result in isolated prolongation of PT, PTT, or both, depending on the location of the factor in the clotting cascade. This approach is useful in determining hereditary clotting factor deficiencies; however, in acquired hemostatic disorders encountered in clinical practice, more than one clotting factor is frequently deficient, so the relative prolongation of PT and PTT must be assessed.

Measurement of PTT as performed in the clinical laboratory is actually "activated" PTT; most refer to it as **PTT**. This test measures the initiation of clotting at the level of factor XII through sequential steps to the final clot endpoint. It does not measure factor VII, factor XIII, or anticoagulants. PTT uses a contact activator (silica, kaolin, or ellagic acid) in the presence of calcium and phospholipid. Because of differences in reagents and laboratory instruments, the normal range for PTT varies among hospital laboratories. Normal ranges for PTT have much more interlaboratory variability than those for PT.

Thus the mechanisms studied by PT and PTT allow the evaluation of clotting factor deficiencies, even though these pathways may not be the same as those occurring physiologically. The PTT can be prolonged by deficiencies of factor XII, prekallikrein, and high-molecular-weight kininogen, yet these deficiencies do not result in bleeding,

Thrombin Time

Thrombin time (TT) measures the final step in the clotting cascade, in which fibrinogen is converted to fibrin. The normal TT varies between laboratories but is usually 11-15 seconds. Prolongation of TT occurs with reduced fibrinogen levels (*hypofibrinogenemia* or *afibrinogenemia*), with dysfunctional fibrinogen *(dysfibrinogenemia)*, or in the presence of substances that interfere with fibrin polymerization, such as heparin and fibrin split products. If heparin contamination is a potential cause of prolonged TT, a reptilase time can be ordered.

Reptilase Time

Reptilase time uses snake venom to clot fibrinogen. Unlike thrombin time, reptilase time is not sensitive to heparin and is prolonged only by reduced or dysfunctional fibrinogen and fibrin split products. Therefore, if TT is prolonged but reptilase time is normal, the prolonged TT is caused by heparin and does not indicate the presence of fibrin split products or reduced concentration or function of fibrinogen.

Mixing Studies

If there is unexplained prolongation of PT or PTT, a mixing study is usually performed. Normal plasma is added to the patient's plasma, and the PT or PTT is repeated. Correction of PT or PTT by 1:1 mixing with normal plasma suggests deficiency of a clotting factor because a 50% level of individual clotting proteins is sufficient to produce normal PT or PTT. If the clotting time is not corrected or only partially corrected, an **inhibitor** is usually present. An inhibitor of clotting may be either a chemical similar to heparin that delays coagulation or an

Table 524.2 Causes of Bleeding Associated with Prolonged Prothrombin Time and Activated Partial Thromboplastin Time

ISOLATED PROLONGED PT	ISOLATED PROLONGED aPTT	PROLONGED PT AND aPTT	CAUSES OF BLEEDING WITHOUT PT/aPTT PROLONGATION
FVII deficiency	Hemophilia A (FVIII deficiency)	Disseminated intravascular coagulation	FXIII deficiency
Mild common pathway factor deficiency (II, V, and X), fibrinogen deficiency	Hemophilia B (FIX deficiency)	Dilutional coagulopathy	von Willebrand disease
Early vitamin K deficiency	Hemophilia C (FXI deficiency)	Liver synthetic dysfunction	Platelet dysfunction
Early liver synthetic dysfunction	von Willebrand disease	Marked vitamin K deficiency	Mild deficiency of FVIII, FIX, and FXI
Direct Xa inhibitor	Acquired FVIII, FIX, or FXI inhibitors	Common pathway factor deficiency (FII, FV, and FX), severe fibrinogen deficiency	α_2-antiplasmin deficiency and other causes of hyperfibrinolysis
—	Heparin	Warfarin or direct thrombin inhibitor, DOAC (not always)	Collagen vascular diseases (i.e., Ehlers-Danlos syndrome)
—	—	Increased tissue factor pathway inhibitor, FV Amsterdam or East Texas bleeding disorder	DOAC

DOAC, Direct oral anticoagulant.

Table 524.3 Coagulation (Clotting) Factors

CLOTTING FACTOR	SYNONYM	DISORDER
I	Fibrinogen	Congenital deficiency (afibrinogenemia) or dysfunction (dysfibrinogenemia)
II	Prothrombin	Congenital deficiency or dysfunction
V	Labile factor, proaccelerin	Congenital deficiency (parahemophilia)
VII	Stable factor or proconvertin	Congenital deficiency
VIII	Antihemophilic factor	Congenital deficiency is hemophilia A (classic hemophilia)
IX	Christmas factor	Congenital deficiency is hemophilia B (sometimes referred to as Christmas disease)
X	Stuart-Prower factor	Congenital deficiency
XI	Plasma thromboplastin antecedent	Congenital deficiency (sometimes referred to as hemophilia C)
XII	Hageman factor	Congenital deficiency is not associated with clinical symptoms
XIII	Fibrin-stabilizing factor	Congenital deficiency

antibody directed against a specific clotting factor or the phospholipid used in clotting tests. In the inpatient setting the most common cause of a prolonged PTT is **heparin contamination** of the sample. The presence of heparin in the sample can be ruled in or out by adding *heparinase* to the sample and repeating the PTT. If the mixing study is not corrected or if its result becomes more prolonged and the patient has clinical bleeding, an inhibitor of a specific clotting factor (antibody directed against the factor), most often factor VIII, factor IX, or factor XI, may be present. If the patient has no bleeding symptoms and both PTT and the mixing study are prolonged, a **lupus-like anticoagulant** (see Chapter 531) is often present. Patients with these findings usually have a long PTT but do not bleed.

Platelet Aggregation

When a qualitative platelet function defect is suspected, platelet aggregation testing is usually ordered. Platelet-rich plasma from the patient is activated with a series of agonists (ADP, epinephrine, collagen, thrombin or thrombin-receptor peptide, and ristocetin). Some platelet aggregometers measure specific adenosine triphosphate release from the platelets, as measured by the generation of luminescence via lumi-aggregometry, and are more sensitive in detecting abnormalities of the platelet release reaction from storage granules. Repeat testing or testing of other symptomatic family members can help to determine the hereditary nature of the defect. Many medications, especially aspirin, other NSAIDs, and valproic acid, alter platelet function testing. Figure 524.1 provides an approach to the differential diagnosis of many common bleeding disorders based on screening tests.

Factor XIII

The PT and PTT reflect only fibrin formation and do not measure cross-linking by factor XIII. Therefore specific testing is required to identify factor XIII deficiency. Clot solubility testing can be performed but only identifies the most severely affected individuals. Quantitative measurement of factor XIII levels can also be performed.

Testing for Thrombotic Predisposition

Hereditary predisposition to thrombosis is associated with a reduction of anticoagulant function (protein C, protein S, AT III); the presence of

Data adapted from Toulon P, Berruyer M, Brionne-François M, et al. Age dependency for coagulation parameters in paediatric populations. Results of a multicentre study aimed at defining the age-specific reference ranges. *Thromb Haemost.* 2016;116:9–16.

a factor V molecule that is resistant to inactivation by protein C (factor V Leiden); elevated levels of procoagulants (a pathogenic variant of the prothrombin gene); or a deficiency of fibrinolysis (plasminogen deficiency); and the rare metabolic disease homocystinuria (see Chapter 527).

Tests of the Fibrinolytic System

Euglobulin clot lysis time is a screening test used in some laboratories to assess fibrinolysis. More specific tests are available in most laboratories to determine the levels of plasminogen, plasminogen activator, and inhibitors of fibrinolysis. An increase in fibrinolysis may be associated with hemorrhagic symptoms, and a delay in fibrinolysis is associated with thrombosis.

DEVELOPMENTAL HEMOSTASIS

The normal newborn infant has reduced plasma concentrations of several procoagulants and anticoagulants compared to adults (see Table 524.4), and this is even more pronounced in preterm infants. During gestation, there is progressive maturation and increase of the clotting factors synthesized by the liver. The extremely premature infant has prolonged PT and PTT values, as well as a marked reduction in anticoagulant protein levels (protein C, protein S, and AT). Levels of fibrinogen, factors V and VIII, VWF, and platelets are near-normal throughout the later stages of gestation (see Chapter 142). Because protein C and protein S are physiologically reduced, factors V and VIII, which are present at normal levels at birth, are not balanced with their regulatory proteins. In contrast, the physiologic deficiency of vitamin K–dependent procoagulant proteins (factors II, VII, IX, and X) is partially balanced by the physiologic reduction of AT. The net effect is that newborns (especially premature infants) are at increased risk for complications of bleeding, clotting, or both. Establishing absolute cutoff values for normal ranges of coagulation proteins in newborn and preterm infants is challenging because of the age-dependent variation and heterogeneity among laboratory instruments and reagents. Repeat testing (or testing parents) may be necessary to confirm a diagnosis of an inherited deficiency.

Chapter 525

Hereditary Clotting Factor Deficiencies (Bleeding Disorders)

Benjamin J. Samelson-Jones, Brian R. Branchford, and Veronica H. Flood

Inherited deficiencies in the coagulation factors responsible for forming cross-linked fibrin clots (as detailed in Chapter 524) can result in bleeding disorders. **Hemophilia A** (factor VIII deficiency) and **hemophilia B** (factor IX deficiency) are the most common and serious congenital coagulation factor deficiencies. The clinical findings in hemophilia A and hemophilia B are virtually identical. Factor XI deficiency is a rare autosomal bleeding disorder discussed in Chapter 525.2. Reduced levels of the *contact factors* (factor XII, high molecular weight kininogen, and prekallikrein) are associated with significant prolongation of *activated partial thromboplastin time* (aPTT; also referred to as **PTT**) but are not associated with clinical bleeding, as discussed in Chapter 525.3.

525.1 Factor VIII or Factor IX Deficiency (Hemophilia A or B)

Benjamin J. Samelson-Jones, Brian R. Branchford, and Veronica H. Flood

Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) are the most common severe inherited bleeding disorders.

PATHOPHYSIOLOGY

The activated forms of factors VIII and IX participate in the enzyme complex responsible for the sustained proteolytic activation of factor X during coagulation. Together with phospholipids and calcium, they form the intrinsic tenase (or factor X activating) complex. Hemophilia A and hemophilia B have similar clinical manifestations because, molecularly, both disorders result in a deficiency of factor X activation, which, in turn, results in insufficient thrombin generation (see Fig. 524.1 in Chapter 524 for a depiction of the in vitro clotting process as it occurs in the test tube). In hemostatically normal individuals, hemorrhage after an injury is constrained by the initial formation of the platelet plug, which is stabilized by the generation of a cross-linked fibrin clot. In people with hemophilia A or B, clot formation is delayed and ineffectual. Inadequate thrombin production leads to failure to form a tightly cross-linked fibrin to support the platelet plug. When untreated bleeding occurs in a closed space, such as a joint, bleeding may stop as the result of **tamponade**. With open wounds, in which tamponade cannot occur, even minor injuries may result in significant blood loss, with a highly friable clot forming slowly; rebleeding occurs during physiologic thrombolysis or with minimal new traumas.

CLINICAL MANIFESTATIONS

The severity of the bleeding phenotype in hemophilia A and B is strongly associated with the amount of residual factor VIII or factor IX, respectively. **Severe hemophilia** is characterized by having <1% normal factor activity, and bleeding is frequent and often spontaneous. Patients with **moderate hemophilia** have factor levels of 1–5% normal and bleed excessively with mild trauma. Individuals with **mild hemophilia** have factor levels 5–40% normal and usually only bleed abnormally after major trauma or surgery; people with mild hemophilia may go many years before the condition is diagnosed.

Because neither factor VIII nor factor IX crosses the placenta, bleeding symptoms may be present at birth. Between 1% and 4% of neonates with hemophilia have intracranial hemorrhages, mostly from birth trauma. However, about 35% and 70% of male infants with severe and nonsevere hemophilia, respectively, *do not bleed* with circumcision. Thus, in the absence of a positive family history (50% of cases), hemophilia may go undiagnosed in the newborn period. Obvious symptoms, such as easy bruising, intramuscular hematomas, and hemarthroses, begin when the child starts to cruise. Bleeding from minor traumatic lacerations of the mouth (torn frenulum) may persist for hours or days and may cause the parents to seek medical evaluation. Even in patients with severe hemophilia, only 90% have evidence of increased bleeding by a year of age.

Although bleeding may occur in any area of the body, the hallmark of hemophilia bleeding is **hemarthrosis**, which can occur spontaneously or after minor trauma. The earliest joint hemorrhages appear most often in the ankles. In the older child and adolescent, hemarthroses of the knees and elbows are also common. Whereas the child's early joint hemorrhages are recognized only after major swelling and fluid accumulation in the joint space, older children are frequently able to recognize bleeding before the physician does: patients report a warm, tingling sensation in the affected joint as the first sign of a joint hemorrhage. Repeated bleeding episodes into the same joint may result in a "target" joint, which becomes more susceptible to recurrent bleeding because of the pathologic changes (see "Chronic Complications").

Although most **muscular hemorrhages** are clinically evident because of localized pain or swelling, bleeding into the iliopsoas muscle requires specific mention. A patient may lose large volumes of blood into the iliopsoas muscle, verging on hypovolemic shock, with only a vague area of referred pain in the groin. The hip is held in a flexed, internally rotated position because of irritation of the iliopsoas. The diagnosis is made clinically from the inability to extend the hip but should be confirmed with ultrasonography, CT, or MRI (Fig. 525.1).

Life-threatening bleeding in the patient with hemophilia is caused by bleeding into vital structures (central nervous system [CNS], upper airway) or by exsanguination (external trauma, gastrointestinal [GI] or iliopsoas hemorrhage). Prompt treatment with clotting factor concentrate for these life-threatening hemorrhages is imperative. If head trauma is of sufficient concern to suggest radiologic evaluation, factor replacement should *precede* radiologic evaluation. Life-threatening hemorrhages require replacement therapy to achieve a level equal to that of normal plasma (100 IU/dL or 100%; see section below on "Treatment").

LABORATORY FINDINGS AND DIAGNOSIS

A reduced level of factor VIII or factor IX will often result in a *prolonged PTT*. In severe hemophilia, the PTT value is usually 2-3 times the upper limit of normal. However, depending on the PTT reagents, people with mild hemophilia can have a PTT in the normal range. Results of the other screening tests of the hemostatic mechanism (platelet count, bleeding time, prothrombin time [PT]) are normal. The specific activity assays for factors VIII and IX confirm the diagnosis of hemophilia. One IU of each factor activity is defined as that amount in 1 mL of normal plasma, referenced against a standard established by the World Health Organization (WHO). Thus 100 mL of normal plasma has 100 IU/dL (100% normal activity) of each factor. The term *% activity* refers to the percentage found in normal plasma (100% activity). Factor concentrates are also referenced against an international WHO standard, so treatment doses are usually referred to in IU.

In the newborn period, factor VIII activity values may be artificially elevated because of the acute-phase response elicited by the birth process. This artificial elevation may cause an infant with mild hemophilia A to have a normal or near-normal measured level. Patients with severe hemophilia A do not have detectable levels of factor VIII. In contrast, factor IX levels are physiologically low in all newborns and only reach adult values at about 6 months of age. If severe hemophilia is present in the family, an undetectable level of factor IX is diagnostic of severe hemophilia B. In some patients with mild factor IX deficiency, the presence of low factor IX activity can be confirmed only after several months of life.

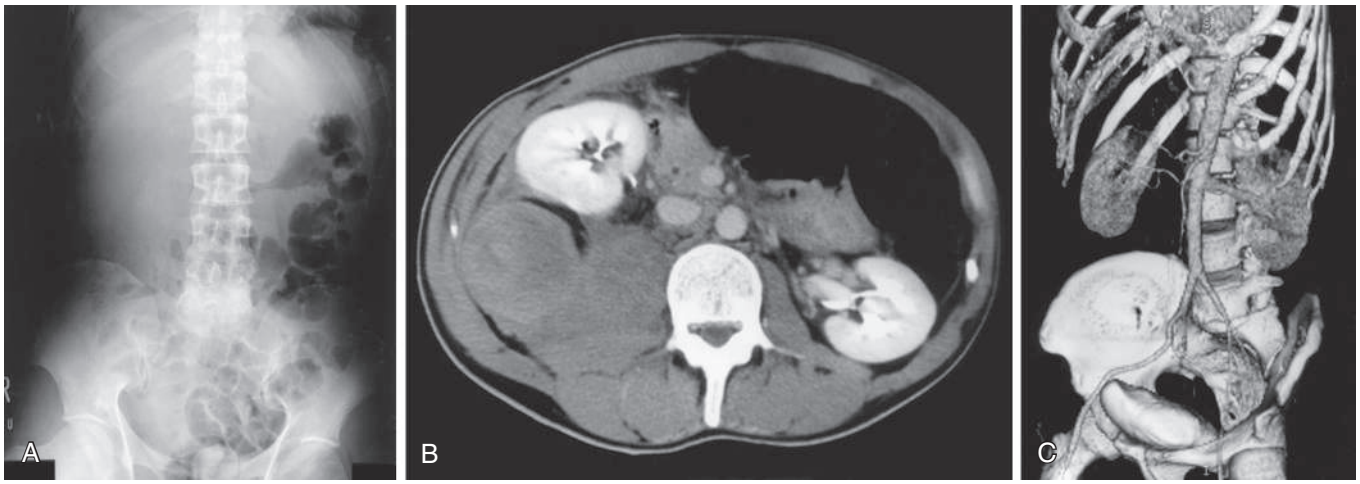

Fig. 525.1 Massive hematoma into the iliopsoas muscle in a patient with hemophilia B. A male with severe deficiency of factor IX (hemophilia B) was admitted for right lower abdominal pain of progressively increasing severity and tenderness. He had had a common cold with severe cough and loss of appetite for approximately 1 week. **A,** Abdominal radiograph shows presence of the psoas sign on the right side and left-shifted colon gas. **B,** CT scan shows massive hematoma in the right iliopsoas muscle, resulting in anterior translocation of the right kidney. **C,** Reconstructed 3-dimensional image shows more clearly the kidney translocation and the extended, but intact, large vessels. These are useful findings for the diagnostic procedures because progressive right lower abdominal pain may closely simulate acute appendicitis. The hemorrhage was successfully managed by replacement of factor IX for 1 week without any recurrence. The patient did not have any inhibitors to factor IX. *(From Miyazaki K, Higashihara M. Massive hemorrhage into the iliopsoas muscle. Intern Med. 2005;44:158–159.)*

The mixing of normal plasma with hemophilia plasma usually corrects PTT value, unless the patient has an inhibitor, as discussed later. An inhibitor titer can be quantified by the Bethesda assay, where 1 Bethesda Unit (BU) neutralizes 1 IU/mL of factor.

DIFFERENTIAL DIAGNOSIS

In young infants with severe bleeding manifestations, the differential diagnosis includes severe thrombocytopenia; severe platelet function disorders, such as Bernard-Soulier syndrome and Glanzmann thrombasthenia; type 3 (severe) von Willebrand disease; and vitamin K deficiency.

GENETICS

The genes for factor VIII and IX (*F8* and *F9*, respectively) are carried near the terminus of the long arm of the X chromosome, making hemophilia an X-linked disorder. It occurs in approximately 1/5,000 males, with 80% having factor VIII deficiency and 20% having factor IX deficiency. Hemophilia appears in all ethnic groups. A third of cases are estimated to be the result of a spontaneous pathogenic variant. Approximately 50% of cases of severe hemophilia A have a specific *F8* change, in which there is an internal inversion within the factor VIII gene (intron 22 inversion). Meanwhile, 98% of hemophilia patients have an identified genetic cause of their hemophilia, which can facilitate diagnosis, prenatal testing, and identification of female carriers.

Some **female carriers** (heterozygotes) have sufficiently low factor level to have abnormal bleeding. Factor levels should be determined in all known or potential carriers to assess the need for treatment in the event of surgery or clinical bleeding. Female carriers with factor levels <40% normal are considered to have hemophilia and should be treated as such. Notably, about 0.2% of people with severe and moderate hemophilia are female, mostly because of skewed lyonization or Turner syndrome. Female carriers with factor levels >40% normal can also have abnormal bleeding and are termed *symptomatic hemophilia carriers*. Historically, female carriers were thought to be asymptomatic, but newer data prove these individuals can also have significant bleeding.

TREATMENT

Disease-specific therapy started early in life is the hallmark of excellent hemophilia care (Table 525.1). Treatment can be divided into on-demand therapy (hemostatic interventions to stop bleeding) and prophylaxis therapy to prevent bleeding. *Prophylaxis is the standard of care for children with severe hemophilia* in countries with sufficient medical resources. Prophylaxis decreases catastrophic bleeding, prevents hemarthrosis, and preserves joint health. The types of hemostatic agents available for hemophilia A and hemophilia B are rapidly expanding, with several new classes of medications receiving regulatory approval (Table 525.2).

On-Demand Treatment

To treat acute bleeding, nothing works better than replacing the deficient coagulation factor. When mild to moderate bleeding occurs, values of factor VIII or factor IX must be raised to hemostatic levels, approximately 50% of normal activity. For life-threatening or major hemorrhages, the dose should aim to achieve levels of 100% activity. Both plasma-derived and recombinant factor VIII and factor IX concentrates are available. Replacement therapy requires intravenous administration, which patients and families often learn to do themselves. The half-lives of standard factor VIII and factor IX are 8-12 hours and 18-24 hours, respectively, although there is wide variability between patients with younger children often having shorter half-lives. There are also bioengineered factor VIII and factor IX products designed to have longer half-lives (termed *extended half-life products*), which reduce the frequency of intravenous administrations necessary to treat bleeds and provide prophylaxis.

Table 525.1 summarizes the treatment recommendations of some common types of hemorrhage in a patient with hemophilia. The calculation of the factor replacement dose is as follows, with the difference between factor VIII and factor IX being because of their different volumes of distribution:

$$\text{Factor VIII dose (IU)} = [\%\ \text{desired raise}] \times [\text{weight (kg)}] \times 0.5$$

$$\text{Factor IX dose (IU)} = [\%\ \text{desired raise}] \times [\text{weight (kg)}] \times 1.3$$

Therefore emergency dosing for factor VIII deficiency is approximately 50 units per kg and emergency dosing for factor IX deficiency is approximately 100-130 units/kg.

It is important to note that patients can have variable recoveries, and different factor products also have slightly different recoveries. Many patients will carry dosing cards detailing their recommended treatments. In general, doses are rounded up to vial size so as not to waste product.

For some patients with *mild* factor VIII deficiency, **desmopressin acetate** can be used to stimulate the cellular release of endogenously

Table 525.1 Treatment of Hemophilia *Without* Inhibitors

TYPE OF HEMORRHAGE	HEMOPHILIA A	HEMOPHILIA B
Hemarthrosis*	50-60 IU/kg factor VIII concentrate† on day 1, then 20 IU/kg the following day. Consider every other day until joint function is normal or back to baseline. Consider prophylaxis.	80-100 IU/kg factor IX concentrate‡ on day 1; then 40 IU/kg the following day. Consider every other day until joint function is normal or back to baseline. Consider prophylaxis.
Muscle or significant subcutaneous hematoma	50 IU/kg factor VIII concentrate; 20 IU/kg every other day treatment may be needed until resolved.	80 IU/kg factor IX concentrate‡; 40 IU/kg every 2-3 days may be needed until resolved.
Mouth, deciduous tooth, or tooth extraction	20 IU/kg factor VIII concentrate†; antifibrinolytic therapy§; remove loose deciduous tooth.	40 IU/kg factor IX concentrate‡; antifibrinolytic therapy§; remove loose deciduous tooth.
Epistaxis	Apply pressure for 15-20 min; pack with petrolatum gauze; give antifibrinolytic therapy§; 20 IU/kg factor VIII concentrate† if this treatment fails.‖	Apply pressure for 15-20 min; pack with petrolatum gauze; antifibrinolytic therapy§; 30 IU/kg factor IX concentrate‡ if this treatment fails.#
Major surgery, life-threatening hemorrhage	50-75 IU/kg factor VIII concentrate; then initiate 25 IU/kg q8-12h to maintain trough level >50 IU/dL for 5-7 days; then 50 IU/kg q24h to maintain trough >25 IU/dL for 7 days; monitor factor VIII levels.	80-120 IU/kg factor IX concentrate‡, then 50-60 IU/kg q12-24h to maintain factor IX at >40 IU/dL for 5-7 days, and then at >30 IU/dL for 7 days; monitor factor IX levels.
Iliopsoas hemorrhage	50 IU/kg factor VIII concentrate; then 25 IU/kg q12h until asymptomatic; then 20 IU/kg every other day, for a total of 10-14 days.**	100 IU/kg factor IX concentrate‡; then 50-60 IU/kg q12-24h to maintain factor IX at >40 IU/dL until patient is asymptomatic; then 40-50 IU every other day, for a total of 10-14 days.**
Hematuria	Bed rest; 1.5× maintenance fluids; if not controlled in 1-2 days, 20 IU/kg factor VIII concentrate; if not controlled, give prednisone (unless patient is HIV-infected).	Bed rest; 1.5× maintenance fluids; if not controlled in 1-2 days, 40 IU/kg factor IX concentrate‡; if not controlled, give prednisone (unless patient is HIV-infected).

*For hip hemarthrosis, orthopedic evaluation for possible aspiration is advisable to prevent avascular necrosis of the femoral head.
†For mild or moderate hemophilia, desmopressin 0.3 μg/kg can be used instead of factor VIII concentrate if the patient is known to respond with a hemostatic level of factor VIII; if repeated doses are given, monitor factor VIII levels for tachyphylaxis.
‡Stated doses apply for recombinant factor IX concentrate; different dosing may apply for long-acting recombinant factor IX concentrates or plasma-derived factor IX.
§Do not give antifibrinolytic therapy until 4-6 hr after a dose of prothrombin complex concentrate.
#Nonprescription coagulation-promoting products may be helpful.
**Repeat radiologic assessment should be performed before discontinuation of therapy.
HIV, Human immunodeficiency virus; IU, international units; q12-24h, every 12 to 24 hours.

Table 525.2 Strengths and Weaknesses of the Old and New Therapeutic Options for Hemophilia

	STRENGTHS	WEAKNESSES
Standard half-life clotting factor concentrates	Effective for both bleeding control and prevention; well established safety and effectiveness profile for decades; measurable FVIII and FIX concentrations as surrogate marker of effectiveness; can result in normal concentrations of FVIII and FIX	Frequent intravenous injections; inhibitor development
Extended half-life clotting factor concentrates	Effective for both bleeding control and prevention; a reduced number of injections; higher trough concentrations; measurable FVIII and FIX concentrations as surrogate markers of effectiveness; can result in normal concentrations of FVIII and FIX	Intravenous route; inhibitor development
Nonreplacement therapies (emicizumab, fitusiran, anti-tissue factor pathway inhibitor antibodies, SerpinPC)	Subcutaneous route; infrequent injections; standard doses for all patients	Need for adjunctive hemostatic treatment; steady state of coagulation activity not within the normal range; thrombotic risk
Gene therapy	Single intravenous injection; restoration of endogenous FVIII and FIX production	Preexisting immunity against adeno-associated viral vectors; immune response against vectors and transfected cells; unknown durability of transduction; need for immunosuppressive therapy; unknown long-term safety

FVIII, factor VIII; FIX, factor IX.
From Mancuso ME, Mahlangu JN, Pipe SW. The changing treatment landscape in haemophilia: from standard half-life clotting factor concentrates to gene editing. *Lancet.* 2021;397:630–640. Table 5.

produced factor VIII to increase its plasma levels. In patients with moderate or severe factor VIII deficiency, the stored levels of factor VIII are inadequate, and desmopressin treatment is ineffective. Desmopressin can be administered intravenously or intranasally, with the latter facilitating home treatment. The intranasal formulation is a higher concentration of desmopressin than that used to treat enuresis or hypopituitarism; the dose is 150 μg (1 spray) for children weighing <50 kg and 300 μg (2 sprays) for children and young adults weighing >50 kg. Most centers administer a trial of desmopressin to determine if the factor VIII levels increase sufficiently for hemostasis. Because desmopressin triggers the release of cellularly stored factor VIII, usually it can only be given twice in a 1-2 day period. The most serious complication is hyponatremia, which can be mitigated by fluid restrictions for the 24 hours after administration. Desmopressin is not effective in the treatment of factor IX deficiency.

Mucosal bleeding often benefits from antifibrinolytic agents such as aminocaproic acid or tranexamic acid that can be given orally or intravenously.

PROPHYLAXIS

Many patients are given lifelong prophylaxis to prevent spontaneous joint bleeding. The World Federation of Hemophilia recommends prophylaxis for children with severe hemophilia and for adults with joint disease. Usually, such programs are initiated at the time of the first or second joint hemorrhage. Young children often require the insertion of a central catheter to ensure venous access for factor replacements. Such regimens are expensive but highly effective in preventing or greatly limiting the degree of joint pathology; complications include central line infection and thrombosis.

The goal of prophylaxis is generally to maintain a measurable plasma factor level (1–2%), when assayed just before the next infusion (trough level); this converts patients from severe to moderate hemophilia. For standard half-life products, this typically requires intravenous administration 2-4 times per week; this frequency is reduced with prophylaxis with extended half-life products.

Another class of hemophilia drugs that promotes hemostasis without factor VIII or factor IX is termed **nonfactor therapies**. Emicizumab is approved for prophylaxis for hemophilia A. Emicizumab is a bispecific, humanized monoclonal antibody that can bridge activated factor IX and factor X to restore factor X activation. It is administered subcutaneously and is given only 1-4 times per month after four weekly loading doses. Because emicizumab mimics some of the biochemistry of activated factor VIII, it dramatically shortens PTT times. It is not used to treat acute bleeds.

Efanesoctocog alfa, a modified extended half-life single recombinant factor VIII protein that decouples recombinant factor VIII from endogenous von Willebrand factor, has demonstrated efficacy in patients with severe hemophilia A. **Fitusiran**, a small interfering RNA molecule that reduces antithrombin synthesis, has been used successfully for prophylaxis in patients with hemophilia A or B with or without inhibitors. **Gene therapy** (valoctocogene roxaparvovec for hemophilia A; etranacogene dezaparvovec for hemophilia B) has demonstrated efficacy in reducing bleeding in adult patients with severe hemophilia.

SUPPORTIVE CARE

Effective measures to avoid trauma include anticipatory guidance, including the use of car seats, seatbelts, and bike helmets and the avoidance of high-risk behaviors. Older males should be counseled to avoid violent contact sports, but this issue is admittedly a challenge; however, active lifestyles are also encouraged to limit obesity. Early psychosocial intervention helps the family achieve a balance between overprotection and permissiveness. Patients with hemophilia should avoid aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) that affect platelet function.

Inhibitor Formation

The formation of neutralizing antibodies, termed *inhibitors*, is the major complication of factor VIII or factor IX replacement therapy. They develop in 20–30% of severe hemophilia A patients and 3–10% of severe hemophilia B patients that receive factor therapy, usually within 20 exposures to factor. Inhibitors may be identified during routine laboratory surveillance or become clinically apparent when bleeding episodes fail to respond to appropriate replacement therapy. There are both patient and product risk factors for inhibitor development, with the underlying hemophilia-causing gene pathogenic variant being the most important with the majority of people with large-gene deletions developing inhibitors. Prophylaxis with plasma-derived factor VIII products decreases the risk of inhibitor development about 1.7-fold compared to recombinant factor VIII products. Intensive early factor exposure during surgery or major trauma increases the risk of inhibitor development, likely through initiating immunologic danger signaling. Patients with inhibitors always require referral to a center that cares for many such patients and has a comprehensive hemophilia program.

Clinically, inhibitor titers are demarcated as low-titer (≤5 BU) and high-titer (>5 BU). Low-titer inhibitors can often be overcome by large amounts of factor, while high-titers necessitate the use of bypassing agents, which can circumvent the inhibitor to promote hemostasis. The two bypassing agents available that can treat acute bleeds are activated prothrombin complex concentrates and recombinant activated factor VII, both of which are administered intravenously. Prophylaxis regimens for bypassing agents have been described, but most hemophilia A patients with inhibitors currently use emicizumab prophylaxis because of its efficacy and ease of administration.

Inhibitor eradication has been prioritized, and it is still recommended since the advent of emicizumab. Low-titer or transient inhibitors often disappear with continued regular factor infusions. Higher titer inhibitors often require immune tolerance induction regimens, in which high doses of factor are administered to attempt to develop immune tolerance. This procedure is successful in about two-thirds of severe hemophilia A patients. Immune tolerance induction with factor IX products is complicated by allergic reactions and the development of nephrotic syndrome in some patients. Rituximab, corticosteroids, and other immunosuppressives have been used in patients with high-titer inhibitors in whom immune tolerance programs have failed, although the use of immunosuppressive therapy has declined with the use of emicizumab prophylaxis for factor VIII deficiency inhibitor patients.

CHRONIC COMPLICATIONS

Long-term complications of hemophilia A and B include chronic arthropathy and the risk of transfusion-transmitted infectious diseases, although both complications have been substantially mitigated with modern hemophilia care, including early initiation of prophylaxis and the use of recombinant protein products or plasma-derived products with advanced donor screening and highly active viricidal procedures.

Chronic arthropathy is the major long-term disability associated with hemophilia. The natural history of severe hemophilia without prophylaxis is one of cyclic recurrent hemorrhages into specific joints, including hemorrhages into the same (target) joint. In young children, the joint distends easily, and a large volume of blood may fill the joint until tamponade ensues or therapy intervenes. After joint hemorrhage, proteolytic enzymes are released by white blood cells into the joint space, and heme iron induces macrophage proliferation, leading to inflammation of the synovium. The synovium thickens and develops frondlike projections into the joint that are susceptible to being pinched and may induce further hemorrhage. The cartilaginous surface becomes eroded and ultimately may even expose raw bone, leaving the joint susceptible to articular fusion. In the older patient with advanced arthropathy, bleeding into the target joint, with its thickened synovium, causes severe pain, because the joint has little space to accommodate blood. Once a target joint develops, the patient is usually given short- or long-term prophylaxis to prevent progression of the arthropathy and reduce inflammation.

In the past, plasma-derived products tragically transmitted hepatitis B virus, hepatitis C virus, and HIV to large numbers of people with hemophilia. Modern plasma-derived products pose a very low risk of spreading identified bloodborne pathogens, but the risk of transmitting unidentified pathogens or emerging agents such as prions remains largely undefined.

COMPREHENSIVE CARE

Patients with hemophilia are best managed through comprehensive hemophilia care centers. Such centers are dedicated to patient and family education and the prevention and treatment of the complications of

hemophilia, including chronic joint disease and inhibitor development. Such centers involve a team that includes physicians, nurses, orthopedists, physical therapists, and psychosocial workers, all focused on hemophilia care. Education remains crucial in hemophilia care because patients who are receiving prophylaxis may be less experienced in recognizing bleeding episodes than affected children from previous eras.

525.2 Factor XI Deficiency

Benjamin J. Samelson-Jones, Brian R. Branchford, and Veronica H. Flood

Factor XI deficiency (previously known as hemophilia C) is an autosomal disorder associated with mild to moderate bleeding symptoms. Bleeding is usually after trauma and surgery, with bleeding most commonly occurring at sites of high fibrinolytic activity, such as the oropharynx and urogenital tract. This focality is likely secondary to the role of factor XI in augmenting thrombin generation for the subsequent activation of *thrombin-activatable fibrinolysis inhibitor* (TAFI). Heavy menstrual bleeding is also common in females with factor XI deficiency. Factor XI deficiency can occur in any ethnic group but is frequently encountered in Ashkenazi Jews with a heterozygous frequency of 1 in 11 individuals. Factor XI deficiency usually (but not always) results in a prolonged PTT; specific factor XI activity assays are diagnostic.

The bleeding phenotype is poorly predicted by the measured factor XI activity. Some patients with severe deficiency (<20% normal activity) may have minimal or no symptoms, whereas other individuals with higher levels experience excessive surgical bleeding. Because spontaneous bleeding is very rare, treatment is focused on perioperative management. Although factor XI concentrates are available in other countries, in the United States, factor XI has to be replaced with fresh-frozen plasma (FFP). For minor surgeries or bleeds, antifibrinolytics such as aminocaproic acid or tranexamic acid are frequently used. For major surgeries, 15-25 mL/kg of FFP in combination with antifibrinolytics is recommended. The factor XI half-life is 50 hours.

525.3 Deficiencies of the Contact Factors (Nonbleeding Disorders)

Benjamin J. Samelson-Jones, Brian R. Branchford, and Veronica H. Flood

Deficiency of the "contact factors"—factor XII, prekallikrein, and high molecular weight kininogen—causes a prolonged PTT but no bleeding symptoms. Because these contact factors function at the step of initiation of the intrinsic clotting system by the reagent used to determine PTT, the PTT is markedly prolonged when these factors are absent. Thus there is the paradoxical situation in which PTT is extremely prolonged with no evidence of clinical bleeding. It is important that individuals with these findings be well informed about the meaning of their clotting factor deficiency because they do not need treatment, even for major surgery.

525.4 Factor VII Deficiency

Benjamin J. Samelson-Jones, Brian R. Branchford, and Veronica H. Flood

Factor VII deficiency is a rare autosomal bleeding disorder that ranges in its presentation from mild to severe bleeding. There is a poor correlation between the clinical severity and the measured factor VII level, although major bleeding is more frequent in patients with <1% activity. Epistaxis and menorrhagia are the most common symptoms, although hemarthroses and intracranial hemorrhages also occur, with the latter reported in 1% of symptomatic cases.

Patients with this deficiency have greatly prolonged PT but normal PTT. Specific factor VII assays are diagnostic. Some recombinant factor VIIa products are approved for the treatment of factor VII deficiency at a dose of 15-30 mcg/kg, which is lower than the dose approved for hemophilia with inhibitors. The plasma half-life of factor VII is 2-6 hours and usually at least three doses at this frequency are required for major bleeding or surgery. Prophylaxis regimens with 2-3 administrations per week have been described in patients with severe bleeding.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

525.5 Factor X Deficiency

Benjamin J. Samelson-Jones, Brian R. Branchford, and Veronica H. Flood

Factor X deficiency is a rare autosomal recessive disorder with variable severity. Mild deficiency results in mucocutaneous and posttraumatic bleeding, whereas severe deficiency (<1–10% normal activity) is associated with joint, GI, and intracranial hemorrhages. Intracranial and umbilical bleeding can be the presenting symptom for neonates. Heterozygous carriers usually have activity >50% normal and are asymptomatic.

A reduced factor X level is associated with prolongation of both PT and PTT; factor X specific assays are diagnostic. Replacement treatment is with FFP or prothrombin complex concentrate (PCC) or plasma-derived factor X concentrates. The plasma half-life of factor X is approximately 40-60 hours, and prophylaxis regimens with PCC or factor X concentrates administered 1-2 times per week are described for patients with severe bleeding.

Although it is rarely a problem in pediatric patients, about 10% of cases of **light-chain amyloidosis** are associated with factor X deficiency, resulting from the adsorption of factor X on the amyloid protein. In the setting of amyloidosis, replacement therapy often is not successful because of the rapid clearance of factor X.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

525.6 Prothrombin (Factor II) Deficiency

Benjamin J. Samelson-Jones, Brian R. Branchford, and Veronica H. Flood

Prothrombin (factor II) deficiency is caused either by a markedly reduced prothrombin level (hypoprothrombinemia) or by functionally abnormal prothrombin (dysprothrombinemia). Laboratory testing in homozygous patients shows prolonged PT and PTT; specific prothrombin assays are diagnostic. Mucocutaneous bleeding in infancy and posttraumatic bleeding later are common. Patients are treated with either FFP or PCC at doses of 15-25 mL/kg or 20-40 U/kg, respectively. The half-life of prothrombin is 3-4 days, and once weekly prophylaxis regimens with PCC are reported.

Acquired factor II deficiency can be seen with a small percentage of patients with a lupus anticoagulant and is usually associated with significant bleeding. It is distinguished from inherited prothrombin deficiency by clinical history and the laboratory identification of antiphospholipid antibodies and abnormal PTT mixing studies.

525.7 Factor V Deficiency

Benjamin J. Samelson-Jones, Brian R. Branchford, and Veronica H. Flood

Deficiency of factor V is an autosomal recessive, mild to moderate bleeding disorder. Factor V circulates with 80% in plasma and 20% in platelet α-granules; this platelet factor V pool has been suggested to ameliorate the bleeding that might be expected from low plasma factor V levels. The most common symptoms are epistaxis, oral cavity bleeding, heavy menstrual periods, and postoperative bleeding; joint, muscle, and intracranial hemorrhages occur rarely.

Laboratory evaluation shows prolonged PT and PTT. Specific assays for factor V show a reduction in factor V levels. FFP is the only currently available therapeutic product that contains factor V. Factor V is lost rapidly from stored FFP. Treatment for major surgery or bleeding is usually 15-25 mL/kg FFP followed by additional doses of 10 mL/kg every 12 hours. Twice weekly FFP prophylaxis regimens are sometimes used for patients with severe bleeding. Platelet transfusions are also an option for acute or prophylactic treatment. Rarely, a patient with a negative family history of bleeding has an *acquired antibody* to factor V, which can be identified in laboratory mixing studies.

525.8 Combined Deficiency of Factors V and VIII

Benjamin J. Samelson-Jones, Brian R. Branchford, and Veronica H. Flood

Combined deficiency of factors V and VIII is an autosomal recessive bleeding disorder that occurs secondary to the absence of intracellular transporters responsible for the shuttling of factors V and VIII from the endoplasmic reticulum to the Golgi compartments, as the result of pathogenic variants in the genes *LMAN1* or *MCFD2*. Factor V and VIII levels are usually between 5–20% of normal. Bleeding symptoms are often mild and most commonly mucocutaneous, traumatic, surgical bleeding. Treatment for major bleeding or surgery is 15-25 mL/kg of FFP.

525.9 Congenital Fibrinogen Disorders

Benjamin J. Samelson-Jones, Brian R. Branchford, and Veronica H. Flood

Congenital fibrinogen disorders are a heterogenous group of rare autosomal recessive or dominant diseases because of qualitative **(dysfibrinogenemia)** or quantitative (**hypofibrinogenemia** or **afibrinogenemia**) reductions in functional fibrinogen. Fibrinogen cleavage by thrombin into fibrin is the final step of the coagulation cascade: polymerization follows cleavage and results in fibrin clot formation. Fibrinogen is also the major integrin ligand during platelet aggregation. Conversely, fibrin also sequesters thrombin to the site of clot formation and supports fibrinolysis by enhancing the activation of plasminogen. The multiple roles of fibrinogen and fibrin in hemostasis underlie the phenotypes of inherited fibrinogen disorders, which can have bleeding and clotting clinical manifestations, sometimes in the same patient. The most common bleeding symptoms are mucocutaneous, soft-tissue, joint, genitourinary, traumatic, surgical bleeding, and heavy menstrual periods. Both venous and arterial thrombosis are rare in the quantitative defects but occur in about 20% of cases of dysfibrinogenemia. Some congenital fibrinogen disorders also have nonhematologic manifestations, including liver disease due to retention of misfolded protein, poor wound healing, and splenic rupture.

Diagnosis is based on a decreased fibrinogen activity. Patients usually will also have a prolonged PT and PTT. Dysfibrinogenemia is defined as a decreased ratio of fibrinogen activity compared to fibrinogen antigen. Treatment for bleeding or major surgery is with FFP, cryoprecipitate, or fibrinogen concentrates, depending on local availability. Because of the variable clinical manifestations, including both bleeding and clotting complications, treatment is tailored to the personal and family history. The half-life of fibrinogen is 2-4 days.

525.10 Factor XIII Deficiency (Fibrin-Stabilizing Factor or Transglutaminase Deficiency)

Benjamin J. Samelson-Jones, Brian R. Branchford, and Veronica H. Flood

Factor XIII deficiency is a rare autosomal bleeding disorder. Factor XIII is a heterotetramer composed of two catalytic A subunits and two carrier B subunits; activation of factor XIII by thrombin frees the activated A subunits, which covalently crosslink fibrin to increase clot strength and constrain fibrinolysis. The different biochemical roles of the A and B subunits result in distinct clinical manifestations. Inherited deficiencies in the factor XIII A-subunit results in soft tissue, umbilical, surgical, joint, and intracranial bleeding; the latter occurs in about a third of cases. Deficiencies in the B-subunit are associated with mild mucocutaneous and surgical bleeding. Because of its role in stabilizing the fibrin clot, factor XIII deficiency often presents with *delayed* abnormal bleeding or bruising symptoms where patients may have mild trauma and then present with an excessive hematoma on the following day. Extrahematologic clinical manifestation of factor XIII deficiency includes delayed umbilical cord separation, poor wound healing, and recurrent miscarriages.

Unlike the other severe inherited coagulation deficiencies, factor XIII deficiency will have normal PTT and PT. Specific activity assays are diagnostic and should be considered in infants with delayed umbilical cord separation, delayed bleeding symptoms, or unexplained intracranial hemorrhage. Treatment for bleeding or major surgery is 20-40 U/kg of factor XIII concentrate. Recombinant A-subunit protein is also available for A-subunit deficiencies. If specific factor XIII replacement therapies are not available, cryoprecipitate is preferred over FFP because of the substantially higher factor XIII content. The half-life of factor XIII is 9-12 days, which facilitates prophylaxis. Because of the high prevalence of intracranial hemorrhage, prophylaxis of 20-40 U/kg factor XIII concentrate every 4 weeks is recommended for patients with <10% normal activity. *Autoimmune acquired* factor XIII deficiency can be differentiated using specific mixing studies or activity assays of platelet lysates.

525.11 Antiplasmin or Plasminogen Activator Inhibitor Deficiency

Benjamin J. Samelson-Jones, Brian R. Branchford, and Veronica H. Flood

Deficiency of either antiplasmin or plasminogen activator inhibitor, both of which are antifibrinolytic proteins, results in increased plasmin generation and premature lysis of fibrin clots. Affected patients have a mild-to-moderate bleeding disorder characterized by delayed bleeding symptoms, typically associated with trauma or surgery. Mucocutaneous bleeding and heavy menstrual bleeding are the most described symptoms, with rare reports of joint or intracranial hemorrhages.

Because results of the usual hemostatic tests are normal, further workup of a patient with a positive bleeding history (especially delayed bleeding) should include *euglobulin clot lysis time*, which measures fibrinolytic activity and yields a shortened result in the presence of these deficiencies. Specific assays for α_2-antiplasmin and plasminogen activator inhibitor are available, although the lower limit of normative values of these assays are not well defined. Antifibrinolytic therapies such as aminocaproic acid or tranexamic acid are the mainstay of treatments for controlling or preventing bleeding because they mitigate the hyperfibrinolysis. FFP can also be used to replace the deficient proteins.

Chapter 526

Von Willebrand Disease

Brian R. Branchford and Veronica H. Flood

Von Willebrand disease (VWD) is the most common inherited bleeding disorder, with an estimated prevalence cited at 1:100 to 1:10,000 depending on the criteria used for diagnosis. Patients with VWD typically present with mucosal bleeding. A family history of either VWD or bleeding symptoms and confirmatory laboratory testing are also required for the diagnosis of VWD.

PATHOPHYSIOLOGY

VWD is caused by a defect in, or deficiency of, von Willebrand factor (VWF). VWF has several functions in coagulation. VWF serves to tether platelets to injured subendothelium via binding sites for platelets and for collagen. VWF also serves as a chaperone, or carrier protein, for factor VIII (FVIII), protecting it from degradation in plasma. VWF is stored in endothelial cell Weibel-Palade bodies and platelet dense granules and circulates as a large, multimeric glycoprotein. Shear stress induces a conformational change in VWF that facilitates its ability to bind platelets through an exposed binding site on platelet glycoprotein Ib (GPIb). This enables VWF to recruit platelets to the site of clot formation, a function dependent on the high molecular weight (HMW) multimer forms of VWF.

VWD typically presents with mucocutaneous bleeding, similar to that seen with other platelet defects. **Epistaxis, easy bruising,** and **menorrhagia** in females are common complaints. However, symptoms are variable and do not necessarily correlate well with VWF levels. **Surgical bleeding**, particularly with dental extractions or adenotonsillectomy, is another common presentation. Severe type 3 VWD may present with joint and/or muscle bleeds. Most patients will have a family history of bleeding, but the VWD genetic variant demonstrates incomplete penetrance (not all carriers of the variant express bleeding symptoms) and variable expressivity (different VWF levels can be found in individuals with the same gene variant). Females are more likely to be diagnosed with VWD because of the potential for symptoms with menorrhagia, but males and females are equally likely to have VWD. However, diagnosis based on symptoms may be difficult, since minor bruising and epistaxis are not uncommon in childhood. Significant unexplained bruising, or bruising in unusual areas (stomach, back, face), in infants and toddlers is more often from nonaccidental trauma than from an underlying bleeding disorder. Gastrointestinal bleeding due to VWD may be complicated by associated angiodysplastic lesions anywhere in the gastrointestinal tract.

CLASSIFICATION

VWD may be caused by quantitative or qualitative defects in VWF. Mild to moderate quantitative defects are classified as type 1 VWD, whereas severe quantitative defects, in which there is no detectable VWF protein, are classified as type 3 VWD. The qualitative defects are grouped together as type 2 VWD.

Type 1 VWD is by far the most common type, accounting for 60–80% of all VWD patients. Typical symptoms include mucosal bleeding, such as epistaxis and menorrhagia, as well as easy bruising and potentially surgical bleeding. Diagnostic guidelines use a VWF level, as measured by the VWF antigen assay **(VWF:Ag)**, of <30 IU/dL for a clear diagnosis of VWD. Antigen and activity are usually symmetrically depressed in type 1 VWD. Patients with VWF:Ag <30 IU/dL are most likely to have a genetic defect in VWF. Patients with VWF:Ag between 30 and 50 IU/dL are said to have "low VWF." Whether or not this category truly represents VWD is a subject of some debate, and the joint guidelines suggest that the resolution should be based on presence or absence of bleeding symptoms. Because some patients with VWF levels in this range do experience bleeding, many physicians elect to treat them, especially perioperatively, for surgical procedures such as tonsillectomy.

Patients with type 1 VWD may have low VWF as a result of increased clearance of their VWF, known as **type 1C VWD**. Diagnosis of this subtype is important *because treatment of these patients with desmopressin is likely to be ineffective, necessitating administration of VWF-containing products instead.*

VWF levels can be influenced by external factors. Blood type has long been known to affect VWF, with lower VWF levels seen in people with blood group O. Stress, inflammation, exercise, menstrual cycle, and pregnancy all increase VWF levels; therefore a single normal VWF level does not necessarily rule out the presence of VWD. Certain diseases, such as **hypothyroidism** (see Chapter 603), and medications, such as valproic acid, can lower VWF levels in affected patients. Repeat testing is often required to confidently rule out or confirm a diagnosis of VWD.

Type 3 VWD is the most severe form and presents with symptoms similar to those seen in *mild hemophilia.* In type 3 VWD the VWF protein is completely absent, and the activity and antigen are both essentially zero. Type 3 VWD is seen at a frequency of approximately 1/1,000,000 members of the general population. In addition to mucosal bleeding, patients may experience joint bleeds, muscle bleeds, or central nervous system (CNS) hemorrhage. Some physicians elect to treat patients with prophylaxis, or modified prophylaxis, after injury, given that these patients typically have very low FVIII (<10 IU/dL). Because type 3 VWD is caused by a complete lack of VWF, *desmopressin is ineffective and treatment with VWF-containing concentrates is required.*

Type 2 VWD is often suspected when a discrepancy exists between the VWF antigen level (often normal) and the VWF activity (often low) because this type represents a qualitative defect, in which an abnormal protein is produced in normal amounts. A ratio of activity to antigen of less than 0.7 may raise concern for type 2 VWD, which itself has multiple subtypes. Multimer evaluation or other specialized testing can be used to discriminate the type 2 subtypes.

Type 2A VWD is characterized by a defect in VWF multimerization and decreased VWF activity in terms of platelet binding. It is the most common of the type 2 variants, accounting for approximately 10% of VWD cases. Type 2A VWD can result from variants that affect multimer assembly and processing, or variants that result in increased proteolysis of secreted VWF. Some variants affect both secretion and clearance of the VWF. Regardless of the mechanism, all type 2A VWD patients lack the HMW multimers, and therefore have reduced VWF activity, which results in bleeding. Symptoms are typically more severe than those seen in type 1 VWD. *Desmopressin may have clinical efficacy for treatment of minor bleeding, but significant surgical challenges or major bleeding symptoms generally require a VWF-containing concentrate for treatment.*

Type 2B VWD results from gain-of-function variants that increase the ability of VWF to bind platelets. This leads to increased clearance of both VWF and platelets from circulation and results in the loss of HMW multimers and decreased VWF activity, similar to that seen in type 2A VWD. Special testing is therefore required to diagnose type 2B VWD, either by direct measurement of the increased platelet binding or by an increased response to low dose ristocetin on platelet aggregation testing. Thrombocytopenia is not always present and may be more prominent during times of stress such as surgery or pregnancy. *Desmopressin is relatively contraindicated in type 2B VWD because it may accelerate VWF-platelet binding and clearance, so treatment with VWF-containing product is necessary.*

Platelet-type pseudo-VWD occurs when a variant in platelet GPIb causes spontaneous binding to VWF and also presents with decreased VWF activity, loss of HMW multimers, and thrombocytopenia similar to type 2B VWD. Specific testing is required to distinguish the two conditions. Because the defect involves platelets, treatment generally requires platelet transfusion.

Type 2M VWD includes those patients with decreased VWF activity but normal (or near normal) multimer distribution. This is generally caused by a defect in the ability of VWF to bind platelet GPIb, but this category also includes patients with defects in VWF-collagen interactions. *Some minor bleeding in type 2M VWD may respond to desmopressin, but because type 2M VWD is a functional defect, treatment with VWF-containing concentrates is usually required.*

Table 526.1 Laboratory Testing for von Willebrand Disease (VWD)

TEST	ABBREVIATION	PURPOSE
VWF antigen	VWF:Ag	Measures total amount of VWF protein present.
VWF activity	VWF:RCo*	Assesses interaction of VWF and platelets as mediated by ristocetin.
VWF activity/antigen ratio	VWF:RCo/VWF:Ag	A decreased ratio (<0.7) is found in type 2A, type 2B, and type 2M VWD.
Factor VIII activity	FVIII	Measures circulating FVIII, which will be very low in type 2N and type 3 VWD.
Multimer distribution	VWF multimers	Allows visualization of VWF multimers, used to identify high molecular weight multimers, which will be absent in types 2A and 2B VWD.

*In some laboratories a GPIb-binding assay, the VWF:GPIbM, is available.
VWF, Von Willebrand factor; GPIb, glycoprotein Ib; RCo, ristocetin cofactor.

Table 526.2 Classification of von Willebrand Disease

	TYPE 1	TYPE 3	TYPE 2A	TYPE 2B*	TYPE 2M	TYPE 2N
VWF:Ag	↓	Absent	↓	↓	↓	Normal or ↓
VWF:RCo	↓	Absent	⇊	⇊	⇊	Normal or ↓
FVIII	Normal	⇊	Normal or ↓	Normal or ↓	Normal or ↓	⇊
Multimer distribution	Normal	Absent	Loss of HMWM	Loss of HMWM	Normal	Normal

*Platelet count is also usually decreased in type 2B VWD.
FVIII, factor VIII; HMWM, high molecular weight multimers; VWF:Ag, von Willebrand factor antigen; VWF:RCo, VWF ristocetin cofactor activity.

Type 2N VWD is characterized by a defect in the ability of VWF to bind FVIII. Some patients with type 2N VWD may be misdiagnosed as mild hemophilia; therefore a high index of suspicion for this diagnosis is required in patients with low FVIII and an absent family history of FVIII deficiency. *Because the VWF in this case is dysfunctional, desmopressin is not usually helpful, and VWF-containing product infusion is typically required.*

LABORATORY DIAGNOSIS

There are no reliable screening tests for VWD. Patients with significant bleeding may present with anemia, and some patients with type 2B VWD or platelet-type pseudo-VWD may have thrombocytopenia. The partial thromboplastin time (PTT) may be prolonged if FVIII is low but especially in type 1 VWD it is often normal, precluding use of the PTT as a screening test. Platelet function analysis has been considered as a screening test for VWD, but suboptimal sensitivity and specificity render results difficult to interpret. Bleeding times are similarly unreliable in diagnosis of VWD.

Unfortunately, no single test can reliably diagnose VWD; therefore a panel of tests is usually required (Table 526.1). These include VWF:Ag, which measures the total amount of VWF protein present, and VWF activity test, typically using the *ristocetin cofactor* activity assay **(VWF:RCo)**, which provides a measure of the amount of functional VWF. FVIII activity is also usually included in the workup. Another test measures VWF binding to platelet GPIb without ristocetin **(VWF:GPIbM)**. This test is now FDA approved and its use is increasing. Collagen binding measures an additional function of VWF. Multimer distribution provides an assessment of HMW multimers (Table 526.2; Fig. 526.1).

Additional specialized testing may be employed to help determine the correct diagnosis. Specific testing for type 1C (clearance defects), type 2B, and type 2N VWD can confirm these diagnoses. Genetic diagnosis is not typically performed, partly because of the large size of the VWF gene and the high number of benign sequence variations. Large gene deletions are responsible for some cases of VWD and will not be detected on routine DNA sequencing. However, use of genetic diagnosis is increasing, particularly for types 2A, 2B, 2M, and 2N VWD.

TREATMENT

Treatment of VWD depends on the type of VWD present and the reason for treatment (Table 526.3). In general, type 1 VWD patients may be treated with **desmopressin**, which increases the amount of circulating VWF (and FVIII) by release from storage in endothelial cells. The exceptions are the rare type 1 patient who lacks a response to desmopressin and patients with type 1C VWD who do respond with an increase in VWF levels, but whose rapid clearance of circulating endogenous VWF results in a rapid return to baseline levels. Treatment of types 2 and 3 VWD requires **VWF-containing concentrates,** similar to the treatment of hemophilia. Dosing depends on the type of VWD and the reason for treatment. Careful monitoring of VWF and FVIII levels is recommended to tailor treatment for surgeries and major trauma. For all types of VWD, adjunct therapy should be considered when possible, such as the use of antifibrinolytics for oral surgery or hormonal treatment for menorrhagia.

Alternate treatment strategies should also be considered, particularly for difficult symptoms or severe VWD. Hormonal therapy for females with menorrhagia, although not specific to VWD, can be very helpful in managing symptoms and improving quality of life. Local treatment of epistaxis, such as nasal cautery or packing, may be helpful in some circumstances. Iron therapy for patients with iron-deficiency anemia may also be required.

Table 526.3 Treatment of Von Willebrand Disease

TREATMENT	VWD TYPES	ROUTE	DOSING
Desmopressin*	Type 1 VWD Some type 2 VWD (use with caution)	IV or IN	0.3 μg/kg IV† 1 spray IN (<50 kg) 2 sprays IN (>50 kg)
Von Willebrand factor (VWF) concentrates‡	Type 3 VWD Type 2 VWD Severe type 1 VWD (or type 1 clearance defects)	IV	40-60 ristocetin cofactor activity units/kg (adjust dose depending on baseline VWF level and desired peak VWF level). If recombinant VWF used, may need to administer additional recombinant FVIII for emergency treatment.
Antifibrinolytics	Mucosal bleeding, all types of VWD	PO or IV	Aminocaproic acid: 100 mg/kg PO loading dose followed by 50 mg/kg every 6 hr§ Tranexamic acid: 1,300 mg PO 3 times daily for 5 days

*Recommended treatment with Stimate brand nasal spray because this form is concentrated to give 150 μg/spray. Other forms are much more dilute and will not result in desired increase in VWF.
†Maximum recommended dose is 20-30 μg/day.
‡Currently both Humate-P and Wilate are approved for treatment of VWD. Vonvendi is a recombinant VWF that is also approved for treatment of VWD but does not contain FVIII.
§Maximum recommended dose is 24 g/day.
IN, Intranasal; IV, intravenous; PO, oral administration.

Chapter 527

Hereditary Predisposition to Thrombosis

Benjamin J. Samelson-Jones and Leslie J. Raffini

Most children that develop clots have multiple risk factors, which may include inherited predispositions to thrombosis. The strength of the inherited prothrombotic risk factors varies. An estimated 30–60% of individuals with *strong* thrombophilias, such as antithrombin deficiency, protein C deficiency, and protein S deficiency, develop thromboembolic disease by age 60; in contrast, less than 10% of individuals with *weak* thrombophilias, such as heterozygous factor V Leiden variant or prothrombin *G20210A* gene variant, develop thromboembolic disease. The inherited thrombophilias with the best understood pathogenesis, population prevalence, and prothrombotic risks are listed in Table 527.1. Some of these disorders may also be acquired or mixed acquired and genetic (Table 527.2).

The inheritance of other thrombophilias is less well understood. Elevated levels of factor VIII (FVIII) and homocysteine are associated with thrombosis, but their levels are not necessarily genetically determined. Additional alterations in plasma proteins have also been associated with increased thrombotic risk, such as elevated concentrations of factors IX and XI, heparin cofactor II deficiency, elevated lipoprotein (a), and dysfibrinogenemia; however, these abnormalities have not gained widespread acceptance in routine testing of children for inherited thrombophilia.

In general, the prothrombotic tendency conferred by these defects is either a result of an increased procoagulant effect (prothrombin gene pathogenic variant, elevated FVIII, hyperhomocysteinemia) or a decreased anticoagulant effect (factor V Leiden, deficiency of protein C, protein S, or antithrombin). Although numerous inherited risk factors for thrombosis have been identified, the majority of individuals who inherit one of these risk factors, even strong thrombophilias, do not necessarily develop thrombosis during childhood. Before evaluating for these disorders, both the limitations of the testing and potential benefits need to be considered.

The **factor V Leiden pathogenic variant** is the result of a single base pair change at nucleotide 1765 within the factor V gene causing an R506Q amino acid substitution in the encoded protein. This pathogenic variant causes activated factor V to become resistant to inactivation by activated protein C. It is the most common inherited risk factor for thrombosis, although its prevalence varies across ethnicities. Individuals who are heterozygous have a 5-7–fold increased relative risk of venous thrombosis, whereas homozygous individuals have an even higher risk. There appears to be a synergistic prothrombotic risk enhancement with the inherited risk of factor V Leiden and the acquired risk of estrogen-containing contraceptives. The baseline annual risk of thrombosis for females of reproductive age is approximately 1/10,000 and increases to 1/2,500 for those taking estrogen-containing contraceptives. For young females who are heterozygous for the factor V Leiden pathogenic variant and on estrogen-containing contraceptives, the annual risk of venous thromboembolism (VTE) increases to 1 in 200. The **prothrombin 20210 gene pathogenic variant** is a G-to-A transition in the 3' untranslated region of the gene that results in increased levels of prothrombin. It is a weaker risk factor for venous thrombosis than factor V Leiden.

Deficiencies of the natural anticoagulation proteins (protein C, protein S, and antithrombin) are less common than the specific genetic pathogenic variants mentioned previously but are associated with a stronger risk of thrombosis. Although heterozygous deficiencies do not often present during childhood, homozygous defects may be embryonically lethal or result in significant symptoms in infancy. Neonates with *homozygous* deficiencies of protein C or protein S may present with **purpura fulminans**. This rare condition is characterized by rapidly spreading purpuric skin lesions resulting from thromboses of the small dermal vessels, followed by bleeding into the skin. In addition, these infants may also develop cerebral thrombosis, ophthalmic thrombosis, disseminated intravascular coagulation, and large-vessel thrombosis. An infant with purpuric skin lesions of unknown cause should receive empiric replacement with fresh-frozen plasma. Definitive diagnosis can be difficult in the sick premature neonate, who may have undetectable levels of these factors but not have a true genetic deficiency. Protein C and antithrombin concentrates are also available and have been demonstrated to be effective.

Elevated levels of homocysteine have been associated with venous *and* arterial thromboses, although the pathogenic mechanisms for thrombosis in homocystinemia are poorly understood. Thromboembolic complications are well described in children with **homocystinuria,** a rare inborn error of metabolism caused by deficiency of cystathione β-synthase that results in plasma levels of homocysteine

Table 527.1 Clinically Relevant Inherited Thrombophilias and Accompanying Diagnostic Laboratory Studies

THROMBOPHILIA	GENERAL POPULATION PREVALENCE (%)	VTE ADULT PATIENT PREVALENCE (%)	ANNUAL INCIDENCE OF VTE (%)	ODDS RATIO FOR FIRST VTE EPISODE IN CHILDHOOD	ODDS RATIO FOR RECURRENT VTE EPISODE IN CHILDHOOD	LABORATORY STUDIES

Prothrombin FII G20210A	Myeloproliferative disorders	
Elevated factor VIII, IX, or XI		

Modified from Hoffman R, Benz Jr. EJ, Silberstein LE, et al., eds. *Hematology Basic Principles and Practice*, 7th ed. Philadelphia: Elsevier, 2018: Table 140.1, p. 2077.

that exceed 100 μmol/L. Much more common are mild to moderate elevations of homocysteine, which may be acquired or associated with a polymorphism in the methylenetetrahydrofolate reductase *(MTHFR)* gene. Although moderate elevations of homocysteine have been associated with both venous and arterial thrombotic events, testing for polymorphisms in the *MTHFR* gene is not indicated because these polymorphisms are common and by themselves (without homocystinemia) are not associated with thromboembolism.

Increased plasma concentrations of FVIII appear to be regulated by both genetic and environmental factors and are associated with an increased risk of thrombosis. High FVIII levels are usually polygenic, although rarely specific changes in the FVIII gene have been identified. FVIII is also an acute-phase reactant and may increase during periods of inflammation.

Although interpretation of gene testing is fairly straightforward, several challenges in interpretation of thrombophilia studies are unique to pediatric patients. Neonates have decreased concentrations of protein C, protein S, and antithrombin that increase rapidly over the first 6 months of life; protein C concentrations remain below adult levels throughout much of childhood. It is important to use pediatric normal ranges when evaluating these values and recognize that often the normal range overlaps with heterozygous defects and that retesting may be required, particularly in young children. Several nongenetic factors may also influence the results of inherited thrombophilia testing, including acute thrombosis, infection, inflammation, hepatic dysfunction, nephrotic syndrome, medication, and vitamin K deficiency. In some patients the hereditary nature may be confirmed by testing the parents.

Thrombophilia testing is considered during childhood when a child develops thrombosis or if a child has relatives with thrombosis or thrombophilia. Thrombophilia testing rarely influences the acute management of a child with a thrombotic event. The majority of children who develop thrombosis have multiple, coexistent *acquired* risk factors (see Table 528.1 in Chapter 528). More than 90% of thromboses in children are associated with indwelling intravascular catheters; inherited thrombophilias are uncommon in this scenario, and testing is generally not warranted. However, inherited thrombophilia is more common in an otherwise healthy child or adolescent who develops a blood clot or in a child who develops unusual or recurrent thrombosis. Thrombophilia testing may be useful in these situations because it may help explain why the child developed a blood clot and inform on the duration of therapy. However, current treatment recommendations do not differ based on the presence or absence of an inherited thrombophilia. The identification of an inherited anticoagulant protein defect, such as antithrombin or protein C deficiency, may allow for replacement therapies while off anticoagulation, such as in the perioperative setting.

The decision to perform thrombophilia testing in an otherwise healthy child with a **family history** of thrombosis or thrombophilia should be carefully considered, weighing the potential advantages and limitations of such an approach. Given that the absolute risk of thrombosis in children is extremely low (0.07/100,000), it is unlikely that an inherited thrombophilia will have any impact on clinical decision-making for a young child. The risk of thrombosis increases with age, so identification of a thrombophilic defect in an adolescent may guide primary thromboprophylaxis in high-risk situations (lower-extremity casting or prolonged immobility), inform the discussion about estrogen-based contraceptives, and promote lifestyle modification to avoid behavioral risk factors (sedentary lifestyle, dehydration, obesity, and smoking). Limitations of such testing include the cost as well as the potential for causing unnecessary anxiety or false reassurance.

In most patients with inherited thrombophilia, the treatment is the same as for patients with no inherited disorders (see Chapter 528). In neonates with purpura fulminans caused by homozygous protein C or S deficiency or in patients with warfarin-induced skin necrosis, heparin-induced thrombocytopenias and severe antithrombin deficiency often require factor replacement (protein C, S or antithrombin concentrates or plasma) in addition to unfractionated heparin or low molecular weight heparin. In less severe antithrombin deficiency, higher than usual doses of heparin may be needed.

Chapter 528

Thrombotic Disorders in Children

Leslie J. Raffini and Brian R. Branchford

Thromboembolic events (TEs) are seen in pediatric tertiary care centers and may result in significant acute and chronic morbidity. TEs in children are rare. Diagnosis and treatment are often extrapolated from adult data because of a current lack of high-quality data in the pediatric setting.

EPIDEMIOLOGY

Although the overall incidence of thrombosis in the general pediatric population is quite low (0.07/100,000), the rate of **venous thromboembolism (VTE)** in hospitalized children is 60/10,000 admissions. Infants <1 year old account for the largest proportion of pediatric VTEs, with a second peak during adolescence.

Most children who develop a TE have multiple risk factors that may be acquired, inherited, or anatomic (Table 528.1). The presence of a central venous catheter (CVC) or peripherally inserted central venous catheter (PICC) is the most important risk factor for VTE in pediatric patients, associated with approximately 90% of neonatal VTE and 60% of childhood VTE. PICC lines may be among the highest-risk CVC subtypes. CVCs are often necessary for the care of premature neonates and children with acute and chronic diseases and are used for intravenous (IV) hyperalimentation, chemotherapy, dialysis, antibiotics, or supportive therapy. CVCs may damage the endothelial lining and/or cause blood flow disruption, increasing the risk of thrombosis. Many other acquired risk factors are associated with thrombosis, including trauma, surgery, infection, inflammation, chronic medical conditions, and certain medications. Cancer, congenital heart disease, and prematurity are the most common medical conditions associated with TEs.

Antiphospholipid antibody syndrome (APS) is characterized by recurrent fetal loss and/or thrombosis (Table 528.2). Antiphospholipid antibodies are associated with venous and, less often, arterial thrombosis. The autoantibodies in APS include lupus anticoagulant, anticardiolipin antibodies, and anti-β_2 glycoprotein I. If all three antibodies are positive **(triple positive)**, the risk of thrombosis is increased. The mechanism by which these antibodies cause thrombosis is not well understood. A diagnosis of APS requires the presence of both clinical and laboratory abnormalities (see "Laboratory Testing"). The laboratory abnormalities must be identified on two separate occasions, at least 12 weeks apart. Because of the high risk of VTE recurrence, patients with APS often require long-term anticoagulation, at least until the antibodies have resolved; the type of antibodies and the presence of arterial thrombosis may have important implications for the type of anticoagulant therapy chosen. Up to 20% of healthy children may have a *transient* lupus anticoagulant, often diagnosed because of a prolonged partial thromboplastin time (PTT) on routine preoperative testing. In this setting, transient antibodies may be associated with a recent viral infection and are not a risk factor for thrombosis. APS is also noted in patients with **systemic lupus erythematosus** (see Chapter 199) and may also be associated with livedo reticularis, neuropsychiatric complications, thrombocytopenia, or anemia; these patients are often persistently positive for the antiphospholipid antibody. **Catastrophic antiphospholipid syndrome** is a rare and potentially fatal disorder characterized by rapid onset of multiorgan thrombosis and/or thrombotic microangiopathies (Table 528.3).

Anatomic abnormalities that impede blood flow also predispose patients to thrombosis at an earlier age. Atresia of the inferior vena cava has been described in association with acute and chronic lower-extremity deep vein thrombosis **(DVT)**. Compression of the left iliac vein by the overlying right iliac artery **(May-Thurner syndrome)** should be considered in patients who present spontaneously with left iliofemoral thrombosis, and thoracic outlet obstruction **(Paget-Schroetter syndrome)** frequently presents with effort-related axillary-subclavian vein thrombosis.

CLINICAL MANIFESTATIONS

Extremity Deep Vein Thrombosis

Children with acute DVT often present with extremity pain, swelling, and discoloration (see Table 524.1). A history of a current or recent CVC in that extremity should be very suggestive. Many times, symptoms of CVC-associated thrombosis are more subtle and chronic, including repeated CVC occlusion (potentially requiring clearance with tissue plasminogen activator [tPA]) or sepsis, or prominent venous collaterals on the chest, face, and neck.

Pulmonary Embolism

Signs and symptoms classically include shortness of breath, pleuritic chest pain, cough, hemoptysis, fever, tachypnea, tachycardia, and/or, in the case of massive pulmonary embolism (PE), hypotension and right-sided heart failure. Based on autopsy studies in pediatric centers, PE is often undiagnosed because young children are unable to describe their symptoms accurately, and their respiratory deterioration may be masked by other conditions (see Chapter 458.1).

Cerebral Sinovenous Thrombosis

Signs and symptoms of cerebral sinovenous thrombosis (CSVT) may be subtle and may develop over many hours or days (see Table 524.1). Neonates with CSVT often present with seizures, whereas older children often complain of headache, vomiting, seizures, visual changes, and/or focal neurologic signs. They may also have papilledema and abducens palsy. Older patients may have a concurrent sinusitis or mastoiditis that has contributed to the thrombosis. Other risk factors may include trauma, meningitis, or dehydration.

Renal Vein Thrombosis

Renal vein thrombosis (RVT) is the most common spontaneous VTE in neonates (see Table 524.1). Affected infants may present with hematuria, an abdominal mass, and thrombocytopenia. Infants of diabetic mothers are at increased risk for RVT, although the mechanism for the increased risk is unknown. Approximately 25% of cases are bilateral.

Portal Vein Thrombosis

Portal vein thrombosis (PVT) often occurs during the neonatal period and is often asymptomatic, only manifesting in those patients who develop symptomatic portal hypertension (e.g., gastrointestinal [GI] bleeding, splenomegaly) after the initial thrombotic event (see Table 524.1). The most common risk factor associated with PVT is an umbilical venous catheter, although sepsis, pancreatitis, cirrhosis, liver transplant, splenectomy, and sickle cell disease are also notable risk factors. A known complication of PVT is cavernous transformation, which confers a risk for variceal bleeding.

Peripheral Arterial Thrombosis

The majority of arterial TEs in children are associated with catheters, often related to umbilical artery lines in neonates or cardiac catheterization via the femoral artery (see Table 524.1). Less common etiologies of arterial thrombosis include homocystinuria and APS. Patients with an arterial thrombosis affecting blood flow to an extremity will present with a cold, pale extremity with poor or absent pulses, which can signify a limb-threatening emergency.

Acute Ischemic Stroke

Acute ischemic stroke (AIS) typically presents with hemiparesis, slurred speech, altered consciousness, or seizures. This condition may occur secondary to pathology that affects the intracranial arteries (e.g., sickle cell disease, vasculitis, vasculopathy, traumatic arterial dissection, or paradoxical embolism across a patent foramen ovale) or may result from venous thrombi that embolize to the arterial circulation (placental

Immune checkpoint inhibitors
Hemophilia bypassing agents

PICC, Peripherally inserted central venous catheter.

thrombi, children with congenital heart disease, or patent foramen ovale allowing right-to-left shunting of an embolic venous thrombosis).

Rapidly Progressive Thrombosis (Thrombotic Storm)

Rapid progression or multifocal thrombosis is a rare complication of APS **(catastrophic antiphospholipid syndrome)**, or heparin-induced thrombocytopenia with thrombosis (see Table 528.3). Multiorgan dysfunction develops in the presence of small vessel occlusion and elevated D-dimer levels, and this may progress to disseminated intravascular coagulation. Treatment includes aggressive anticoagulation, often with direct thrombin inhibitors or fondaparinux, followed by prolonged warfarin therapy. In rare cases, plasmapheresis and/or immunosuppression and/or antiinflammatory therapy may be warranted.

DIAGNOSIS

Compression ultrasound with Doppler flow is the most common imaging study for the diagnosis of extremity DVT and chest CT is used most frequently for the diagnosis of PE (Fig. 528.1). Echocardiogram is often used to detect and follow right atrial clots, most often detected in patients with central catheter tips in the right atrium. Other diagnostic imaging options include CT and MR venography, which are noninvasive, although the sensitivity and specificity of these studies is not known. These studies may be particularly helpful in evaluating proximal or abdominal thrombosis. For the diagnosis of CSVT and AIS, the most sensitive imaging study is brain MRI with venography or diffusion-weighted imaging.

Table 528.2 Sydney Investigational Criteria for the Diagnosis of the Antiphospholipid Syndrome

CLINICAL
• Vascular thrombosis (one or more episodes of arterial, venous, or small-vessel thrombosis). For histopathologic diagnosis, there should be no evidence of inflammation in the vessel wall.
• Pregnancy morbidities attributable to placental insufficiency, including: (a) three or more otherwise unexplained recurrent spontaneous miscarriages before 10 weeks of gestation, (b) one or more fetal losses after the 10th week of gestation, (c) stillbirth, and (d) episode of preeclampsia, preterm labor, placental abruption, intrauterine growth restriction, or oligohydramnios that are otherwise unexplained.
LABORATORY
• Medium- or high-titer aCL or anti-β_2GPI IgG and/or IgM antibody present on two or more occasions, at least 12 weeks apart, measured by standard ELISA.
• Lupus anticoagulant in plasma, on two or more occasions, at least 12 weeks apart, detected according to the guidelines of the ISTH SSC Subcommittee on Lupus Anticoagulants and Phospholipid-Dependent Antibodies.
"Definite APS" is considered present if at least one of the clinical criteria and one of the laboratory criteria are met.

aCL, Anticardiolipin; aPL, antiphospholipid; β_2GPI, β_2-glycoprotein I; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin.
Modified from Miyakis S, Lockshin MD, Atsumi T, et al. International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS). *Thromb Haemost.* 2006;4:295–306. Table 2.

Table 528.3 Proposed Criteria for the Classification of Catastrophic Antiphospholipid Syndrome

1. Evidence of involvement of three or more organs, systems and/or tissues*
2. Development of manifestations simultaneously or in less than a week
3. Confirmation by histopathology of small vessel occlusion in at least one organ or tissue†
4. Laboratory confirmation of the presence of antiphospholipid antibodies (lupus anticoagulant and/or anticardiolipin antibodies)‡
DEFINITE CATASTROPHIC APS
• All four criteria
PROBABLE CATASTROPHIC APS
• All four criteria, except for only involvement of two organs, systems, and/or tissues
• All four criteria, except for the absence of laboratory confirmation at least 6 weeks apart because of the early death of a patient never previously tested for aPL before the catastrophic APS event
• Criteria 1, 2, and 4
• Criteria 1, 3, and 4 and the development of a third event in more than a week but less than a month, despite anticoagulation

*Usually, clinical evidence of vessel occlusions, confirmed by imaging techniques when appropriate. Renal involvement is defined by a 50% rise in serum creatinine, severe systemic hypertension (≥180/100 mm Hg) and/or proteinuria (≥500 mg/24 h).
†For histopathologic confirmation, significant evidence of thrombosis must be present, although, in contrast with Sydney criteria, vasculitis may coexist occasionally.
‡If the patient had not been previously diagnosed as having an APS, the laboratory confirmation requires that the presence of antiphospholipid antibodies must be detected on two or more occasions at least 6 weeks apart (not necessarily at the time of the event), according to the proposed preliminary criteria for the classification of definite APS.
aPL, Antiphospholipid; APS, antiphospholipid syndrome

LABORATORY TESTING

All children with a VTE should have a complete blood count and a baseline prothrombin time (PT) and PTT to assess their coagulation status in

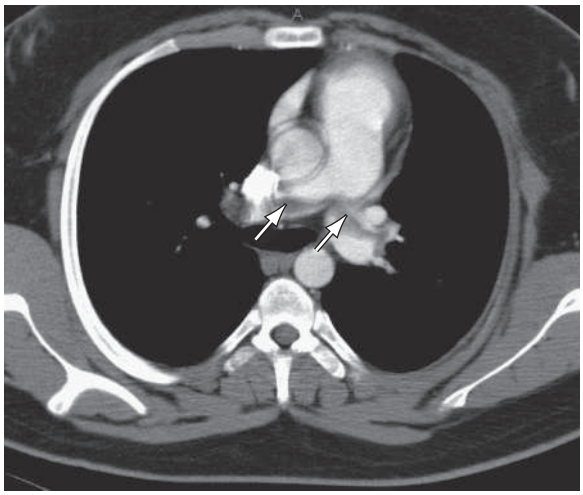

Fig. 528.1 Chest CT scan from a 15-yr-old male with a large pulmonary embolism. Large filling defects are present in the right and left main pulmonary arteries *(arrows)*.

anticipation of anticoagulation treatment. In adults with suspected DVT, the D-dimer level has a high negative predictive value, but the predictive value is not as well established for children. The D-dimer is a fragment produced when fibrin is degraded by plasmin and is a measure of both clot formation and subsequent fibrinolysis. Based on the clinical scenario, other laboratory studies, such as renal and hepatic function, may be indicated. Testing for APS includes evaluation for the lupus anticoagulant as well as anticardiolipin and anti–β_2-glycoprotein antibodies and should be considered in patients with inflammatory disorders, recent trauma, surgery, or infection, and those who present with thrombosis and no other obvious risk factors.

There is debate regarding which patients should have testing for inherited risk factors. Thrombophilia testing rarely influences the acute management of a child with a thrombotic event, and natural anticoagulants like protein C and S or antithrombin (AT) may appear to have low levels due to consumption during the acute phase of thrombosis, even if the patient does not have an existing deficiency of these proteins (see Chapter 527). Identification of an inherited thrombophilia may influence the duration of treatment, particularly for those with a *strong* thrombophilia, and may aid in counseling patients about their risk of recurrence. **Unprovoked** (absence of risk factors) thrombosis and a family history of thrombotic events may be a clue to an inherited thrombophilia, although they may coincide with a known risk factor.

The evaluation and interpretation of coagulation studies in pediatric patients may be complicated by the developing hemostatic system and the differences in normal ranges between infants and adults (see Chapter 527).

TREATMENT

Therapeutic options for children with thrombosis may include observation, anticoagulation, thrombolysis, and surgery. In premature neonates and critically ill children who are at high risk of bleeding, the potential benefits must be weighed against the risks, and close observation with repeat imaging may be an option. The majority of nonneonates with symptomatic thrombosis are treated with anticoagulant therapy. The goal of anticoagulation is to reduce the risk of embolism, halt clot extension, and prevent recurrence (see Chapter 528.1). Systemic or endovascular thrombolysis may be indicated for organ- or limb-threatening thrombosis. Surgery may be necessary for life- or limb-threatening thrombosis when there is a contraindication to thrombolysis. The optimal treatment for a child with AIS depends on the likely etiology and the size of the infarct and may include either anticoagulation or antiplatelet therapy such as aspirin. Children with sickle cell disease who develop stroke are treated acutely with erythrocytapheresis to rapidly lower the percentage of hemoglobin S and may also receive ongoing chronic red blood cell transfusions (or erythrocytapheresis) to reduce recurrence risk.

A summary of management recommendations for various types of VTE can be found in (Tables 528.4 and 528.5)

COMPLICATIONS

Complications of VTE include recurrent thrombosis (local or distant), and development of post-thrombotic syndrome (PTS). Over time, due to venous hypertension or damaged endovascular valves, patients may develop pain, swelling, edema, discoloration, and ulceration of the affected limb. Several prospective studies in adults have shown PTS to be present in 17–50% of patients with a history of thrombosis. The likelihood of developing PTS has been shown to increase with age, thrombus burden, and delay in anticoagulation therapy.

528.1 Anticoagulant and Thrombolytic Therapy

Leslie J. Raffini and Brian R. Branchford

Initial options for anticoagulation in children have generally included unfractionated heparin (UFH) or low molecular weight heparin (LMWH), followed by LMWH or warfarin for outpatient management (see Tables 528.4 and 528.5). Clinical trials of several direct oral anticoagulants (DOACs) have demonstrated the safety and efficacy of these drugs to treat VTE in children, and the landscape of treatment options for children with thrombosis is changing rapidly as these drugs gain regulatory approval. DOACs act by inhibiting factor Xa or thrombin (Table 528.6).

The optimal duration of anticoagulation for children with TEs is not well established. American Society of Hematology (ASH) guidelines recommend that pediatric patients with provoked DVT or PE receive ≤3 months of anticoagulation and those with unprovoked DVT or PE receive 6-12 months of therapy. Patients with strong inherited thrombophilia, recurrent thrombosis, and APS (or other nonmitigatable risk factors) may require indefinite anticoagulation.

UNFRACTIONATED HEPARIN

Both UFH and LMWH act by catalyzing the action of AT. UFH consists of large molecular weight polysaccharide chains that interact with AT, supporting the inhibition of factor Xa and thrombin, as well as other serine proteases.

Heparin Dosing

A therapeutic heparin dose achieves a prolongation of the PTT of 1.5-2.5 the upper limit of normal. A bolus dose of 75-100 units/kg results in a therapeutic PTT in the majority of children. This bolus should be followed by a continuous infusion. Initial dosing is based on age, with infants having the highest requirements. It is important to continue to monitor the PTT closely. In some situations, such as patients with a lupus anticoagulant, those with elevated factor VIII, or neonates, the PTT may not accurately reflect the degree of anticoagulation, and heparin can be monitored using a heparin anti-Xa level of 0.35-0.7 units/mL.

Heparin Complications

Maintaining the PTT in the therapeutic range can be difficult in young children. The bioavailability of heparin is difficult to predict and may be influenced by plasma proteins, including AT level. In many patients, this results in multiple dose adjustments requiring close monitoring with frequent venipuncture. UFH also requires continuous IV access, which may be difficult to maintain in young children.

The most common adverse effect related to heparin therapy is bleeding. There are case reports of life-threatening bleeding in children treated with heparin. The true frequency of bleeding in pediatric patients receiving heparin has not been well established and is reported as 1–24%. If the anticoagulant effect of heparin must be reversed immediately, protamine sulfate may be administered to neutralize the heparin. With an elimination half-life of approximately 30 minutes, the anticoagulant effect of this drug typically wears off in approximately 2-3 hours after stopping the infusion. UFH is cleared by the liver and kidney.

Other adverse effects include osteoporosis (with long-term use) and **heparin-induced thrombocytopenia (HIT)**. Although rare in pediatric populations, HIT is a prothrombotic, immune-mediated

Table 528.4 Management Considerations for Pediatric Thromboembolic Events

VTE	MANAGEMENT RECOMMENDATION	COMMENTS
Symptomatic DVT	Anticoagulation Provoked—treat <3 months (or until provoking factor is resolved) Unprovoked—treat 6-12 months, or longer based on risk/benefit analysis Thrombolysis considered if life- or limb-threatening VTE IVC filter considered if absolute contraindication to anticoagulation	Observation may be necessary or reasonable for premature neonates or critically ill children at high risk of bleeding Recommendations vary regarding utility of radiographic follow-up
Asymptomatic DVT	Anticoagulation or observation	Natural history is unclear, decision may vary based on VTE- and patient-specific factors
Massive PE (hemodynamic compromise)	Thrombolysis followed by anticoagulation	
Submassive PE (no hemodynamic compromise)	Anticoagulation alone	
CVC-related	Anticoagulation Removal of CVC if not functioning or no longer needed	Duration of anticoagulation needed before CVC removal is still being investigated, and recommendations vary
Renal vein thrombosis (RVT)	Unilateral: Anticoagulation alone Bilateral: Consider thrombolysis for bilateral RVT (life- or organ-threatening)	
Portal vein thrombosis (PVT)	Occlusive: Anticoagulation Nonocclusive: Observation (close radiologic follow-up)	Observe for cavernous transformation. Bleeding risk with anticoagulation increases in the setting of portal hypertension (and associated esophageal varices)
Cerebral Sinovenous Thrombosis (CSVT)	Anticoagulation (radiologic follow-up recommended) Acetazolamide if concomitant increased intracranial pressure	Decision in patients with intracranial hemorrhage needs to be individualized, but some patients may benefit from anticoagulation

CVC, Central venous catheter; DVT, deep vein thrombosis; IVC, inferior vena cava; PE pulmonary embolism; VTE, venous thromboembolism

Table 528.5 Comparison of Antithrombotic Agents

	rTPA	UNFRACTIONATED HEPARIN	WARFARIN	LMW HEPARIN (ENOXAPARIN)
Indication	Recent onset of life- or limb-threatening thrombus	Acute or chronic thrombus, prophylaxis	Subacute or chronic thrombosis, thromboprophylaxis for cardiac valves	Acute or chronic thrombus, prophylaxis
Administration	IV continuous infusion	IV continuous infusion	PO once daily	SC injection twice daily
Monitoring	"Lytic state": FDP or D-dimer	PTT	INR	Anti–factor Xa activity
Other	Higher risk of bleeding	Difficult to titrate; requires frequent dose adjustments; higher dose required in newborns	Heavily influenced by other drugs and diet	More stable and easy to titrate; concern of osteopenia with long-term use

complication in which antibodies develop to a complex of heparin and platelet factor-4. These antibodies result in platelet activation, stimulation of coagulation, thrombocytopenia, and in some cases, life-threatening thrombosis. If HIT is strongly suspected, heparin must be discontinued immediately. An alternative parenteral anticoagulant, including the direct thrombin inhibitors argatroban or bivalirudin, may be used in this situation.

LOW MOLECULAR WEIGHT HEPARIN

In contrast to UFH, LMWH contains smaller molecular weight polysaccharide chains. The interaction of the smaller chains with AT results primarily in the inhibition of factor Xa, with less of an effect on thrombin. The several LMWHs available have variable inhibitory effects on thrombin. For this reason, the PTT is not a reliable measure of the anticoagulant effect of LMWH, and the anti–factor Xa activity is used instead. Because of the ease of dosing and need for less monitoring, *LMWH is the most frequently used anticoagulant in pediatric patients.* Although dalteparin was the first (and currently only) LMWH approved by the Food and Drug Administration (FDA) for use in children (older than 1 month of age), enoxaparin is the LMWH that has been studied and used more often in pediatric patients.

Enoxaparin Dosing

The recommended standard starting dose of enoxaparin for infants <2 months old is 1.5 mg/kg/dose subcutaneously every 12 hours and for patients >2 months old, 1 mg/kg every 12 hours, although many

centers use slightly higher doses for children <2 years old. In general, peak levels are achieved 3-6 hours after injection. A therapeutic anti–factor Xa level, drawn 4 hours after the second or third dose, should be 0.5-1.0 IU/mL; the dose can be titrated to achieve this range. The elimination half-life of enoxaparin is 4-6 hours. Enoxaparin is cleared by the kidney and should be used with caution in patients with renal insufficiency. It should be avoided in patients with renal failure.

After an initial period of anticoagulation with heparin or LMWH, patients may continue to receive LMWH as an outpatient for the duration of therapy or may be transitioned to an oral anticoagulant such as warfarin.

Direct Thrombin Inhibitors

Argatroban and bivalirudin are IV direct thrombin inhibitors that are used in the setting of HIT, complex heart disease/failure cases with ventricular assist devices, or other relatively uncommon situations in pediatrics. They have short half-lives but cannot be fully reversed. Dosing has not been well established in children.

WARFARIN

Warfarin is an oral anticoagulant that competitively interferes with vitamin K metabolism, exerting its action by decreasing concentrations of the vitamin K–dependent coagulation factors II, VII, IX, and X, as well as protein C and protein S. Therapy should be started while a patient is anticoagulated with heparin or LMWH because of the risk of warfarin-induced skin necrosis. This transient hypercoagulable condition may occur when levels of protein C drop more rapidly than the procoagulant factors.

Dosing

Warfarin therapy is often initiated with a weight-based loading dose, with subsequent dose adjustments made according to a nomogram. When initiating warfarin therapy, UFH or LMWH should be continued until the international normalized ratio (INR) is therapeutic for 2 days. In most patients, this takes 5-7 days. The PT is used to monitor the anticoagulant effect of warfarin. Because the thromboplastin reagents used in PT assays have widely varying sensitivities, the PT performed in one laboratory cannot be compared with that performed in another laboratory. As a result, the INR was developed as a mechanism to standardize the variation in the thromboplastin reagent. The target INR range depends on the clinical situation. In general, a range of 2.0-3.0 is the target for the treatment of VTE. High-risk patients, such as those with mechanical heart valves, APS, or recurrent thrombosis, may require a higher target range.

Polymorphisms in *CYP2C9* and *VKORC1* affect the pharmacokinetics and pharmacodynamics of warfarin. Pharmacogenetic testing can identify wild-type responders, as well as those who are more sensitive (increased risk of bleeding). Genotyping in adults may help select warfarin dose, monitor for bleeding, or choose a DOAC instead of warfarin for patients highly sensitive and at risk for hemorrhage.

Complications

Bleeding is the most common adverse effect of warfarin. The risk of serious bleeding in children receiving warfarin for the treatment of VTE has been reported at 0.5% per year. Children who have supratherapeutic INR are at higher risk. There is considerable interpatient variation in dose. Diet, medications, and illness may influence the metabolism of warfarin, requiring frequent dose adjustments and laboratory studies. Numerous medications can affect the pharmacokinetics of warfarin by altering its clearance or rate of absorption. These effects can have a profound impact on the INR and must be considered when monitoring a patient receiving warfarin.

The strategies used to reverse warfarin therapy depend on the clinical situation and whether there is bleeding. Vitamin K can be administered to reverse the effect of warfarin but takes some time to have an effect. If the patient is having significant bleeding, a nonactivated plasma-derived 4-factor prothrombin complex concentrate (PCC) or fresh-frozen plasma (FFP, 15 mL/kg) should be given along with the vitamin K. PCCs have not been well investigated in children.

Nonhemorrhagic complications are uncommon in children, although hair loss has been reported. Warfarin is a teratogen, particularly in the first trimester. **Warfarin embryopathy** is characterized by bone and cartilage abnormalities known as *chondrodysplasia punctata*. Affected infants may have nasal hypoplasia and excessive calcifications in the epiphyses and vertebrae.

DIRECT ORAL ANTICOAGULANTS

Oral direct thrombin inhibitors (dabigatran) or inhibitors of factor Xa (apixaban, rivaroxaban, edoxaban) are approved for the prevention or treatment of thrombosis in patients >18 years old (see Table 528.6), and dabigatran is FDA-approved for children older than 3 months of age. Fixed dosing, oral administration, no dietary interference with vitamin

Table 528.7 Guidelines for Therapeutic Anticoagulation Treatment Duration

INDICATION	RISK FACTOR	THERAPEUTIC ANTICOAGULATION TREATMENT DURATION
First VTE episode	Provoked, reversible	3 mo
	Provoked, chronic	3 mo, then continue anticoagulation with either therapeutic or prophylaxis regimens until the risk factor is resolved
	Unprovoked	6–12 mo
Recurrent VTE	Reversible	3 mo
	Chronic	If recurrence occurs while the patient was on prophylaxis regimen, after first VTE episode, restart therapeutic regimen until risk factor is resolved
	Unprovoked	Restart therapeutic regimen for at least 3 mo and then switch to lifelong VTE prophylaxis regimen

VTE, Venous thromboembolism.
From Shoag J, Davis JA, Corrales-Medina FF. Venous thromboembolism in pediatrics. *Pediatr Rev.* 2021;42:78–87.

K, and no need to monitor laboratory tests, as well as initial results suggesting noninferiority to warfarin and fewer bleeding episodes, have favored the use of DOACs. Clinical trials have demonstrated the safety and efficacy of dabigatran and rivaroxaban in children. Drugs are available to *reverse* the effects of DOACs if indicated. DOACs should be avoided in patients with APS in the presence of arterial thrombosis.

THROMBOLYTIC THERAPY

Although anticoagulation alone is often effective at managing thrombosis while awaiting natural fibrinolysis, more rapid clot resolution may sometimes be necessary or desirable. In these situations, a thrombolytic agent that can activate the fibrinolytic system is of potential benefit. The pharmacologic activity of thrombolytic agents depends on the conversion of endogenous plasminogen to plasmin. Plasmin is then able to degrade several plasma proteins, including fibrin and fibrinogen. Because of the high risk of bleeding, thrombolytic therapy is generally reserved for patients with life- or limb-threatening thrombosis.

tPA is available as a recombinant product and has become the primary agent used for thrombolysis in children, although proper dose finding studies have not been performed. Depending on the situation, tPA may be used systemically or locally with catheter-directed thrombolysis, sometimes with the addition of mechanical clot lysis devices operated by interventional radiologists.

Dosing

An extremely wide range of doses of tPA has been used for systemic therapy, and no consensus exists as to the optimal dose. Systemic tPA doses of 0.1-0.6 mg/kg/hr were previously recommended, although recent reports indicate successful therapy with fewer bleeding complications using prolonged infusions with very low doses—0.01-0.06 mg/kg/hr.

Monitoring

There is no specific laboratory test to document a "therapeutic range" for thrombolytic therapy. It is important to maintain the fibrinogen >100 mg/dL and the platelet count >75,000 × 10^9/L during treatment. Supplementation of plasminogen using FFP is generally recommended in neonates before initiating thrombolysis because of their low baseline levels.

The clinical and radiologic response to thrombolysis should be closely monitored. The duration of therapy depends on the clinical response. Invasive procedures, including urinary catheterization, arterial puncture, and rectal temperatures, should be avoided.

The role of adjuvant UFH during thrombolytic therapy is controversial. Animal models have demonstrated that thrombolytic therapy can induce a procoagulant state with activation of the coagulation system, generation of thrombin, and extension or reocclusion of the thrombosis. In pediatric patients thought to be at low risk for bleeding, adjuvant UFH should be considered using doses of 10-20 units/kg/hr. The recommended duration of therapy is noted in Table 528.7.

Complications

The most serious complication from thrombolysis is bleeding, which has been reported in 0–40% of patients. Absolute contraindications to thrombolysis include major surgery within 7 days, history of significant bleeding (intracranial, pulmonary, or GI), peripartum asphyxia with brain damage, uncontrolled hypertension, and severe thrombocytopenia. In the event of serious bleeding, thrombolysis should be stopped, and cryoprecipitate should be given to replace fibrinogen.

THROMBOPROPHYLAXIS

There have been no formal trials of VTE prevention in children, although many institutions are starting to develop and use risk-guided algorithms to identify children who may benefit from mechanical (sequential compression devices) or pharmacologic (low-dose anticoagulant) prevention strategies in the absence of concomitant bleeding risk. Hospitalized adolescents with multiple risk factors for thrombosis who are immobilized for a prolonged period are a group that expert consensus would suggest may benefit from prophylactic treatment with enoxaparin, 0.5 mg/kg every 12 hours (maximum 30 mg).

ANTIPLATELET THERAPY

Inhibition of platelet function using agents such as aspirin is more likely to be protective against arterial TEs than VTEs. Aspirin, or acetylsalicylic acid (ASA), exerts its antiplatelet effect by irreversibly inhibiting cyclooxygenase, preventing platelet thromboxane A_2 production. Aspirin is used routinely in children with Kawasaki disease and may also be useful in children with stroke, ventricular assist devices, and single-ventricle cardiac defects. The recommended dose of aspirin to achieve an antiplatelet effect in children is 1-5 mg/kg/day.

Chapter 529

Postneonatal Vitamin K Deficiency

Brian R. Branchford, Benjamin J. Samelson-Jones, and Veronica H. Flood

Vitamin K deficiency occurring after the neonatal period is usually secondary to insufficient vitamin K intake, malabsorption, or alterations in the intestinal flora as a consequence of antibiotics. The biologic activity of the "vitamin K–dependent factors" (coagulation factors II, VII, IX, and X, as well as the natural anticoagulants protein C and protein S) requires vitamin K for their posttranslational carboxylation. In the absence of vitamin K, only nonfunctional forms of these proteins are synthesized, which are ineffective for hemostasis. Severe vitamin K deficiency will result in a prolonged prothrombin time (PT) and partial thromboplastin time (PTT), although early deficiency may only demonstrate a prolonged PT because of the short half-life of factor VII. Plasma levels of uncarboxylated factor II are measured in the PIVKA-II (proteins induced by vitamin K absence) test and elevated levels are diagnostic of vitamin K deficiency, although clinical history and basic coagulation labs are usually sufficient to make the diagnosis. It can often be clinically helpful to distinguish between deficiencies of the vitamin K–dependent factors and deficiencies in the clotting factors synthesized by hepatocytes due to liver disease (see Chapter 530), which includes the vitamin K–dependent factors as well as factors V and XI.

Intestinal malabsorption of fats may accompany cystic fibrosis, biliary atresia, or other liver diseases and results in a deficiency of fat-soluble dietary vitamins including vitamin K.

Prophylactic administration of water-soluble vitamin K orally is indicated in these patients (2-5 mg/24 hr for children and 5-10 mg/24 hr for adolescents and adults). Vitamin K may also be administered at 1-2 mg intravenously. Broad-spectrum antibiotics can alter the intestinal flora, reducing the vitamin K that is produced in the gastrointestinal tract. Patients have only a few weeks of vitamin K stores. The anticoagulant properties of warfarin (Coumadin) depend on interference with vitamin K, with a concomitant reduction of the vitamin K–dependent clotting factors. **Rat poison** (superwarfarin) produces a similar deficiency that should be considered in young children presenting with bleeding and bruising with a history compatible with ingestion. There are also cases of illicit drugs being adulterated with vitamin K antagonists. Vitamin K is a specific antidote for these substances. Four factor prothrombin complex concentrates contain all the vitamin K–dependent clotting factors; they are available for warfarin reversal and have been used to rapidly replace vitamin K–dependent clotting factors in urgent scenarios. Dosing is based on the international normalized ratio (INR), and vitamin K should also be administered.

Chapter 530

Coagulopathy in Liver Disease

Brian R. Branchford and Veronica H. Flood

Because all the clotting factors *except* factor VIII (which is synthesized in liver sinusoids and extrahepatic endothelium) are produced exclusively in hepatocytes, coagulation abnormalities are very common in patients with severe liver disease (Table 530.1). Only 15% of such patients have significant clinical bleeding states, possibly because of concomitant reduction in anticoagulation proteins (protein C and S). The severity of the coagulation abnormality appears to be directly proportional to the extent of hepatocellular damage. The most common mechanism causing the hemostasis defect is decreased synthesis of coagulation factors. Patients with severe liver disease characteristically have normal to increased (not reduced) levels of factor VIII activity in plasma. In some instances, **disseminated intravascular coagulation** (DIC; see Chapter 510), hypofibrinogenemia, or hyperfibrinolysis may complicate liver disease, making laboratory differentiation of severe liver disease from DIC-related clotting factor consumption difficult. These entities, as well as vitamin K deficiency (see Chapter 529), may be distinguished by comparing levels of a hepatically synthesized factor (such as factor V), a hepatically synthesized vitamin K–dependent factor (such as factor VII), and a nonhepatically synthesized factor that could be subject to consumption (such as factor VIII).

Treatment of the coagulopathy of liver disease should be reserved for patients with clinical bleeding rather than used to normalize the lab values. Because a reduction in vitamin K–dependent coagulation factors is common in those with acute or chronic liver disease, a trial of vitamin K supplementation can be given. Vitamin K can be given orally, subcutaneously, or preferably intravenously (not intramuscularly) at a dose of 1 mg/24 hr for infants, 2-5 mg/24 hr for children, and 5-10 mg/24 hr for adolescents and adults. Inability to correct coagulopathy with vitamin K indicates that the coagulopathy may be caused by reduced levels of clotting factors that are not vitamin K–dependent and/or by inadequate production of precursor vitamin K proteins. Treatment for bleeding consists of factor replacement with **fresh-frozen plasma** (FFP) or **cryoprecipitate**. FFP (10-15 mL/kg) contains all clotting factors, but replacement of fibrinogen for severe hypofibrinogenemia may require cryoprecipitate at a dose of 1 unit per 5-10 kg body weight, or a fibrinogen concentrate if a patient is unable to tolerate excess fluid volume. In severe liver disease, it is often difficult to attain correction of abnormal clotting studies despite vigorous therapy with FFP and cryoprecipitate, and such attempts are often complicated by volume overload concerns. Some patients with bleeding as a result of liver disease have responded to therapy with desmopressin (DDAVP), whereas others have responded to treatment with recombinant factor VIIa, albeit at a dose lower than typically given for hemophilia. Recombinant factor VIIa is contraindicated in DIC.

Desmopressin (0.3 μg/kg intravenously) is effective in shortening bleeding time, prompts endothelial cell release of von Willebrand factor and factor VIII, promotes platelet activation, and is therefore used effectively to augment hemostasis before diagnostic liver biopsy in the setting of hepatic insufficiency/failure. In clinical trials of adults, recombinant factor VIIa has not been shown to be effective for the treatment of bleeding caused by severe liver disease, possibly because of its short half-life (3-6 hours). Frequently, severe liver disease is associated with moderate prolongation of coagulation disorder screening tests (partial thromboplastin time [PTT]; prothrombin time [PT]) that is not corrected by vitamin K or plasma replacement. Another diagnostic clue may be a low serum albumin level because this protein is also synthesized in the liver.

Table 530.1 Coagulation Changes in Liver Disease

CHANGES IN PROCOAGULANT PROTEINS	CHANGES IN ANTICOAGULANT PROTEINS	CHANGES IN ANTIFIBRINOLYTIC PROTEINS
Decreased fibrinogen and factors FII, FV, FVII, FIX, FX, and FXI	Decreased protein C	Decreased α_2-antiplasmin and thrombin-activatable fibrinolysis inhibitor
Increased FVIII	Decreased protein S	FXIII decreased in some patients
Increased VWF, decreased ADAMTS-13	Decreased antithrombin	Increased tissue plasminogen activator

ADAMTS-13, A disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13.
From Han H, Hensch L, Hui SKR, Teruya J. Evaluation and management of coagulopathies and thrombophilias in pediatric patients. *Clin Lab Med.* 2021;41:83–100. Table 4.

Chapter 531

Acquired Inhibitors of Coagulation

Brian R. Branchford and Veronica H. Flood

Acquired circulating anticoagulants **(inhibitors)** are antibodies that react, or cross-react, with clotting factors or components used in coagulation screening tests (phospholipids), thereby prolonging screening tests, such as prothrombin time (PT) and partial thromboplastin time (PTT), although not all of them result in a clinical bleeding state. Some of these anticoagulants are autoantibodies that react with phospholipid and thereby interfere with clotting in vitro *but not in vivo.* This group comprises anticardiolipin and anti-beta(2)-glycoprotein-Ib antibodies, but the most common subtype of these **antiphospholipid antibodies** has been referred to as the *lupus anticoagulant* (see Chapter 528.1). This unfortunately named antibody is neither found exclusively in patients with systemic lupus erythematosus (SLE; see Chapter 199), nor does its presence consistently signify the concomitant presence of SLE in a patient. It can also be seen in those with other collagen vascular diseases and in association with HIV infection. In otherwise healthy children, spontaneous lupus-like inhibitors have developed transiently after incidental viral infection and can be seen in up to 26% of screening tests in asymptomatic subjects. These transient inhibitors are usually not associated with either bleeding or thrombosis.

Although the classic lupus anticoagulant is more often associated with a predisposition to thrombosis than with bleeding symptoms, bleeding symptoms in a patient with the lupus anticoagulant may be caused by **thrombocytopenia**, which may be a manifestation of the antiphospholipid syndrome or of lupus itself (alone or occasionally in context with Evans syndrome), or, rarely, by a coexistent specific autoantibody against prothrombin (factor II). The antiprothrombin antibody does not inactivate prothrombin but rather causes accelerated clearance of the protein, resulting in low levels of prothrombin and subsequent inadequate hemostasis.

Rarely, antibodies may arise spontaneously against a specific clotting factor, such as *factor VIII* or *von Willebrand factor*, leading to acquired hemophilia A or von Willebrand disease (VWD), but this is usually seen more frequently in adult patients. These patients are prone to excessive hemorrhage and may require specific treatment. In patients with a hereditary deficiency of a clotting factor (factor VIII or factor IX), antibodies may develop after exposure to transfused factor concentrates. These hemophilic inhibitory antibodies are discussed in Chapter 525.1.

LABORATORY FINDINGS

Inhibitors against specific coagulation factors usually affect factors VIII, IX, and XI, or, rarely, prothrombin (factor II). Depending on the target of the antibody and the target's participation in the intrinsic, extrinsic, or common coagulation cascade pathway, the PT and/or PTT may be prolonged. The mechanism by which the inhibitory antibody functions determines whether mixing patient plasma with normal plasma will normalize (correct) the clotting time. Patient plasma that contains antibodies directed against the active site of a clotting factor (factor VIII or factor IX) will not correct on 1:1 mixing with normal plasma, whereas antibodies that lead to increased clearance of the factor (such as antiprothrombin antibodies) will correct on such mixing studies. Specific factor assays are used to determine which factor is involved, and the pattern of abnormalities in PT, PTT, and/or thrombin time (TT) is used to guide initial investigation.

TREATMENT

Management of the bleeding patient with an acquired inhibitory autoantibody against factor VIII or IX is the same as for the patient with congenital hemophilia who has an alloantibody against factor VIII or factor IX. Infusions of recombinant factor VIIa or activated prothrombin complex concentrate may be needed to control significant bleeding. Occasionally, high-dose coagulation factor VIII or IX concentrates may be effective. Immunosuppressive agents have been used "off label" to treat the inhibitor or reduce titers. Acute bleeding caused by an antiprothrombin antibody can often be treated with a plasma infusion and may resolve with a short course of corticosteroid therapy.

Asymptomatic spontaneous inhibitors that arise after a viral infection tend to disappear within a few weeks to months. Inhibitors seen with an underlying disease, such as those associated with SLE, often resolve during the treatment of the underlying disease.

Chapter 532

Disseminated Intravascular Coagulation

Benjamin J. Samelson-Jones and Leslie J. Raffini

Disseminated intravascular coagulation (DIC) is an acquired clinicopathologic syndrome characterized by the widespread pathologic activation of the coagulation system, which results in both microvascular thrombi and the consumption of clotting factors, anticoagulant proteins, and platelets. Microvasculature injury can contribute to organ dysfunction, while hemorrhage can be life-threatening in a minority of cases. The diagnosis of DIC is based on the laboratory findings and clinical manifestations within the appropriate clinical context. The

simultaneous occurrence of bleeding and clotting is clinically challenging, with management starting from appropriately recognizing this syndrome.

ETIOLOGY

DIC is always a secondary complication of an underlying disorder (Table 532.1) and never an isolated diagnosis. The complex pathogenesis involves the loss of localization and excessive activation of coagulation leading to unregulated thrombin generation and microvascular fibrin deposition. Dysfunction of the vascular endothelium can both precipitate and amplify this process. The excessive activation consumes platelets, procoagulant clotting factors (factor V, factor VIII, prothrombin, and fibrinogen), and anticoagulant proteins (protein C, protein S, and antithrombin). The fibrinolytic system can also become dysregulated with endothelial injury and plasma protein consumption.

Table 532.1 Causes of Disseminated Intravascular Coagulation in Children

INFECTIONS
Meningococcemia (purpura fulminans)
Bacterial sepsis (staphylococcal, streptococcal, *Escherichia coli*, *Salmonella*)
Rickettsia (Rocky Mountain spotted fever)
Viruses (cytomegalovirus, herpes simplex, hemorrhagic fevers)
Malaria
Fungi
TISSUE INJURY
Central nervous system trauma (massive head injury)
Fat embolism
Crush injury
Profound shock or asphyxia
Hypothermia or hyperthermia (heat shock)
Massive burns
MALIGNANCY
Acute promyelocytic leukemia
Acute monoblastic leukemia
Disseminated solid tumors (rhabdomyosarcoma, neuroblastoma)
VENOM OR TOXINS
Toxic shock syndrome
Snakebites
Spider bites
MICROANGIOPATHIC DISORDERS
Severe thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome
Vascular malformations
GASTROINTESTINAL DISORDERS
Fulminant hepatitis
Ischemic bowel
Pancreatitis
HEREDITARY THROMBOTIC DISORDERS
Homozygous/compound heterozygous protein C, protein S, or antithrombin deficiency
PERINATAL
Maternal toxemia
Abruptio placentae
Severe respiratory distress syndrome
Meconium aspiration syndrome
Necrotizing enterocolitis
Erythroblastosis fetalis
Fetal demise of a twin
MISCELLANEOUS
Severe acute graft rejection
Acute hemolytic transfusion reaction
Severe collagen-vascular disease
Kawasaki disease
Heparin-induced thrombosis
Infusion of activated prothrombin complex concentrates
Hyperpyrexia/encephalopathy, hemorrhagic shock syndrome

Adapted from Montgomery RR, Scott IP. Hemostasis: diseases of the fluid phase. In Nathan DG, Oski FA, eds. *Hematology of Infancy and Childhood*, 4th ed. Philadelphia: Saunders, 1993.

LABORATORY FINDINGS

Although DIC is characterized by a number of abnormal laboratory findings, none are specific for the diagnosis. The consumption of coagulation factors and platelets often results in a prolonged prothrombin time (PT), an increased partial thromboplastin time (PTT), and low platelet counts. Low fibrinogen is seen in severe disease, but as an acute-phase reactant, fibrinogen may be high or normal early in the disease process; declining fibrinogen levels, even within the normal range, can suggest DIC. Fibrinogen degradation products and D-dimer levels are frequently highly elevated. Factors V and VIII are usually both reduced in DIC, whereas in acute hepatic disease, factor VIII may be normal or elevated. Thrombi in the microvasculature can lead to red blood cell fragmentation and a **microangiopathic hemolytic anemia** with elevated lactate dehydrogenase and characteristic blood smear morphology, including schistocytes, helmet cells, and microspherocytes.

CLINICAL MANIFESTATIONS

DIC may be subclinical with only laboratory abnormalities, termed *nonovert DIC*. Clinical manifestations include thrombotic and hemorrhagic complications, as well as organ dysfunction. Bleeding frequently first occurs from sites of venipuncture or surgical incision, and the skin may show petechiae, purpura, and ecchymoses. Localized large-vessel arterial or venous thromboembolic events can occur. Tissue necrosis may involve many organs and can be most spectacularly seen as infarction of large areas of skin and subcutaneous tissue. A compromised blood supply can lead to organ dysfunction including organ failure, especially to the lungs, kidneys, liver, and brain.

MANAGEMENT

The primary treatment of DIC is resolving the underlying triggering disease process. Blood components support is recommended for active hemorrhage or in patients requiring invasive procedures; this may consist of platelet infusions (for thrombocytopenia), cryoprecipitate (for hypofibrinogenemia), and fresh-frozen plasma (for replacement of other coagulation factors and anticoagulant proteins). Blood product support in the absence of bleeding should not be based solely on laboratory abnormalities, but clinical practice varies on the importance of minor bleeding symptoms. Hemostatic products with activated clotting factors such as recombinant factor VIIa (FVIIa) and activated prothrombin complex concentrate (aPCC) theoretically may worsen the widespread and unregulated generation of thrombin. Likewise, systemic antifibrinolytics are generally contraindicated except in clinical scenarios associated with hyperfibrinolysis such as acute promyelocytic leukemia and early trauma.

DIC patients with overt thromboembolic complications should receive therapeutic anticoagulation, usually with unfractionated heparin, as outlined in Chapter 528.1; stringent attention to replacement therapy is warranted to maintain an adequate platelet count to limit bleeding. Prophylactic anticoagulation may be carefully used in patients with DIC at high risk of thromboembolic events that are not actively bleeding. Most patients should receive mechanical thromboprophylaxis such as sequential compression devices.

The prognosis of patients with DIC is primarily dependent on the outcome of the treatment of the primary disease and prevention of end-organ damage.

Chapter 533

Platelet and Blood Vessel Disorders

Brian R. Branchford, Benjamin J. Samelson-Jones, and Veronica H. Flood

MEGAKARYOPOIESIS

Platelets are anuclear cellular fragments produced by megakaryocytes (large polyploid cells) within the bone marrow, lung, and other tissues. When the megakaryocyte approaches maturity, budding of the cytoplasm occurs, and large numbers of platelets are liberated. Platelets circulate with a life span of 7-10 days. **Thrombopoietin (TPO)** is the primary growth factor that controls platelet production (Fig. 533.1). Levels of TPO appear to correlate inversely with platelet number and megakaryocyte mass, with highest expression in the thrombocytopenic states associated with decreased marrow megakaryopoiesis, and may be variable in states of increased platelet production.

The platelet plays multiple hemostatic roles. The platelet surface possesses a number of important receptors for adhesive proteins, including **von Willebrand factor (VWF)** and fibrinogen, as well as receptors for agonists that trigger platelet aggregation, such as thrombin, collagen, and adenosine diphosphate (ADP). After injury to the blood vessel wall, the extracellular matrix containing adhesive and procoagulant proteins is exposed. Subendothelial collagen binds VWF, which then undergoes a conformational change that induces binding of the platelet glycoprotein Ib (GPIb) complex, the VWF receptor. This process is called *platelet adhesion.* Platelets then undergo activation. During the process of activation, the platelets generate thromboxane A_2 from arachidonic acid via the enzyme cyclooxygenase. After activation, platelets release agonists, such as ADP, adenosine triphosphate (ATP), calcium ions (Ca^{2+}), serotonin, and coagulation factors, into the surrounding milieu from dense and alpha granules. Binding of VWF to the GPIb complex triggers a complex signaling cascade that results in activation of the fibrinogen receptor, the major platelet integrin glycoprotein αIIb-β_3 (GPIIb-IIIa). Circulating fibrinogen binds to this receptor on activated platelets, linking platelets in a process called *aggregation.* This series of events forms a hemostatic plug at the site of vascular injury. The serotonin and histamine that are liberated during activation increase local vasoconstriction. In addition to acting in concert with the vessel wall to form the platelet plug, the platelet provides the catalytic phospholipid surface on which coagulation factors assemble and eventually generate thrombin through a sequential series of enzymatic cleavages. Lastly, the platelet contractile proteins and cytoskeleton mediate clot retraction.

THROMBOCYTOPENIA

The normal platelet count is 150-450 × 10^9/L. *Thrombocytopenia* refers to a reduction in platelet count to <150 × 10^9/L, although clinically significant bleeding is not seen until counts drop well below 50 × 10^9/L. Causes of thrombocytopenia include decreased production on either a congenital or an acquired basis, sequestration of the platelets within an enlarged spleen or other organ, and increased destruction of normally synthesized platelets on either an immune or a nonimmune basis (Tables 533.1-533.3, Fig. 533.2, and Chapter 524).

533.1 Immune Thrombocytopenia

Brian R. Branchford and Veronica H. Flood

The most common cause of acute onset of thrombocytopenia in an otherwise-well child is immune thrombocytopenia **(ITP)** (also called immune or idiopathic thrombocytopenic purpura).

EPIDEMIOLOGY

In a small number of children, estimated at 1/20,000, 1-4 weeks after exposure to a common viral infection, an autoantibody directed against the platelet surface develops with resultant sudden onset of thrombocytopenia. A recent history of viral illness is described in 50–65% of children with ITP. The peak age is 1-4 years, although the age ranges from early in infancy to elderly. In childhood, males and females are equally affected. ITP seems to occur more often in late winter and spring after the peak season of viral respiratory illness. Approximately 5–10% of ITP may recur more than 3 months after initial disease resolution.

PATHOGENESIS

The exact antigenic target for most such antibodies in most cases of childhood acute ITP remains undetermined, although in chronic ITP, many patients demonstrate antibodies against αIIb-β_3 and GPIb. After binding of the antibody to the platelet surface, circulating antibody-coated platelets are recognized by the Fc receptor on splenic macrophages, ingested, and destroyed. The most common identifiable viruses that have been described in association with ITP include Epstein-Barr

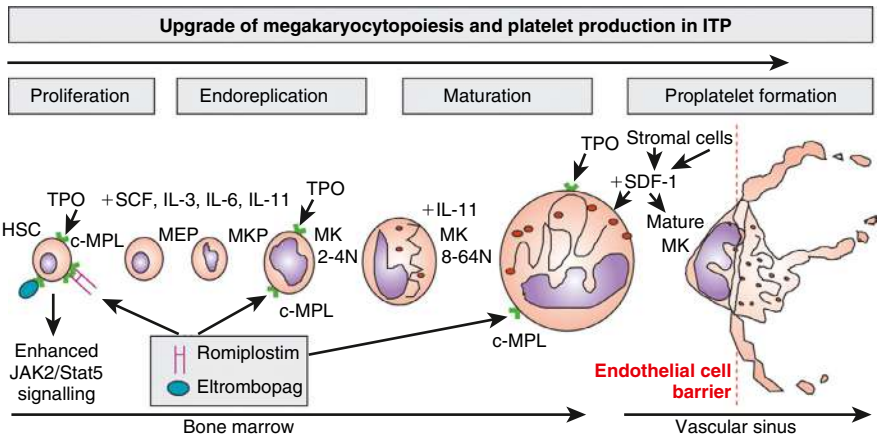

Fig. 533.1 Scheme of megakaryocytopoiesis and platelet production in immune thrombocytopenia (ITP). Hematopoietic stem cells (HSC) are mobilized, and megakaryocyte (MK) and erythroid progenitors (MEP) accumulate with MK-committed progenitors (MKP), giving rise to mature MKs under control of thrombopoietin (TPO) working with chemokines, cytokines, and growth factors, including stem cell factor (SCF) and interleukin (IL)-3, IL-6, and IL-11. Endoreplication results in ploidy changes in MKs and increased chromosome number (up to 64N). Mature MKs migrate to the endothelial cell barrier delimiting the vascular sinus and, under the influence of stromal-derived factor-1 (SDF-1), give rise to proplatelets that protrude into the circulation and produce large numbers of platelets under hemodynamic determinants. Therapeutically given romiplostim and eltrombopag enter the marrow and join with TPO to stimulate megakaryocytopoiesis and platelet production. *(From Nurden AT, Viallard JF, Nurden P. New-generation drugs that stimulate platelet production in chronic immune thrombocytopenic purpura. Lancet 2009;373:1563–1569.)*

Table 533.1 Differential Diagnosis of Thrombocytopenia in Children and Adolescents

DESTRUCTIVE THROMBOCYTOPENIAS
Primary Platelet Consumption Syndromes
Immune thrombocytopenias
- Acute and chronic ITP
- Autoimmune diseases with chronic ITP as a manifestation
  - Cyclic thrombocytopenia
  - Autoimmune lymphoproliferative syndrome and its variants
  - Systemic lupus erythematosus
  - Evans syndrome
  - Antiphospholipid antibody syndrome
  - Neoplasia-associated immune thrombocytopenia
- Thrombocytopenia associated with HIV
- Neonatal immune thrombocytopenia
  - Alloimmune
  - Autoimmune (e.g., maternal ITP)
- Drug-induced immune thrombocytopenia (including heparin-induced thrombocytopenia)
- Posttransfusion purpura
- Allergy and anaphylaxis
- Posttransplant thrombocytopenia

Nonimmune thrombocytopenias
- Thrombocytopenia of infection
  - Bacteremia or fungemia
  - Viral infection
  - Protozoan
- Thrombotic microangiopathic disorders
  - Hemolytic-uremic syndrome
  - Eclampsia, HELLP syndrome
  - Thrombotic thrombocytopenic purpura
  - Bone marrow transplantation–associated microangiopathy
  - Drug induced (quinine, etc.)
- Platelets in contact with foreign material
- Congenital heart disease
- Drug-induced via direct platelet effects (ristocetin, protamine)
- Type 2B VWD or platelet-type VWD

Combined Platelet and Fibrinogen Consumption Syndromes
Disseminated intravascular coagulation
Kasabach-Merritt syndrome
Hemophagocytic lymphohistiocytosis (inherited or acquired)

IMPAIRED PLATELET PRODUCTION
Hereditary disorders (see Table 533.2)
Acquired disorders
- Aplastic anemia
- Myelodysplastic syndrome
- Marrow infiltrative process—neoplasia
- Osteopetrosis
- Nutritional deficiency states (iron, folate, vitamin B12, anorexia nervosa)
- Drug- or radiation-induced thrombocytopenia
- Neonatal hypoxia or placental insufficiency

SEQUESTRATION
Hypersplenism
Hypothermia
Burns

ASSOCIATION WITH OTHER DISEASES
Fanconi anemia
Congenital amegakaryocytic thrombocytopenia
Shwachman-Diamond syndrome
Hemophagocytic lymphohistiocytosis
TAFRO syndrome

HELLP, Hemolysis, elevated liver enzymes, and low platelets; HIV, human immunodeficiency virus; ITP, immune thrombocytopenic purpura; TAFRO, thrombocytopenia, ascites, myelofibrosis renal dysfunction, organomegaly (a variant of multicentric Castleman disease); VWD, von Willebrand disease.
From Wilson DB. Acquired platelet defects. In: Orkin SH, Fisher DE, Ginsburg D, et al., eds. *Nathan and Oski's Hematology and Oncology of Infancy and Childhood*, 8th ed. Philadelphia: Elsevier, 2015: Box 34.1, p. 1077.

virus (EBV; see Chapter 301) and HIV (see Chapter 322), and ITP is also noted as a rare occurrence after measles, mumps, and rubella (MMR) vaccination. EBV-related ITP is usually of short duration and follows the course of infectious mononucleosis. HIV-associated ITP is usually chronic. In some patients, ITP appears to arise in children infected with *Helicobacter pylori* or rarely after vaccines. The SARS-CoV-2 virus responsible for the COVID-19 infection has been associated with development of ITP, as have some of the vaccines for this virus.

CLINICAL MANIFESTATIONS

The classic presentation of ITP is a previously healthy 1–4-year-old child who has sudden onset of generalized petechiae and purpura. The parents often state that the child was fine the previous day but is now covered with bruises and purple dots. There may be bleeding from the gums and mucous membranes, particularly with *profound thrombocytopenia* (platelet count $<10 \times 10^9$/L). There is a history of a preceding viral infection 1-4 weeks before the onset of thrombocytopenia. Findings on physical examination are typically normal, other than petechiae and purpura. *Splenomegaly, lymphadenopathy, bone pain, and pallor are rare.* A simple classification system to characterize the severity of bleeding in ITP on the basis of symptoms and signs rather than platelet count includes:

1. No symptoms
2. Mild symptoms: Bruising and petechiae, occasional minor epistaxis, very little interference with daily living
3. Moderate symptoms: More severe skin and mucosal lesions, more troublesome epistaxis, and menorrhagia
4. Severe symptoms: Bleeding episodes—menorrhagia, epistaxis, melena—requiring transfusion or hospitalization, symptoms interfering seriously with the quality of life

The presence of abnormal findings such as hepatosplenomegaly, bone or joint pain, remarkable lymphadenopathy, other cytopenias, or congenital anomalies suggests other diagnoses (e.g., leukemia, genetic syndromes). When the onset is insidious, especially in an adolescent, chronic ITP or the possibility of a systemic illness, such as **systemic lupus erythematosus** (SLE), is more likely. In addition, presentation at an atypical age (neonates, adolescents) should suggest an underlying disease.

OUTCOME

Severe bleeding is rare (<3% of cases in one large international study). In 70–80% of children who present with acute ITP, spontaneous resolution occurs within 6 months. Therapy does not appear to affect the natural history of the illness. Fewer than 1% of patients develop an **intracranial hemorrhage** (ICH). Proponents of interventional therapy argue that the objective of early therapy is to raise the platelet count to $>20 \times 10^9$/L and prevent the rare development of ICH. There is no evidence that therapy prevents serious bleeding. Approximately 20% of children who present with acute ITP go on to have chronic ITP. The outcome/prognosis may be related more to age; ITP in younger children is more likely to resolve, whereas development of chronic ITP in adolescents approaches 50%.

LABORATORY FINDINGS

Severe thrombocytopenia (platelet count $<20 \times 10^9$/L) is common, and platelet size is normal or increased, reflective of increased platelet turnover (Fig. 533.3). In acute ITP, the hemoglobin value, white blood cell (WBC) count, and differential count are usually normal. Hemoglobin may be decreased in the context of profuse nosebleeds (epistaxis) or menorrhagia. Bone marrow examination, *which is not routinely indicated in this disease*, shows normal granulocytic and erythrocytic series, with characteristically normal or increased numbers of megakaryocytes. Some of the megakaryocytes may appear to be immature and reflect increased platelet turnover. *Indications for bone marrow aspiration/biopsy* include an abnormal WBC count or differential or unexplained anemia, as well as history and physical examination findings suggestive of a bone marrow failure syndrome or malignancy. Other laboratory tests should be performed as indicated by the history and examination. HIV studies should be done in at-risk populations, especially sexually active teens. Platelet antibody testing is seldom useful in acute ITP. A direct antiglobulin test (Coombs) should be done if there is unexplained anemia to rule out **Evans syndrome** (autoimmune hemolytic anemia and thrombocytopenia; see Chapter 506). Evans syndrome may be idiopathic or an early sign of SLE, autoimmune lymphoproliferative syndrome, or common variable immunodeficiency

Table 533.2 Inherited Platelet Disorders

PLATELET DEFECT	GENE DEFECT (CHROMOSOMAL LOCATION)	CLINICAL AND LABORATORY CHARACTERISTICS	BLEEDING TREATMENT
DEFECTS IN PLATELET ADHESION			
Bernard-Soulier syndrome (BSS)	Autosomal recessive: *GP1BA* (17p13) *GP1BB* (22q11) *GP9* (3q21) Autosomal dominant: Ala156Val, GP1BA - Bolzano variant	• Often severe bleeding phenotype • Thrombocytopenia • Large platelets • Platelet aggregation: absent ristocetin-induced response • Flow cytometry: reduced or absent CD42a (GPIX)/CD42b (GP1bα) • *GP1BA* & *GP1BB* gene sequencing	• Supportive care • Platelet transfusion (risk of alloantibodies) • Antifibrinolytics • rFVIIa
Velocardiofacial/DiGeorge syndrome (VCFS)	22q11.2 deletion including *GP1BB*	• Thrombocytopenia • Large platelets and α-granules • Cardiac, thymus, parathyroid, facial, and cognitive abnormalities	• Supportive care
Platelet-type von Willebrand disease (PT-VWD)	Autosomal dominant: gain of function variants in *GP1BA*	• Thrombocytopenia • Large platelets • Platelet clumping • Decreased VWF:Ag, VWF multimers • Platelet aggregation: low dose ristocetin-induced platelet agglutination • *GP1BA* gene sequencing	• Supportive care • Platelet transfusion • Antifibrinolytics • rFVIIa
DEFECTS OF PLATELET AGGREGATION			
Glanzmann thrombasthenia (GT)	Autosomal recessive: *ITGA2B* (17Q21.32) *ITGB3* (17q21.32)	• Often severe bleeding phenotype • Normal platelet count and morphology • Platelet aggregation: absent response to all agonists except ristocetin • Flow cytometry: absent or reduced CD41 and CD61	• Supportive care • rFVIIa (considered the first line) • Platelet transfusion (risk of HPA alloantibodies) • Antifibrinolytics
DEFECTS IN AGONISTS RECEPTORS			
Thromboxane-prostanoid (TP) receptor defects	Autosomal recessive *TBXA2R* (19p13.3)	• Mild bleeding phenotype • Platelet aggregation: abnormal response to arachidonic acid and U46619 • *TBXA2R* gene sequencing	• Supportive care
ADP receptor defects P2Y12	Autosomal recessive *P2RY12* (3q23–25)	• Mild bleeding phenotype • Platelet aggregation: abnormal response to ADP • *P2RY12* gene sequencing	• Supportive care
Collagen receptor defects GPVI	Autosomal recessive *GP6* (19q13.4)	• Mild bleeding phenotype • Platelet aggregation: abnormal response to collagen • *GP6* gene sequencing	• Supportive care
PLATELET GRANULES DEFECTS (A-GRANULES)			
Gray platelet syndrome (GPS)	Autosomal recessive *NBEAL2* (3p21)	• Progressive myelofibrosis • Thrombocytopenia • Large pale platelets on blood smears • Absent α-granules on TEM • *NBEAL2* gene sequencing	• Supportive care • Antifibrinolytics • DDVAP • Platelet transfusion • Splenectomy
Arthrogryposis, renal dysfunction, and cholestasis syndrome (ARC syndrome)	Autosomal dominant *VPS33B* (15q26) *VIPAS39* (14q24)	• Thrombocytopenia • Large pale platelets on blood smears • Absent α-granules on TEM • Lethal early in life • *VPS33B* & *VIPAS39* sequencing	• Supportive care • Platelet transfusion • Antifibrinolytics

Continued

Table 533.2 Inherited Platelet Disorders—cont'd

PLATELET DEFECT	GENE DEFECT (CHROMOSOMAL LOCATION)	CLINICAL AND LABORATORY CHARACTERISTICS	BLEEDING TREATMENT
Quebec platelet disorder (QPD)	Autosomal recessive Tandem duplication of *PLAU* (10q22.2)	• Delayed-onset bleeding not responding to platelet transfusion • Variable thrombocytopenia • Abnormal urokinase in platelets detected with immunoblot or ELISA • *PLAU* duplication testing	• Supportive care • Antifibrinolytics
Paris-Trousseau/Jacobsen syndrome (PTS)	Autosomal dominant Deletion of chromosome 11q23–24 Hemizygous deletion of *FLI1* (11q24.1 – q24.3)	• Thrombocytopenia • Large platelets • Giant α-granules on TEM • Immature megakaryocytes in the bone marrow • Cognitive, cardiac, and facial abnormalities	• Supportive care • Antifibrinolytics • Platelet transfusion
PLATELET GRANULES DEFECTS (δ-GRANULES)			
Hermansky-Pudlak syndrome (HPS)	Autosomal recessive HPS1–10 (*HPS1, AP3B1, HPS3, HPS4, HPS5, HPS6, DTNBP1, BLOC1S3, BLOC1S6,* and *AP3D1*)	• Decreased to absent δ-granules • Lumiaggregometry: decreased/absent ATP release • Whole-mount EM • Gene sequencing of 10 candidate genes • Oculocutaneous albinism	• Supportive care • Antifibrinolytics • Platelet transfusion • DDAVP
Chediak-Higashi syndrome (CHS)	Autosomal recessive *LYST* (1q42 – 1q42.2)	• Giant eosinophilic inclusions in neutrophils • Decreased to absent δ-granules • Lumiaggregometry: decreased/absent ATP release • Hypopigmentation and immunodeficiency	• Supportive care
PLATELET CYTOSKELETAL DEFECTS			
Wiskott-Aldrich syndrome (WAS) / X-linked thrombocytopenia	X-linked *WAS* (Xp11.23 – p11.22) encoding WAS protein	• Thrombocytopenia • Small platelets • Recurrent infections and eczema • Decreased/absent intracellular • WASp per immunoblot/ELISA • *WAS* gene sequencing	• Supportive care • Platelet transfusion • Antifibrinolytics • Splenectomy (not recommended)
ARPC1B deficiency	Autosomal recessive *ARPC1B* (7q22.1)	• Small platelets • Inflammatory disease, recurrent infections, small vessel vasculitis, abnormal platelet function • Decreased/absent intracellular • ARPC1B per immunoblot • *ARPC1B* gene sequencing	• Supportive care • Antifibrinolytics • Platelet transfusion
MYH9-related disease (MYH9-RD)	Autosomal dominant *MYH9* (22q12–13) encoding nonmuscle myosin heavy chain IIA	• Thrombocytopenia • Large platelets • Döhle-like inclusions in neutrophils • Myosin IIA aggregates in neutrophils - immunofluorescence microscopy • Variable degree of renal disease, sensorineural hearing loss, presenile cataract	• Supportive care • Platelet transfusion • Antifibrinolytics • THPO receptor agonists

VWF, Von Willebrand factor; HPA, human platelet antigen; ADP, adenosine diphosphate; TEM, transmission electron microscopy; EM, electron microscopy; ELISA, enzyme-linked immunosorbent assay; DDAVP, desmopressin; THPO, thrombopoietin.
Modified from Al-Huniti A, Kahr WHA. Inherited platelet disorders: diagnosis and management. *Transfu Med Rev* 2020;34:277–285. Table 1.

syndrome. An antinuclear antibody should be considered in adolescents, especially with other features of SLE (see Chapter 199).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The well-appearing child with moderate to severe thrombocytopenia, an otherwise normal complete blood cell count (CBC), and normal exam findings has a limited differential diagnosis that includes exposure to medication inducing drug-dependent antibodies, splenic sequestration because of previously unappreciated portal hypertension, and, rarely, early aplastic processes, such as Fanconi anemia (see Chapter 517). Other than congenital thrombocytopenia syndromes (see Chapter 533.8), such as thrombocytopenia–absent radius (TAR) syndrome and MYH9-related thrombocytopenia, most marrow processes that interfere with platelet production eventually cause abnormal synthesis of red blood cells (RBCs) and WBCs and therefore manifest diverse abnormalities on the CBC. Disorders that cause increased platelet destruction on a nonimmune basis are usually serious systemic illnesses with obvious clinical findings such as **hemolytic-uremic syndrome** (HUS) and **disseminated intravascular**

Table 533.3	Classification of Fetal and Neonatal Thrombocytopenias*
Fetal	**Alloimmune thrombocytopenia**
	Congenital infection (CMV, toxoplasma, rubella, HIV, syphilis)
	Aneuploidy (trisomy 18, 13, or 21, triploidy, Turner syndrome)
	Autoimmune condition (maternal ITP, SLE)
	Severe Rh hemolytic disease
	Congenital/inherited (Wiskott-Aldrich, Noonan, Cornelia deLange, Jacobsen syndromes)
Early-onset neonatal (<72 hr)	**Placental insufficiency** (PET, IUGR, diabetes)
	Perinatal asphyxia
	Perinatal infection (*Escherichia coli*, GBS, herpes simplex)
	DIC
	Alloimmune thrombocytopenia
	Autoimmune condition (maternal ITP, SLE)
	Congenital infection (CMV, toxoplasma, rubella, HIV)
	Thrombosis (aortic, renal vein)
	Bone marrow disease (congenital leukemia, HLH)
	Kasabach-Merritt syndrome
	Metabolic disease (propionic and methylmalonic acidemia)
	Congenital/inherited (TAR, CAMT)
Late-onset neonatal (>72 hr)	**Late-onset sepsis**
	NEC
	Congenital infection (CMV, toxoplasma, rubella, HIV)
	Autoimmune
	Kasabach-Merritt syndrome
	Metabolic disease (propionic and methylmalonic acidemia)
	Congenital/inherited (TAR, CAMT)

*The most common conditions are shown in **bold**.
CAMT, Congenital amegakaryocytic thrombocytopenia; CMV, cytomegalovirus; DIC, disseminated intravascular coagulation; GBS, group B streptococcus; HIV, human immunodeficiency virus; HLH, hemophagocytic lymphohistiocytosis; ITP, immune thrombocytopenic purpura; IUGR, intrauterine growth restriction; NEC, necrotizing enterocolitis; PET, preeclampsia; SLE, systemic lupus erythematosus; TAR, thrombocytopenia with absent radii.
From Roberts I, Murray NA. Neonatal thrombocytopenia: causes and management. *Arch Dis Child Fetal Neonatal Ed* 2003;88:F359–F364.

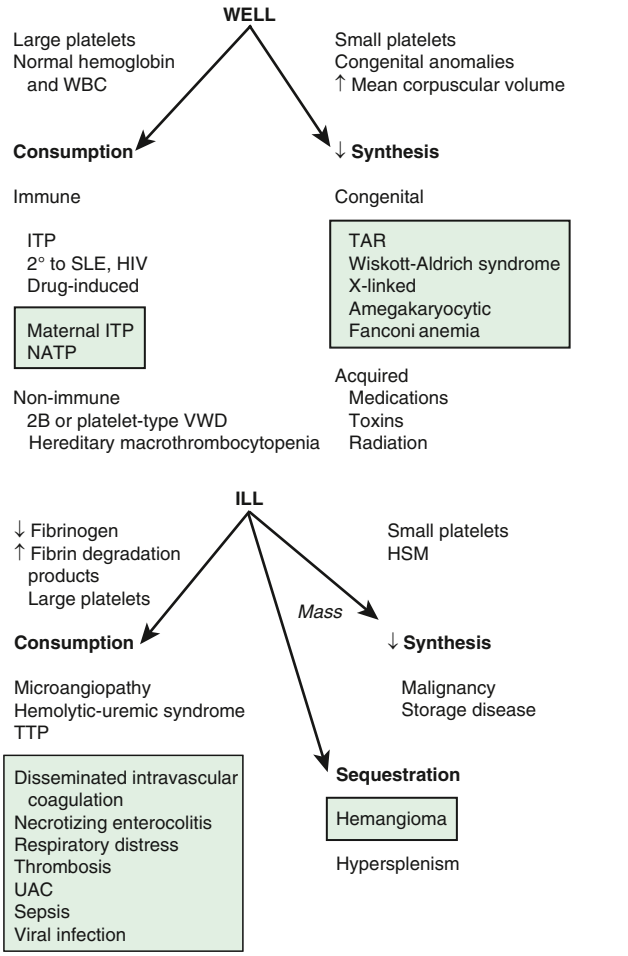

Fig. 533.2 Differential diagnostic algorithm of childhood thrombocytopenic syndromes. The syndromes initially are separated by their clinical appearance. Clues leading to the diagnosis are shown in *italics*. The mechanisms and common disorders leading to these findings are shown in the *lower part* of the figure. Disorders that commonly affect neonates are listed in the *shaded boxes*. HSM, Hepatosplenomegaly; ITP, immune thrombocytopenia; NATP, neonatal alloimmune thrombocytopenic purpura; SLE, systemic lupus erythematosus; TAR, thrombocytopenia–absent radius; TTP, thrombotic thrombocytopenic purpura; UAC, umbilical artery catheter; VWD, von Willebrand disease; WBC, white blood cell. *(From Scott JP. Bleeding and thrombosis. In Kliegman RM, ed. Practical Strategies in Pediatric Diagnosis and Therapy. Philadelphia: Saunders, 1996. p. 849; and Kliegman RM, Marcdante KJ, Jenson HB, et al., eds. Nelson Essentials of Pediatrics, 5th ed. Philadelphia: Saunders, 2006. p. 716.)*

coagulation (DIC) (see Fig. 533.2, and Table 532.1 in Chapter 532). Patients receiving heparin may develop heparin-induced thrombocytopenia. Isolated enlargement of the spleen suggests the potential for hypersplenism caused by liver disease or portal vein thrombosis. Autoimmune thrombocytopenia may be an initial manifestation of SLE, HIV infection, common variable immunodeficiency, and, rarely, lymphoma or autoimmune lymphoproliferative syndrome. Wiskott-Aldrich syndrome (WAS) must be considered in young males found to have thrombocytopenia with *small* platelets, particularly if there is a history of eczema and recurrent infection (see Chapter 165.2). Bernard-Soulier syndrome, on the other hand, involves a macrothrombocytopenia. Gray platelet syndrome is usually associated with splenomegaly and pale-colored platelets on peripheral smear.

TREATMENT

A number of treatment options exist (Table 533.4), but there are no current high-quality data showing that treatment affects either short- or long-term clinical outcome of ITP in children. Many patients with new-onset ITP have mild symptoms, with findings limited to petechiae and purpura on the skin, despite severe thrombocytopenia. Compared with untreated controls, treatment appears to be capable of inducing a more rapid rise in platelet count to the presumed safe level of >20 $\times$ 10^9/L, although no data indicate that early therapy prevents ICH.

Antiplatelet antibodies bind to transfused platelets as well as they do to autologous platelets. Thus platelet transfusion in ITP is usually contraindicated unless life-threatening bleeding is present. Management guidelines for ITP in children and adults reinforce existing emphasis on prioritizing watchful waiting for spontaneous resolution or outpatient therapy in the uncommon cases for which treatment is needed. Initial approaches to the management of pediatric ITP include the following:

1. No therapy other than education and counseling of the family and patient for patients with minimal, mild, and moderate symptoms, as defined earlier. This approach emphasizes the usually benign nature of ITP and avoids the therapeutic roller coaster that ensues once interventional therapy is begun. This approach is much less costly, and side effects are minimal. Observation is recommended for children with no bleeding or *only* mild bleeding symptoms such as bruising or petechiae.
2. Treatment with either intravenous immunoglobulin (IVIG) or corticosteroids, particularly for children who present with *mucocutaneous* bleeding. IVIG at a dose of 0.8-1.0 g/kg/day for 1-2 days induces a rapid rise in platelet count (usually >20 × 10^9/L) in 95% of patients within 48 hours. IVIG appears to induce a response by downregulating Fc-mediated phagocytosis of antibody-coated platelets. IVIG therapy is both expensive and time-consuming and typically requires inpatient admission. Additionally, after infusion, there is a risk of headaches and vomiting, suggestive of IVIG-induced aseptic meningitis.
3. Corticosteroid therapy has been used for many years to treat acute and chronic ITP in adults and children. Doses of prednisone at 1-4 mg/kg/day appear to induce a more rapid rise in platelet count than in untreated patients with ITP. Corticosteroid therapy is usually continued for a short course (approximately 5 days) until a rise in platelet count to >20 × 10^9/L has been achieved to avoid the long-term side effects of corticosteroid therapy, especially growth failure, diabetes mellitus, and osteoporosis.

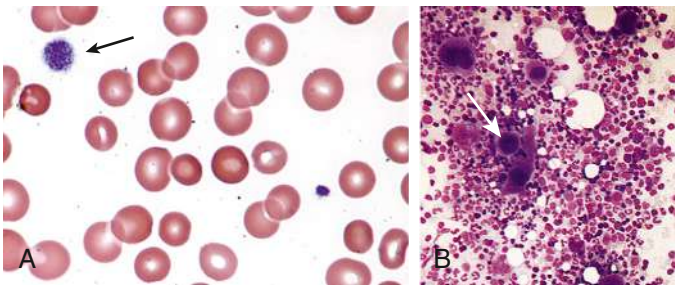

Fig. 533.3 Blood and marrow aspirate from child with immune thrombocytopenia. **A**, Blood smear shows large platelets. **B**, Bone marrow aspirate shows increased numbers of megakaryocytes, many of which appear immature. *(From Blanchette V, Bolton-Maggs P: Childhood immune thrombocytopenic purpura: diagnosis and management. Pediatr Clin North Am 2008;55:393–420. Fig 4.)*

Each of these medications may also be used to treat subsequent ITP exacerbations/recurrences, which usually occur several weeks after an initial course of therapy in 5–10% of patients. In the special case of ICH, multiple modalities should be used, including platelet transfusion (although not recommended in other bleeding manifestations), IVIG, high-dose corticosteroids, and prompt consultation by neurosurgery and general surgery (splenectomy).

Patients who are bleeding significantly (<5% of children with ITP) should be treated. ICH remains rare, and there are no data showing that treatment actually reduces its incidence. *Mucosal bleeding* in particular is the most significant in terms of predicting severe bleeding, but specific predictive indices, such as positive or negative predictive values, are not currently well established.

The role of **splenectomy** in ITP should be reserved for one of two circumstances: (1) the older child (≥4 years) with severe ITP that has lasted >1 year **(chronic ITP)** and whose symptoms are not easily controlled with therapy and/or (2) when life-threatening hemorrhage (e.g., ICH) complicates acute ITP if the platelet count cannot be corrected rapidly with transfusion of platelets and administration of IVIG and corticosteroids. Splenectomy is associated with a lifelong risk of overwhelming postsplenectomy infection caused by encapsulated organisms, increased risk of thrombosis, and the potential development of pulmonary hypertension in adulthood. As an alternative to splenectomy**, rituximab** has been used in children to treat chronic ITP. In 30–40% of children, rituximab has induced a partial or complete remission. TPO receptor agonists have also been used to increase platelet count and are approved for pediatric use.

CHRONIC AUTOIMMUNE THROMBOCYTOPENIC PURPURA

Approximately 20% of patients who present with acute ITP have persistent thrombocytopenia for >12 months and are said to have *chronic* ITP. At that time, a careful reevaluation for associated disorders should be performed, especially for autoimmune disease (e.g., SLE), chronic infectious disorders (e.g., HIV), and nonimmune causes of chronic thrombocytopenia, such as type 2B and platelet-type von Willebrand disease (VWD), X-linked thrombocytopenia, autoimmune lymphoproliferative syndrome, common variable immunodeficiency syndrome, autosomal macrothrombocytopenia, and WAS. The presence of coexisting *H. pylori* and hepatitis C infection should be considered and, if found, treated. Therapy should be aimed at controlling symptoms and

Table 533.4 Treatment Options for Immune Thrombocytopenia (ITP)

	PROS	CONS	COST
Observation	Does not expose patient to unnecessary medications	May increase parent and physician anxiety	Relatively inexpensive
IVIG	Rapid response in most cases	IV administration, side effects	Expensive
Corticosteroids	Oral, effective in 70–80% of patients, minimal side effects with short courses	Side effects, may not affect long term outcome	Inexpensive
Rituximab	Long-term remission in 40–60% of patients	IV administration, immune suppression, potential for reactivation of hepatitis	Very expensive
Splenectomy	Curative in 80% of patients	Requires surgery and anesthesia, lifelong risk of infection	Expensive
Thrombopoietin receptor agonists	Potential for oral administration, 40–60% of patients respond	Not curative, usually required long term, can cause elevated liver enzymes	Very expensive

IV, Intravenous; IVIG, intravenous immunoglobulin.
Adapted from Flood VH, Scott JP. Bleeding and thrombosis. In: Kliegman R, Lye P, Bordini B, et al. eds. *Nelson Pediatric Symptom-Based Diagnosis.* Philadelphia: Elsevier, 2017.

preventing serious bleeding. In ITP, the spleen is the primary site of both antiplatelet antibody synthesis and platelet destruction. Splenectomy is successful in inducing complete remission in 64–88% of children with chronic ITP. This effect must be balanced against the lifelong risk of overwhelming postsplenectomy infection and/or thrombosis. This decision is often affected by quality-of-life issues, as well as the ease with which the child can be managed using medical therapy, such as IVIG, corticosteroids, IV anti-D, or rituximab. Two effective agents that act to stimulate thrombopoiesis, **romiplostim** and **eltrombopag** (see Fig. 533.1), are approved to treat adults and children with chronic ITP. Although these do not address the mechanism of action of ITP, the increase in platelet count may be enough to compensate for the increased destruction and allow the patient to have resolution of bleeding and maintain a platelet count >50 × 10^9/L.

533.2 Drug-Induced Thrombocytopenia

Brian R. Branchford and Veronica H. Flood

A number of drugs are associated with immune thrombocytopenia as the result of either an immune process or megakaryocyte injury. Some common drugs used in pediatrics that cause thrombocytopenia include valproic acid, phenytoin, carbamazepine, sulfonamides, vancomycin, and trimethoprim-sulfamethoxazole. Most of these drugs may affect platelet function as well as the count itself. Heparin-induced thrombocytopenia (and rarely an associated thrombosis) is seldom seen in pediatrics, but it occurs when, after exposure to heparin, the patient has an antibody directed against the heparin–platelet factor 4 complex. Recommended treatment for heparin-induced thrombocytopenia includes direct thrombin inhibitors such as argatroban or bivalirudin and removal of all sources of heparin, including central venous catheter line flushes.

533.3 Nonimmune Platelet Destruction

Brian R. Branchford and Veronica H. Flood

The syndromes of DIC (see Chapter 532), HUS (see Chapter 560.5), and thrombotic thrombocytopenic purpura (see Chapter 533.5) share the hematologic picture of a thrombotic microangiopathy in which there exists RBC destruction and consumptive thrombocytopenia caused by platelet and fibrin deposition in the microvasculature. The microangiopathic hemolytic anemia is characterized by the presence of RBC fragments, including helmet cells, schistocytes, spherocytes, and burr cells.

533.4 Hemolytic-Uremic Syndrome

See Chapter 560.5.

533.5 Thrombotic Thrombocytopenic Purpura

Brian R. Branchford and Veronica H. Flood

Thrombotic thrombocytopenic purpura (TTP) is a rare thrombotic microangiopathy characterized by the pentad of fever, microangiopathic hemolytic anemia, thrombocytopenia, abnormal renal function, and central nervous system (CNS) changes; TTP is clinically similar to HUS (Table 533.5). Although TTP can be congenital, the acquired form is more common and usually presents in adults and occasionally in adolescents. Microvascular thrombi within the CNS cause subtle, shifting neurologic signs that vary from changes in affect and orientation to aphasia, blindness, and seizures. Initial manifestations are often nonspecific (weakness, pain, emesis), and prompt recognition of this disorder is critical. Laboratory findings provide important clues to the diagnosis and show microangiopathic hemolytic anemia characterized by morphologically abnormal RBCs, with schistocytes, spherocytes, helmet cells, and an elevated reticulocyte count in association with thrombocytopenia. Coagulation studies are usually nondiagnostic. Blood urea nitrogen and creatinine are sometimes elevated. The **treatment** of acquired TTP is plasmapheresis (plasma exchange), which is effective in 80–95% of patients. Treatment with plasmapheresis should be instituted on the basis of thrombocytopenia and microangiopathic hemolytic anemia even if other symptoms are not yet present because of the high mortality (80–90%) in patients without timely intervention. Rituximab, corticosteroids, and splenectomy are reserved for refractory cases. *Caplacizumab,* an anti-VWF humanized immunoglobulin, blocks the interaction of ultralarge (i.e., most likely to bind platelets) VWF multimers with platelets, and many result in rapid resolution of acute TTP.

The majority of cases of TTP are acquired, caused by an autoantibody-mediated **deficiency of ADAMTS13** (a disintegrin and metalloproteinase with a thrombospondin type 1 motif member 13) that is responsible for cleaving the high-molecular-weight multimers of VWF and appears to play a pivotal role in the evolution of the thrombotic microangiopathy (Fig. 533.4) that results in a preponderance of ultralarge multimers that more adeptly bind platelets, triggering the microangiopathy. In contrast, levels of ADAMTS13 in HUS are usually normal.

Congenital ADAMTS13 deficiency causes rare familial cases of TTP/HUS, usually manifested as recurrent episodes of thrombocytopenia, hemolytic anemia, jaundice, and renal involvement, with or without neurologic changes, that often present in infancy in the context of an intercurrent illness. Treatment of hereditary TTP with recombinant ADAMTS13 has been successful when patients are refractory to fresh frozen plasma therapy. Abnormalities of the complement system have now also been implicated in rare cases of familial TTP. ADAMTS13 deficiency can be treated by repeated infusions of fresh-frozen plasma.

533.6 Kasabach-Merritt Syndrome

Brian R. Branchford and Veronica H. Flood

See also Chapter 691.

The association of a giant hemangioma with localized intravascular coagulation causing consumptive thrombocytopenia and hypofibrinogenemia is called Kasabach-Merritt syndrome. In most patients, the site of the hemangioma is obvious, but retroperitoneal and intra-abdominal hemangiomas may require body imaging for detection. Platelet trapping and activation of coagulation occurs inside the hemangioma, with fibrinogen consumption and generation of fibrin(ogen) degradation products. Arteriovenous malformation within the lesions can cause heart failure. Pathologically, Kasabach-Merritt syndrome appears to develop more often as a result of a kaposiform hemangioendothelioma or tufted hemangioma rather than a simple hemangioma. The peripheral blood smear shows microangiopathic changes.

Multiple modalities have been used to treat Kasabach-Merritt syndrome, including propranolol, surgical excision (if possible), laser photocoagulation, high-dose corticosteroids, local radiation therapy, antiangiogenic agents such as interferon-α_2, and vincristine. Over time, most patients who present in infancy have regression of the hemangioma. Treatment of the associated coagulopathy may benefit from a trial of antifibrinolytic therapy with ε-aminocaproic acid (Amicar) or anticoagulation with low molecular weight heparin.

Table 533.5 ADAMTS13 Deficiency and Thrombotic Thrombocytopenic Purpura

DISEASE	PATHOPHYSIOLOGY	LAB FINDINGS	MANAGEMENT
Thrombotic thrombocytopenic purpura (TTP)	*Acquired*: Ab to ADAMTS13 *Congenital*: Inadequate ADAMTS13 production	Ab to ADAMTS13 ADAMTS13 <10%	*Acquired*: Plasmapheresis with plasma *Congenital*: Scheduled plasma infusions

Autoimmune TTP may be transient, recurrent, drug (ticlopidine, clopidogrel) associated, or seen in some pregnancy-associated cases of TTP.
ADAMTS13 pathogenic variants are often familial and chronic-relapsing RRP.

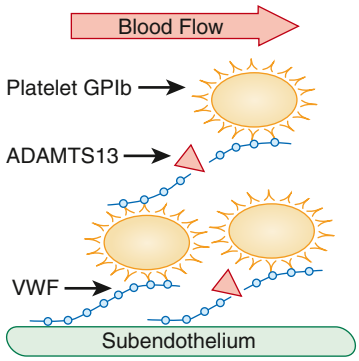

Fig. 533.4 Pathogenesis of thrombotic thrombocytopenic purpura (TTP). The von Willebrand factor (VWF) multimers facilitate platelet adhesion to the subendothelium by binding to exposed connective tissue and then to platelet glycoprotein Ib (GPIb). In flowing blood shear stress unfolds ultralarge VWF multimers in the platelet-rich thrombus and enables ADAMTS13 to cleave a specific Tyr-Met bond in the second of the three A domains in VWF subunits. Cleavage reduces VWF multimer size and limits thrombus growth. In the absence of ADAMTS13, VWF-dependent platelet accumulation continues and eventually results in microvascular thrombosis and TTP. *(Courtesy Dr. J. Evan Sadler, Washington University.)*

533.7 Sequestration

Brian R. Branchford and Veronica H. Flood

Thrombocytopenia develops in individuals with massive splenomegaly, such as those with portal vein thrombosis or liver disease, because the spleen acts as a reservoir for platelets and may sequester a large number of them. Most such patients also have mild leukopenia and anemia on CBC. Individuals who have thrombocytopenia caused by splenic sequestration should undergo a workup to diagnose the etiology of splenomegaly, including infectious, inflammatory, infiltrative, neoplastic, obstructive, and hemolytic causes.

533.8 Congenital Thrombocytopenic Syndromes

Brian R. Branchford and Veronica H. Flood

See Table 533.2.

Congenital amegakaryocytic thrombocytopenia (CAMT) usually manifests within the first few days to week of life, when the child presents with petechiae and purpura caused by profound thrombocytopenia. CAMT is caused by a rare defect in hematopoiesis as a result of pathogenic variants in the *MPL* gene that encodes the stem cell TPO receptor. Other than skin and mucous membrane abnormalities, findings on physical examination are normal. Examination of the bone marrow shows an absence of megakaryocytes. These patients often progress to marrow failure (aplasia). Hematopoietic stem cell transplantation (HSCT) is curative.

Thrombocytopenia–absent radius (TAR) syndrome consists of thrombocytopenia (absence or hypoplasia of megakaryocytes) that presents in early infancy with bilateral radial anomalies of variable severity, ranging from mild changes to marked limb shortening (Fig. 533.5). Many such individuals also have other skeletal abnormalities of the ulna, radius, and lower extremities. *Present thumbs help to differentiate this disorder from Fanconi anemia.* Intolerance to cow's milk formula (present in 50%) may complicate management by triggering gastrointestinal (GI) bleeding, increased thrombocytopenia, eosinophilia, and a leukemoid reaction. The thrombocytopenia of TAR syndrome frequently remits over the first few years of life. The molecular basis of TAR syndrome is linked to *RBM8A*. A few patients have been reported to have a syndrome of **amegakaryocytic thrombocytopenia with radioulnar synostosis** caused by a pathogenic variant in the *HOXA11* gene. In contrast to TAR syndrome, this clinical disorder presents with marrow aplasia.

WAS is characterized by microthrombocytopenia, with tiny platelets, eczema, and recurrent infection as a consequence of immune deficiency (see Chapter 165.2). WAS is inherited as an X-linked disorder, and the gene implicated in WAS has been identified. The WAS protein appears to play an integral role in regulating the cytoskeletal architecture of both platelets and T lymphocytes in response to receptor-mediated cell signaling. The WAS protein is common to all cells of hematopoietic lineage. Molecular analysis of families with X-linked thrombocytopenia has shown that many affected members have a single nucleotide pathogenic variant within the WAS gene, whereas individuals with the full manifestation of WAS have large gene deletions. Examination of the bone marrow in WAS shows the normal number of megakaryocytes, although they may have bizarre morphologic features. Transfused platelets have a normal life span in these patients. Splenectomy often corrects the thrombocytopenia, suggesting that the platelets formed in WAS have accelerated destruction. After splenectomy, these patients are at increased risk for overwhelming infection and require lifelong antibiotic prophylaxis against encapsulated organisms. Approximately 5–15% of patients with WAS develop lymphoreticular malignancies (involving mostly leukemias and lymphomas). Successful HSCT from an unaffected donor cures WAS. **X-linked macrothrombocytopenia** and **dyserythropoiesis** have been linked to pathogenic variants in *GATA1*, which encodes an erythroid and megakaryocytic transcription factor.

MYH9-related thrombocytopenias include a number of diverse hereditary thrombocytopenia syndromes (e.g., Sebastian, Epstein, May-Hegglin, Fechtner) characterized by autosomal dominant macrothrombocytopenia, neutrophil inclusion bodies, and a variety of physical anomalies, including sensorineural deafness, renal disease, and eye disease. These have all been shown to be caused by different pathogenic variants in the *MYH9* gene (nonmuscle myosin-IIa heavy chain 9). The thrombocytopenia is usually mild and not progressive. Some other individuals with recessively inherited macrothrombocytopenia have abnormalities in chromosome 22q11. Pathogenic variants in the gene for glycoprotein Ibβ, an essential component of the platelet VWF receptor, can result in **Bernard-Soulier syndrome** (see Chapter 533.13), a macrothrombocytopenic disease. A diagnostic approach to genetic platelet disorders is noted in Figure 533.6.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

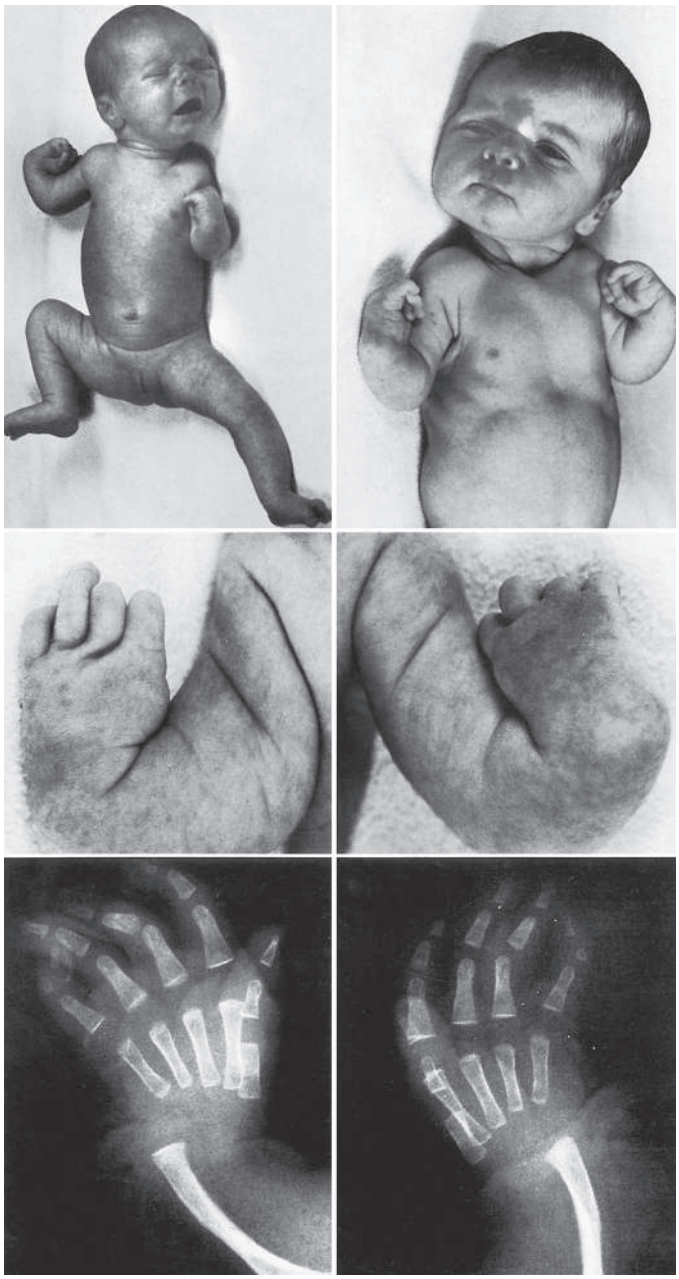

Fig. 533.5 A newborn, the first child of young, healthy parents, with fully expressed thrombocytopenia–absent radius (TAR) syndrome, including hypereosinophilia and anemia. Hypoplasia of the distal humeri and the shoulder girdles, bilateral hip dysplasia, mild talipes calcaneus, and clinodactyly of both little fingers are seen. This patient had a pronounced allergy to cow's milk, with exposure followed by diarrhea, vomiting, and decreased weight and platelet count, making a cow's milk–free diet mandatory. A persistent depressed nasal bridge and development of pronounced bowed legs are seen. *(From Wiedemann H-R, Kunze J, Grosse F-R, eds. Clinical Syndromes, 3rd ed. [English translation]. London: Mosby-Wolfe, 1997. p. 430.)*

533.9 Neonatal Thrombocytopenia

Brian R. Branchford and Veronica H. Flood

Thrombocytopenia in the newborn rarely is indicative of a primary disorder of megakaryopoiesis. It is usually the result of systemic illness or transfer of maternal antibodies directed against fetal platelets (see Table 533.3). Neonatal thrombocytopenia often occurs in association with congenital viral infections, especially rubella, cytomegalovirus, protozoal infection (e.g., toxoplasmosis), and syphilis, and perinatal bacterial infections, especially those caused by gram-negative bacilli. Thrombocytopenia associated with DIC may be responsible for severe spontaneous bleeding. The constellation of marked thrombocytopenia and abnormal abdominal findings is common in necrotizing enterocolitis and other causes of necrotic bowel. Thrombocytopenia in an ill child requires a prompt search for viral and bacterial pathogens.

Antibody-mediated thrombocytopenia in the newborn occurs because of transplacental transfer of maternal antibodies directed against fetal platelets. **Neonatal alloimmune thrombocytopenia (NAIT)** is caused by the development of maternal antibodies against paternally inherited antigens present on fetal platelets that are recognized as foreign by the maternal immune system. The incidence of NATP is 1/4,000-5,000 live births. The clinical manifestations of NAIT are those of an apparently well child who, within the first few days after delivery, has generalized petechiae and purpura. Laboratory studies show a normal maternal platelet count but moderate to severe thrombocytopenia in the newborn. Detailed review of the history should show no evidence of maternal thrombocytopenia. Up to 30% of infants with severe NAIT may have ICH, either prenatally or in the perinatal period. Unlike Rh disease, first pregnancies may be severely affected. Subsequent pregnancies are often more severely affected than the first.

The **diagnosis** of NAIT is made by checking for the presence of maternal alloantibodies directed against the father's platelets. Specific studies can be done to identify the target alloantigen. The most common cause is incompatibility for the platelet alloantigen HPA-1a. Specific DNA sequence polymorphisms have been identified that permit informative prenatal testing to identify at-risk pregnancies. The differential diagnosis of NAIT includes transplacental transfer of maternal IgG antiplatelet autoantibodies (maternal ITP), and, more commonly, viral or bacterial infection.

Treatment of NAIT requires the administration of IVIG prenatally to the mother if the status is known before birth. Therapy usually begins in the second trimester and is continued throughout the pregnancy. Fetal platelet count can be monitored by percutaneous umbilical blood sampling. Delivery should be performed by cesarean section to reduce risk for ICH from vaginal delivery. After delivery, if severe thrombocytopenia persists, transfusion of platelets that share the maternal alloantigens (e.g., washed maternal platelets) will cause a rise in platelet counts to provide effective hemostasis. However, a random donor platelet transfusion is more likely to be readily available. Some centers have units available that may lack the antigens most often involved. After there has been one affected child, genetic counseling is critical to inform the parents of the high risk of thrombocytopenia in subsequent pregnancies.

Children born to mothers with immune thrombocytopenic purpura **(maternal ITP)** appear to have a lower risk of serious hemorrhage than infants born with NAIT, although severe thrombocytopenia may occur. The mother's preexisting platelet count may have some predictive value in that severe maternal thrombocytopenia before delivery appears to predict a higher risk of fetal thrombocytopenia. In mothers who have had splenectomy for ITP, the maternal platelet count may be normal and is not predictive of fetal thrombocytopenia.

Treatment includes prenatal administration of corticosteroids to the mother and IVIG and sometimes corticosteroids to the infant after delivery. Thrombocytopenia in an infant, whether a result of NAIT or maternal ITP, usually resolves within 2-4 months after delivery. The period of highest risk is the immediate perinatal period.

Two syndromes of congenital failure of platelet production often present in the newborn period. In **CAMT** the newborn manifests petechiae and purpura shortly after birth. Findings on physical examination are otherwise normal. Megakaryocytes are absent from the bone marrow. This syndrome is caused by a pathogenic variant in the megakaryocyte TPO receptor that is essential for development of all hematopoietic cell lines. Pancytopenia eventually develops, and HSCT is curative. **TAR syndrome** consists of thrombocytopenia that presents in early infancy, with bilateral radial anomalies of variable severity, ranging from mild changes to marked limb shortening. It frequently remits over the first few years of life (see Chapter 533.8 and Fig. 533.5).

533.10 Thrombocytopenia From Acquired Disorders Causing Decreased Production

Brian R. Branchford and Veronica H. Flood

Disorders of the bone marrow that inhibit megakaryopoiesis usually affect RBC and WBC production. Infiltrative disorders, including malignancies, such as acute lymphocytic leukemia, histiocytosis, lymphomas, and storage disease, usually cause either abnormalities on physical examination (lymphadenopathy, hepatosplenomegaly, or masses), abnormalities of the WBC count, or anemia. Aplastic processes may present as isolated thrombocytopenia, although there are usually clues on the CBC (leukopenia, neutropenia, anemia, or macrocytosis). Children with constitutional aplastic anemia (Fanconi anemia) often (but not always) have abnormalities on examination, including radial and/or thumb anomalies, other skeletal anomalies, short stature, microcephaly, and hyperpigmentation. Bone marrow examination should be performed when thrombocytopenia is associated with abnormalities found on physical examination or on examination of the other blood cell lines.

533.11 Platelet Function Disorders

Brian R. Branchford and Veronica H. Flood

There is no simple and reliable test to screen for abnormal platelet function. Bleeding time and the platelet function analyzer (PFA-100) have been used, but neither has sufficient sensitivity or specificity to rule in or rule out a platelet defect, especially one with mild-moderate phenotypic expression. Bleeding time measures the interaction of platelets with the blood vessel wall and thus is affected by both platelet count and platelet function. The predictive value of bleeding time is problematic because bleeding time is dependent on other factors, including the technician's skill and the patient's cooperation, often a challenge in the infant or young child; it is not recommended in high resource settings. The PFA-100 measures platelet adhesion and aggregation in whole blood at high shear when the blood is exposed to either collagen-epinephrine or collagen-ADP. Results are reported as the closure time in seconds. The use of the PFA-100 as a screening test remains controversial. For patients with a positive history of bleeding suggestive of VWD or platelet dysfunction, specific VWF testing and platelet function studies should be done, irrespective of the results of the bleeding time or PFA-100.

Platelet function in the clinical laboratory is measured using platelet aggregometry. In the aggregometer, agonists, such as collagen, ADP, ristocetin, epinephrine, arachidonic acid, and thrombin (or the thrombin receptor peptide), are added to platelet-rich plasma, and the clumping of platelets over time is measured by an automated machine through either light transmission or electric impedance. At the same time, other instruments measure the release of granular contents, such as ATP, from the platelets after activation. The ability of platelets to aggregate and their metabolic activity can thus be assessed simultaneously. When a patient is being evaluated for possible platelet dysfunction, it is critically important to exclude the presence of other exogenous agents and to study the patient, if possible, off all medications for 2 weeks, especially those with any potential antiplatelet effects. Further evaluation using flow cytometric analysis of surface receptors or molecular and/or genetic testing is often necessary to make a more definitive diagnosis.

533.12 Acquired Disorders of Platelet Function

Brian R. Branchford and Veronica H. Flood

A number of systemic illnesses are associated with platelet dysfunction, most frequently liver disease, kidney disease (uremia), and disorders that trigger increased amounts of fibrin degradation products. These disorders frequently cause prolonged bleeding time and are often associated with other abnormalities of the coagulation mechanism. *The most important element of management is to treat the primary illness.* If treatment of the primary process is not feasible, infusions of

desmopressin have been helpful in augmenting hemostasis and correcting bleeding time. In some patients, transfusions of platelets and cryoprecipitate have also been helpful in improving hemostasis.

Many medications alter platelet function. The most common drug in adults that alters platelet function is acetylsalicylic acid *(aspirin)*. Aspirin irreversibly acetylates the enzyme cyclooxygenase, which is critical in the formation of thromboxane A_2. Aspirin usually causes moderate platelet dysfunction that becomes more prominent if there is another abnormality of the hemostatic mechanism. In children, common drugs that reversibly inhibit platelet function include other nonsteroidal anti-inflammatory drugs (NSAIDs), valproic acid, and high-dose penicillin. Specific agents to inhibit platelet function therapeutically include those that block the platelet ADP receptor (clopidogrel) and αIIb-β_3 receptor antagonists, as well as aspirin.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

533.13 Congenital Abnormalities of Platelet Function

Brian R. Branchford and Veronica H. Flood

Severe platelet function defects usually present with petechiae and purpura shortly after birth, especially after vaginal delivery (see Table 533.2). Defects in the platelet GPIb complex (the VWF receptor) or the αIIb-β_3 complex (the fibrinogen receptor) cause severe congenital platelet dysfunction. Although laboratory tests of platelet function are available, molecular characterization by genetic testing is rapidly progressing for platelet disorders.

Bernard-Soulier syndrome, a severe congenital platelet function disorder, is caused by absence or severe deficiency of the GPIb complex (VWF receptor) on the platelet membrane. This syndrome is characterized by a macrothrombocytopenia, with giant platelets and greatly prolonged bleeding time (>20 min) or PFA-100 closure time. Patients may have significant mucocutaneous and GI bleeding. Platelet aggregation tests classically demonstrate absent ristocetin-induced platelet aggregation but normal aggregation to all other agonists. Ristocetin induces the binding of VWF to platelets and agglutinates platelets. Results of studies of VWF antigen and activity are normal. The GPIb complex interacts with the platelet cytoskeleton; a defect in this interaction is believed to be the cause of the large platelet size. This receptor deficiency can also be detected by flow cytometry. Bernard-Soulier syndrome is inherited as an autosomal recessive disorder. Causative pathogenic variants are usually identified in the genes encoding the GPIb complex of glycoproteins Ibα, Ibβ, V, and IX.

Glanzmann thrombasthenia is a congenital disorder associated with severe platelet dysfunction that yields prolonged bleeding time and a normal platelet count. Platelets have normal size and morphologic features on the peripheral blood smear, and closure times for PFA-100 or bleeding time are extremely abnormal. Aggregation studies classically demonstrate abnormal or absent aggregation with all agonists used except ristocetin because ristocetin agglutinates platelets and does not require a metabolically active platelet. This disorder is caused by deficiency of the platelet fibrinogen receptor αIIb-β_3, the major integrin complex on the platelet surface that undergoes conformational changes by inside-out signaling when platelets are activated. This receptor deficiency can also be detected by flow cytometry. Fibrinogen binds to this complex when the platelet is activated and causes platelets to aggregate. Glanzmann thrombasthenia is caused by pathogenic variants in the genes for αIIb or β_3 and is inherited in an autosomal recessive manner. For both Bernard-Soulier syndrome and Glanzmann thrombasthenia, the **diagnosis** is confirmed by flow cytometry of the patient's platelet glycoproteins. Bleeding in Glanzmann thrombasthenia may be quite severe and is typically mucocutaneous, including epistaxis, gingival, and GI bleeding. There are reports of curative therapy using stem cell transplant.

Hereditary deficiency of platelet storage granules occurs in two well-characterized but rare syndromes that involve deficiency of intracytoplasmic granules. **Dense granule deficiency** is characterized by absence of the granules that contain ADP, ATP, Ca^{2+}, and serotonin. This disorder is diagnosed by the finding that ATP is not released on platelet aggregation studies and ideally is characterized by transmission electron microscopic studies. **Hermansky-Pudlak syndrome** (with nine subtypes) is a dense granule deficiency caused by defects in lysosomal storage. Affected patients present with oculocutaneous albinism and hemorrhage caused by the platelet defect; some patients also develop granulomatous colitis resembling

Table 533.6 Comparison of Nine Types of Hermansky-Pudlak Syndrome

+, Present; –, absent; CAH, congenital adrenal hyperplasia; ILD, interstitial lung disease.

Crohn disease or pulmonary fibrosis/interstitial lung disease (Table 533.6). **Chédiak-Higashi syndrome** also presents with a dense granule defect, immune dysfunction, and albinism. **Gray platelet syndrome** is caused by the absence of platelet α granules, resulting in large platelets that are large and appear gray on Wright stain of peripheral blood. In this rare syndrome, aggregation and release are absent with most agonists other than thrombin and ristocetin. Transmission electron microscopic studies are diagnostic. Autosomal recessive gray platelet syndrome is caused by defects in the *NBEAL2* gene, while autosomal dominant disease is associated with a pathogenic variant in *GFI1B*. This disorder may also be associated with familial leukemia. **Quebec platelet syndrome** is caused by degradation of platelet α granules caused by defects in *PLAU*, which encodes a urokinase-type plasminogen activator. Treatment usually involves antifibrinolytic therapy.

OTHER HEREDITARY DISORDERS OF PLATELET FUNCTION

Abnormalities in the pathways of platelet signaling/activation and release of granular contents cause a heterogeneous group of platelet function defects that are usually manifested as increased bruising, epistaxis, and menorrhagia. Symptoms may be subtle and are often made more obvious by high-risk surgery, such as tonsillectomy or adenoidectomy, or by administration of NSAIDs. In the laboratory, bleeding time is variable, and closure time as measured by the PFA-100 is frequently, but not always, prolonged. Platelet aggregation studies show deficient aggregation with one or two agonists and/or abnormal release of granular contents.

The formation of thromboxane from arachidonic acid (AA) after the activation of phospholipase is critical to normal platelet function. Deficiency or dysfunction of enzymes, such as cyclooxygenase and thromboxane synthase, which metabolize AA, causes abnormal platelet function. In the aggregometer, platelets from such patients do not aggregate in response to AA.

The most common platelet function defects are those characterized by variable bleeding time/PFA closure times and abnormal aggregation with one or two agonists, usually ADP and/or collagen. Some of these individuals have only decreased release of ATP from intracytoplasmic granules; the significance of this finding is debated.

TREATMENT OF PATIENTS WITH PLATELET DYSFUNCTION

Successful treatment depends on the severity of both the diagnosis and the hemorrhagic event. In all but severe platelet function defects, desmopressin, 0.3 μg/kg intravenously, may be used for mild to moderate bleeding episodes. In addition to its effect on stimulating levels of VWF and factor VIII, desmopressin corrects bleeding time and augments hemostasis in many individuals with mild to moderate platelet function defects. Antifibrinolytic therapy may be useful for mucosal bleeds. For individuals with Bernard-Soulier syndrome or Glanzmann thrombasthenia, platelet transfusions of 0.5-1 unit single donor platelets correct the defect in hemostasis and may be lifesaving. Rarely, alloantibodies develop to the deficient platelet protein, rendering the patient refractory to the transfused platelets. In such patients, the use of recombinant factor VIIa has been effective, and this treatment was recently approved for platelet-refractory Glanzmann's thrombasthenia. In both conditions, HSCT has been curative.

533.14 Disorders of the Blood Vessels

Brian R. Branchford and Veronica H. Flood

Disorders of the vessel walls or supporting structures mimic the findings of a bleeding disorder, although coagulation studies are usually normal. The findings of petechiae and purpuric lesions in such patients are often attributable to an underlying vasculitis or vasculopathy. Skin biopsy can be particularly helpful in elucidating the type of vascular pathology.

IgA VASCULITIS (HENOCH-SCHÖNLEIN PURPURA)

See Chapter 210.1.

EHLERS-DANLOS SYNDROME

See Chapter 744.

OTHER ACQUIRED DISORDERS

Scurvy, chronic corticosteroid therapy, and severe malnutrition are associated with "weakening" of the collagen matrix that supports the blood vessels. Therefore these factors are associated with easy bruising, and, particularly in the case of scurvy, bleeding gums and loosening of the teeth. Lesions of the skin that initially appear to be petechiae and purpura may be seen in vasculitic syndromes, such as SLE. Leukocytoclastic vasculitis may present with nonthrombocytopenic purpura (see Chapter 210). A unique variant of leukocytoclastic vasculitis is associated with exercise.

Section 8
The Spleen

Chapter 534
Anatomy and Function of the Spleen

Allison S. Remiker and Amanda M. Brandow

ANATOMY

The splenic precursor is recognizable by 5 weeks of gestation. At birth, the spleen weighs approximately 11 g. Thereafter, it enlarges until puberty, reaching an average weight of 150 g, and then diminishes in size during adulthood. Approximately 15% of patients will have an accessory spleen. The major splenic components are a lymphoid compartment *(white pulp)* and a filtering system *(red pulp)*. The white pulp consists of periarterial lymphatic sheaths (PALS; T-zone) of T lymphocytes with embedded germinal centers containing B lymphocytes. The red pulp has a skeleton of fixed reticular cells, mobile macrophages, partially collapsed endothelial passages (cords of Billroth), and splenic sinuses. A *perifollicular zone (PFZ)* (known as the marginal zone in murine models) is rich in dendritic (antigen-presenting) cells and natural killer cells and separates the red pulp from the white pulp. The splenic capsule contains smooth muscle and contracts in response to epinephrine. Approximately 10% of the blood delivered to the spleen flows rapidly through a closed vascular network. The other 90% flows more slowly through an open system (the *splenic cords*), where it is filtered through 1-5 μm slits before entering the splenic sinuses.

FUNCTION

The unique anatomy and blood flow of the spleen enable it to perform reservoir, filtering, and immunologic functions. The spleen

Crohn disease or pulmonary fibrosis/interstitial lung disease (Table 533.6). **Chédiak-Higashi syndrome** also presents with a dense granule defect, immune dysfunction, and albinism. **Gray platelet syndrome** is caused by the absence of platelet α granules, resulting in large platelets that are large and appear gray on Wright stain of peripheral blood. In this rare syndrome, aggregation and release are absent with most agonists other than thrombin and ristocetin. Transmission electron microscopic studies are diagnostic. Section 8
The Spleen

Chapter 534
Anatomy and Function of the Spleen

Allison S. Remiker and Amanda M. Brandow

ANATOMY

The splenic precursor is recognizable by 5 weeks of gestation. At birth, the spleen weighs approximately 11 g. Thereafter, it enlarges until puberty, reaching an average weight of 150 g, and then diminishes in size during adulthood. Approximately 15% of patients will have an accessory spleen. The major splenic components are a lymphoid compartment *(white pulp)* and a filtering system *(red pulp)*. The white pulp consists of periarterial lymphatic sheaths (PALS; T-zone) of T lymphocytes with embedded germinal centers containing B lymphocytes. The red pulp has a skeleton of fixed reticular cells, mobile macrophages, partially collapsed endothelial passages (cords of Billroth), and splenic sinuses. A *perifollicular zone (PFZ)* (known as the marginal zone in murine models) is rich in dendritic (antigen-presenting) cells and natural killer cells and separates the red pulp from the white pulp. The splenic capsule contains smooth muscle and contracts in response to epinephrine. Approximately 10% of the blood delivered to the spleen flows rapidly through a closed vascular network. The other 90% flows more slowly through an open system (the *splenic cords*), where it is filtered through 1-5 μm slits before entering the splenic sinuses.

FUNCTION

The unique anatomy and blood flow of the spleen enable it to perform reservoir, filtering, and immunologic functions. The spleen

receives 5–6% of the cardiac output but normally contains only 25 mL of blood. It can retain much more when it enlarges, leading to **cytopenias**. Hematopoiesis in the red pulp is a major splenic function at 3-6 months of fetal life but subsequently disappears. *Splenic hematopoiesis* can be resumed in patients with myelofibrosis or severe hemolytic anemia. Factor VIII, iron, plasmablasts, plasma cells, and one third of the circulating platelet mass are sequestered in the spleen and can be released by stress or epinephrine stimulation. **Thrombocytosis** and **leukocytosis** occur with loss of the splenic reservoir function. A high platelet count after the loss of splenic function or splenectomy is not associated with an increased risk of thrombosis in children.

Slow blood flow past macrophages and through small openings in the sinus walls facilitates the filtering functions of the spleen removing any particles >1 micron in size from the circulation. Excess membrane is removed from young red blood cells (RBCs) and loss of this function is characterized by target cells, poikilocytosis, and decreased osmotic fragility. The spleen is the primary site for destruction of old RBCs, and this function is assumed by other reticuloendothelial cells after splenectomy. The spleen also removes damaged/abnormal RBCs (e.g., spherocytes, antibody-coated RBCs) and damaged/senescent platelets. Intracytoplasmic inclusions may be removed from RBCs without cell lysis. Functional or anatomic hyposplenia is characterized by continued circulation of cells containing nuclear remnants **(Howell-Jolly bodies)**, denatured hemoglobin **(Heinz bodies)**, and other debris in RBCs. This debris may appear as "pits" on indirect microscopy.

The spleen plays a large role in host defense against infection. Mechanical filtration occurs removing parasitized erythrocytes, as well as unopsonized bacteria. The spleen is the largest lymphoid organ in the body and contains almost half the body's total immunoglobulin-producing B lymphocytes. The spleen processes foreign material to stimulate production of opsonizing antibody. Upon antigenic challenge, B and T cells are developed in the spleen, with subsequent release of immunoglobulins. Production of immune-mediating proteins important in bacterial clearance occurs in the spleen including complement, opsonins, properdin, and tuftsin. Thus young (nonimmune) or hyposplenic individuals are at increased risk for **sepsis** caused by pneumococci and other encapsulated bacteria. The spleen can also use phagocytosis to trap and destroy intracellular parasites. The spleen has a minor role in antibody response to intramuscularly or subcutaneously injected antigens but is required for early antibody production after exposure to intravenous antigens. Additionally, the spleen is important in the pathogenesis of immune-mediated cytopenias (IMCs). Antibody-coated platelets or erythrocytes are phagocytosed via mechanisms associated with splenic macrophages. The spleen also serves as a reservoir for antibody producing plasma cells involved in IMCs.

Chapter 535

Splenomegaly

Allison S. Remiker and Amanda M. Brandow

CLINICAL MANIFESTATIONS

A soft, thin spleen is palpable in 15% of neonates, 10% of normal children, and 5% of adolescents. In most individuals, the spleen must be 2-3 times its normal size before it is palpable. The spleen is best examined when standing on the right side of a supine patient by palpating across the abdomen as the patient inspires deeply or with the patient in the right lateral decubitus position. A splenic edge felt more than 2 cm below the left costal margin is abnormal. An enlarged spleen might descend into the pelvis; when splenomegaly is suspected, the abdominal examination should begin at a lower starting point. Superficial abdominal venous distention may be present when splenomegaly is a result of portal hypertension. Patients may also complain of left upper quadrant pain as the spleen enlarges. Radiologic detection or confirmation of splenic enlargement is done with ultrasonography, CT, MRI, positron emission tomography, or technetium-99m sulfur colloid scan. The latter also assesses splenic function.

DIFFERENTIAL DIAGNOSIS

Table 535.1 lists specific causes of splenomegaly. A thorough history with a focus on systemic complaints (e.g., fever, night sweats, malaise, weight loss) and a complete physical examination (with special attention to lymphadenopathy, jaundice, hepatomegaly, rashes, joint swelling, petechiae, ecchymoses), in combination with a complete blood count and careful review of the peripheral smear, can help guide diagnosis.

Pseudosplenomegaly

Abnormally long mesenteric connections may produce a *wandering* or ptotic spleen. An enlarged left lobe of the liver, a left upper quadrant mass, or a splenic hematoma may be mistaken for splenomegaly. Splenic **cysts** may contribute to splenomegaly or mimic it; these may be congenital (epidermoid) or acquired (pseudocyst) after trauma or infarction. Cysts are usually asymptomatic and are found on radiologic evaluation. **Splenosis** after splenic rupture or an accessory spleen (present in 15% of normal individuals) may also mimic splenomegaly; most are not palpable. The syndrome of **congenital polysplenism** includes cardiac defects, left-sided organ anomalies, bilobed lungs, biliary atresia, and pseudosplenomegaly (see Chapter 480.11).

Hypersplenism

Increased splenic function (sequestration or destruction of circulating cells) can result in peripheral blood **cytopenias** (thrombocytopenia, neutropenia, anemia), increased bone marrow activity, and splenomegaly. It is usually secondary to another disease and may be cured by treatment of the underlying condition or, if absolutely necessary, may be moderated by splenectomy. Table 535.1 lists the most common diseases associated with massive splenomegaly.

Congestive Splenomegaly

Splenomegaly may result from obstruction in the hepatic, portal, or splenic veins leading to hypersplenism. Wilson disease (see Chapter 405.2), galactosemia (see Chapter 107.2), biliary atresia (see Chapter 404.1), and α_1-antitrypsin deficiency (see Chapter 405) may result in hepatic inflammation, fibrosis, and vascular obstruction. Congenital abnormalities (absence or hypoplasia) of the portal or splenic veins may cause vascular obstruction. Septic omphalitis or thrombophlebitis (spontaneous or as a result of umbilical venous catheterization in neonates) may result in secondary obliteration of these vessels. Splenic venous flow may be obstructed by masses of sickled erythrocytes leading to infarction. When the spleen is the site of vascular obstruction, splenectomy cures hypersplenism. However, because obstruction usually is in the hepatic or portal systems, **portacaval shunting** may be more helpful since both portal hypertension and thrombocytopenia contribute to variceal bleeding.

IMMUNOLOGIC AND INFLAMMATORY PROCESSES*
Systemic lupus erythematosus
Juvenile idiopathic arthritis
Mixed connective tissue disease
Systemic vasculitis
Serum sickness
Drug hypersensitivity, especially to phenytoin
Graft-versus-host disease
Sjögren syndrome
Cryoglobulinemia
Amyloidosis
Sarcoidosis
Autoimmune lymphoproliferative syndrome‡
Castleman disease‡
Posttransplant lymphoproliferative disease
Large granular lymphocytosis and neutropenia
Histiocytosis syndromes‡
Macrophage activation syndrome
Hemophagocytic lymphohistiocytosis (genetic, acquired)‡

MALIGNANCIES
Primary: leukemia (acute, chronic)‡, lymphoma‡, angiosarcoma, mastocytosis
Metastatic

STORAGE DISEASES
Lipidosis (Gaucher disease‡, Niemann-Pick disease, infantile GM1 gangliosidosis)
Mucopolysaccharidoses (Hurler, Hunter-type)
Mucolipidosis (I-cell disease, sialidosis, multiple sulfatase deficiency, fucosidosis)
Defects in carbohydrate metabolism: galactosemia, fructose intolerance, glycogen storage disease IV
Sea-blue histiocyte syndrome
Tangier disease
Wolman disease
Hyperchylomicronemia type I, IV

CONGESTIVE DISEASE*
Heart failure
Intrahepatic cirrhosis or fibrosis
Extrahepatic portal (thrombosis), splenic, and hepatic vein obstruction (thrombosis, Budd-Chiari syndrome)

*Common.
†Chronic or recurrent infection suggests underlying immunodeficiency.
‡Associated with hypersplenomegaly.
CML, Chronic myelogenous leukemia; CMV, cytomegalovirus; EBV, Epstein-Barr virus; G6PD, glucose-6-phosphate dehydrogenase; HHV-6, human herpesvirus 6; HIV, human immunodeficiency virus.

Chapter 536

Hyposplenism, Splenic Trauma, and Splenectomy

Allison S. Remiker and Amanda M. Brandow

HYPOSPLENISM

Congenital absence (asplenia) or underdevelopment (hyposplenia) of the spleen is associated with complex cyanotic heart defects, dextrocardia, bilateral trilobed lungs, and heterotopic abdominal organs (**Ivemark syndrome**; see Chapter 480.11). Patients with isolated congenital asplenia have pathogenic variants in *RPSA* in ~40% of cases. Right atrial isomerism (Ivemark syndrome), a form of heterotaxy, may have asplenia associated with pathogenic variants of *GDF1*. Splenic function is usually normal in children with congenital polysplenia. **Functional hyposplenism** may occur in normal neonates, especially premature infants. Children with sickle cell hemoglobinopathies (see Chapter 511.1) may have splenic hypofunction as early as 6 months of age. In this setting, the spleen eventually autoinfarcts and becomes fibrotic and permanently nonfunctional. Functional hyposplenism may also occur in malaria (see Chapter 334), after irradiation to the left upper quadrant, and when the reticuloendothelial function of the spleen is overwhelmed (as in severe hemolytic anemia or metabolic storage disease). Thrombosis of the splenic/celiac arteries or splenic vein is associated with functional hyposplenism. Splenic hypofunction has been reported occasionally in patients with autoimmune diseases (i.e., juvenile idiopathic arthritis, lupus, sarcoidosis), nephritis, inflammatory bowel disease, celiac disease, chronic hepatitis, Pearson syndrome, Fanconi anemia, those with use of high-dose corticosteroids, and graft-versus-host disease (Table 536.1).

Splenic hypofunction is characterized by **red blood cell (RBC) inclusions** in peripheral blood smears (Howell-Jolly or Heinz bodies), "pits" on interference microscopy, and poor uptake of technetium or other spleen scans (Table 536.2 and Fig. 536.1). Reduced immunoglobulin M memory B cells may also be detected and is a risk factor for overwhelming **sepsis**. Patients with functional hyposplenism or asplenia are at increased risk for sepsis from **encapsulated bacteria** and benefit from antibiotic prophylaxis and urgent evaluation when febrile.

Table 536.1 Diseases Associated with Hyposplenism or Splenic Atrophy

CONGENITAL FORMS	**AUTOIMMUNE DISORDERS**
Normal and premature neonates	Systemic lupus erythematosus
Isolated congenital hypoplasia	Juvenile idiopathic arthritis
Ivemark syndrome	Glomerulonephritis
Autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome	Granulomatosis with polyangiitis
	Goodpasture syndrome
	Sjögren syndrome
Hypoparathyroidism syndrome	Polyarteritis nodosa
Stormorken syndrome	Thyroiditis
Heterotaxia syndromes	Sarcoidosis
GASTROINTESTINAL DISORDERS	**INFECTIOUS DISEASES**
Celiac disease	Pneumococcal meningitis
Inflammatory bowel disease	HIV/AIDS
Whipple disease	Malaria
Dermatitis herpetiformis	**IATROGENIC FORMS**
Intestinal lymphangiectasia	Exposure to methyldopa
Idiopathic chronic ulcerative enteritis	High-dose steroids
	Total parenteral nutrition
	Splenic irradiation
HEPATIC DISORDERS	**ALTERATION IN SPLENIC CIRCULATION**
Active chronic hepatitis	Thrombosis of splenic artery
Primary biliary cirrhosis	Thrombosis of splenic vein
Hepatic cirrhosis and portal hypertension	Thrombosis of celiac artery
Alcoholism and alcoholic hepatopathy	**MISCELLANEOUS**
	Amyloidosis
HEMATOLOGIC AND ONCOLOGIC DISORDERS	
Sickle cell disease (all genotypes)	
Bone marrow transplantation	
Chronic graft-versus-host disease	
Acute leukemia	
Chronic myeloproliferative disorders	
Fanconi syndrome	
Splenic tumors	
Mastocytosis	

From Di Sabatino A, Carsetti R, Corazza GR. Post-splenectomy and hyposplenic states. *Lancet* 2011;378:86–97.

SPLENIC TRAUMA

Injury to the spleen may occur with abdominal trauma. Small splenic capsular tears may cause abdominal or referred left shoulder pain as a result of diaphragmatic irritation by blood. Larger tears result in more severe blood loss, with similar pain and signs of **hypovolemic shock**. Previously enlarged spleens (as in patients with infectious mononucleosis) are more likely to rupture with minor trauma. *Patients with splenomegaly should avoid contact sports and other activities that increase the risk of splenic trauma.* CT scan with intravenous contrast is the best imaging modality to assess splenic trauma in a hemodynamically stable patient. In emergent situations extended focused assessment with sonography in trauma (E-FAST) should be considered as an initial evaluation, although the sensitivity and specificity in children is variable.

Treatment of a small capsular injury should include careful observation with attention to changes in vital signs or abdominal findings, serial hemoglobin determinations, and the availability of prompt surgical intervention if a patient's condition deteriorates (see Chapter 80). RBC transfusion requirements should be minimal (<25 mL/kg/48 hr). These patients are usually hospitalized for 10-14 days and have their activities restricted for months. Laparotomy, with or without splenectomy, is indicated for more marked abdominal bleeding, in patients who have clinical instability or deterioration, or when other organ damage is suspected. Partial splenectomy and splenic repair should be substituted for total splenectomy when feasible to maintain some splenic immune function. Nonoperative management is typically possible in >90% of patients. Delayed splenic rupture is quite rare in children.

SPLENECTOMY

Splenectomy should be limited to specific indications where medical therapy is (or has been) ineffective. These include traumatic splenic rupture, anatomic defects, splenic malignancy (i.e., splenic marginal zone lymphoma [SMZL]), severe transfusion-dependent hemolytic anemia, refractory and severe immune-mediated cytopenias, metabolic storage diseases, and secondary hypersplenism. There are certain conditions where splenectomy should be avoided because of increased risk of complications and/or better alternative treatments. These include autoimmune lymphoproliferative syndrome (ALPS), hereditary stomatocytosis (HSt), hereditary xerocytosis (HX), cold agglutinin disease (CAD), paroxysmal cold hemoglobinuria (PCH), Gaucher disease, and thrombocytopenia in hepatic cirrhosis. *The major long-term risk of splenectomy is sudden, overwhelming postsplenectomy infections (sepsis or meningitis).* This risk is especially high in children <5 years old at surgery. The risk of sepsis is less when splenectomy is performed for trauma, RBC membrane defects, and immune thrombocytopenia (2–4%) than when there is sickle cell anemia, thalassemia, or a preexisting immune deficiency (Wiskott-Aldrich syndrome, Hodgkin disease) or reticuloendothelial blockade (storage disease, severe hemolytic anemia) (8–30%). The overall risk is 2-5 per 1,000 asplenic patient-years,

Table 536.2 Diagnostic Techniques for and Features of Spleen Dysfunction

	DESCRIPTION	COMMENTS
Immunoglobulin M memory B cells	Cells dependent on spleen for survival. Produced in marginal zone.	Special tests required.
Technetium-99m–labeled sulfur colloidal scintiscan	Quantitation of splenic uptake of colloidal sulfur particles enables a fairly accurate static assessment of spleen function.	Hypertrophy of the left hepatic lobe might be a limiting factor (this technique does not clearly show whether the mass originated in the liver or the spleen in the presence of an overlapping hypertrophic left hepatic lobe).
Technetium-99m–labeled or rubidium-81–labeled heat-damaged autologous erythrocyte clearance	Measurement of clearance time allows a dynamic evaluation of spleen function.	Preexisting erythrocyte defects, difficult erythrocyte incorporation of the radioisotope, and false-positive or false-negative results in relation to excessive or insufficient heat damage make the test not suitable for clinical practice.
Detection of Howell-Jolly bodies by staining	Erythrocytes with nuclear remnants Flow cytometry	No need for special equipment; inaccurate in the quantitation of splenic hypofunction.
Detection of pitted erythrocytes by phase-interference microscopy	Erythrocytes with membrane indentations (4% upper limit of the normal range)	Need for phase-interference microscopy; counts enable a wide range of measurements and correlate with radioisotopic methods.

From Di Sabatino A, Carsetti R, Corazza GR. Post-splenectomy and hyposplenic states. *Lancet* 2011;378:86–97. Table 1.

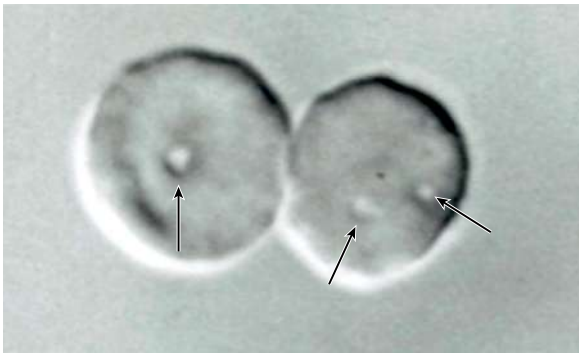

Fig. 536.1 Characteristic pitted erythrocytes in hyposplenism. A pitted erythrocyte is recognizable on phase-interference microscopy by the characteristic "pit" on the cell membrane *(arrows). (From Di Sabatino A, Carsetti R, Corazza GR. Post-splenectomy and hyposplenic states. Lancet. 2011;378:86–97. Fig 2.)*

with a lifelong risk of overwhelming postsplenectomy infections of 5%; more than half occur within 2 years after splenectomy, although the risk remains lifelong. The use of laparoscopic splenectomy has decreased surgical morbidity and hospitalization time.

Encapsulated bacteria, such as *Streptococcus pneumoniae* (>60% of cases), *Haemophilus influenzae,* and *Neisseria meningitidis,* account for >80% of cases of postsplenectomy sepsis. Because the spleen is responsible for filtering the blood and for early antibody responses, sepsis (with or without meningitis) can progress rapidly, leading to death within 12-24 hours of onset. Febrile splenectomized patients should be evaluated and treated promptly with antibiotics to cover the organisms previously mentioned. This treatment should be initiated at home if access to definitive medical care will be delayed. Common empiric antibiotics include amoxicillin-clavulanate or cefdinir. A broad-spectrum cephalosporin (cefotaxime or ceftriaxone) is recommended until specific antibiotic susceptibility and presence, or absence of meningitis is known. Vancomycin (to cover penicillin-resistant pneumococci) should be initiated, depending on the illness severity and susceptibilities of pneumococci at the institution. Splenectomized patients are also at increased risk for contracting protozoal infections, such as malaria and babesiosis. Serious infections may occur after an animal bite or lick (particularly dogs) and is caused by *Capnocytophaga canimorsus* or *C. cynodegmi*. Prophylactic antibiotics should be given after a bite potentially to prevent sepsis caused by these organisms (see Chapter 765).

Preoperative, intraoperative, and postoperative management may decrease the risk of postsplenectomy infection. It is important to be certain of the need for splenectomy and, if possible, to postpone the operation until the patient is ≥5 years of age. *Pneumococcal, meningococcal, and H. influenzae conjugate vaccines given at least 14 days before splenectomy may reduce postsplenectomy sepsis.* The 7-valent (PCV7) was replaced by the 13-valent pneumococcal polysaccharide-protein conjugate vaccine (PCV13). Thus, depending on what primary pneumococcal vaccine was given, a single dose of PCV13 may be recommended. In addition, the 23-valent pneumococcal polysaccharide vaccine (Pneumovax) should be given at age ≥2 years and a second dose 5 years later. Yearly influenza vaccine should also be given because influenza infection is a risk factor for secondary pneumococcal infections. Prophylaxis with oral penicillin VK (125 mg twice daily for children <5 years old; 250 mg twice daily for children ≥5 years) should be given until at least 5 years of age and for at least 2 years after splenectomy. Although the greatest risk is in the immediate postoperative period, reports of deaths occurring years after splenectomy suggest that the risk (and the need for prophylaxis) may be lifelong. Lifelong prophylaxis should be strongly considered in patients who have had an invasive pneumococcal infection or who have an underlying immune deficiency. In children with sickle cell disease, penicillin prophylaxis should be started as soon as the diagnosis is made. Prophylaxis may be continued into adulthood for higher-risk patients, including those with a history of pneumococcal sepsis, but effectiveness in this older group has not been well documented.

In patients with traumatic injury, splenic repair or partial splenectomy should be considered in an attempt to preserve splenic function. Partial splenectomy or partial *splenic embolization* may be sufficient to ameliorate some forms of hemolytic anemia. Up to 50% of children whose spleen is removed because of trauma have spontaneous splenosis; *surgical splenosis* (distributing small pieces of spleen throughout the abdomen) may decrease the risk of sepsis in patients whose splenectomy is necessitated by trauma. However, in both these settings, the splenic tissue that regrows frequently has poor function.

In addition to postsplenectomy sepsis, splenectomized patients may be at risk for **thromboembolic complications**, including arterial and venous thrombosis and pulmonary hypertension. These findings have been reported regardless of the underlying reason for splenectomy and the postsplenectomy platelet count. Proposed mechanisms include loss of filtering function of the spleen, allowing abnormal RBCs to remain in the circulation and activate the coagulation cascade. Portal vein thrombosis has been reported as a complication of laparoscopic splenectomy. The etiology of pulmonary hypertension is not well understood. It has been described in chronic hemolytic conditions including thalassemia, sickle cell disease, and hereditary spherocytosis, indicating there may be a relation to ongoing chronic hemolysis postsplenectomy.

Section 9

The Lymphatic System

Chapter 537

Anatomy and Function of the Lymphatic System

Michael E. Kelly and Richard L. Tower

The lymphatic system participates in many biologic processes, including fluid homeostasis, absorption of dietary fat, and initiation of specific immune responses. Besides these well-known, classical functions, several novel and unexpected physiologic and pathophysiologic functions of the lymphatics have been recently discovered, including blood pressure regulation, reverse cholesterol transport, association with metabolic diseases and obesity, and an important role in the preparation for neonatal respiration. This system includes circulating lymphocytes, lymphatic vessels, lymph nodes, spleen, tonsils, adenoids, Peyer patches, and thymus. **Lymph** is an ultrafiltrate of blood and is collected by lymphatic capillaries that are present in all organs where blood flows except the bone marrow and retina. Lymphatic capillaries form progressively larger vessels that drain regions of the body. The lymphatic vessels carry lymph to the lymph nodes, where it is filtered through sinuses, particulate matter and infectious organisms are phagocytosed, and antigens are presented to surrounding lymphocytes. These actions stimulate antibody production, T-cell responses, and cytokine secretion (see Chapter 165). Lymph is ultimately returned to the intravascular circulation.

The composition of lymph can vary with the site of lymph drainage. It is usually clear, but lymph drained from the intestinal tract may be milky **(chylous)** because of the presence of fats. The protein content is intermediate between an exudate and a transudate. The protein level may be increased with inflammation and in lymph drained from the liver or intestines. Lymph also contains variable numbers of lymphocytes and antigen-presenting cells.

Embryonic lymphatic development is a stepwise process that starts in the embryonic veins, where lymphatic endothelial cell (LEC) progenitors are initially specified. The differentiation and maturation of these progenitors continues as they bud from the veins to produce scattered primitive lymph sacs, from which most of the lymphatic vasculature is derived. *PROX1* gene expression is important to LEC specification, and studies have shown the critical importance of bone morphogenetic protein (BMP), Wnt, Notch, and vascular endothelial growth factor (VEGF) signaling pathways in lymphatic system development.

Little is known about the establishment of organ-specific lymphatics at later stages. Studies using lineage-tracing technology suggest a venous and nonvenous origin of LECs giving rise to organ-specific lymphatics in the mesentery, skin, and heart. Lymphatic vessels also run parallel to the dural sinuses in the central nervous system. The embryonic origin of the meningeal lymphatics has not been determined.

Chapter 538

Abnormalities of Lymphatic Vessels

Michael E. Kelly and Richard L. Tower

LYMPHATIC MALFORMATIONS

Developmental lymphatic anomalies including **lymphatic malformations (LMs) and complex lymphatic anomalies (CLAs)** manifest as localized or multifocal lesions of the lymphatic vasculature, respectively (see International Society for the Study of Vascular Anomalies [**ISSVA**] classification; www.issva.org).

Cystic LMs are the most common *congenital* lymphatic anomalies. They occur as solitary lesions of variable size that are classified as macrocystic, microcystic, or mixed cystic LM. LMs commonly infiltrate soft tissues and can be found anywhere on the body, although they occur more frequently on the head, neck, and axilla.

CLAs are multifocal lymphatic vascular lesions involving both soft tissue and bone and often result in disruption of central collecting lymphatic channels. They include **generalized lymphatic anomaly (GLA), Gorham-Stout disease (GSD)** (Fig. 538.1), **kaposiform lymphangiomatosis (KLA), and central conducting lymphatic anomalies (CCLA)** (Fig. 538.2). CLAs are rare diseases with overlapping and variable clinical features. Common features include bone involvement, lymphatic leakage into the thoracic (chylous effusion) and abdominal (chylous ascites) cavities and mesenteric involvement leading to protein losing enteropathy. In addition to common features, GSD is uniquely associated with progressive cortical bone loss (see Fig. 538.1). KLA can be distinguished by the presence of spindle cells on histology, an aggressive clinical course, and evidence of consumptive coagulopathy and hemorrhage. CCLA, or channel type anomaly is characterized by dilation, malformation, and dysfunction of the major abdominal or thoracic lymphatic vessels.

LMs can also occur as combined malformations with other blood vessel types like capillaries (capillary-lymphatic malformation) or veins (lymphatic-venous malformation). LMs are commonly associated with **PIK3CA-related overgrowth spectrum (PROS) disorders**, which include **Klippel-Trenaunay syndrome (KTS), CLOVES (congenital lipomatous overgrowth, vascular malformations, epidermal nevi, and scoliosis/skeletal/spinal anomalies) and Proteus syndrome** (Fig. 538.3).

Genetics

Somatic, activating variants in the *PIK3CA* gene that encodes the p110α catalytic subunit of PI3K are present at variable frequencies in most (80%) isolated LMs and LMs associated with PROS. These activating *PIK3CA* variants are identical to those found in venous malformations and in many human cancers. The genetics of CLAs are far more diverse. Activating *PIK3CA* gene variants have been identified in several patients diagnosed with GLA. In addition, pathologic genetic variants in genes involved in the RAS-MAPK signaling pathway have been implicated in other CLAs. Activating *NRAS* gene variants are associated with KLA while two patients with GSD were found to have activating gene variants in *KRAS*. Somatic, pathologic genetic variants in both the *ARAF* and *CBL* genes have been found in patients diagnosed with CCLA as have inactivating germline pathogenic variants in *EPHB4*. The role of RAS/MAPK pathway activation in CLAs is further reinforced by the observation that patients with known RASopathies, including Noonan and Noonan-like syndrome, can present with central conducting lymphatic anomalies.

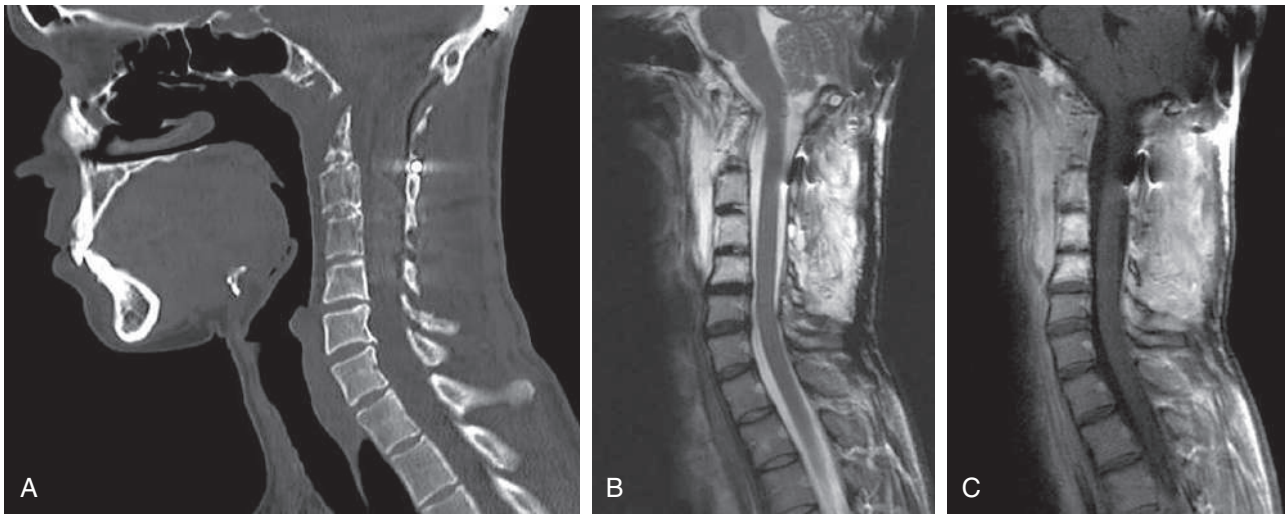

Fig. 538.1 Gorham–Stout disease. **A,** CT sagittal reformat. Multiple erosive changes in the occiput, clivus, and the cervical spine. (**B**) Sagittal T2-weighted fat-saturated (FS) MRI sequence. High signal is seen in the clivus and C 1–5 vertebral and the surrounding soft tissue. **C,** Postgadolinium T1 FS MRI. Enhancement is seen in the areas of osseous and soft tissue abnormalities. *(From Trenor III CC, Chaudry G. Complex lymphatic anomalies. Sem Pediatr Surg 2014;23:186–190. Fig. 3.)*

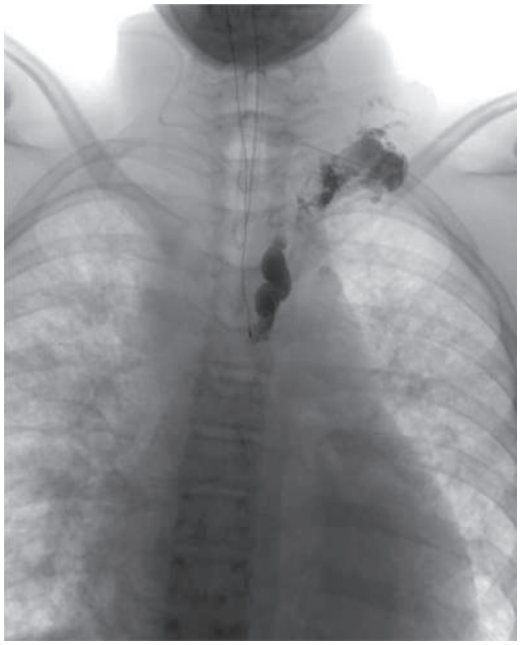

Fig. 538.2 Intranodal lymphangiogram in 15-year-old male with central conducting lymphatic anomaly and recurrent pericardial effusions. Stagnant flow is seen in the patulous superior portion of the thoracic duct. Direct puncture of the terminal portion demonstrates marked dilation with no spontaneous emptying.

Treatment

A decision to treat an LM depends on the anatomic location, involvement of local structures, and symptoms. Referral to a specialized vascular anomalies clinic with the expertise to guide appropriate imaging and treatment decisions is recommended. For localized macrocystic LMs, **interventional radiology (IR) administration of sclerosing agents** (OK432, ethanol, bleomycin) is most effective. For lesions involving skin and mucosa, **laser treatments** may be used.

Most patients with CLAs have extensive and invasive disease, necessitating systemic therapeutic approaches. The mTOR inhibitor **sirolimus** has had excellent effects in patients with vascular anomalies, including those patients with CLAs. A majority of CLA patients showed improvements in functional impairment and quality of life measures, whereas fewer showed evidence of decreased disease burden by imaging. **Combining sirolimus with bisphosphonates** may be even more effective in CLA patients with significant bone disease. **Alpelisib,** a *PIK3CA* inhibitor, has been used with success in patients with PROS and in a growing number of GLA patients with a known *PIK3CA* pathologic variant. Small numbers of patients with KLA who were known to have pathogenic variants in either NRAS or CBL experienced clinical improvement with **trametinib**, a MEK inhibitor. Trametinib also induced remodeling of the central lymphatics and induced symptom resolution in a patient with CCLA who had an *ARAF* pathogenic variant, as well a patient with Noonan syndrome and a *SOS1* pathogenic variant with severe lymphatic abnormalities.

LYMPHEDEMA

Lymphedema is a localized swelling caused by impaired lymphatic flow and can be primary (congenital) or acquired. **Primary lymphedemas** are grouped as LMs because they result from dysgenesis of lymphatic networks during early development. Primary lymphedema may be found in Turner syndrome, Noonan syndrome, autosomal dominantly inherited Milroy disease, and other chromosomal abnormalities. Pathologic variants in multiple genes, including the vascular endothelial growth factor receptor–3 gene *(VEGFR3), GJC2*, *PTPN14*, and *GATA2,* are associated with primary lymphedema (www.issva.org) (Table 538.1). Autosomal recessive, dominant or de novo pathogenic variants of *VEGFR3* produce Milroy disease. Pathologic variants in other genes are associated with specific syndromes: *CCBE1* (Hennekam), *FOXC2* (lymphedema distichiasis), *SOX18* (hypotrichosis-telangiectasia-lymphedema), *KMT2D/MLL2,* and *KDM6A* (Kabuki). Unilateral or bilateral lower extremity lymphedema in an adolescent may be Meige disease.

Acquired obstruction of the lymphatics is much more common than primary disorders and result from tumor, postirradiation fibrosis, and postinflammatory scarring. **Filariasis** is an important cause of lymphedema in Africa, Asia, and Latin America. One third of the 120 million infected persons (primarily older adolescents and adults) have lymphedema or a hydrocele. Injury to the major lymphatic vessels can cause

Fig. 538.3 Photographs and MRIs of participants with isolated LM, CLOVES, KTS, and FAVA. **A,** An 8-month-old male with isolated LM. Note swelling in deltoid region without cutaneous vascular signs. Coronal and sagittal fat-saturated T2-weighted MRI demonstrates macrocystic LM (a multilocular cystic mass) involving the anterolateral aspects of the right shoulder without muscular infiltration *(arrows)*; humeral head *star*. **B,** A 19-month-old female with CLOVES syndrome. Note asymmetric distribution of truncal lipomatous masses and bilateral lower extremity involvement. Coronal fat-saturated T1-weighted MRI after contrast administration demonstrates moderate heterogeneous enhancement of the bilateral truncal masses *(arrows)*. Axial T1-weighted MRI without contrast depicts truncal lipomatous overgrowth *(arrows)*; segment VI of the liver *(asterisk)*.

Continued

Fig. 538.3, cont'd **C,** A 3-yr-old male (KT4) with KTS. Note capillary-lymphatic malformation and overgrowth involving right lower extremity. Coronal and axial fat-saturated T2-weighted MRI shows the persistent marginal vein system *(bent arrows)* and marked enlargement of the subcutaneous tissues because of a combination of lymphatic fluid and fat *(straight arrow)*. There are also intramuscular venous malformations. **D,** A 9-yr-old male (F8) with FAVA of the left gastrocnemius muscle; note absence of overgrowth and cutaneous vascular anomalies. Sagittal fat-saturated T1-weighted MRI after contrast administration demonstrates the longitudinal distribution of the diffuse, fibro-adipose vascular anomaly *(arrows)*. Axial fat-saturated T2-weighted MRI with (upper) and without (lower) contrast. Note right head of the gastrocnemius muscle is diffusely replaced by a contrast enhancing heterogeneous soft tissue lesion *(arrows)*. CLOVES, congenital lipomatous overgrowth, vascular malformations, epidermal nevis, spinal/skeletal anomalies/scoliosis; FAVA, fibro-adipose vascular anomaly; KTS, Klippel-Trenaunay syndrome; LM, lymphatic malformations. *(From Luks VL, Kamitaki N, Vivero MP, et al. Lymphatic and other vascular malformative/overgrowth disorders are caused by somatic mutations in PIK3CA. J Pediatr. 2015;166:1048–1054.)*

Table 538.1 Chromosomal, Gene, and Syndromes Associated with Lymphedema

	SYNDROMES	KNOWN GENES, CHROMOSOMAL LOCI, INHERITANCE PATTERN
Primary lymphedema	Milroy disease	*VEGFR3* AR, AD
	Meige disease	Familial lymphedema
		No known gene
Chromosomal aneuploidy	Turner syndrome	45,X
	Klinefelter syndrome	47,XXY
	Trisomy 21	47,XX+21; 47,XY+21
	Trisomy 13	47,XX+13; 47,XY+13
	Trisomy 18	47,XX+18; 47,XY+18
Other genetic and syndromic disorders	Emberger syndrome (primary lymphedema with myelodysplasia)	*GATA2*(3q21.3), AD
	Lymphedema-distichiasis syndrome	*FOXC2*(16q24.1), AD
	Hennekam lymphangiectasia-lymphedema syndrome 1 (HKLLS1)	*CCBE1*(18q21.32), AR
	Hennekam lymphangiectasia-lymphedema syndrome 2 (HKLLS2)	*FAT4*(4q28.1), AR
	Hypotrichosis-lymphedema-telangiectasia ± renal defect syndrome (HLTRS)	*SOX18*(20q13.33), AR/AD
	Microcephaly with or without chorioretinopathy, lymphedema, or mental retardation (MCLMR)	*KIF11*(10q23.33), AD
	Microcephaly and chorioretinopathy, 1 (MCCRP1)	*TUBGCP6*(22q13.33), AR

	Cholestasis-lymphedema syndrome (Aagenaes syndrome)	*LSC1*, AR
	Ectodermal dysplasia, hypo/anhidrotic, lymphedema and immunodeficiency; immunodeficiency 33	*IKBKG*, (Xq28), XLR

AD, Autosomal dominant; AR, Autosomal recessive; XLR, X-linked recessive.
Modified from Unolt M, Barry J, Digilio MC, et al. Primary lymphedema and other lymphatic anomalies are associated with 22q11.2 deletion syndrome. *Eur J Med Genetics.* 2018;61:411–415. Table 1.

collection of lymph fluid in the abdomen (chylous ascites) or chest (chylothorax).

Untreated lymphedema can be disabling and is associated with immune dysfunction, inflammation, fibrosis, adipose tissue overgrowth, and lymphangiosarcoma. Treatment modalities attempt to reduce localized swelling through massage, exercise, and compression. Lymphatic reconstructive procedures, including lymphovenous bypass and lymphatico-lymphatic anastomosis are increasingly used to achieve lymphatic decongestion, especially in the early stages of disease.

LYMPHANGIOLEIOMYOMATOSIS

Lymphangioleiomyomatosis **(LAM)** is characterized by proliferation of lymphatic endothelial cells and smooth muscle cells in the lungs, leading to airway and lymphatic obstruction, cyst formation, pneumothorax, and respiratory failure. It may initially be mistaken for asthma. LAM occurs in young females and is associated with pathogenic variants in the tuberous sclerosis tumor-suppressor gene *TSC2* in one third of cases. **Sirolimus** stabilizes lung function, reduces symptoms, and improves life quality. Lung transplantation may be required.

LYMPHANGITIS

Lymphangitis is an inflammation of the lymphatics that drain an area of infection. Tender, erythematous streaks extend proximally from the infected area. Regional nodes may also be tender. Group A streptococci and *Staphylococcus aureus* are the most common pathogens, and therapy should include antibiotics that treat these organisms.

The Lymphatic System

Chapter 537

Anatomy and Function of the Lymphatic System

Michael E. Kelly and Richard L. Tower

The lymphatic system participates in many biologic processes, including fluid homeostasis, absorption of dietary fat, and initiation of specific immune responses. Besides these well-known, classical functions, several novel and unexpected physiologic and pathophysiologic functions of the lymphatics have been recently discovered, including blood pressure regulation, reverse cholesterol transport, association with metabolic diseases and obesity, and an important role in the preparation for neonatal respiration. This system includes circulating lymphocytes, lymphatic vessels, lymph nodes, spleen, tonsils, adenoids, Peyer patches, and thymus. **Lymph** is an ultrafiltrate of blood and is collected by lymphatic capillaries that are present in all organs where blood flows except the bone marrow and retina. Lymphatic capillaries form progressively larger vessels that drain regions of the body. The lymphatic vessels carry lymph to the lymph nodes, where it is filtered through sinuses, particulate matter and infectious organisms are phagocytosed, and antigens are presented to surrounding lymphocytes. These actions stimulate antibody production, T-cell responses, and cytokine secretion (see Chapter 165). Lymph is ultimately returned to the intravascular circulation.

The composition of lymph can vary with the site of lymph drainage. It is usually clear, but lymph drained from the intestinal tract may be milky **(chylous)** because of the presence of fats. The protein content is intermediate between an exudate and a transudate. The protein level may be increased with inflammation and in lymph drained from the liver or intestines. Lymph also contains variable numbers of lymphocytes and antigen-presenting cells.

Embryonic lymphatic development is a stepwise process that starts in the embryonic veins, where lymphatic endothelial cell (LEC) progenitors are initially specified. The differentiation and maturation of these progenitors continues as they bud from the veins to produce scattered primitive lymph sacs, from which most of the lymphatic vasculature is derived. *PROX1* gene expression is important to LEC specification, and studies have shown the critical importance of bone morphogenetic protein (BMP), Wnt, Notch, and vascular endothelial growth factor (VEGF) signaling pathways in lymphatic system development.

Little is known about the establishment of organ-specific lymphatics at later stages. Studies using lineage-tracing technology suggest a venous and nonvenous origin of LECs giving rise to organ-specific lymphatics in the mesentery, skin, and heart. Lymphatic vessels also run parallel to the dural sinuses in the central nervous system. The embryonic origin of the meningeal lymphatics has not been determined.

Chapter 538

Abnormalities of Lymphatic Vessels

Michael E. Kelly and Richard L. Tower

LYMPHATIC MALFORMATIONS

Developmental lymphatic anomalies including **lymphatic malformations (LMs) and complex lymphatic anomalies (CLAs)** manifest as localized or multifocal lesions of the lymphatic vasculature, respectively (see International Society for the Study of Vascular Anomalies [**ISSVA**] classification; www.issva.org).

Cystic LMs are the most common *congenital* lymphatic anomalies. They occur as solitary lesions of variable size that are classified as macrocystic, microcystic, or mixed cystic LM. LMs commonly infiltrate soft tissues and can be found anywhere on the body, although they occur more frequently on the head, neck, and axilla.

CLAs are multifocal lymphatic vascular lesions involving both soft tissue and bone and often result in disruption of central collecting lymphatic channels. They include **generalized lymphatic anomaly (GLA), Gorham-Stout disease (GSD)** (Fig. 538.1), **kaposiform lymphangiomatosis (KLA), and central conducting lymphatic anomalies (CCLA)** (Fig. 538.2). CLAs are rare diseases with overlapping and variable clinical features. Common features include bone involvement, lymphatic leakage into the thoracic (chylous effusion) and abdominal (chylous ascites) cavities and mesenteric involvement leading to protein losing enteropathy. In addition to common features, GSD is uniquely associated with progressive cortical bone loss (see Fig. 538.1). KLA can be distinguished by the presence of spindle cells on histology, an aggressive clinical course, and evidence of consumptive coagulopathy and hemorrhage. CCLA, or channel type anomaly is characterized by dilation, malformation, and dysfunction of the major abdominal or thoracic lymphatic vessels.

LMs can also occur as combined malformations with other blood vessel types like capillaries (capillary-lymphatic malformation) or veins (lymphatic-venous malformation). LMs are commonly associated with **PIK3CA-related overgrowth spectrum (PROS) disorders**, which include **Klippel-Trenaunay syndrome (KTS), CLOVES (congenital lipomatous overgrowth, vascular malformations, epidermal nevi, and scoliosis/skeletal/spinal anomalies) and Proteus syndrome** (Fig. 538.3).

Genetics

Somatic, activating variants in the *PIK3CA* gene that encodes the p110α catalytic subunit of PI3K are present at variable frequencies in most (80%) isolated LMs and LMs associated with PROS. These activating *PIK3CA* variants are identical to those found in venous malformations and in many human cancers. The genetics of CLAs are far more diverse. Activating *PIK3CA* gene variants have been identified in several patients diagnosed with GLA. In addition, pathologic genetic variants in genes involved in the RAS-MAPK signaling pathway have been implicated in other CLAs. Activating *NRAS* gene variants are associated with KLA while two patients with GSD were found to have activating gene variants in *KRAS*. Somatic, pathologic genetic variants in both the *ARAF* and *CBL* genes have been found in patients diagnosed with CCLA as have inactivating germline pathogenic variants in *EPHB4*. The role of RAS/MAPK pathway activation in CLAs is further reinforced by the observation that patients with known RASopathies, including Noonan and Noonan-like syndrome, can present with central conducting lymphatic anomalies.

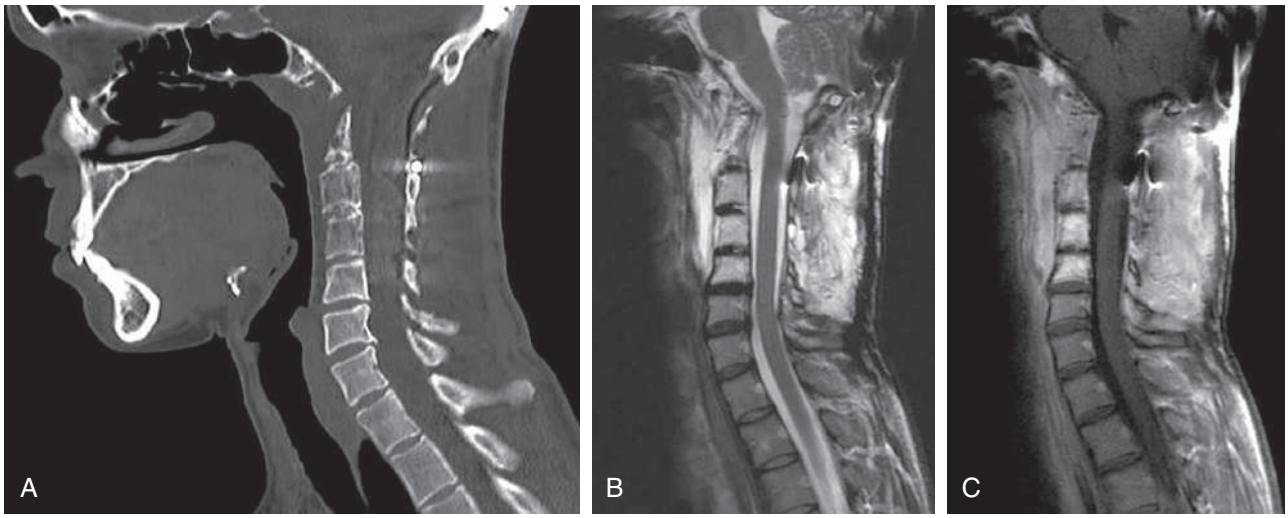

Fig. 538.1 Gorham–Stout disease. **A,** CT sagittal reformat. Multiple erosive changes in the occiput, clivus, and the cervical spine. (**B**) Sagittal T2-weighted fat-saturated (FS) MRI sequence. High signal is seen in the clivus and C 1–5 vertebral and the surrounding soft tissue. **C,** Postgadolinium T1 FS MRI. Enhancement is seen in the areas of osseous and soft tissue abnormalities. *(From Trenor III CC, Chaudry G. Complex lymphatic anomalies. Sem Pediatr Surg 2014;23:186–190. Fig. 3.)*

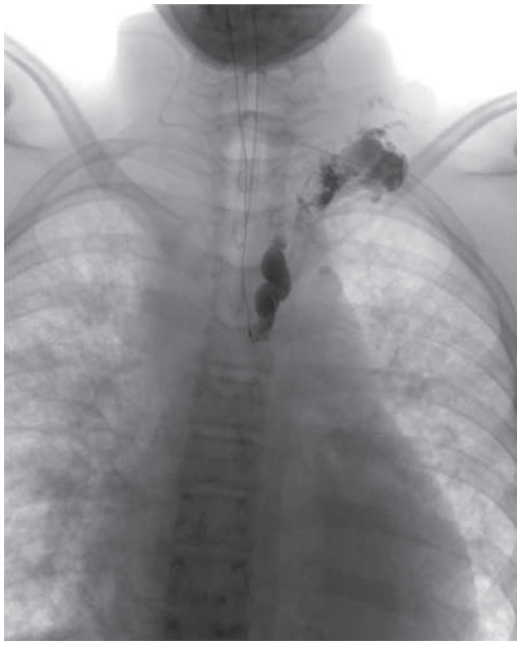

Fig. 538.2 Intranodal lymphangiogram in 15-year-old male with central conducting lymphatic anomaly and recurrent pericardial effusions. Stagnant flow is seen in the patulous superior portion of the thoracic duct. Direct puncture of the terminal portion demonstrates marked dilation with no spontaneous emptying.

Treatment

A decision to treat an LM depends on the anatomic location, involvement of local structures, and symptoms. Referral to a specialized vascular anomalies clinic with the expertise to guide appropriate imaging and treatment decisions is recommended. For localized macrocystic LMs, **interventional radiology (IR) administration of sclerosing agents** (OK432, ethanol, bleomycin) is most effective. For lesions involving skin and mucosa, **laser treatments** may be used.

Most patients with CLAs have extensive and invasive disease, necessitating systemic therapeutic approaches. The mTOR inhibitor **sirolimus** has had excellent effects in patients with vascular anomalies, including those patients with CLAs. A majority of CLA patients showed improvements in functional impairment and quality of life measures, whereas fewer showed evidence of decreased disease burden by imaging. **Combining sirolimus with bisphosphonates** may be even more effective in CLA patients with significant bone disease. **Alpelisib,** a *PIK3CA* inhibitor, has been used with success in patients with PROS and in a growing number of GLA patients with a known *PIK3CA* pathologic variant. Small numbers of patients with KLA who were known to have pathogenic variants in either NRAS or CBL experienced clinical improvement with **trametinib**, a MEK inhibitor. Trametinib also induced remodeling of the central lymphatics and induced symptom resolution in a patient with CCLA who had an *ARAF* pathogenic variant, as well a patient with Noonan syndrome and a *SOS1* pathogenic variant with severe lymphatic abnormalities.

LYMPHEDEMA

Lymphedema is a localized swelling caused by impaired lymphatic flow and can be primary (congenital) or acquired. **Primary lymphedemas** are grouped as LMs because they result from dysgenesis of lymphatic networks during early development. Primary lymphedema may be found in Turner syndrome, Noonan syndrome, autosomal dominantly inherited Milroy disease, and other chromosomal abnormalities. Pathologic variants in multiple genes, including the vascular endothelial growth factor receptor–3 gene *(VEGFR3), GJC2*, *PTPN14*, and *GATA2,* are associated with primary lymphedema (www.issva.org) (Table 538.1). Autosomal recessive, dominant or de novo pathogenic variants of *VEGFR3* produce Milroy disease. Pathologic variants in other genes are associated with specific syndromes: *CCBE1* (Hennekam), *FOXC2* (lymphedema distichiasis), *SOX18* (hypotrichosis-telangiectasia-lymphedema), *KMT2D/MLL2,* and *KDM6A* (Kabuki). Unilateral or bilateral lower extremity lymphedema in an adolescent may be Meige disease.

Acquired obstruction of the lymphatics is much more common than primary disorders and result from tumor, postirradiation fibrosis, and postinflammatory scarring. **Filariasis** is an important cause of lymphedema in Africa, Asia, and Latin America. One third of the 120 million infected persons (primarily older adolescents and adults) have lymphedema or a hydrocele. Injury to the major lymphatic vessels can cause

Fig. 538.3 Photographs and MRIs of participants with isolated LM, CLOVES, KTS, and FAVA. **A,** An 8-month-old male with isolated LM. Note swelling in deltoid region without cutaneous vascular signs. Coronal and sagittal fat-saturated T2-weighted MRI demonstrates macrocystic LM (a multilocular cystic mass) involving the anterolateral aspects of the right shoulder without muscular infiltration *(arrows)*; humeral head *star*. **B,** A 19-month-old female with CLOVES syndrome. Note asymmetric distribution of truncal lipomatous masses and bilateral lower extremity involvement. Coronal fat-saturated T1-weighted MRI after contrast administration demonstrates moderate heterogeneous enhancement of the bilateral truncal masses *(arrows)*. Axial T1-weighted MRI without contrast depicts truncal lipomatous overgrowth *(arrows)*; segment VI of the liver *(asterisk)*.

Continued

Fig. 538.3, cont'd **C,** A 3-yr-old male (KT4) with KTS. Note capillary-lymphatic malformation and overgrowth involving right lower extremity. Coronal and axial fat-saturated T2-weighted MRI shows the persistent marginal vein system *(bent arrows)* and marked enlargement of the subcutaneous tissues because of a combination of lymphatic fluid and fat *(straight arrow)*. There are also intramuscular venous malformations. **D,** A 9-yr-old male (F8) with FAVA of the left gastrocnemius muscle; note absence of overgrowth and cutaneous vascular anomalies. Sagittal fat-saturated T1-weighted MRI after contrast administration demonstrates the longitudinal distribution of the diffuse, fibro-adipose vascular anomaly *(arrows)*. Axial fat-saturated T2-weighted MRI with (upper) and without (lower) contrast. Note right head of the gastrocnemius muscle is diffusely replaced by a contrast enhancing heterogeneous soft tissue lesion *(arrows)*. CLOVES, congenital lipomatous overgrowth, vascular malformations, epidermal nevis, spinal/skeletal anomalies/scoliosis; FAVA, fibro-adipose vascular anomaly; KTS, Klippel-Trenaunay syndrome; LM, lymphatic malformations. *(From Luks VL, Kamitaki N, Vivero MP, et al. Lymphatic and other vascular malformative/overgrowth disorders are caused by somatic mutations in PIK3CA. J Pediatr. 2015;166:1048–1054.)*

	Ectodermal dysplasia, hypo/anhidrotic, lymphedema and immunodeficiency; immunodeficiency 33	*IKBKG*, (Xq28), XLR

AD, Autosomal dominant; AR, Autosomal recessive; XLR, X-linked recessive.
Modified from Unolt M, Barry J, Digilio MC, et al. Primary lymphedema and other lymphatic anomalies are associated with 22q11.2 deletion syndrome. *Eur J Med Genetics.* 2018;61:411–415. Table 1.

collection of lymph fluid in the abdomen (chylous ascites) or chest (chylothorax).

Untreated lymphedema can be disabling and is associated with immune dysfunction, inflammation, fibrosis, adipose tissue overgrowth, and lymphangiosarcoma. Treatment modalities attempt to reduce localized swelling through massage, exercise, and compression. Lymphatic reconstructive procedures, including lymphovenous bypass and lymphatico-lymphatic anastomosis are increasingly used to achieve lymphatic decongestion, especially in the early stages of disease.

LYMPHANGIOLEIOMYOMATOSIS

Lymphangioleiomyomatosis **(LAM)** is characterized by proliferation of lymphatic endothelial cells and smooth muscle cells in the lungs, leading to airway and lymphatic obstruction, cyst formation, pneumothorax, and respiratory failure. It may initially be mistaken for asthma. LAM occurs in young females and is associated with pathogenic variants in the tuberous sclerosis tumor-suppressor gene *TSC2* in one third of cases. **Sirolimus** stabilizes lung function, reduces symptoms, and improves life quality. Lung transplantation may be required.

LYMPHANGITIS

Lymphangitis is an inflammation of the lymphatics that drain an area of infection. Tender, erythematous streaks extend proximally from the infected area. Regional nodes may also be tender. Group A streptococci and *Staphylococcus aureus* are the most common pathogens, and therapy should include antibiotics that treat these organisms.

Chapter 539

Lymphadenopathy

Zachary T. Graff and Richard L. Tower

Palpable lymph nodes are common in pediatrics and often pose a diagnostic challenge. Lymph node enlargement can be caused by proliferation of normal lymphoid elements or by infiltration with malignant or other phagocytic cells. In most patients, a careful history and a complete physical examination suggest the proper diagnosis.

DIAGNOSIS

What Is the Site of the Mass?

The differential diagnosis of a mass varies greatly based on anatomic location. Although pathologic masses can occur in any site, masses occurring in the supraclavicular and lower half of the neck are more likely to reflect pathologic lymphadenopathy than in other sites of the body.

Is the Mass a Lymph Node?

Nonlymphoid masses (cervical rib, thyroglossal cyst, branchial cleft cyst or infected sinus, cystic hygroma, goiter, thyroiditis, sternomastoid muscle tumor of infancy, neurofibroma) occur frequently in the neck and less often in other areas.

Is the Node Enlarged?

Lymph nodes are not usually palpable in the newborn. With antigenic exposure, lymphoid tissue increases in volume. They are not considered enlarged until their diameter exceeds 1 cm for cervical and axillary nodes, 1.5 cm for inguinal nodes, and epitrochlear >0.5 cm. Other lymph nodes usually are not palpable or visualized with plain radiographs.

What are the Characteristics of the Node?

Acutely infected nodes are usually tender. There may also be erythema and warmth of the overlying skin. Fluctuance suggests abscess formation. *Tuberculous* nodes may be matted. With chronic infection, many of these signs are not present. A firm, fixed, nonmobile (to adjacent or underlying tissues), nontender node should always raise the question of malignancy, regardless of the presence or absence of systemic symptoms or other abnormal physical findings. Tumors or tumor-involved nodes are often present for >2 weeks and may be associated with local extension (voice change, dysphagia, otalgia) or systemic signs (fever, weight loss, night sweats).

Is the Lymphadenopathy Localized or Generalized?

Generalized adenopathy (enlargement of >2 noncontiguous node regions) is caused by systemic disease (Table 539.1) and is often accompanied by abnormal physical findings in other systems. In contrast, *regional adenopathy* is most frequently the result of infection in the involved node and/or its drainage area (Table 539.2). When caused by infectious agents other than bacteria, adenopathy may be characterized by atypical anatomic areas, a prolonged course, a draining sinus, lack of prior pyogenic infection, and unusual clues in the history (cat scratches, tuberculosis exposure, venereal disease). The histopathologic pattern may also help with a differential diagnosis (Table 539.3).

Table 539.1 Differential Diagnosis of Generalized Lymphadenopathy

NEONATE	CHILD	ADOLESCENT
COMMON CAUSES		
CMV	Nonspecific viral infections	Viral infections
HIV	EBV	EBV
Syphilis	CMV	CMV
Toxoplasmosis	HIV	HIV
	Toxoplasmosis	Measles
	Measles	Toxoplasmosis
		Syphilis
RARE CAUSES		
Chagas disease (congenital)	Serum sickness	Serum sickness
Congenital leukemia	SLE, JIA	SLE, JIA
Congenital tuberculosis	Leukemia/lymphoma	Leukemia/lymphoma

TREATMENT

Evaluation and treatment of lymphadenopathy is guided by the probable etiologic factor, as determined from the history and physical examination. Many patients with **cervical adenopathy** have a history compatible with viral infection and are observed without intervention. If bacterial infection is suspected, antibiotic treatment covering at least streptococci and staphylococci is indicated. Those who do not respond to oral antibiotics, as demonstrated by persistent swelling and fever, require intravenous (IV) antistaphylococcal antibiotics. If there is no response in 1-2 days, or if there are signs of airway obstruction or significant toxicity, ultrasound, CT, or MRI of the neck with contrast should be obtained. If *pus* is present, it may be aspirated, or if it is extensive, it may require incision and drainage. Gram stain and culture of the pus should be obtained. The sizes of involved nodes should be documented before treatment. Failure to decrease in size within 14 days also suggests the need for further evaluation. This evaluation may include a complete blood cell count (CBC) with differential; Epstein-Barr virus, cytomegalovirus, *Toxoplasma,* and *Bartonella henselae* titers; anti–streptolysin O or anti-DNase B serologic tests; tuberculin skin test or gamma interferon assay; and chest radiograph to evaluate for mediastinal adenopathy. If these are not diagnostic, consultation with an infectious diseases or oncology specialist may be helpful. Biopsy should be considered if there is persistent or unexplained fever, weight loss, night sweats, supraclavicular location, mediastinal mass, hard nodes, or fixation of the nodes to surrounding tissues. Biopsy may also be indicated if there is an increase in size over baseline in 2 weeks, no decrease in size in 4-6 weeks, no regression to "normal" in 8-12 weeks, or if new signs and symptoms develop.

Table 539.2 Sites of Regional Lymphadenopathy and Associated Diseases

CERVICAL
Oropharyngeal infection (viral, group A streptococcal, staphylococcal, or fusobacterial)
Scalp infection (tinea)
Mycobacterial lymphadenitis (tuberculous and nontuberculous mycobacteria)

*Unilateral.
†Bilateral.
CMV, Cytomegalovirus; EBV, Epstein-Barr virus; HHV-6, human herpesvirus 6.
From Kliegman RM, Toth H, Bordini BJ, Basel D, eds. *Nelson Pediatric Symptom-Based Diagnosis: Common Diseases and Their Mimics*, 2nd ed. Philadelphia: Elsevier, 2023: Table 48.2, p. 890.

Differentiating benign disorders from a malignancy may initially be difficult. Hard, nontender, nonerythematous nodes involving multiple regions (including mediastinum and abdomen), hepatic or splenic enlargement, fever, night sweats, and weight loss suggest malignancy or a granulomatous process. Persistence of symptoms and lymphadenopathy >2 weeks and certain locations (supraclavicular, mediastinal, abdominal) also suggest malignancy. Cytopenias and elevated blood lactate dehydrogenase are associated with malignancy and certain infectious and inflammatory disorders. Ultrasound is useful in distinguishing malignancy from reactive nodes. CT with contrast is helpful in identifying other affected nodes and organs. Although fine needle aspiration (FNA) is sometimes used as an initial approach to diagnosis, excisional biopsies are often needed and are the preferred diagnostic approach to fully appreciate the lymph node architecture and genomic profiling when malignant conditions are being considered.

539.1 Kikuchi-Fujimoto Disease (Histiocytic Necrotizing Lymphadenitis)

Zachary T. Graff and Richard L. Tower

Kikuchi-Fujimoto disease is a rare, usually self-limiting disease that is seen in all ethnic groups; children and adults may be affected. Familial cases have been reported. The etiology is unknown, although infectious and autoimmune diseases such as systemic lupus erythematosus (SLE) have been associated. The differential diagnosis includes infectious lymphadenitis, lymphoma, tuberculosis, and SLE.

Presentation is varied but most often presents as firm, painful unilateral posterior cervical adenopathy evolving over several weeks. Fever is frequently reported. Labs are often normal; however, elevated erythrocyte sedimentation rate (ESR), elevated CRP, atypical lymphocytosis, and leukopenia can be seen. Nodes range in size from 0.5-6.0 cm, are painful or tender in only 50% of cases, may be multiple, and must be differentiated from lymphoma. Node involvement may occasionally be bilateral or rarely present in axillary, supraclavicular, or intraabdominal lymph nodes. Ultrasound usually shows multiple conglomerated, unilateral cervical lymphadenopathy with perinodal fat swelling and even size distribution. Aseptic meningitis is an uncommon associated feature.

The diagnosis is made by lymph node biopsy. Histologic features include paracortical lymph node expansion with patchy, well-circumscribed areas of necrosis showing karyorrhexis, an absence of neutrophils and eosinophils, a CD68+/MPO+ histiocytic infiltrate, and CD123+/TCL1+ plasmacytoid dendritic cells. Kikuchi-Fujimoto disease usually resolves within 6 months, although relapses have occurred up to 16 years later. Treatment is typically symptomatic including rest and analgesics. Therapy with systemic steroids is reserved for patients with severe symptoms. Recurrences occur in ~5-20% depending on site (higher recurrences with bone, CNS, or skin involvement). Patients should be followed for the possible development of systemic lupus erythematosus. Rarely, the disease has been fatal.

539.2 Sinus Histiocytosis with Massive Lymphadenopathy (Rosai-Dorfman Disease)

Zachary T. Graff and Richard L. Tower

The uncommon, benign, and usually self-limited Rosai-Dorfman disease (RDD) is a non-Langerhans cell histiocytosis that has a worldwide distribution but is more common in individuals of African descent. The etiology is unknown, but immune dysfunction is suspected. Lesional histiocytes are $S100^+$, $CD68^+$, and $CD1a^-$. It is not a single entity, but a

Table 539.3 Differential Diagnosis for the Histologic Patterns Seen in Pediatric Lymphadenopathies

HISTOLOGIC PATTERN	DIFFERENTIAL DIAGNOSIS	KEY FEATURES
Isolated follicular hyperplasia	Nonspecific reactive pattern Viral infections HIV lymphadenitis Measles Follicular lymphoma Primary immunodeficiencies	Multinucleated Warthin-Finkeldey cells seen in both HIV and measles Expansile irregular follicles in acute HIV Normal polarization of germinal center cells and phenotyping helpful to rule out follicular lymphoma
Follicular hyperplasia with PTGC	Nonspecific reactive pattern Nodular lymphocyte predominant Hodgkin lymphoma	Cytologically atypical cells seen in nodular lymphocyte predominant Hodgkin lymphoma are absent in PTGC
Paracortical hyperplasia	EBV infectious mononucleosis HSV1/2 CMV Varicella Measles Classic Hodgkin lymphoma Drug-induced lymphadenopathy Primary immunodeficiencies Non-Hodgkin B-cell and T-cell lymphoma	Polymorphic with numerous immunoblasts RS-like cells express CD20, unlike RS cells of classic Hodgkin lymphoma Warthin-Finkeldey cells may be seen in measles and HSV lymphadenitis Well-delineated necrosis in HSV Intranuclear inclusions may be seen in CMV, HSV, and varicella Associated monocytoid B-cell hyperplasia seen in CMV lymphadenitis
Suppurative	Bacterial lymphadenitis, Staphylococcus, Streptococcus, Haemophilus, Yersinia, *Francisella tularensis*, Brucella HSV lymphadenitis Kawasaki	Poorly formed granulomas also may be seen in bacterial infections Necrotic foci beneath the capsule seen in Kawasaki
Necrotizing granulomas	Mycobacteria, tuberculous, and nontuberculous Fungal infections CSD Kikuchi-Fujimoto lymphadenitis/SLE	Acellular (caseating) necrosis with numerous giant cells seen in mycobacterial and fungal infections CSD palisading histiocytes with neutrophilic microabscesses Kikuchi-Fujimoto lymphadenitis/SLE necrosis with nuclear debris and absence of neutrophils; C-shaped histiocytes; clusters of immunoblasts and plasmacytoid dendritic cells
Nonnecrotizing granulomas	Sarcoidosis; infections; nonspecific	
Histiocytoses	HLH, Rosai-Dorfman disease	
Miscellaneous	Toxoplasmosis • Triad: follicular hyperplasia, monocytoid B-cell hyperplasia, epithelioid histiocytes extend into lymphoid follicles • Kimura • Follicular hyperplasia and interfollicular eosinophils	

CMV, cytomegalovirus; CSD, cat-scratch disease; EBV, Epstein Barr virus; HLH, hemophagocytic lymphohistiocytosis; HSV, herpes simplex virus; PTGC, progressive transformation of germinal centers; SLE, systemic lupus erythematosus.
From Faraz M, Rosando FGN. Reactive lymphadenopathies. *Clin Lab Med.* 2021;41:433–451. Table 1.

pattern, and can be associated with neoplasia or autoimmune disease. It can be sporadic or associated with inherited conditions. Some patients have somatic pathogenic variants in *NRAS*, *KRAS*, and *MAP2K1*. Familial RDD has been noted in patients with pathogenic variants in *SLC29A3*. RDD may coexist with SLE, JIA, and autoimmune hemolytic anemia.

Patients can be classified as classical (nodal) RDD or extranodal RDD. **Classical RDD** patients present with massive *bilateral*, painless, mobile cervical adenopathy with or without fever, night sweats, and weight loss. Other lymph node involvement can include mediastinal, axillary, and inguinal, although retroperitoneal involvement is rare. **Extranodal RDD** occurs in 43% of cases. Soft tissue involvement has been reported in many organ systems. The most common sites are the skin, followed by the nasal cavity and sinuses, palate, orbit, bone, and central nervous system. Lab abnormalities can include normocytic anemia, leukocytosis (typically neutrophilia), elevated ESR, and polyclonal elevation of immunoglobulin G (hypergammaglobulinemia). Initial imaging studies are determined by symptoms and sites of suspected disease.

A biopsy that demonstrates histiocytes with hypochromatic nuclei with pale cytoplasm containing engulfed erythrocytes, plasma cells, and lymphocytes (emperipolesis), and immunoreactivity to S100 protein, in conjunction with expected clinical features, is diagnostic. IgG4-positive cells are often abundant. Occasionally, autoantibodies to erythrocytes or synovium may be present. The differential diagnosis includes Langerhans cell histiocytosis, myeloproliferative disorders, lymphoma, and hyper-IgG4 syndrome. After diagnosis, whole-body imaging with MRI or PET scan is recommended to evaluate for extranodal RDD.

Observation alone is a reasonable treatment choice for patients with uncomplicated nodal/cutaneous disease, as spontaneous remissions are seen in 20–50% of these patients. Symptomatic patients may benefit from surgical resection or debulking with the presence of single-site disease. Systemic therapy is typically reserved for severe, refractory, multifocal, or unresectable disease. Steroids are helpful in reducing nodal size; however, durable responses are often not seen with steroids alone. Various immunomodulatory (sirolimus) and chemotherapy regimens have been used successfully in severe disease, with treatment courses ranging from 6-12 months followed by close observation. Targeted therapies, including MEK inhibitors, have shown promising early results with studies ongoing. Radiation therapy has modest efficacy in RDD but has been used successfully in emergent therapy with visual or airway compromise. RDD may recur for many years with an unpredictable clinical course.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

539.3 Castleman Disease (Angiofollicular Lymph Node Hyperplasia)

Zachary T. Graff and Richard L. Tower

Castleman disease (CD) is an uncommon nonmalignant B-cell lymphoproliferative disorder and is also called **angiofollicular lymph node hyperplasia**. CD causes lymph node enlargement and is classified as either unicentric (involving a single lymph node or lymph node region) or multicentric (involving multiple lymph node regions). **Unicentric CD** typically presents with enlargement of a single bulky lymph node, most often in the mediastinum, neck, or abdomen, which can be asymptomatic or present with locally compressive symptoms. Patients may have fever, night sweats, weight loss, and fatigue. Diagnosis is made by an excisional lymph node biopsy. Staging imaging is performed with CT scan of chest/abdomen/pelvis or PET-CT scan to evaluate for multicentric disease. Management includes surgical resection when possible and is associated with a benign course, although patients should be educated on an increased risk of lymphoma.

Multicentric CD is subclassified based on the etiologic driver of the disease, either human herpes virus-8 (HHV-8), peripheral neuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, skin changes (POEMS) syndrome, or idiopathic. An underlying immunocompromised state is the primary risk factor for HHV-8 CD, particularly patients with HIV. Other forms of multicentric CD have no known risk factors. HHV-8 and idiopathic multicentric CD are driven by the excessive production of interleukin-6 (IL-6). Lymphadenopathy is often small volume and is present in peripheral and central lymph node chains. Constitutional symptoms such as fever, night sweats, and weight loss are more common at presentation compared to unicentric CD. Fluid collections including ascites, cytopenias, and liver/kidney dysfunction are also seen and indicate more aggressive disease. Diagnosis is again made by excisional lymph node biopsy as well as consistent clinical features. To determine type of multicentric CD, testing for HIV, HHV-8, and evaluation for POEMS (polyneuropathy, organomegaly, edema/endocrinopathy, monoclonal-protein, skin) syndrome is needed. Serum inflammatory markers are often tested at baseline and used to track disease. The differential diagnosis is broad even after lymph node biopsy, including infection, autoimmune disease, and malignancy. There is no standard treatment for multicentric Castleman disease. For symptomatic HHV-8+ multicentric CD, rituximab +/- etoposide with antiretroviral therapy for HIV+ patients have achieved excellent relapse-free survival. Idiopathic multicentric CD is managed with anti-IL-6 directed therapy (siltuximab) and steroids. Even after initial responses, symptoms can return after stopping therapy. Rituximab, steroids, and additional immunomodulatory medications (particularly the mTOR inhibitor sirolimus) are used next in patients that have had an inadequate response to therapy. Cytotoxic chemotherapy can be used for severe disease with organ dysfunction after failure of first-line therapy.

TAFRO (thrombocytopenia, anasarca, fever, reticulum fibrosis, organomegaly) syndrome is thought to be a subtype of multicentric Castleman disease based on the histologic appearance of the lymph node. Although there are overlapping features, TAFRO may be a distinct entity (Fig. 539.1).

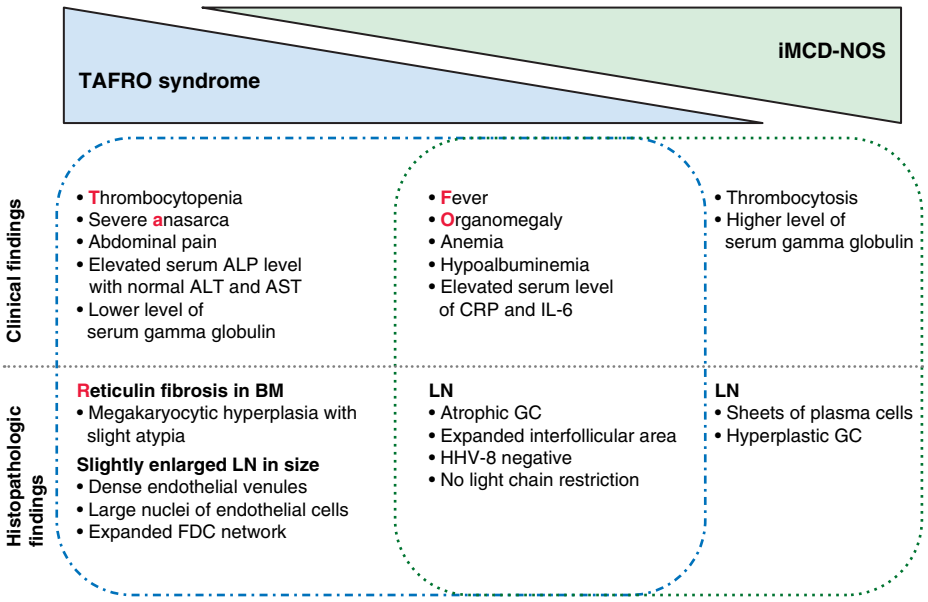

Fig. 539.1 Summary of the clinical and histopathologic features of TAFRO syndrome and iMCD-NOS. Although TAFRO syndrome and iMCD-NOS have clinicopathologic features in common, TAFRO syndrome has unique characteristics that can distinguish it from iMCD-NOS. ALP, alkaline phosphatase; ALT, Alanine transaminase; AST, aspartate transaminase; BM, bone marrow; CRP, C-reactive protein; FDC, follicular dendritic cell; GC, germinal center; HHV, human herpes virus; LN, lymph node; iMCD, idiopathic multicentric Castleman disease; NOS, not otherwise specified; TAFRO, thrombocytopenia, anasarca, fever, reticulin fibrosis, organomegaly. *(From Igawa T, Sato Y. TAFRO syndrome. Hematol Oncol Clin N Am. 2018;32:107–118. Fig. 4.)*

Cancer and Benign Tumors

PART XX

Chapter 540

Epidemiology of Childhood and Adolescent Cancer

Barbara L. Asselin

Cancer in patients younger than 20 years is uncommon, with an age-adjusted annual incidence of 19.6 per 100,000 children age 0-19 years, representing only approximately 1% of all new cancer cases in a year in the United States, or an estimated 16,000 new cases in 2021. This translates to nearly a 1 in 300 chance of developing cancer by age 20 years. Although the relative 5-year survival rates have improved from 61% in 1975–1977 to 85.1% in 2011–2017 in all age-groups 0-19 years (Fig. 540.1), **malignant neoplasms** remain the leading cause of disease-related (noninjury) mortality (9%) among persons 1-19 years of age, with 1,800-1,900 cancer-related deaths annually in the United States among children and adolescents 0-19 years of age. The relative contribution of cancer to the overall mortality in infants 0-1 year old and adolescents 15-19 years old is lower than for children age 1-14 years. The impressive improvements in survival over the last four decades are attributed primarily to advances in treatment, supportive care, and enrollment in clinical trials for the majority of patients. Ongoing multi-institutional cooperative clinical trials are investigating novel therapies and ways to improve survival rates further while decreasing treatment-related long-term complications. Because increasingly more patients survive their disease, clinical investigations also are focusing on the quality of life among survivors and the late outcomes of therapy for pediatric and adult survivors of childhood cancer. The **National Cancer Institute** (NCI; https://www.cancer.gov/types/childhood-cancers/) estimated that as of January 1, 2018, there were approximately 483,000 persons alive (in all age-groups) who had survived childhood cancer (diagnosed at ages 0-19 years). Given the overall improvement in survival rates coupled with the increased incidence of childhood cancer observed in recent decades, the number of survivors will continue to increase.

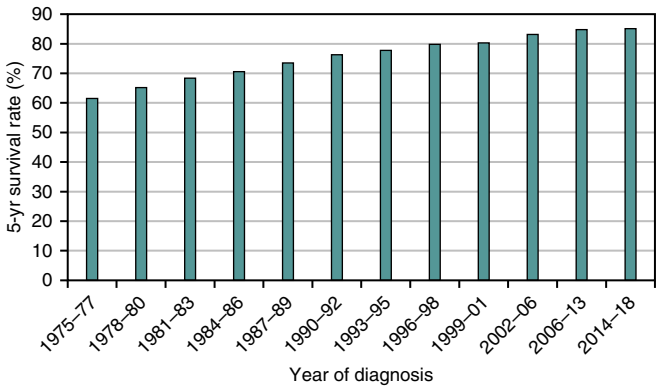

Fig. 540.1 The 5-year relative survival rates (%) by year of diagnosis of all cancers in children ≤19 years old. The difference between the periods 1975–1977 and 2014–2018 is statistically significant ($p < .05$). Rates based on follow-up of patients into 2018 from Surveillance, Epidemiology, and End Results (SEER) database. *(Data compiled from Howlader N, Noone AM, Krapcho M, et al., eds. SEER Cancer Statistics Review, 1975-2018. Bethesda, MD: National Cancer Institute. https://seer.cancer.gov/csr/1975_2018/. Based on November 2020 SEER data submission, posted to the SEER website, April 2021.)*

Pediatric malignancies differ greatly from adult malignancies in both prognosis and distribution by histology and tumor site. **Lymphohematopoietic cancers** (i.e., acute lymphoblastic leukemia, myeloid leukemia, Hodgkin and non-Hodgkin lymphomas) account for approximately 40%, **central nervous system cancers** for approximately 30%, and **embryonal tumors** and **sarcomas** for approximately 10% among the broad categories of childhood cancers (Table 540.1). In contrast, the **epithelial tumors** (or **adenocarcinomas**) of organs such as lung, colon, breast, and prostate often seen among adults, are rare malignancies in children. Incidence patterns in the pediatric age-group show two peaks, in early childhood and in adolescence (Fig. 540.2). During the first year of life, *embryonal tumors* such as neuroblastoma, nephroblastoma (Wilms tumor), retinoblastoma, rhabdomyosarcoma, hepatoblastoma, and medulloblastoma are most common (Figs. 540.3 and 540.4). These tumors are much less common in older children and adults after cell differentiation processes have slowed considerably. Embryonal tumors, acute leukemias, non-Hodgkin lymphomas, and gliomas peak in incidence from 2-5 years of age. As children age, bone malignancies, Hodgkin disease, gonadal germ cell malignancies (testicular and ovarian carcinomas), and other carcinomas increase in incidence. Adolescence is a transitional period between the common early childhood malignancies and characteristic carcinomas of adulthood (see Fig. 540.4).

Incidence rates also vary by *gender* (generally higher in males vs females), *ethnicity* (leukemia more common in Hispanic children than White or Black children; brain tumors more common in White children), and between countries (data assembled by the International Agency for Research in Cancer in Lyon, France, http://www.iarc.who.int/). These variations are not fully understood but likely reflect differences in genetic susceptibility and environmental exposures related to both known and unknown causes and risk factors for cancer (Table 540.2). Over the past four decades, 1975–2018, the U.S. Surveillance, Epidemiology, and End Results Program (SEER) data show some increases in the incidence of children and adolescents diagnosed with cancer (annual percent change about 1%), particularly in occurrence of leukemia, brain, and lymphoma and among adolescents. Interestingly, a similar increased incidence of malignancies diagnosed in childhood was observed between 1980 and 2010 in an international population-based registry study involving 62 countries. Reasons postulated to explain these increases include, but are not limited to, improved diagnosis, better record keeping, and development of data registries. Further analysis of trends among subpopulations, geographic variations, and incidence rates in high-income vs low-income countries are needed to clarify the role of *genetic ancestry, environmental factors,* and *technology* as explanations of these time trends in cancer in children.

Table 540.1 Age-Adjusted Incidence and Survival Rates of Malignant Neoplasms by Tumor Type in U.S. Children

	ANNUAL INCIDENCE RATES PER 1 MILLION CHILDREN, 2014–2018					5-YR SURVIVAL (%), AGE ≤19 YR AT DIAGNOSIS, 2011–2017
	AGE <1 YR	AGE 1-4 YR	AGE 5-9 YR	AGE 10-14 YR	AGE 15-19 YR	
All malignancies combined	265	227	137	164	252	85.1

Table 540.2 Known Risk Factors for Selected Childhood Cancers

CANCER TYPE	RISK FACTOR	COMMENTS
Acute lymphoid leukemia	Ionizing radiation	Therapeutic irradiation for cancer treatment
	Ethnicity	Hispanic children have higher incidence compared with White or Black children White children have a higher rate than Black children
	Immunodeficiency	SCID, Wiskott-Aldrich syndrome
	Genetic factors*	Down syndrome is associated with an estimated 10-20–fold increased risk NF1 Li-Fraumeni syndrome (*TP53* pathogenic variants) Noonan syndrome Chromosome breakage syndromes Bloom syndrome Ataxia-telangiectasia
Acute myeloid leukemias/ myelodysplastic syndrome	Chemotherapeutic agents	Alkylating agents and epipodophyllotoxins associated with risk of secondary leukemia
	Genetic factors*	Down syndrome (particularly acute megakaryocytic leukemia) NF1 Fanconi anemia and other inherited marrow failure syndromes Li-Fraumeni syndrome GATA2 deficiency Noonan syndrome Familial monosomy 7 and other chromosomal pathogenic variants
Brain cancers	Therapeutic ionizing radiation to the head	Radiation therapy as part of cancer treatment
	Genetic factors*	NF1 is strongly associated with optic gliomas, and, to a lesser extent, with other central nervous system tumors Li-Fraumeni syndrome Tuberous sclerosis Noonan syndrome Von Hippel-Landau syndrome FAP syndrome
Hodgkin disease	Family history	Monozygotic twins and siblings of cases are at increased risk
	Infections	EBV is associated with increased risk
Non-Hodgkin lymphoma	Immunodeficiency	Congenital immunodeficiency disorders (e.g., SCID and Wiskott-Aldrich syndrome) Immunosuppressive therapy for other conditions associated with increased risk
	Infections	EBV is associated with Burkitt lymphoma PTLD-EBV plays role in development of B-cell lymphoproliferative disease seen in immunocompromised hosts, especially those on immunosuppression following organ transplantation
Osteosarcoma	Ionizing radiation	Cancer radiation therapy
	Chemotherapy	Alkylating agents increase risk
	Genetic factors*	Li-Fraumeni syndrome Second malignancy in hereditary retinoblastoma with *RB1* pathogenic variant
Ewing sarcoma	Ethnicity	White children have about a ninefold higher incidence rate than Black children in the United States
Neuroblastoma		Beckwith-Wiedemann syndrome Li-Fraumeni
Retinoblastoma	Genetic factors*	Familial; pathogenic variant of *RB1* without other syndromic features—also with high risk of second malignancies
Wilms tumor	Genetic factors*	WAGR syndrome *WT1* germline pathogenic variant Beckwith-Wiedemann syndrome Li-Fraumeni syndrome
	Ethnicity	Asian children reportedly have about half the rates of White and Black children
Rhabdomyosarcoma	Genetic factors*	Li-Fraumeni syndrome NF1 Beckwith-Wiedemann syndrome DICER1 syndrome Gorlin syndrome

Continued

Table 540.2 Known Risk Factors for Selected Childhood Cancers—cont'd

CANCER TYPE	RISK FACTOR	COMMENTS
Hepatoblastoma	Genetic factors*	Beckwith-Wiedemann syndrome Gardner syndrome; FAP
Malignant germ cell tumors	Cryptorchidism	Cryptorchidism is a risk factor for testicular germ cell tumors

*See Chapter 541 for additional information.
SCID, Severe combined immunodeficiency syndrome; NF1, neurofibromatosis type1; FAP, familial adenomatous polyposis; EBV, Epstein-Barr virus; PTLD, posttransplant lymphoproliferative disorder; WAGR, Wilms, aniridia, genitourinary anomalies, and retardation syndrome.
From Ripperger T, Bielack SS, Borkhardt A, et al. Childhood cancer predisposition syndromes – a concise review and recommendations by the Cancer Predisposition Working Group of the Society for Pediatric Oncology and Hematology. *Am J Med Genet.* 2017;173:1017–1037, with data compiled from Porter CC, Druley TE, Erez A, et al. Recommendations for surveillance for children with leukemia-predisposing conditions. *Clin Cancer Res.* 2017;23(11):e14–e22.

Childhood cancer includes a diverse array of malignant tumors, termed "cancers," and nonmalignant tumors arising from disorders of genetic processes involved in control of cellular growth and development. Although many genetic conditions are associated with increased risks for childhood cancer, such conditions are believed to account for 8–10% of all occurrences (see Chapter 541). The most notable germline genetic conditions that impart susceptibility to childhood cancer are Li-Fraumeni *(P53)* syndrome, neurofibromatosis types 1 and 2, Down syndrome, Beckwith-Wiedemann syndrome, tuberous sclerosis, von Hippel-Landau disease, Noonan syndrome, ataxia-telangiectasia, and familial adenomatous polyposis syndrome and associated conditions (see Table 540.2). Consensus guidelines for surveillance screening in pediatric cancer predisposition syndromes were developed during a workshop of the Pediatric Cancer Working Group of the **American Association for Cancer Research** (AACR) and are available online through the AACR Open Access journal website (http://clincancerres.aacrjournals.org/content/23/11).

Compared with adult epithelial tumors, an extremely small fraction of pediatric cancers appears to be explained by known **environmental exposures** (see Table 540.2). Ionizing radiation exposure and several chemotherapeutic agents explain only a small number of pediatric cases (see Chapter 758). The association between fetal exposures and pediatric cancer is largely not established, with the exception of maternal diethylstilbestrol intake during pregnancy and subsequent vaginal adenocarcinoma in adolescent daughters. Environmental exposures that have been studied without convincing evidence for a causal role include nonionizing power frequency electromagnetic fields, pesticides, parental occupational chemical exposures, dietary factors, in vitro fertilization, and tobacco smoke exposure. Viruses associated with certain pediatric cancers include **polyomaviruses** (BK, JC, SV40) associated with brain cancer and **Epstein-Barr virus** (EBV) associated with certain subtypes of non-Hodgkin lymphoma.

The etiology of cancer in children still is poorly understood, and epidemiology studies demonstrate that the likely mechanisms are multifactorial, possibly resulting from potential interactions between genetic susceptibility traits and environmental exposures. Ongoing studies are investigating the role of **polymorphisms** of genes encoding enzymes, which function in the activation or metabolism of xenobiotics, protection of cells against oxidative stress, DNA repair, and/or immune modulation.

Curative therapy with chemotherapy, radiation, and/or surgery can adversely affect a child's development and result in serious long-term medical and psychosocial effects in childhood and adulthood. Potential adverse late effects include subsequent second malignancy, early mortality, infertility, reduced stature, cardiomyopathy, pulmonary fibrosis, osteoporosis, neurocognitive impairment, affective disorders, and altered social functioning (see Chapter 542). Much has been learned about the incidence of late effects from large, multisite cohort studies such as the **Childhood Cancer Survivor Study**, an ongoing study of medical and psychosocial outcomes in survivors, which has provided data for the development of clinical care guidelines for survivors (http://www.survivorshipguidelines.org).

Given the relative rarity of specific types of childhood cancer and the sophisticated technology and expertise required for diagnosis, treatment, and monitoring of late effects, all children with cancer should be treated with standardized clinical protocols in pediatric clinical research settings whenever possible. Promoting such treatment, the **Children's Oncology Group** is an international multi-institutional research consortium that facilitates cooperative clinical, biologic, and epidemiologic research in more than 200 affiliated institutions in the United States, Canada, and other countries (http://childrensoncologygroup.org/). Coordinated participation in such research trials has been a major factor in the increased survival for many children with cancer.

INFLUENCING THE INCIDENCE OF CANCER

There are only a few recognized environmental causes of childhood cancer that can be avoided or counteracted. One example is immunization against **hepatitis B**, which decreases the risk of hepatocellular carcinoma in adolescence and adulthood, and **human papillomavirus** vaccination, which prevents cervical cancer and HPV-positive oropharyngeal cancers and anal cancers. Associations between cumulative radiation exposure from common diagnostic radiologic tests such as CT scans and an increased risk of malignancy later in life are of great concern for pediatricians. Guidelines to ensure the safe clinical use of diagnostic imaging are being evaluated (http://www.imagegently.org/). An objective of pediatric medicine is *to teach children how to adopt healthy lifestyles to reduce their risk of cancer during adulthood,* such as avoiding tobacco, alcohol, high-fat diets, and obesity.

Chapter 541

Molecular and Cellular Biology of Cancer

Kristopher R. Bosse and Stephen P. Hunger

Cancer is a complex of diseases arising from alterations that can occur in a wide variety of genes. Multiple pathogenic gene variants and other genetic aberrations, some germline but most acquired (somatic), are required for cells to become fully malignant. These genetic changes lead to alterations in normal cellular processes that control cell proliferation and survival, including signal transduction, cell-cycle control, DNA repair, cellular growth and differentiation, translational regulation, senescence, and apoptosis (programmed cell death).

GENES INVOLVED IN ONCOGENESIS

Two major classes of genes are implicated in the development of cancer: oncogenes and tumor-suppressor genes. **Protooncogenes** are cellular genes that are important for normal cellular function and code for various proteins, including transcription factors, growth factors, and growth factor receptors. These proteins are vital components in the networks of signal transduction that regulate cell growth, division, and differentiation. Protooncogenes can be altered to form **oncogenes**—genes that, when translated, can contribute to malignant transformation of a cell.

Oncogenes can be divided into five different classes based on their mechanisms of action. Changes in any of these normal cellular components can result in unchecked cell growth. Some oncogenes code for **growth factors** that bind to a receptor and stimulate the production of a protein. Other oncogenes code for **growth factor receptors**, which are proteins on the cell surface. When growth factors bind to a growth factor receptor, they can turn the receptor on or off. Pathogenic genetic variants or posttranslational modifications of the receptor can result in it being permanently turned on, with consequent unregulated growth. **Signal transducers** or effectors make up another class. Signal transducers are responsible for taking the signal from the cell surface receptor to the cell nucleus. **Transcription factors** are molecules that bind to specific areas of the DNA and control transcription. **MYC** and **MYCN** are examples of transcription factors that when activated by pathogenic variants or amplification cause overstimulation of cell division. The final class of oncogenes **interferes with apoptosis**, or programmed cell death. Cells that no longer respond to the signal to die can lead to uncontrolled cell proliferation.

The three main mechanisms by which protooncogenes are activated are **amplification**, **pathogenic variants**, and **translocation** or **interstitial deletion** (Table 541.1). *MYC* or *MYCN,* which code for proteins that regulate transcription, are examples of protooncogenes that are activated by amplification. Patients with neuroblastoma in which the *MYCN* gene is amplified 10-300–fold have a poorer clinical outcome. Point pathogenic genetic variants can also activate protooncogenes. The *NOTCH1* protooncogene codes for a membrane-bound receptor integral to cell fate and differentiation pathways during normal development that undergoes proteolytic cleavage on ligand-induced activation, so that the protein can enter the nucleus and activate target gene transcription. *NOTCH1* has pathogenic variants in approximately 75% of **T-cell acute lymphoblastic leukemias** (ALLs), resulting in a *constitutively activated* protein important in leukemogenesis.

The third mechanism by which protooncogenes become activated is chromosomal translocation or interstitial deletion. In some leukemias and lymphomas, transcription factor–controlling sequences are relocated adjacent to transcriptionally active T-cell receptors or immunoglobulin genes, resulting in dysregulated transcription of these genes and leukemogenesis. A prominent example are translocations that bring *c-MYC* under control of the immunoglobulin heavy-chain gene *(IGH)* or kappa *(IGκ)* or lambda *(IGλ)* light-chain genes in **Burkitt lymphoma**. Chromosomal translocations that join genes from two different chromosomes or interstitial deletions or inversions within a chromosome can also result in **fusion genes**; transcription of the fusion gene results in production of a chimeric protein with new and potentially oncogenic activity. Examples of cancers associated with fusion genes include the childhood solid tumors **Ewing sarcoma [t(11;22)]** and **alveolar rhabdomyosarcoma [t(2;13)** or **t(1;13)]**. These translocations result in novel messenger RNA transcripts that are useful as diagnostic markers. The best-described translocation in leukemia is the **Philadelphia chromosome t(9;22)**, which produces the BCR-ABL1 protein found in **chronic myelogenous leukemia** and specific subtypes of **ALL**. BCR-ABL1 is a constitutively active tyrosine kinase. In addition, the protein is localized to the cytoplasm instead of the nucleus, exposing the kinase to a new spectrum of substrates.

Alteration in the regulation of **tumor-suppressor genes** is another mechanism involved in oncogenesis. Tumor-suppressor genes are important regulators of cellular growth and apoptosis. They have been called *recessive* oncogenes because the inactivation of both alleles of a tumor-suppressor gene is typically required for expression of a malignant phenotype.

Knudson's "2-hit" model of cancer development was based on the eye tumor **retinoblastoma** developing at a significantly younger age in children with the familial versus the sporadic form of the disease, and that tumors were often multifocal in familial cases but were almost always unifocal in sporadic cases. Knudson postulated that sporadic cases of retinoblastoma required somatic pathogenic variants to inactivate both copies of a gene, whereas in familial cases, children must inherit an inactivated allele from one parent and consequently only require the somatic inactivation of the remaining normal allele. This hypothesis was confirmed 15 years later following the discovery of the ***RB*** tumor-suppressor gene.

Another major tumor-suppressor protein is **TP53**, which is known as the "guardian of the genome" because it detects the presence of chromosomal damage and prevents the cell from dividing until repairs have been made. In the presence of damage beyond repair, TP53 initiates apoptosis and the cell dies. More than 50% of all tumors have abnormal TP53 proteins. Pathogenic variants in the *TP53* gene are important in many cancers, including breast, colorectal, lung, esophageal, stomach, ovarian, and prostatic carcinomas, as well as gliomas, sarcomas, and some leukemias.

SYNDROMES PREDISPOSING TO CANCER

Several syndromes are associated with an increased risk of developing malignancies, which can be characterized by different mechanisms (Table 541.2). One mechanism involves the *inactivation of tumor-suppressor genes* such as *RB* in **familial retinoblastoma**. Interestingly, patients with retinoblastoma in which one of the alleles is inactivated throughout the patient's body are also at a very high risk for developing osteosarcoma. A familial syndrome, **Li-Fraumeni syndrome**, in which one *TP53* pathogenic variant allele is inherited, also has been described in patients who develop sarcomas, leukemias, adrenocortical carcinoma, and cancers of the breast, bone, lung, and brain. **Neurofibromatosis** (NF) is a condition characterized by the proliferation of cells of neural crest origin. NF patients are at a higher risk of developing nervous system tumors, breast cancer, leukemia, pheochromocytomas, and other tumors. NF is inherited in an autosomal dominant manner, although 50% of cases present without a family history and occur secondary to the high rate of spontaneous pathogenic variants of the *NF1* gene.

A second mechanism responsible for an inherited predisposition to develop cancer involves *defects in DNA repair.* Syndromes associated with an excessive number of broken chromosomes caused by repair defects include **Bloom syndrome** (short stature, photosensitive telangiectatic erythema), **ataxia-telangiectasia** (childhood ataxia with progressive neuromotor degeneration, ocular telangiectasias), and **Fanconi anemia** (short stature, skeletal and renal anomalies, pancytopenia). As a result of the decreased ability to repair chromosomal defects, cells accumulate

Table 541.1 Oncogene Activators of Pediatric Tumors

MECHANISM	CHROMOSOME	GENES	PROTEIN FUNCTION	TUMOR
Chromosomal translocation	t(9;22)	*BCR::ABL1*	Chimeric tyrosine kinase	CML, ALL
	t(1;19)	*TCF3 (E2A)::PBX1*	Chimeric transcription factor	ALL
	t(8;14)	*MYC::IGH*	Transcription factor	Burkitt lymphoma
	t(15;17)	*PML::RARA*	Chimeric transcription factor	APML
	11q23 and others (over 50 fusions partners)	*KMT2A (MLL)*	Regulation of gene expression	Infant leukemia, ALL, AML, treatment-related leukemias
	t(12;21)	*ETV6::RUNX1*	Chimeric protein	ALL
	t(2;13) or t(1;13)	*PAX3* or *PAX7::FOXO1*	Transcription factor	Rhabdomyosarcoma
	t(11;22)	*EWS::FLI1*	Transcription factor	Ewing sarcoma
Gene amplification	2p	*MYCN*	Transcription factor	Neuroblastoma
	7p	*EGFR*	Growth factor receptor, tyrosine kinase	Glioblastoma, lung cancer
Point pathogenic gene variant	1p or 12p	*NRAS* or *KRAS*	Guanosine triphosphatase	AML, ALL, JMML, rhabdomyosarcoma, neuroblastoma
	10q	*RET*	Tyrosine kinase	MEN2
	2p	*ALK*	Tyrosine kinase	Neuroblastoma
	9q	*NOTCH1*	Transmembrane receptor	ALL

ALL, Acute lymphoblastic leukemia; AML, acute myeloid leukemia; APML, acute promyelocytic leukemia; CML, chronic myelogenous leukemia; JMML, juvenile myelomonocytic leukemia; MEN2, multiple endocrine neoplasia, type 2.

Table 541.2 Familial or Genetic Susceptibility to Malignancy

DISORDER	TUMOR/CANCER	COMMENT
CHROMOSOMAL DELETION/ANEUPLOIDY SYNDROMES		
Chromosome 11p13 deletion syndrome	Wilms tumor	Also known as WAGR syndrome (Wilms tumor, aniridia, genitourinary abnormalities, mental retardation); deletion typically includes *WT1* gene
Chromosome 13q14 deletion syndrome	Retinoblastoma, sarcoma	Associated with intellectual disability, characteristic craniofacial abnormalities; deletion typically includes *RB1* gene
Trisomy 21	ALL, AML, AMKL, TMD	Risk of ALL is increased 20-fold, risk of AMKL is increased 500-fold; high cure rates; more prone to chemotherapy toxicity; AMKL associated with *GATA1* pathogenic variants
Klinefelter syndrome (47,XXY)	Breast cancer, extragonadal germ cell tumors	
Trisomy 8	Myeloid neoplasms	Most commonly mosaic trisomy 8
Monosomy 5 or 7	AML, MDS	
CHROMOSOMAL INSTABILITY SYNDROMES		
Xeroderma pigmentosum	Basal cell and squamous cell carcinomas, melanoma	Autosomal recessive; failure to repair UV-damaged DNA; *XP/POLH* pathogenic variants
Fanconi anemia	AML, MDS, rare head, neck, and skin tumors, GI and GU cancers	Autosomal recessive; chromosome fragility; positive diepoxybutane (DEB) test result; pathogenic variants in *FANCX* gene family (includes at least 21 members)
Bloom syndrome	AML, MDS, ALL, lymphoma, and solid tumors	Associated with growth deficiency, malar rash; autosomal recessive; increase sister chromatid exchange (SCE); pathogenic variants in *BLM* gene; member of the RecQ helicase gene (unwinds DNA)
Ataxia-telangiectasia	Lymphoma, leukemia, less often central nervous system and other solid tumors	Associated with progressive ataxia, oculocutaneous telangiectasias; autosomal recessive; sensitive to radiation-induced DNA damage; increased risk of treatment-related morbidity; biallelic pathogenic variant in *ATM* tumor-suppressor gene
Nijmegen breakage syndrome	Leukemia, lymphoma	Associated with microcephaly, characteristic facies, immunodeficiency; biallelic pathogenic variants in *NBN* gene
Werner syndrome (progeria)	Soft tissue sarcomas, osteosarcoma, melanoma	Associated with accelerated aging; autosomal recessive; pathogenic variants in *WRN* gene

Table 541.2 Familial or Genetic Susceptibility to Malignancy—cont'd

DISORDER	TUMOR/CANCER	COMMENT
IMMUNODEFICIENCY SYNDROMES		
Wiskott-Aldrich syndrome	Lymphoma, leukemia	Associated with thrombocytopenia, eczema, and recurrent infections; X-linked recessive; *WASP* pathogenic variants
X-linked lymphoproliferative syndrome (XLP)	B-cell lymphoproliferative disease, lymphomas, HLH	Associated with fulminant and often fatal EBV infection; X-linked; pathogenic variants in the *SH2D1A* gene
X-linked agammaglobulinemia (XLA)	Lymphoproliferative disorders, colorectal cancer	Associated with absence of B cells; X-linked; pathogenic variants in *BTK* gene
Severe combined immunodeficiency (SCID)	Leukemia, lymphoma	X-linked or autosomal recessive; pathogenic variants in *IL2RG* and *ADA* genes
SYNDROMES ARISING FROM PATHOGENIC VARIANTS IN TUMOR SUPRESSORS OR ONCOGENES		
Neurofibromatosis 1	Neurofibroma, optic glioma, acoustic neuroma, astrocytoma, meningioma, pheochromocytoma, rhabdomyosarcoma, MPNST, neuroblastoma, leukemias	Associated with café-au-lait macules, axillary/inguinal freckling, Lisch nodules; autosomal dominant; pathogenic variants in tumor-suppressor gene *NF1*
Neurofibromatosis 2	Bilateral acoustic neuromas, meningiomas	Autosomal dominant; pathogenic variants in tumor-suppressor gene *NF2*
Tuberous sclerosis	Facial angiofibromas, renal cell carcinoma, renal angiomyolipomas, myocardial rhabdomyoma	Autosomal dominant; pathogenic variants in tumor-suppressor gene *TSC1* or *TSC2*
Noonan syndrome	JMML, ALL, neuroblastoma, brain tumors	Associated with distinct facial features, short stature, and heart defects; autosomal dominant; caused by RAS/MAPK pathway pathogenic variants (most frequently *PTPN11*)
Gorlin-Goltz syndrome (nevoid basal cell carcinoma syndrome)	Multiple basal cell carcinomas, medulloblastoma	Associated with odontogenic keratocysts, skeletal and skin anomalies; autosomal dominant; pathogenic variants in *PTCH1 or SUFU* gene
Li-Fraumeni syndrome	Osteosarcoma, soft tissue sarcoma, acute leukemias, breast and brain cancer, adrenal cortical tumors	Autosomal dominant; pathogenic variants in *TP53* tumor-suppressor gene
Beckwith-Wiedemann syndrome (BWS)	Wilms tumor, hepatoblastoma, neuroblastoma, rhabdomyosarcoma	Associated with macrosomia, macroglossia, hemihypertrophy, omphalocele; epigenetic/genomic alterations of chromosome 11p15
Von Hippel-Landau syndrome	Hemangioblastomas of the brain and retina, pheochromocytoma, renal cell carcinoma	Autosomal dominant; pathogenic variants of tumor-suppressor *VHL* gene
Multiple endocrine neoplasia, type 1 (Wermer syndrome)	Parathyroid, pancreatic islet cell and pituitary tumors	Associated with hyperparathyroidism, ZES; autosomal dominant; pathogenic variants in *MEN1* tumor-suppressor gene
Multiple endocrine neoplasia syndrome, type 2A (Sipple syndrome)	Medullary thyroid carcinoma, parathyroid tumors, pheochromocytoma	Associated with hyperparathyroidism; autosomal dominant; pathogenic variants in *RET* gene
Multiple endocrine neoplasia type 2B (multiple mucosal neuroma syndrome)	Mucosal neuromas, pheochromocytoma, medullary thyroid carcinoma	Associated with Marfan habitus, neuropathy; autosomal dominant; pathogenic variants in *RET* gene
Familial adenomatous polyposis (FAP)	Colorectal, thyroid, stomach and small intestinal cancer, hepatoblastoma	Associated with multiple colon polyps; autosomal dominant; pathogenic variants in *APC* gene
Juvenile polyposis syndrome	Colorectal, stomach, small intestinal and rectal cancer	Autosomal dominant; pathogenic variants in *BMPR1A* and *SMAD4* gene
Hereditary nonpolyposis colorectal cancer (HNPCC, Lynch syndrome)	Colorectal cancer, endometrial and stomach cancer, many other cancers	Autosomal dominant; pathogenic variants in DNA mismatch repair genes *MSH2, MLH1, PMS1, PMS2,* and *MSH6*
Turcot syndrome	Colorectal cancer, brain tumors (glioblastoma, medulloblastoma)	Autosomal dominant; pathogenic variants in *APC* or *MLH1* gene
Gardner syndrome	Colorectal cancer, other tumors similar to FAP	Subtype of FAP; autosomal dominant; pathogenic variants in *APC* gene
Constitutional mismatch repair deficiency syndrome (CMMRD)	Many different types of hematologic malignancies and brain and CNS tumors, colorectal carcinomas, and several other rare tumors	Autosomal recessive; homozygous germline pathogenic variants in the *MLH1, MSH2, MSH6,* or *PMS2* genes; tumors with very high variant burden, pathogenic variants of only one allele of the same genes results in Lynch syndrome
Peutz-Jeghers syndrome	Breast cancer, colorectal cancer, pancreatic cancer	Associated with hamartomatous polyps of GI tract; freckling of mouth, lips, fingers, and toes; autosomal dominant; pathogenic variants in *STK11* gene

Continued

Table 541.2 Familial or Genetic Susceptibility to Malignancy—cont'd

DISORDER	TUMOR/CANCER	COMMENT
Hereditary hemochromatosis	Hepatocellular carcinoma	Autosomal dominant; pathogenic variants in the *HFE* gene; malignancy associated with cirrhotic liver
Glycogen storage disease type 1 (von Gierke disease)	Hepatocellular carcinoma, liver adenomas	Autosomal recessive; pathogenic variants in *G6PC* or *SLC37A4* gene
Diamond-Blackfan anemia (DBA)	Colorectal and other GI cancers, AML, MDS, osteogenic sarcoma	Autosomal dominant; pathogenic variants in the small or large subunit-associated ribosomal protein genes (most often *RPS19*)
Shwachman-Diamond syndrome	AML, MDS	Associated with neutropenia, diarrhea, and failure to thrive; autosomal recessive; pathogenic variants in *SBDS* gene
DICER1 syndrome	Pleuropulmonary blastoma (PPB), cystic nephromas, ovarian Sertoli-Leydig tumors, multinodular goiter	Autosomal dominant; associated with pathogenic variants in *DICER1* gene
Familial neuroblastoma	Neuroblastoma	Autosomal dominant; pathogenic variants in *ALK* or *PHOX2B* gene
Hereditary paraganglioma-pheochromocytoma syndrome (PGL/PCC)	PGL, PCCs	Autosomal dominant; pathogenic variants in the mitochondrial enzyme succinate dehydrogenase protein family (*SDHA, B, C,* or *D*)
Severe congenital or cyclic neutropenia	AML, MDS	Associated with increased bacterial infections; typically autosomal dominant; pathogenic variants in *ELANE* or *HAX1* (Kostmann syndrome) gene
Rhabdoid predisposition syndrome 1 and 2	Atypical teratoid rhabdoid tumors, rhabdoid tumor of kidney, medulloblastoma, choroid plexus tumor	*SMARCB1/SMARCA4* tumor suppression genes
Predisposition to medulloblastoma	Medulloblastoma	*SUFU,* tumor suppression gene
Rothmund-Thomson syndrome	Skin, bone	*ANAPC1/RECQL4* stability gene
Multiple exostosis	Chondrosarcoma	*EXT1/EXT2,* tumor suppression gene
PTEN Hamartoma tumor syndromes: Cowden, Bannayan-Riley-Ruvalcaba, proteus, proteus-like syndromes	Breast, thyroid, renal, colon, melanoma	*PTEN, AKT1, PIK3CA, AKT3, PIK3R2, WWP1* germline or somatic pathogenic variants
BRCA1/2	Brain, solid tumors in children	Heterozygous pathogenic variants increase risk

ALL, Acute lymphoblastic leukemia; AML, acute myeloid leukemia; AMKL, acute megakaryocytic leukemia; CNS, central nervous system; EBV, Epstein-Barr virus; GI, gastrointestinal; GU, genitourinary; HLH, hemophagocytic lymphohistiocytosis; JMML, juvenile myelomonocytic leukemia; MAPK, mitogen-activated protein kinase; MDS, myelodysplastic syndrome; MPNST, malignant peripheral nerve sheath tumor; PTEN, phosphatase and tensin homolog; TMD, transient myeloproliferative disorder; UV, ultraviolet; ZES, Zollinger-Ellison syndrome.

abnormal DNA that results in significantly increased rates of cancer, especially leukemia. **Xeroderma pigmentosum** likewise increases the risk of skin cancer because of defects in repair to DNA damaged by ultraviolet light. **Constitutional mismatch repair deficiency syndrome** (CMMRD) is a disorder that results from the loss of both alleles of genes integral in repairing errors that occur during DNA replication, leading to the accumulation of multiple potentially pathogenic genetic alterations. These disorders display an autosomal recessive pattern.

The third category of inherited cancer predisposition is characterized by *defects in immune surveillance.* This group includes patients with **Wiskott-Aldrich syndrome**, severe combined immunodeficiency, common variable immunodeficiency, and the X-linked lymphoproliferative syndrome. The most common types of malignancy in these patients are lymphoma and leukemia. Cure rates for immunodeficient children with cancer are much poorer than for immunocompetent children with similar malignancies, suggesting a role for the immune system in cancer treatment as well as in cancer prevention.

Genome-wide association studies (GWAS) in a diverse array of childhood tumors, including ALL and neuroblastoma, have defined common **single nucleotide polymorphisms (SNPs)** in genes that are associated with cancer predisposition and collectively define regions of the genome that are critical in tumorigenesis. These alterations may occur in the coding or noncoding regions of the genome and typically lead to a relatively modest increase in cancer risk (2-10–fold over background) compared to the cancer susceptibility syndromes previously discussed, which may be associated with a lifetime risk of 50–100% of developing cancer. Furthermore, **whole genome sequencing** efforts across diverse pediatric cancers have identified that at least 8% of children who develop malignancy have a germline cancer-predisposing gene pathogenic variant. Many of these predisposing pathogenic variants occur in children without a family history of cancer or a known cancer predisposition syndrome.

OTHER FACTORS ASSOCIATED WITH ONCOGENESIS

Viruses

Several viruses have been implicated in the pathogenesis of malignancy. The association of the **Epstein-Barr virus (EBV)** with Burkitt lymphoma and nasopharyngeal carcinoma was identified more than 40 years ago, although EBV infection alone is not sufficient for malignant transformation. EBV is also associated with mixed cellularity and lymphocyte-depleted Hodgkin disease, as well as some T-cell lymphomas, which is particularly intriguing because EBV normally does not infect T lymphocytes. The most conclusive evidence for a role of EBV in lymphogenesis is the direct causal role of EBV for **B-cell lymphoproliferative disease** in immunocompromised persons, especially those with HIV infection or those receiving immunosuppression after organ

transplantation. **Human herpesvirus 8 (HHV-8)** is associated with the development of Kaposi sarcoma.

Children who are chronically infected with **hepatitis B virus** (hepatitis B surface antigen positive) have a 100-fold increased risk of developing **hepatocellular carcinoma**. In adults the latency period between viral infection and development of hepatocellular carcinoma approaches 20 years. However, in children who acquire the viral infection through perinatal transmission, the latency period can be as short as 6-7 years. The additional factors that are required for the malignant transformation of virally infected hepatocytes are not clear. **Hepatitis C virus** infection is another risk factor for hepatocellular carcinoma and is also associated with a subset of B-cell non-Hodgkin lymphomas such as splenic lymphoma.

Almost all cervical carcinomas are caused by **human papillomaviruses (HPVs)**. High-risk HPVs include types 16 and 18 but also types 31, 33, 34, 45, 52, and 58, which together cause >90% of cervical cancers. Vaccines against the major oncogenic subtypes are now available and are likely to save hundreds of millions of lives worldwide. The low-risk HPVs, including 6 and 11, which are commonly found in genital warts, are almost never associated with malignancies. Like other virus-associated cancers, the presence of HPV alone is not sufficient to cause malignant transformation. The mechanism by which the HPV-associated **oncoproteins HPV E6** and **E7** induce malignant transformation is thought to involve both the TP53 and the RB tumor-suppressor proteins, as well as other pathways that are critical in cell cycle progression, maintenance of telomerase and genomic stability, and apoptosis.

Radiation

Children who are exposed to ionizing radiation, either via environmental factors or from medical diagnostics or treatment, are also at an increased of developing cancer over their lifetime, especially leukemias, brain, breast, skin, or thyroid malignancies. This increased pediatric cancer risk is likely due both to the enhanced radiosensitivity of the developing organs of children and their longer postexposure life expectancy. Diagnostic imaging (e.g., CT scans) and therapeutic radiation for children with cancer are a major source of childhood radiation exposure. However, CT scan dose-reduction strategies, the increased use of MRI in pediatric medical centers, and the shift in therapeutic practice in oncology to proton radiotherapy all have been integral in lowering the exposure of children to ionizing radiation.

Genomic Imprinting

The development of cancer has also been linked to *genomic imprinting*, which is the selective inactivation of one of two alleles of certain genes depending on parental origin. **Beckwith-Wiedemann syndrome (BWS)** (see Chapter 113), the most commonly identified imprinting disorder, is an overgrowth syndrome characterized by macrosomia, macroglossia, hemihypertrophy, omphalocele, and renal anomalies that is also associated with an increased risk of Wilms tumor, hepatoblastoma, rhabdomyosarcoma, neuroblastoma, and adrenocortical carcinoma. This increased risk in developing cancer is directly associated with changes in the promoter methylation patterns (or loss of heterozygosity) of imprinted genes on chromosome 11p15.5. Normally, the maternally derived *IGF2* (insulin-like growth factor receptor 2) allele at this genomic locus is inactivated, thus suppressing *IGF2* expression. However, children with BWS show a gain of methylation in this promoter region, which allows for expression from both maternal and paternal *IGF2* alleles, leading to growth factor overexpression. Concurrently, the neighboring maternal *H19* gene (which encodes ncRNA and miRNA critical in growth suppression) is silenced by this hypermethylation, ultimately resulting in a progrowth phenotype and predisposition to tumor development.

Telomerase

Telomeres are a series of tens to thousands of TTAGGG DNA sequence repeats at the ends of chromosomes that are important for stabilizing the chromosomal ends and limiting breakage, translocation, and loss of DNA material. With DNA replication there is a progressive shortening of telomere length, which is a hallmark of cellular aging and acts as a replicative senescence signal. In a majority of cancers, **telomerase** (encoded by the *TERT* gene), an enzyme that adds telomeres to the ends of chromosomes, becomes activated, usually through pathologic variants in the *TERT* promoter. The telomerase-driven maintenance of telomere length in tumors enables unrestrained cellular proliferation by relieving a main checkpoint to cellular life span.

Chapter 542

Principles of Cancer Diagnosis

Julia C. Meade, Erika D. Friehling, and A. Kim Ritchey

Childhood cancer is uncommon and can manifest with symptoms seen with nonmalignant illnesses. The challenge for the pediatrician is to be alert to the clues suggesting a diagnosis of cancer. In addition to the classic manifestations, any persistent, unexplained symptom or sign should be evaluated as potentially emanating from a cancerous or precancerous condition.

SIGNS AND SYMPTOMS

The symptoms and signs of cancer are variable and nonspecific in pediatric patients. The types of cancer that occur during the first 20 years of life vary dramatically as a function of age—more so than at any other comparable age range (see Chapter 540). Unlike cancers in adults, childhood cancers usually originate from the deeper, visceral structures and from the parenchyma of organs rather than from the epithelial layers that line the ducts and glands of organs and compose the skin. In children, dissemination of disease at diagnosis is common, and presenting symptoms or signs are often caused by systemic involvement. **Pain was one of the initial presenting symptoms in >50% of children with cancer in one study.** Infants and young children cannot express or localize their symptoms well.

Solid tumors may produce **mass effects** that are nonspecific, such as compression of the thoracic airways or superior vena cava (lymphoma), the optic chiasm and hypothalamic-pituitary region (craniopharyngioma), and the fourth ventricle (cerebellar astrocytoma). Another factor is the variability in the physiology and biology of the host related to growth and development during infancy, childhood, and adolescence.

The signs of cancer in children are often attributed to other causes before the malignancy is recognized. Delays in diagnosis are particularly problematic during late adolescence and are the result of a variety of factors prominent in this age-group, including historic lack and complexity of health insurance coverage.

Although there is no clearly established set of warning signs of cancer in young people, the most common cancers in children suggest some guidelines that may be helpful in early recognition of signs and symptoms of cancer (Table 542.1). Most of the symptoms and signs are not specific and might represent other possibilities in a differential diagnosis. Nonetheless, these clues encompass the common cancers of childhood and have been very useful in early detection.

PHYSICAL EXAMINATION

Physical examination findings in a child with malignancy are dependent on whether the cancer is systemic or localized. The cancers most common in children involve the lymphoid and hematopoietic system. When the bone marrow is compromised by malignancy (e.g., leukemia, disseminated neuroblastoma), typical findings include pallor from anemia; bleeding, petechiae, or purpura from thrombocytopenia or coagulopathy; cellulitis or other localized infection from leukopenia; and skin nodules (especially in infants) and hepatosplenomegaly

Table 542.1 Common Manifestations of Childhood Malignancies

	SIGNS AND SYMPTOMS	POTENTIAL ETIOLOGY AND POSSIBLE DIAGNOSIS
Constitutional/ systemic	Fever, persistent or recurrent infection, neutropenia	Bone marrow infiltration from leukemia, neuroblastoma
	Fever of unknown origin, weight loss, night sweats	Hodgkin and non-Hodgkin lymphoma
	Painless, persistent lymphadenopathy	Leukemia, Hodgkin lymphoma, non-Hodgkin lymphoma, Burkitt lymphoma, thyroid carcinoma
	Hypertension	Renal or adrenal tumor such as neuroblastoma, pheochromocytoma, or Wilms tumor
	Soft tissue mass	Ewing sarcoma, osteosarcoma, neuroblastoma, thyroid carcinoma, rhabdomyosarcoma, Langerhans cell histiocytosis
	Pain	Bone marrow involvement (ALL) or metastatic disease (neuroblastoma), primary bone tumors, Langerhans cell histiocytosis
Neurologic/ ophthalmologic	Headache with emesis, visual disturbances, ataxia, papilledema, cranial nerve palsies	Increased intracranial pressure from primary brain tumor or metastasis
	Leukocoria (white pupil)	Retinoblastoma
	Periorbital ecchymosis	Neuroblastoma
	Miosis, ptosis, heterochromia	Horner syndrome: compression of cervical sympathetic nerves from neuroblastoma
	Opsoclonus myoclonus, ataxia	Paraneoplastic syndrome from neuroblastoma
	Exophthalmos, proptosis	Mass effect from rhabdomyosarcoma, lymphoma, or Langerhans cell histiocytosis
Respiratory/ thoracic	Cough, stridor, pneumonia, tracheal-bronchial compression; superior vena cava syndrome	Anterior mediastinal mass due to germ cell tumor, non-Hodgkin lymphoma, or Hodgkin lymphoma
	Vertebral or nerve root compression; dysphagia	Posterior mediastinal mass from neuroblastoma or Ewing sarcoma
Gastrointestinal	Abdominal mass	Neuroblastoma, Wilms tumor, lymphoma
	Diarrhea	Vasoactive intestinal peptide secretion from neuroblastoma, ganglioneuroma
Hematologic	Pallor, anemia	Bone marrow infiltration from leukemia, neuroblastoma
	Petechiae, thrombocytopenia	Bone marrow infiltration from leukemia, neuroblastoma
Musculoskeletal	Bone pain, limp, arthralgia	Osteosarcoma, Ewing sarcoma, leukemia, metastatic neuroblastoma
Endocrine	Diabetes insipidus	Pituitary tumor, Langerhans cell histiocytosis
	Poor growth	Diencephalic syndrome from hypothalamic tumor
	Galactorrhea	Pituitary tumor/prolactinoma
	Precocious puberty	Germ cell tumor (cranial or extracranial), adrenocortical carcinoma, hepatoblastoma

ALL, Acute lymphoblastic leukemia
Adapted from Marcdante KJ, Kliegman RM, Jenson HB, et al., eds. *Nelson Essentials of Pediatrics*. 6th ed. Philadelphia: Saunders; 2011. p. 588.

from malignant leukocytosis. Abnormalities found in lymphatic malignancies include peripheral **adenopathy** (Fig. 542.1) and signs of superior vena cava syndrome from an anterior **mediastinal mass** (Fig. 542.2), including respiratory distress, and facial and neck plethora and edema. Enlargement of cervical lymph nodes is common in children, but when persistent, progressive, and painless, it often suggests **lymphoma**. Supraclavicular adenopathy suggests underlying malignancy.

Abnormalities of the central nervous system (CNS) that can indicate cancer include headaches, vomiting, cranial nerve palsies, ataxia, afebrile seizures, ptosis, decreased visual activity, neuroendocrine deficits, and increased intracranial pressure, which may be diagnosed by the presence of papilledema (Fig. 542.3). Any focal neurologic deficit in the motor or sensory system, especially a decrease in cranial nerve function, should prompt further investigation for malignancy.

Ophthalmologic presentation of malignancy includes a **white pupillary reflex** (Fig. 542.4) rather than the usual red reflection from incident light. A white pupillary reflex is essentially pathognomonic for retinoblastoma, although some benign conditions can mimic this finding. **Proptosis** can be produced by rhabdomyosarcoma, neuroblastoma, lymphoma, and Langerhans cell histiocytosis. In the few first years of life, Horner syndrome, periorbital ecchymosis, iris heterochromia, and opsoclonus-myoclonus all suggest a diagnosis of neuroblastoma.

Abdominal masses can be divided into upper and lower locations. Malignancies in the upper abdomen include Wilms tumor, neuroblastoma, and hepatoblastoma. Enlargement of the liver or spleen

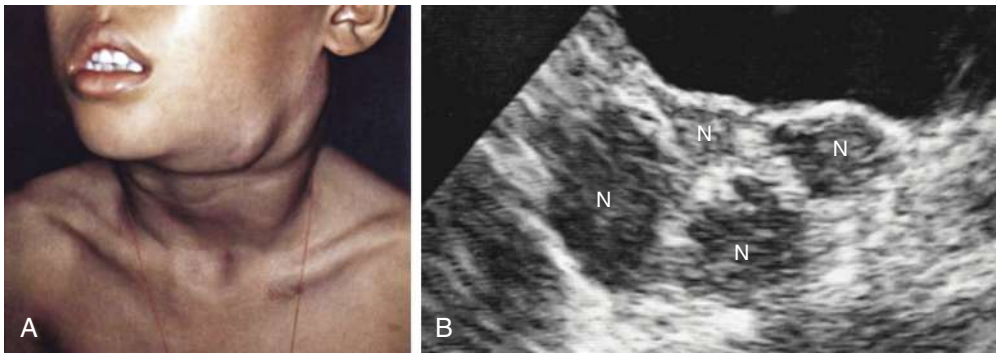

Fig. 542.1 Cervical lymphadenopathy. Manifestations on physical examination (**A**), and ultrasound examination (**B**). N, Abnormally enlarged lymph nodes. *(From Sinniah D, D'Angio GJ, Chatten J, et al. Atlas of Pediatric Oncology. London: Arnold; 1996.)*

from leukemia can be mistaken for an upper abdominal mass. Lower abdominal masses non-Hodgkin lymphoma, neuroblastoma, germ cell tumors (ovarian), and sarcomas.

Rhabdomyosarcoma can occur as an extremity mass, particularly in adolescents, but also as a mass in the head and neck region (e.g., orbit, nasopharynx, and others). These tumors can be deceptively benign in

appearance, but as with all unexplained masses, require immediate attention. Sacrococcygeal masses in neonates are usually **teratomas**, which are usually benign but can undergo malignant transformation if not removed promptly. **Neuroblastoma** can present as "blueberry muffin" spots on the skin of neonates or as periorbital ecchymosis in older children.

AGE-RELATED MANIFESTATIONS

Because various types of cancer in children occur at specific ages, the physician should tailor the history and physical examination based on the age of the child. The **embryonal tumors**, including neuroblastoma, retinoblastoma, and hepatoblastoma usually occur during the first 2 years of life (see Fig. 540.4). The peak age for presentation of **Wilms tumor** is 3-4 years. Two thirds of patients with **rhabdomyosarcoma** present before age 6 with another smaller peak in adolescence. From 1-4 years of age, **acute lymphoblastic leukemia** peaks in incidence. **Brain tumors** have a peak incidence in the first decade of life. **Non-Hodgkin lymphomas** are uncommon earlier than 5 years of age but steadily increase thereafter. During adolescence, bone tumors, Hodgkin lymphoma, and gonadal and soft tissue sarcomas predominate. Hence, for infants and toddlers, special attention should be paid to the possibility of embryonal and intraabdominal tumors. Preschool-age and early school-age children showing compatible signs and symptoms should be specifically evaluated for **leukemia**. School-age children might present with lymphoma or with brain tumors. Adolescents require assessment for bone and soft tissue sarcomas and gonadal malignancies, as well as for Hodgkin lymphoma.

EARLY DETECTION

The prognosis of malignancy in children depends primarily on tumor type, extent of disease at diagnosis, and rapidity of response to treatment. Early diagnosis helps to ensure that appropriate therapy is given in a timely manner and thus optimizes the chances of cure. Because most physicians in general practice rarely encounter children with undiagnosed cancer, they should remember to investigate the possibility of malignancy, especially when they encounter an atypical course of a common childhood condition, unusual manifestations that do not fit common conditions, and any persistent symptom that defies diagnosis. It is also good practice to obtain a three-generation family pedigree with specific attention to a family history of cancer. A strong family history of cancer would suggest a referral for a cancer predisposition evaluation.

Delays in diagnosis are particularly likely in certain clinical situations. The cardinal symptom of both **osteosarcoma** and **Ewing sarcoma** is localized and usually persistent pain. Because these tumors occur during the second decade of life, a time of increased physical activity, patients often assume the pain results from trauma. Prompt radiologic evaluation can help confirm the diagnosis. **Lymphoma**, especially during adolescence, often manifests as an anterior mediastinal mass. Symptoms such as chronic cough, unexplained shortness of breath, or "new-onset asthma" are typical with this presentation and are often overlooked. Tumors of the nasopharynx or middle ear can mimic infection. Prolonged, unexplained ear pain, nasal discharge, retropharyngeal swelling, and trismus should be investigated as possible signs of malignancy.

Early symptoms of **leukemia** may be limited to prolonged or unexplained low-grade fever. Bone and joint pain may present with refusal to walk. Blood counts with abnormalities in two or more cell lines might indicate the need for bone marrow examination, even when leukemic blast cells are not seen in the blood smear (see Table 542.1).

Mass screening for children with malignancy is not feasible. A screening program to detect early-stage neuroblastoma was successful in documenting more cases of the disease but had no impact on overall outcome. However, certain children are at increased risk for cancer and require an individualized plan to ensure early detection of malignancy. Select examples include children with certain chromosome abnormalities, such as Down syndrome, Klinefelter syndrome, and WAGR syndrome (Wilms tumor, *a*niridia, *g*enital abnormalities, mental *r*etardation); children with overgrowth syndromes, such as Beckwith-Wiedemann syndrome or hemihypertrophy; and children with certain inherited single-gene disorders, including hereditary retinoblastoma, Li-Fraumeni syndrome, familial adenomatous polyposis, and neurofibromatosis (see Table 541.2).

ENSURING THE DIAGNOSIS

When a malignant neoplasm is suspected, the immediate goal is to confirm the diagnosis. A tentative diagnosis can often be established based on the patient's age, symptoms, and location of masses. Selected imaging techniques and tumor markers can facilitate the diagnostic approach (Table 542.2 and Fig. 542.5). Especially when a solid tumor is present, the pediatric oncologist, surgeon, and pathologist should work as a team to determine the site of biopsy, amount of tissue required, and whether percutaneous image-guided biopsy, incisional biopsy, or excisional biopsy and tumor resection are indicated. For select situations, at the time of the initial diagnostic procedure, plans for bone marrow aspiration and biopsy and placement of central venous access may be appropriate.

Pathologic evaluation of pediatric malignancies requires appropriate handling of tissue so that multiple different techniques can be used to obtain a diagnosis. It is important that some fresh tissue not be placed in formalin. Along with routine light microscopy, pathologic evaluation may include immunochemistry, flow cytometry, cytogenetics, molecular genetic studies (e.g., fluorescence in situ hybridization, tumor whole exome sequencing, and evaluation of circulating tumor genes with cell-free DNA detection in blood). Additional technologies include DNA microarray analysis and cancer genome sequencing that can identify specific gene expression patterns and sequences in tumors, which can facilitate more accurate classification and treatment.

STAGING

Once a specific diagnosis is confirmed, studies to define the extent of the malignancy are necessary to determine prognosis and treatment. Table 542.2 outlines the minimum evaluation required for common pediatric malignancies. In addition, for many tumors (e.g., Wilms tumor, neuroblastoma, rhabdomyosarcoma), a surgical staging system is used. Surgical stage can be determined at the time of the initial diagnostic procedure or subsequently. For example, a patient who has abdominal surgery for possible Wilms tumor should have careful evaluation and biopsy of all adjacent lymph nodes. A child with rhabdomyosarcoma can require a subsequent biopsy of sentinel lymph nodes as determined by scintigraphy or dye injection adjacent to the primary tumor. The pathologist facilitates staging by examining margins of the specimen to determine residual tumor.

Chapter 543

Principles of Cancer Treatment

Erika D. Friehling, Julia C. Meade, Archie Bleyer, and A. Kim Ritchey

Treatment of children with cancer begins with an absolute requirement for the *correct diagnosis* (including subtype), proceeds through accurate and thorough *staging* of the extent of disease and determination of *prognostic subgroup*, provides appropriate multidisciplinary and usually multimodal therapy, and requires assiduous evaluation for possible recurrent disease and late effects of the disease and the therapies rendered. Throughout treatment, every child with cancer should have the benefit of the expertise of specialized teams of providers of pediatric cancer care, including pediatric oncologists, pathologists, radiologists, surgeons, radiation oncologists, nurses, and support staff, including nutritionists, social workers, psychologists, pharmacists, other medical specialists, and teachers trained to work with seriously ill children.

The best chance for cure of cancer is during the initial course of treatment; the cure rates for patients with recurrent disease are much lower than those for patients with primary disease. All patients with cancer should be referred to an appropriate specialized center as soon as possible when the diagnosis of cancer is suspected. All such centers in North America are identified on the **Children's Oncology Group** website (http://www.childrensoncologygroup.org) and on the **National Cancer Institute** (NCI) cancer trials website (http://www.clinicaltrials.gov). In the United States, the NCI's Clinical Trials Cooperative Groups Program is associated with a >80% reduction in the incidence of mortality from childhood cancer over 40 years despite an overall increase in cancer incidence during this interval (Fig. 543.1). After what appeared to be a plateau in the rate of decline in mortality in the early 2000s, there is evidence that the mortality rate continues to decline. Notably, a greater decline in mortality has been seen in the adolescent and young adult population when compared with children <15 years old, reversing prior trends (Fig. 543.2). The most current information on treatment of all types of childhood cancer is available in the PDQ (Physician Data Query) on the NCI website (http://www.cancer.gov/cancertopics/pdq/pediatrictreatment).

DIAGNOSIS AND STAGING

Accurate diagnosis and staging of the extent of disease are imperative because the nature of therapy depends strongly on the type of cancer. In addition, **prognostic subgroups** based on the stage of disease have been established for most cancers that occur in children. Accordingly, children with a better prognosis are treated with less intensive therapy, including lower doses of chemotherapy or radiation therapy, a shorter duration of treatment, or elimination of at least one treatment modality (radiation therapy, chemotherapy, surgery). Accurate staging thus reduces the risk of excessive acute toxicity and long-term effects of therapy in patients whose prognosis indicates that less therapy is required for cure. **Overtreatment** of patients with a more favorable prognosis is a definite risk if the patient is not referred to a cancer treatment center. Conversely, **undertreatment** also is a clear risk if the diagnosis and stage are not correct, resulting in a compromise of an otherwise high potential for cure.

Diagnostic imaging is a critical phase of evaluation in most children with solid tumors. MRI, CT, ultrasonography, scintigraphy (nuclear medicine scans), positron emission tomography (PET), and spectroscopy, as appropriate, all serve a clear purpose in the evaluation of children with cancer, not only before treatment to determine the extent of disease and the appropriate therapy but also during follow-up to determine whether the therapy was effective (see Chapter 542). In addition, response to treatment as determined by imaging techniques is being increasingly used to guide changes in the therapy.

Expertise in pathology and laboratory medicine provides critical diagnostic support and guides therapy in most children with cancer. Relatively noninvasive methods of obtaining tumor tissue such as percutaneous image-guided biopsy can be performed in pediatric centers with appropriate expertise in diagnostic imaging, interventional radiology, cytology, and anesthesia support. Sentinel node mapping is helpful in the staging of some children's cancers. Determining the adequacy of surgery by evaluating frozen sections of the surgical margins for tumor cells is essential in many tumor operations.

A MULTIMODAL, MULTIDISCIPLINARY APPROACH

Many pediatric subspecialists are involved in the evaluation, treatment, and management of children with cancer, including provision of primary therapy and supportive care services (Fig. 543.3). More than two of the primary modalities are often used together, with chemotherapy the most widely used, followed in order of use by surgery, radiation therapy, and biologic agent therapy (Fig. 543.4).

The **leukemias** that occur in childhood usually are managed with chemotherapy alone, with a small proportion of patients receiving cranial radiation therapy to prevent or treat overt central nervous system (CNS) leukemia. Children with **non-Hodgkin lymphoma** also are treated with chemotherapy alone, except for radiation therapy for CNS involvement. Localized therapy with surgery or irradiation, or both, is an important component of treatment of most solid tumors, including **Hodgkin lymphoma**, but systemic multiagent chemotherapy usually is necessary because tumor dissemination generally is present even if undetectable. Chemotherapy alone usually is not adequate to eradicate gross residual tumors. Therefore it is not unusual for children with malignant tumors to require treatment with all three modalities (see Fig. 543.4). Unfortunately, most treatments that are effective in children with cancer have a narrow therapeutic index (a low ratio of efficacy to toxicity). The acute and late effects of these treatments can be minimized but not entirely avoided.

Biologic agent therapy is an important modality in a few childhood cancers (see Fig. 543.4). This type of treatment generally refers to immunotherapy, biologic response modifiers, or endogenously occurring molecules that have therapeutic effects in supraphysiologic doses. Examples are retinoic acid therapy in acute promyelocytic leukemia, monoclonal antibody therapy for neuroblastoma and certain non-Hodgkin lymphomas, tyrosine kinase inhibitors such as imatinib mesylate for chronic myelogenous and Philadelphia chromosome–positive leukemias, and radioactive metaiodobenzylguanidine (MIBG) therapy for neuroblastoma. In addition, immune therapy directed at tumor cell antigens with modification of T-cell receptors (TCRs) or chimeric antigen receptors (CARs) have improved survival in patients with chemotherapy-resistant diseases (leukemia, lymphoma) and have shown promise in solid tumors and brain tumors.

Chemotherapy is used more widely in children than in adults because children better tolerate the acute adverse effects, and the malignant diseases that occur in childhood are more responsive to chemotherapy than are malignant diseases of adults. **Radiation therapy** is used sparingly in children because of its association with growth impairment and with the development of second malignant neoplasms.

Whenever possible, treatment is given on an outpatient basis. Children should remain living at home and in school as much as possible throughout treatment. Increasingly, pediatric cancer therapies are being administered to ambulatory patients, with the advent of such innovations as programmable infusion pumps, oral chemotherapeutic regimens, early discharge from hospital with intensive outpatient supportive care, and home healthcare services. Some patients miss a considerable amount of school in the first year after diagnosis because of the intensity of therapy or its adverse effects and the ensuing complications of the disease or therapy. Tutoring should be encouraged so that children do not fall behind in their schooling; counseling should be provided as appropriate. In-hospital school services should be provided for patients who must spend much of their time as inpatients receiving therapy for disease or for managing adverse effects. Upon completion of therapy, referral for pediatric neuropsychiatric testing in a specialized center is often recommended to ensure they are well supported in their education.

De novo or acquired resistance to chemotherapy and radiation therapy remains an obstacle to cure. Ongoing discoveries of molecular and cellular

mechanisms that explain the cancer process have led to increasingly specific antineoplastic therapies, generally referred to as **molecularly targeted therapies**. Their most prominent feature is a relative lack of normal tissue toxicity, such that the additional therapeutic benefit occurs with minimum additional toxicity. Many biologic agent therapies, such as imatinib and selumetinib, fall into this category (Table 543.1). **Complementary** and **alternative** therapies are increasingly being provided by parents to their children with cancer, with or without knowledge of the medical professionals entrusted with the child's care (see Chapter 7). Collaboration with the family and a pharmacist specializing in chemotherapy can minimize unwanted interactions from supplements.

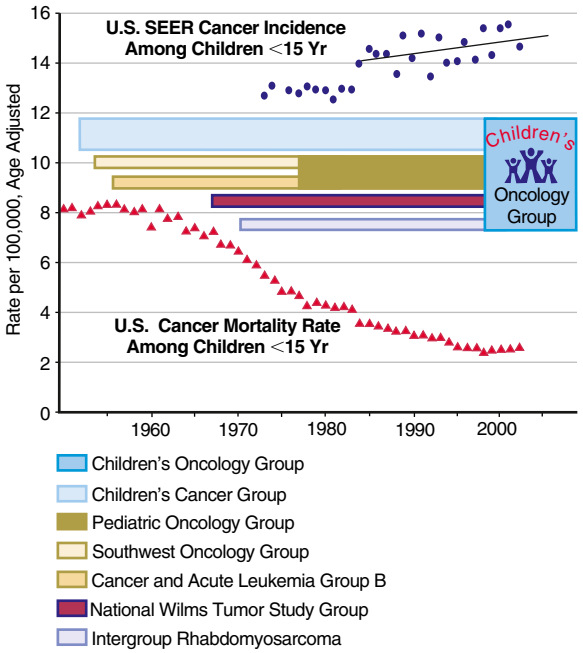

Fig. 543.1 Reduction in the national cancer mortality rate among children younger than 15 years of age *(triangles)* in the United States as a direct consequence of the National Cooperative Group Program sponsored by the National Cancer Institute and compared with the rising incidence of cancer before age 15 *(circles)*. The *horizontal bars* indicate the duration of the existence of the national pediatric cancer cooperative groups, beginning with the Children's Cancer Group in 1955. Other groups are the Pediatric Oncology Group, which was derived from the Pediatrics Divisions of the Southwest Oncology Group and the Cancer and Acute Leukemia Group B; the National Wilms Tumor Study Group; and the Intergroup Rhabdomyosarcoma Study Group. In 2000 the four pediatric cooperative groups merged into the Children's Oncology Group. *(Incidence and mortality rate data from Ries LAG, Eisner MP, Kosary CL, et al., eds. SEER Cancer Statistics Review, 1975–2002. Bethesda, MD: National Cancer Institute; http://seer.cancer.gov/csr/1975_2002/, based on November 2004 SEER [Surveillance, Epidemiology, and End Results] data submission. The mortality rate data are national rates, and the incidence data are derived from the SEER program, representing approximately 15% of the United States. The most current information on treatment of all types of childhood cancer is available in the PDQ [Physician Data Query] on the NCI website, http://www.cancer.gov/cancertopics/pdq/pediatrictreatment.)*

DISCUSSING THE TREATMENT PLAN WITH THE PATIENT AND FAMILY

The diagnostic and treatment plan must be carefully explained to parents and, if the child is old enough to understand, to the patient. Children should be given as much information as they can understand and would be useful to them. All questions should be answered openly and honestly. Effects of treatment, such as loss of hair during chemotherapy, the possible need to amputate a limb, and possible temporary or permanent functional impairment, must be anticipated and fully discussed. The possibility and probability of death from cancer should be covered in an age-appropriate manner. It usually is necessary to repeat explanations several times before

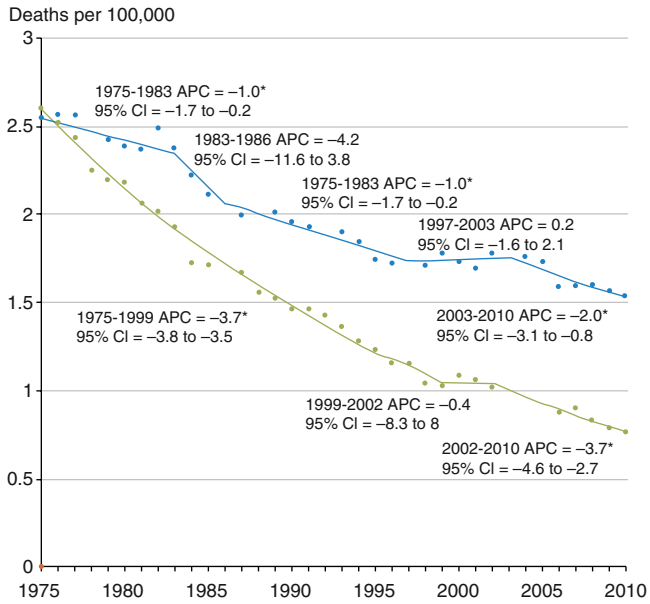

Fig. 543.2 Age-adjusted mortality trends for all malignant cancers among children <20 yr old in the United States from 1975 through 2010, along with annual percentage changes (APCs) for join point segments. *Asterisk* indicates that the slope of the join point segment is statistically different from zero ($p < .05$). The *green line* indicates leukemias and lymphomas, and the *blue line* indicates all other cancer sites; CI, confidence interval. *(From Smith MA, Altekruse SF, Adamson PC, et al. Fig. 543.4 The primary modalities of therapy used in the treatment of children with cancer. The relative sizes of the circles designate the approximate proportion of overall role in the management of pediatric cancers.

Table 543.1 Tyrosine Kinase Inhibitors and Monoclonal Antibodies for Pediatric Cancers

AGENT	TARGET	MALIGNANCY
Imatinib	BCR-ABL	CML Philadelphia chromosome–positive ALL
	PDGFRα cKIT	Hypereosinophilic syndrome Gastrointestinal stromal tumor
Dasatinib, nilotinib	BCR-ABL	CML Philadelphia chromosome–positive ALL
Brentuximab	CD30	Hodgkin lymphoma
Rituximab	CD20	Non-Hodgkin lymphoma
Selumetinib	MAPK/MEK	Plexiform neurofibroma Low-grade glioma
Bevacizumab	VEGFR-1, -2	Low-grade glioma
Crizotinib, lorlatinib	ALK/ROS	Neuroblastoma Anaplastic large cell lymphoma Inflammatory myofibroblastic tumor
Dinutuximab	GD2	Neuroblastoma
Blinatumomab	CD19	Leukemia Lymphoma

ALL, Acute lymphoblastic leukemia; CML, chronic myelogenous leukemia.

distraught family members fully understand. Throughout treatment, parents, patients, siblings, and medical staff will all need help in expressing feelings of anxiety, depression, guilt, and anger. The pediatrician, pediatric oncologist, and nurses should call on experienced professionals, including pediatric social workers, child psychologists and psychiatrists, child life specialists, and teachers with special expertise in managing students with cancer, to assist when needed.

TREATMENTS

Chemotherapy

The most widely used modality in pediatric cancer therapy is chemotherapy (see Fig. 543.4). Therapy usually involves a combination of drugs with different mechanisms of action and nonoverlapping toxicities. Sequential single-drug therapy rarely results in complete responses, and partial responses usually are infrequent, transient, and grow progressively shorter in duration with each drug used. Most of the cytotoxic drugs for childhood cancer are selected from several classes of agents, including alkylating agents, antimetabolites, antibiotics, hormones, plant alkaloids, and topoisomerase inhibitors (Table 543.2). The increased metabolic and cell cycle activity of malignant cells makes them more susceptible to the cytotoxic effects of these types of agents (Fig. 543.5).

Because most antineoplastic agents are cell cycle dependent, their adverse effects usually are related to the proliferation kinetics of individual cell populations. Most susceptible are tissues or organs with high rates of cell turnover: bone marrow, oral and intestinal mucosa, epidermis, liver, and spermatogonia. The most common acute adverse effects are **myelosuppression** (with neutropenia and thrombocytopenia the most problematic), immunosuppression, nausea and vomiting, hepatic dysfunction, upper and lower gastrointestinal mucositis, dermatitis, and alopecia. Fortunately, the tissues affected also recover relatively quickly, so that the acute adverse effects are usually reversible. Life-threatening effects of many chemotherapy agents include severe neutropenia with infection, fungemia, or fungal pneumonia as a result of immunosuppression, and septicemia, not infrequently linked to indwelling intravascular devices (Table 543.3; see Chapters 223 and 224). **Cardiomyopathy** caused by anthracyclines (e.g., doxorubicin, daunorubicin) and **renal failure** from platinum-containing agents also may be life-threatening or disabling. Assistance from a supportive care team can also provide safe and effective support for toxicities associated with chemotherapy, such as pain and nausea.

Least susceptible to chemotherapy and radiation therapy are cells that do not replicate or that replicate slowly, such as neurons, muscle cells, connective tissue, and bone. Children are not exempt from toxicities of these tissues, probably because they are still undergoing proliferation, although at a slower pace than other tissues, during growth and growth spurts.

Physically, children can endure the acute adverse effects of chemotherapy better than adults can in many ways. The maximum tolerated dosage in children, when expressed based on body surface area or body weight, typically is greater than that in adults. A comparison of anticancer drugs tested in phase I trials in both adult and pediatric patients showed that the maximum tolerated dosage in children was greater than that in adults for 70% of the agents, equal to that in adults for 15%, and less than the adult dose for only 15% of the agents. For all the drugs that were compared, the mean pediatric maximum tolerated dosage was greater than the adult mean.

Pharmacogenomics

Interindividual variability in the response to similar doses of a given medication is an inherent characteristic of both adult and pediatric populations. Variations in the germline genome can lead to differences in drug response at the level of individual patients. **Pharmacogenomics** represents the combination of pharmacology and genomics and is defined as the broader application of genetic testing strategies to identify factors predictive of drug efficacy and risk of adverse drug reactions.

Thiopurine *S*-methyltransferase **(TPMT)** is an enzyme that catalyzes the methylation of the chemotherapy 6-mercaptopurine (6MP) used in the treatment of acute lymphoblastic leukemia (ALL). To exert its cytotoxic effects, 6MP requires metabolism to thioguanine nucleotides, and this reaction is prevented by TPMT. Of the general population, 89% has normal TPMT activity, 11% has intermediate activity, and 0.3% has low activity. In patients with low or intermediate activity variants of TPMT, there is accumulation of cytotoxic thioguanine nucleotides (Fig. 543.6). These patients are at increased risk for **severe myelosuppression** if treated with routine doses of thiopurines and require a 10-15–fold reduction in dose to minimize this risk.

TPMT genotype is not the only determinant of intolerance to thiopurines; genetic variation in *NUDT15,* a nucleotide diphosphatase that reduces the incorporation of thioguanine into DNA, may also be involved. Reduction or loss of *NUDT15* activity results in increased cytotoxicity. Patients who have inherited reduced-function *NUDT15* alleles tolerate thiopurine doses that are much lower (10%) than normal. It is reasonable to expect that both *TPMT* and *NUDT15* genotypes will need to be considered for individualized thiopurine treatment, identifying patients who will benefit from specific dosing regimens and those who will be at risk for short-term and long-term toxicities.

Immunotherapy

Tumor-directed immune therapies employ and enhance the patient's immune system to kill malignant cells. Tumor antigen–specific monoclonal antibodies have been incorporated into the standard therapy of

Table 543.2 Common Chemotherapeutic Agents Used in Pediatric Cancer

DRUG	MECHANISM OF ACTION OR CLASSIFICATION	INDICATION(S)	ADVERSE REACTIONS (PARTIAL LIST)	COMMENTS
Methotrexate	Folic acid antagonist; inhibits dihydrofolate reductase	ALL, non-Hodgkin lymphoma, osteosarcoma, Hodgkin lymphoma, medulloblastoma	Myelosuppression, mucositis, stomatitis, dermatitis, hepatitis With long-term administration, osteopenia and bone fractures With high-dose administration, renal and CNS toxicity With intrathecal administration, arachnoiditis, leukoencephalopathy, and leukomyelopathy	Systemic administration may be PO, IM, or IV; also may be administered intrathecally Plasma methotrexate levels must be monitored with high-dose therapy and when low doses are administered to patients with renal dysfunction, and leucovorin rescue applied accordingly
6-Mercaptopurine (Purinethol)	Purine analog; inhibits purine synthesis	ALL	Myelosuppression, hepatic necrosis, mucositis; allopurinol increases toxicity	Allopurinol inhibits metabolism
Cytarabine (cytosine arabinoside; Ara-C)	Pyrimidine analog; inhibits DNA polymerase	ALL, AML, non-Hodgkin lymphoma, Hodgkin lymphoma	Nausea, vomiting, myelosuppression, conjunctivitis, mucositis, CNS dysfunction With intrathecal administration, arachnoiditis, leukoencephalopathy, and leukomyelopathy	Systemic administration may be PO, IM, or IV; may also be administered intrathecally
Cyclophosphamide (Cytoxan)	Alkylates guanine; inhibits DNA synthesis	ALL, non-Hodgkin lymphoma, Hodgkin lymphoma, soft tissue sarcoma, Ewing sarcoma, Wilms tumor, neuroblastoma	Nausea, vomiting, myelosuppression, hemorrhagic cystitis, pulmonary fibrosis, inappropriate ADH secretion, bladder cancer, anaphylaxis	Requires hepatic activation and thus is less effective in presence of liver dysfunction Mesna prevents hemorrhagic cystitis
Ifosfamide (IFEX)	Alkylates guanine; inhibits DNA synthesis	Non-Hodgkin lymphoma, Wilms tumor, soft tissue sarcoma	Nausea, vomiting, myelosuppression, hemorrhagic cystitis, pulmonary fibrosis, inappropriate ADH secretion, CNS dysfunction, cardiac toxicity, anaphylaxis	Mesna prevents hemorrhagic cystitis
Doxorubicin (Adriamycin), daunorubicin (Cerubidine), and idarubicin (Idamycin)	Binds to DNA, intercalation	ALL, AML, osteosarcoma, Ewing sarcoma, Hodgkin lymphoma, non-Hodgkin lymphoma, neuroblastoma	Nausea, vomiting, cardiomyopathy, red urine, tissue necrosis on extravasation, myelosuppression, conjunctivitis, radiation dermatitis, arrhythmia	Dexrazoxane reduces risk of cardiotoxicity
Dactinomycin	Binds to DNA, inhibits transcription	Wilms tumor, rhabdomyosarcoma, Ewing sarcoma	Nausea, vomiting tissue necrosis on extravasation, myelosuppression, radiation dermatitis, mucosal ulceration	
Bleomycin (Blenoxane)	Binds to DNA, cleaves DNA strands	Hodgkin disease, non-Hodgkin lymphoma, germ cell tumors	Nausea, vomiting, pneumonitis, stomatitis, Raynaud phenomenon, pulmonary fibrosis, dermatitis	
Vincristine (Oncovin)	Inhibits microtubule formation	ALL, non-Hodgkin lymphoma, Hodgkin disease, Wilms tumor, Ewing sarcoma, neuroblastoma, rhabdomyosarcoma	Local cellulitis, peripheral neuropathy, constipation, ileus, jaw pain, inappropriate ADH secretion, seizures, ptosis, minimal myelosuppression	IV administration only; must not be allowed to extravasate
Vinblastine (Velban)	Inhibits microtubule formation	Hodgkin lymphoma, non-Hodgkin lymphoma, Langerhans cell histiocytosis, CNS tumors	Local cellulitis, leukopenia	IV administration only; must not be allowed to extravasate
L-Asparaginase	Depletion of L-asparagine	ALL; AML, when used in combination with cytarabine	Allergic reaction pancreatitis, hyperglycemia, platelet dysfunction and coagulopathy, encephalopathy	Pegaspargase now preferred to L-asparaginase
Pegaspargase (Oncaspar) Calaspargase-pegol-mknl (Asparlas)	Polyethylene glycol conjugate of L-asparagine	ALL	Indicated for prolonged asparagine depletion and for patients with allergy to L-asparaginase

Table 543.2 Common Chemotherapeutic Agents Used in Pediatric Cancer—cont'd

DRUG	MECHANISM OF ACTION OR CLASSIFICATION	INDICATION(S)	ADVERSE REACTIONS (PARTIAL LIST)	COMMENTS
Prednisone and dexamethasone (Decadron)	Lymphatic cell lysis	ALL; Hodgkin lymphoma, non-Hodgkin lymphoma	Cushing syndrome, cataracts, diabetes, hypertension, myopathy, osteoporosis, avascular necrosis, infection, peptic ulceration, psychosis	
Carmustine (BiCNU)	Carbamylation of DNA; inhibits DNA synthesis	CNS tumors, non-Hodgkin lymphoma, Hodgkin lymphoma	Nausea, vomiting, delayed myelosuppression (4-6 wk); pulmonary fibrosis, carcinogenic stomatitis	Phenobarbital increases metabolism, decreases activity
Carboplatin and cisplatin (Platinol)	Inhibits DNA synthesis	Osteosarcoma, neuroblastoma, CNS tumors, germ cell tumors	Nausea, vomiting, renal dysfunction, myelosuppression, ototoxicity, tetany, neurotoxicity, hemolytic-uremic syndrome, anaphylaxis	Aminoglycosides may increase nephrotoxicity
Etoposide (Vepesid)	Topoisomerase inhibitor	ALL, non-Hodgkin lymphoma, germ cell tumor, Ewing sarcoma	Nausea, vomiting, myelosuppression, secondary leukemia	
Tretinoin (all *trans*-retinoic acid) and isotretinoin (*cis*-retinoic acid; Accutane)	Enhances normal differentiation	Acute promyelocytic leukemia; neuroblastoma	Dry mouth, hair loss, pseudotumor cerebri, premature epiphyseal closure, birth defects	

ADH, Antidiuretic hormone; ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CNS, central nervous system; IM, intramuscular; IV, intravenous; PO, oral.

neuroblastoma (anti–ganglioside GD_2). The antiangiogenic agent bevacizumab (monoclonal antibody against vascular endothelial growth factor A) is used in the treatment of low-grade gliomas.

Chimeric antigen receptor T cells (CAR-T cells) are genetically engineered to make new TCRs that can recognize and attach to an antigen on the tumor cell. This results in T-cell proliferation, cytolysis, and cytokine release with subsequent tumor cell death (Fig. 543.7). The B-cell antigen CD19 is the antigen targeted in children with ALL and some adults with lymphoma. The response to therapy in children with chemotherapy-resistant ALL is dramatic. Other antigens may be targeted, including CD22, CD30 (lymphomas), CD171, GD2 (neuroblastoma), EGFR, and HER2 (glioblastoma).

Side effects of CAR-T therapy are common and potentially serious and are caused by the **cytokine release syndrome (CRS)**. Manifestations

Table 543.3 Infectious Complications of Malignancy

PREDISPOSING FACTOR	ETIOLOGY	SITE OF INFECTION	INFECTIOUS AGENTS
Neutropenia	Chemotherapy, bone marrow infiltration	Sepsis, shock, pneumonia, soft tissue, proctitis, mucositis	Viridans group streptococcus, *Staphylococcus aureus, Staphylococcus epidermidis, Escherichia coli, Pseudomonas aeruginosa, Candida, Aspergillus,* anaerobic oral and rectal bacteria
Immunosuppression, lymphopenia, lymphocyte-monocyte dysfunction	Chemotherapy, corticosteroid	Pneumonia, meningitis, disseminated viral infection	*Pneumocystis jiroveci, Cryptococcus neoformans, Mycobacterium, Nocardia, Listeria monocytogenes, Candida, Aspergillus, Strongyloides, Toxoplasma,* varicella-zoster virus, cytomegalovirus, herpes simplex
Indwelling central venous catheter	Nutrition, administration of chemotherapy	Line sepsis, tract of tunnel, exit site	*S. epidermidis, S. aureus, Candida albicans, P. aeruginosa, Aspergillus, Corynebacterium, Enterococcus faecalis, Mycobacterium fortuitum, Propionibacterium acnes*

of CRS include hypotension, vascular leak, myalgias, cerebral edema, seizures, and confusion. Symptoms correlate with the extent of the tumor burden and require supportive care. Tocilizumab, an anti–interleukin-6 receptor monoclonal antibody, is the treatment of choice for CRS. B-cell aplasia may also develop and requires immune globulin replacement.

Immune checkpoint inhibitors are drugs (monoclonal antibodies) which enhance the ability of T-cells to attack cancer cells. Checkpoints on T-cells and cancer cells include PD-1/PD-L1 (programed death protein and programed death ligand-1), which normally dampen the T-cell response. CTLA-4 and LAG-3 are additional immune checkpoint molecules. Thus checkpoint inhibitors allow the T-cell to kill the cancer cells more effectively. Immune-related adverse events (irAEs) due to activated T cells include autoimmune-like disorders affecting many tissues including skin, liver, lung, CNS, and gastrointestinal and endocrine organs.

Surgery

Superb pediatric surgical and anesthesia services are indispensable for children with cancer. The pediatric surgeon's role varies depending on the type of tumor. For **solid tumors**, complete resection with documented evidence of negative margins often is required for cure or long-term control. Considerable prolongation of life usually depends on the tumor's resectability and the actual extent of resection.

Except for pontine gliomas and retinoblastoma, all solid tumors in children require a tissue diagnosis; therefore biopsy of the suspected neoplasm is paramount. Staging with sentinel node biopsies has become the standard of care for several pediatric malignancies. Surgical expertise is essential for implantation of vascular access devices and removal and replacement of such devices when infection or thrombosis supervenes (see Chapter 224).

Minimally invasive endoscopic surgical techniques are being used when indicated and, if the patient's condition permits, for biopsy and resection of tumor, direct ascertainment of residual disease and assessment of response, lysis of adhesions, and splenectomy.

Radiation Therapy

Radiation therapy is used sparingly in children, who are more susceptible than adults to the adverse delayed effects of ionizing radiation. A major advance in pediatric radiation therapy is the application of **conformal radiation** to children with cancer. This technique, most often applied as **intensity-modulated radiation therapy**, spares normal tissue by conforming the radiation volume to the shape of the tumor, thereby enabling delivery of higher doses to the tumor with lower exposure of normal tissue adjacent to the tumor or in the path of the radiation beam. Another example is **proton-beam radiotherapy**. With more focused beams and better sedation and immobilization techniques, radiation therapy is becoming more common in children. Acute adverse effects from radiation therapy depend on which part of the body is irradiated and the means of administration. **Dermatitis** is the most common general adverse effect because skin is always in the treatment field. Nausea and diarrhea are common subacute adverse effects with abdominal radiation therapy. **Mucositis** typically occurs to some extent whenever oral or intestinal mucosa is in the treatment volume. **Somnolence** is common with cranial irradiation. **Alopecia** occurs where hair is in the radiation field.

Most radiation therapy schedules require treatment 5 days per week for 4-7 weeks, depending on the dose needed to control the tumor and the amount and nature of normal tissue in the field. Most adverse effects are not noted until the second half of the course of irradiation. Late effects can occur months to years after radiation therapy and usually are dose-dependent manifestations. The type of delayed toxicity also depends on the site of irradiation. Examples are impaired growth resulting from cranial or vertebral irradiation, endocrine dysfunction from hypothalamic irradiation, pulmonary or cardiac insufficiency from chest irradiation, strictures and adhesions from abdominal irradiation, and infertility from pelvic irradiation. Second malignancy can also develop in the radiation field, such as breast cancer from chest irradiation and brain tumors from CNS irradiation.

ACUTE TOXIC EFFECTS AND SUPPORTIVE CARE

Adverse treatment effects that occur early in therapy can result in oncologic emergencies. These include metabolic disorders, bone marrow suppression, and compression by tumors on vital structures (Table 543.4). In **tumor lysis syndrome (TLS)**, uric acid, phosphate, and potassium are released in the circulation in large quantities from death of tumor cells. Hyperuricemia can lead to impairment of renal function, which further exacerbates the metabolic abnormalities. TLS can occur before therapy in patients with a large tumor burden (e.g., Burkitt lymphoma, lymphoblastic lymphoma, and leukemia presenting with a high white blood cell count), but it is usually seen within 12-48 hours of initiating chemotherapy. TLS is infrequently reported in other tumors (Hodgkin lymphoma, neuroblastoma, hepatoblastoma). Before therapy is initiated, the serum levels of uric acid, electrolytes, calcium, phosphorus, and creatinine should be measured, and adequate hydration ensured. Allopurinol (a xanthine oxidase inhibitor) should be started to prevent further accumulation of uric acid. In patients with established TLS with high uric acid levels or those at high risk for TLS, rasburicase (an enzyme that degrades uric acid) should be given. Symptomatic hyperkalemia and hyperphosphatemia with subsequent hypocalcemia can develop in the setting of inadequate renal function.

Virtually all chemotherapy regimens can produce **myelosuppression**, as can malignancies that invade and replace bone marrow. **Anemia** can

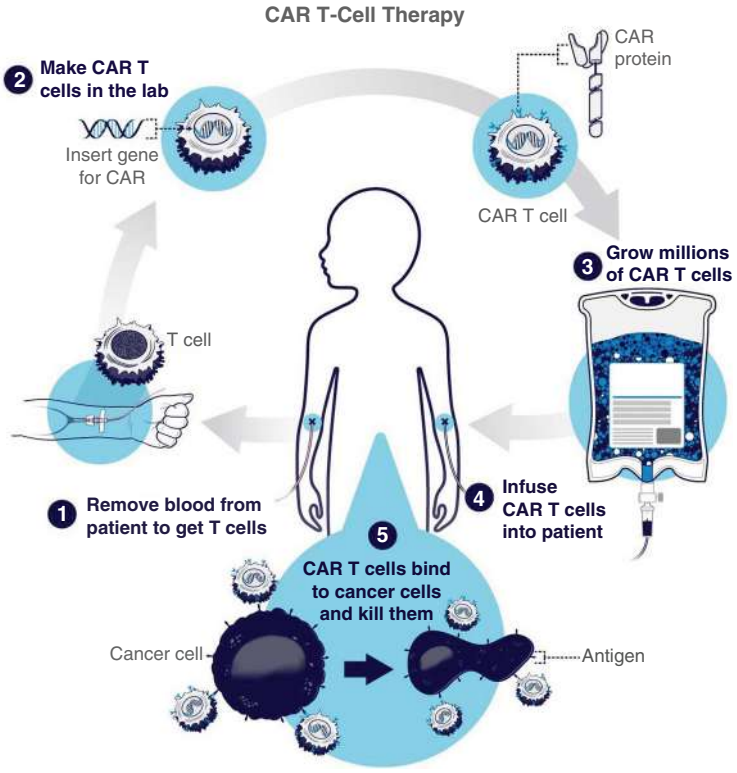

Fig. 543.7 Chimeric antigen receptor (CAR) T-cell therapy. CAR T-cell therapy is a type of treatment in which a patient's T cells are genetically engineered in the laboratory so they will bind to specific proteins (antigens) on cancer cells and kill them. *(1)* A patient's T cells are removed from their blood. Then *(2)* the gene for a special receptor called a chimeric antigen receptor is inserted into the T cells in the laboratory. The gene encodes the engineered CAR protein that is expressed on the surface of the patient's T cells, creating a CAR T cell. *(3)* Millions of CAR T cells are grown in the laboratory. *(4)* They are then given to the patient by intravenous infusion. *(5)* The CAR T cells bind to antigens on the cancer cells and kill them. *(Courtesy National Institutes of Health, National Cancer Institute, Bethesda, Maryland. https://www.cancer.gov/about-cancer/treatment/research/car-t-cell-therapy-infographic)*

Table 543.4 Oncologic Emergencies

CONDITION	MANIFESTATIONS	ETIOLOGY	MALIGNANCY	TREATMENT
METABOLIC				
Hyperuricemia	Uric acid nephropathy	Tumor lysis syndrome	Lymphoma, leukemia	Allopurinol, hydration, rasburicase
Hyperkalemia	Arrhythmias, cardiac arrest	Tumor lysis syndrome	Lymphoma, leukemia	Kayexalate, sodium bicarbonate, calcium gluconate, glucose, and insulin; check for pseudohyperkalemia from leukemic cell lysis in test tube
Hyperphosphatemia	Hypocalcemic tetany; metastatic calcification, photophobia, pruritus	Tumor lysis syndrome	Lymphoma, leukemia	Hydration, forced diuresis; stop alkalinization; oral aluminum hydroxide to bind phosphate
Hyponatremia	Seizure, lethargy (may also be asymptomatic)	SIADH; fluid, sodium losses in vomiting	Leukemia, CNS tumor	Restrict free water for SIADH; replace sodium if depleted
Hypercalcemia	Anorexia, nausea, polyuria, pancreatitis, gastric ulcers; prolonged PR, shortened QT interval	Bone resorption; ectopic parathormone, vitamin D, or prostaglandins	Metastasis to bone, rhabdomyosarcoma, leukemia	Hydration and furosemide diuresis; corticosteroids; calcitonin, bisphosphonates
HEMATOLOGIC				
Anemia	Pallor, weakness, heart failure	Bone marrow suppression or infiltration; blood loss	Any with chemotherapy	Packed red blood cell transfusion
Thrombocytopenia	Petechiae, hemorrhage	Bone marrow suppression or infiltration	Any with chemotherapy	Platelet transfusion
Disseminated intravascular coagulation	Shock, hemorrhage	Sepsis, hypotension, tumor factors	Promyelocytic leukemia, others	Fresh-frozen plasma; platelets, cryoprecipitate, treat underlying disorder
Neutropenia	Infection	Bone marrow suppression or infiltration	Any with chemotherapy	If febrile, administer broad-spectrum antibiotics, and filgrastim (G-CSF) if appropriate

Table 543.4 Oncologic Emergencies—cont'd

CONDITION	MANIFESTATIONS	ETIOLOGY	MALIGNANCY	TREATMENT
Hyperleukocytosis (>100,000/mm^3)	Hemorrhage, thrombosis; pulmonary infiltrates, hypoxia; tumor lysis syndrome	Leukostasis; vascular occlusion	Leukemia	Leukapheresis; chemotherapy; hydroxyurea
Graft versus host disease	Dermatitis, diarrhea, hepatitis	Immunosuppression and nonirradiated blood products; bone marrow transplantation	Any with immunosuppression	Corticosteroids; cyclosporine; tacrolimus; antithymocyte globulin
SPACE-OCCUPYING LESIONS				
Spinal cord compression	Back pain ± radicular *Cord above T10:* symmetric weakness, increased deep tendon reflex; sensory level present; toes up *Conus medullaris (T10-L2):* symmetric weakness, increased knee reflexes; decreased ankle reflexes; saddle sensory loss; toes up or down *Cauda equina (below L2):* asymmetric weakness; loss of deep tendon reflex and sensory deficit; toes down	Metastasis to vertebra and extramedullary space	Neuroblastoma, ewing, glioma	Corticosteroids, surgery, chemotherapy, radiotherapy
Increased intracranial pressure	Confusion, coma, emesis, headache, hypertension, bradycardia, seizures, papilledema, hydrocephalus; cranial nerve III and VI palsies	Primary or metastatic brain tumor	Medulloblastoma, glioma	Corticosteroids, ventriculostomy, radiotherapy, chemotherapy
Superior vena cava syndrome	Distended neck veins, plethora, edema of head and neck, cyanosis, Horner syndrome	Superior mediastinal mass	Lymphoma Germ cell tumor	Chemotherapy, radiotherapy
Tracheal compression	Respiratory distress	Mediastinal mass compressing trachea	Lymphoma Neuroblastoma	Radiation, corticosteroids

CNS, Central nervous system; G-CSF, granulocyte colony-stimulating factor; SIADH, syndrome of inappropriate antidiuretic hormone secretion.
Adapted from Kliegman RM, Marcdante KJ, Jenson HB, et al., eds. *Nelson Essentials of Pediatrics*. 6th ed. Philadelphia: Saunders; 2011. p. 590.

be corrected by transfusions of packed erythrocytes, and **thrombocytopenia** can be corrected by platelet infusions. Patients receiving immunosuppressive therapy should receive irradiated blood products to prevent graft-versus-host disease and leukoreduced blood products to prevent transfusion-associated reactions and infections. **Neutropenia** (neutrophil counts <500/μL) poses a risk of life-threatening infection. Patients with febrile neutropenia should be hospitalized and treated with empirical broad-spectrum intravenous antimicrobial therapy pending the results of appropriate cultures of blood, urine, or any obvious sites of infection (see Chapter 223). Treatment is continued until fever resolves and the neutrophil count rises. If fever persists for more than 3-5 days while the patient is receiving broad-spectrum antibiotics, the possibility of fungal infection must be considered. Fungal infections caused by *Candida* and *Aspergillus* are common in immunosuppressed patients. Opportunistic organisms such as *Pneumocystis jiroveci* can produce fatal pneumonia. Prophylactic treatment with trimethoprim-sulfamethoxazole is given when severe or prolonged immunosuppression is anticipated.

Viruses of low pathogenicity can produce serious disease in the setting of immunosuppression caused by malignancy or its treatment. Patients should not be given live-virus vaccines. Children who are receiving chemotherapy and who are exposed to chickenpox should receive varicella-zoster immunoglobulin, or if varicella-zoster immunoglobulin is not available, oral acyclovir should be considered. If clinical disease develops, the child should be hospitalized and treated with intravenous acyclovir.

Depending on the type of cancer therapy, patients can lose >10% body weight. Patients sometimes reduce their food intake because of temporary, treatment-associated nausea, stomatitis, and vomiting. Appetite loss is not a cause for alarm. **Malnutrition** is a particular risk in patients receiving radiation therapy involving the abdomen or the head and neck, intensive chemotherapy, or total body irradiation and high-dose chemotherapy before marrow transplantation. If oral supplementation proves inadequate, such patients may require enteral tube feedings or parenteral hyperalimentation.

Adequate **pain management** is critical. The World Health Organization (WHO) guidelines are particularly useful in the management of pain associated with cancer and cancer therapy (see Chapter 93). Assistance from a **supportive care** team can provide safe and effective support for toxicities associated with chemotherapy, such as pain and nausea.

LATE EFFECTS

Late effects of therapy can cause substantial morbidity (Table 543.5). The type of late effects depends on the child's age at treatment, the location(s) of the cancer, and the therapy administered. These effects can be either from the tumor or its treatment. For example, a brain or spinal tumor can leave the child with a permanent paresis or autonomic dysfunction; anthracycline-induced cardiomyopathy usually produces refractory cardiac dysfunction; and the leukoencephalopathy caused by intrathecal methotrexate and CNS radiation therapy often is only partially reversible.

Successful surgical resection can result in loss of important functional structures. Irradiation can produce irreversible organ damage, with symptoms and functional limitations depending on the organ involved and the severity of the damage. Many problems related to radiation therapy do not become obvious until the patient is fully grown, such as asymmetry between irradiated and nonirradiated areas or extremities. Irradiation of fields that include endocrine organs can cause hypothyroidism, pituitary dysfunction, or infertility. In sufficient doses, cranial irradiation can produce neurologic dysfunction, and spinal irradiation can produce growth deficiency.

Chemotherapy also carries the risk of long-lasting organ damage. Of particular concern are **leukoencephalopathy** after high-dose

methotrexate therapy; **infertility** in patients treated with alkylating agents (e.g., cyclophosphamide); **myocardial damage** caused by anthracyclines; **pulmonary fibrosis** caused by bleomycin; **renal dysfunction** caused by ifosfamide, nitrosourea, or platinum agents; and **hearing loss** from cisplatin. Development of these sequelae may be dose related and usually is irreversible. Appropriate baseline and intermittent testing should be performed before these drugs are administered to ensure that there is no preexisting damage to the organs likely to be affected and to permit monitoring of the effects of treatment-induced changes.

Perhaps the most serious late effect is the occurrence of **second cancers** in patients successfully cured of a first malignancy. The risk

Table 543.5 Late Effects and High-Risk Features of Childhood Cancer and Its Treatment

LATE EFFECTS	EXPOSURE	SELECTED HIGH-RISK FACTORS	AT-RISK DIAGNOSTIC GROUPS
NEUROCOGNITIVE			
Neurocognitive deficits Functional deficits in: • Executive function • Sustained attention • Memory • Processing speed • Visual-motor integration Learning deficits Diminished IQ Behavioral change	Chemotherapy: • Methotrexate Radiation affecting brain: • Cranial • Ear/infratemporal • Total body irradiation (TBI)	Age <3 yr old at time of treatment Female Supratentorial tumor Premorbid or family history of learning or attention problems Radiation doses >24 Gy Whole-brain irradiation	Acute lymphoblastic leukemia Brain tumor Sarcoma (head and neck or osteosarcoma)
NEUROSENSORY			
Hearing loss, sensorineural	Chemotherapy: • Cisplatin • Carboplatin Radiation affecting hearing: • Cranial • Infratemporal • Nasopharyngeal	Higher cisplatin dose (360 mg/m^2) Higher radiation dose impacting ear (>30 Gy) Concurrent radiation and cisplatin	Brain tumor Germ cell tumor Sarcoma (head and neck) Neuroblastoma Hepatoblastoma
Hearing loss, conductive Tympanosclerosis Otosclerosis Eustachian tube dysfunction	Radiation affecting hearing: • Cranial • Infratemporal • Nasopharyngeal	Higher radiation dose affecting ear (>30 Gy)	Brain tumor Sarcoma (head and neck)
Visual impairment Cataracts Lacrimal duct atrophy Xerophthalmia Retinopathy Glaucoma	Chemotherapy: • Busulfan • Glucocorticoids Radiation affecting eye: • Cranial • Orbital/eye • TBI	Higher radiation dose impacting eye (≥15 Gy for cataracts; >45 Gy for retinopathy and visual impairment)	Brain tumor Acute lymphoblastic leukemia Retinoblastoma Rhabdomyosarcoma (orbital) Allogeneic HSCT
Peripheral neuropathy, sensory	Chemotherapy: • Vincristine • Vinblastine • Cisplatin • Carboplatin Brentuximab vedotin	Higher cisplatin dose (≥300 mg/m^2)	Acute lymphoblastic leukemia Brain tumor Hodgkin lymphoma Germ cell tumor Non-Hodgkin lymphoma Sarcoma Neuroblastoma Wilms tumor Carcinoma
NEUROMOTOR

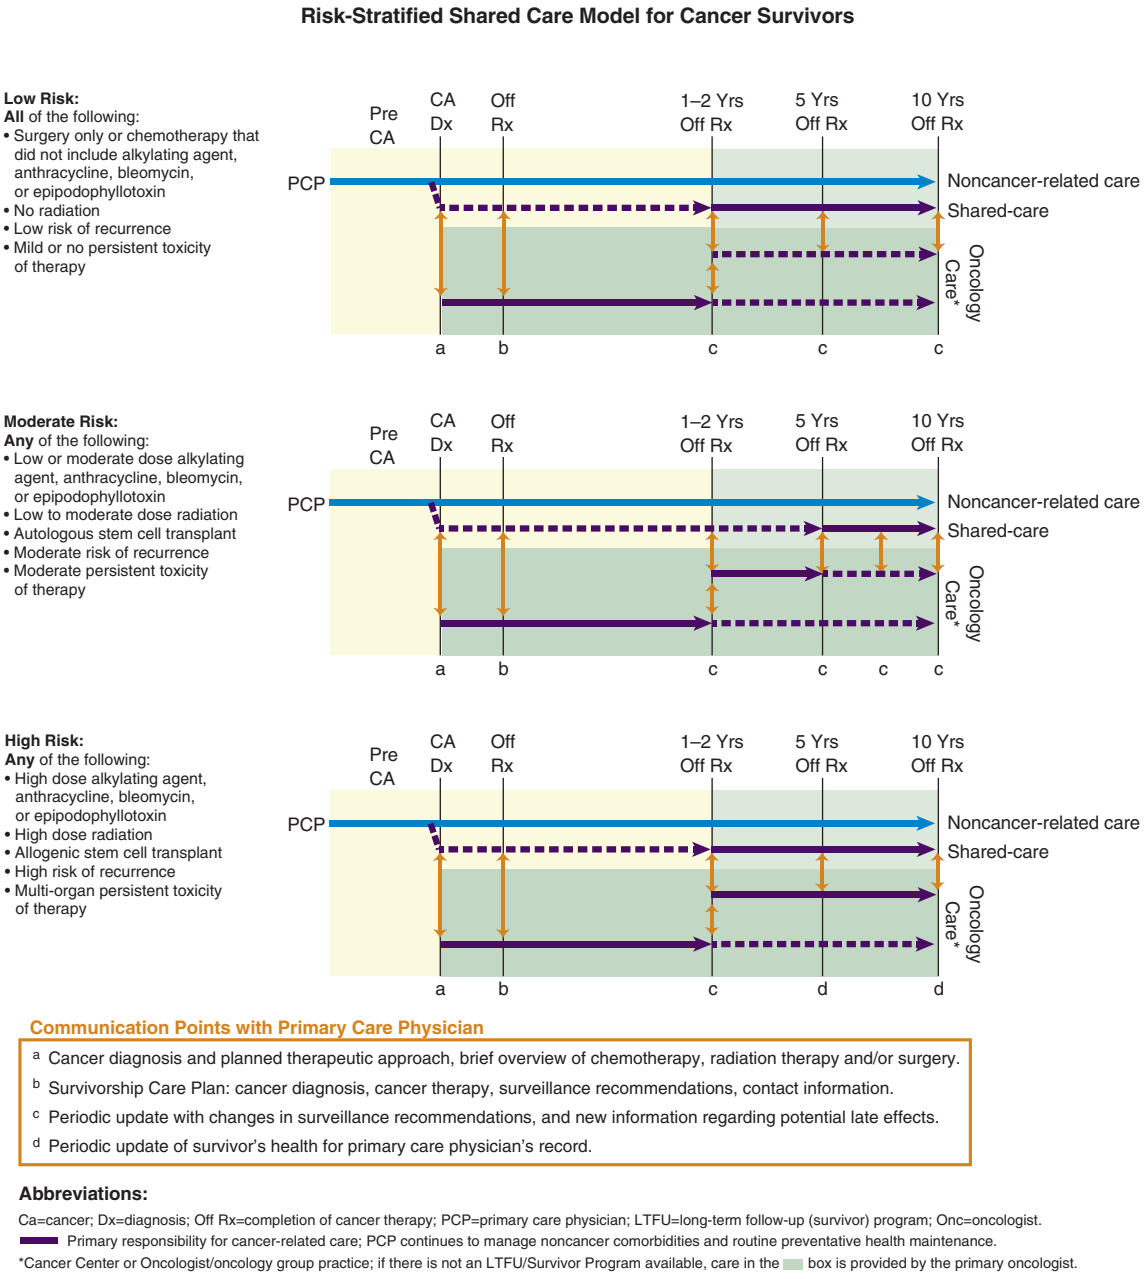

Fig. 543.8 Proposed risk-stratified shared care model for childhood cancer survivors. *Purple solid line* denotes primary responsibility cancer-related care; risk stratification is based on determination of the long-term follow-up staff. *(Adapted from McCabe MS, Partridge A, Grunfeld, E, Hudson MM. Risk-based health care, the cancer survivor, the oncologist, and the primary care physician. Semin Oncol. 2013;40:804–812; with data from Oeffinger KC, McCabe MS. Models for delivering survivorship care. J Clin Oncol. 2006;24:5117–5124.)*

appears to be cumulative, increasing by approximately 0.5% per year, resulting in approximately a 12% incidence at 25 years after treatment. Patients who have been treated for childhood cancer should be examined annually with particular attention to possible late effects of therapy, including second malignancies (Fig. 543.8).

Risk-stratified therapy over the past few decades has been shown to reduce late morbidity and mortality. A good resource for the pediatrician, patient, and family who must anticipate the possibilities is available at http://www.survivorshipguidelines.org.

PALLIATIVE CARE

At all stages of caring for children with cancer, principles of palliative care should be applied to relieve pain and suffering and to provide comfort (see Chapter 8). Early involvement of palliative or supportive care teams is beneficial. **Pain** is a serious cause of suffering among patients with cancer. It may be the result of organ obstruction or compression or bone metastasis, or it may be neuropathic. Pain should be managed in a stepwise manner, as recommended by the WHO, in accordance with the principles of selecting the appropriate analgesic, prescribing the appropriate dosage, administering the drug by the appropriate route, and choosing an appropriate dosing schedule to prevent persistent pain and to relieve breakthrough pain (see Chapter 93). In addition, the dosage should be titrated aggressively while attempts are made to prevent, anticipate, and manage side effects. Adjuvant drugs and sequential trials of analgesic drugs should be considered.

The goals in the care of dying patients are to avoid distress for the patient, family, and caregivers; to provide care consistent with the patient's and family's wishes; and to comply with and advocate for clinical, cultural, and ethical standards.

Chapter 544

The Leukemias

A. Kim Ritchey, Erika D. Friehling, Julia C. Meade, David G. Tubergen, and Archie Bleyer

INTRODUCTION

The leukemias are the most common malignant neoplasms in childhood, accounting for approximately 31% of all malignancies that occur in children younger than 15 years old. Each year, leukemia is diagnosed in approximately 3,100 children and adolescents <20 years old in the United States, an annual incidence of 4.8 cases per 100,000 children. Acute lymphoblastic leukemia (ALL) accounts for approximately 77% of cases of childhood leukemia, acute myelogenous leukemia (AML) for approximately 11%, chronic myelogenous leukemia (CML) for 2–3%, and juvenile myelomonocytic leukemia (JMML) for 1–2%. The remaining cases consist of a variety of acute and chronic leukemias that do not fit classic definitions for ALL, AML, CML, or JMML.

The leukemias may be defined as a group of malignant diseases in which genetic abnormalities in a hematopoietic cell give rise to an unregulated clonal proliferation of cells. The progeny of these cells have a growth advantage over normal cellular elements because of their increased rate of proliferation and a decreased rate of spontaneous apoptosis. The result is a disruption of normal marrow function and, ultimately, marrow failure. The clinical features, laboratory findings, and responses to therapy vary depending on the type of leukemia.

544.1 Acute Lymphoblastic Leukemia

Erika D. Friehling, A. Kim Ritchey, Julia C. Meade, and Archie Bleyer

Leukemia (ALL) was the first disseminated cancer shown to be curable. It is a heterogeneous group of malignancies with distinctive genetic abnormalities that result in varying clinical behaviors and responses to therapy.

EPIDEMIOLOGY

Acute lymphoblastic leukemia is diagnosed in approximately 3,100 children and adolescents <20 years old in the United States each year. It has a striking peak incidence at 2-3 years of age and occurs more in males than in females at all ages. The disease is more common in children with certain chromosomal abnormalities, such as Down syndrome, Li-Fraumeni, Bloom syndrome, and ataxia-telangiectasia. Among identical twins, the risk to the second twin if one twin develops leukemia is greater than that in the general population. The risk is >70% if ALL is diagnosed in the first twin during the first year of life and the twins shared the same (monochorionic) placenta. If the first twin develops ALL by 5-7 years of age, the risk to the second twin is at least twice that of the general population, regardless of zygosity.

ETIOLOGY

In virtually all cases, the etiology of ALL is unknown, although several genetic and environmental factors are associated with childhood leukemia (Table 544.1). Most cases of ALL are thought to be caused by post-conception somatic pathogenic gene variants in lymphoid cells. However, the identification of the leukemia-specific fusion-gene sequences in archived neonatal blood spots of some children who develop ALL at a later date indicates the importance of in utero events in the initiation of the malignant process in some cases. The long lag period before the onset of the disease in some children, reported to be as long as 14 years, supports the concept that additional genetic modifications are required for disease expression. Moreover, those same pathogenic variants have been found in neonatal blood spots of children who *never* go on to develop leukemia.

Exposure to medical diagnostic radiation both in utero and in childhood is associated with an increased incidence of ALL (see Chapter 758). In addition, published descriptions and investigations of geographic clusters of cases have raised concern that environmental factors can increase the incidence of ALL. Thus far, no such factors other than radiation have been identified in the United States. In certain developing countries, there is an association between B-cell ALL (B-ALL) and Epstein-Barr virus (EBV) infections.

CELLULAR CLASSIFICATION

The classification of ALL depends on characterizing the malignant cells in the bone marrow to determine the morphology, phenotype as measured by cell membrane markers, and cytogenetic and molecular genetic features. **Morphology** is usually adequate alone to establish a diagnosis, but the other studies are essential for disease classification, which can have a major influence on the prognosis and the choice of appropriate therapy. The current system used is the World Health Organization (WHO) classification of leukemias. Phenotypically, surface markers show that approximately 85% of cases of ALL are classified as **B-lymphoblastic leukemia** (previously termed precursor B-ALL or pre–B-ALL), approximately 15% are **T-lymphoblastic leukemia**, and approximately 1% are derived from mature B cells. The rare leukemia of mature B cells is termed **Burkitt leukemia** and is one of the most rapidly growing cancers in humans, requiring a different therapeutic approach than other subtypes of ALL. A small percentage of children with leukemia have a disease characterized by surface markers of both lymphoid and myeloid derivation.

Chromosomal abnormalities are used to subclassify ALL into prognostic groups (Table 544.2). Many genetic alterations, including inactivation of tumor-suppressor genes and pathogenic gene variants that activate the *JAK-STAT* or *RAS* pathways, have been discovered (Fig. 544.1).

The polymerase chain reaction (PCR) and fluorescence in situ hybridization (FISH) techniques offer the ability to pinpoint molecular genetic abnormalities and can be used to detect small numbers of malignant cells at diagnosis as well as during follow-up (**minimal residual disease [MRD]**, see later) and are of proven clinical utility. DNA microarray and whole genome sequencing make it possible to analyze the expression of thousands of genes in the leukemic cell.

Table 544.1 Predisposing Factors of Acute Lymphoblastic Leukemia

GENETIC SUSCEPTIBILITY
Congenital syndromes: Down syndrome, Fanconi anemia, ataxia telangiectasia, Bloom syndrome, Nijmegen breakage syndrome
Inherited gene variants: *ARID5B, IKZF1, CEBPE, CDKN2A,* or *CDKN2B, PIP4K2A, ETV6*
Constitutional Robertsonian translocation between chromosomes 15 and 21, rob(15;21)(q10;q10)
Single nucleotide polymorphisms: rs12402181 in miR-3117 and rs62571442 in miR-3689d2
ENVIRONMENTAL FACTORS
Pesticide exposure
Ionizing radiation
Childhood infections

From Malard F, Mohty M. Acute lymphoblastic leukaemia. *Lancet.* 2020;395:1146–1158. Panel, p. 1147.

CLINICAL MANIFESTATIONS

The initial presentation of ALL usually is nonspecific and relatively brief. Anorexia, fatigue, malaise, irritability, and intermittent low-grade fever are often present. Bone or joint pain, particularly in the lower extremities, may be present. Less often, symptoms may be of several months' duration, may be localized predominantly to the bones or joints, and may include joint swelling. Bone pain is severe and can wake the patient at night. As the disease progresses, signs and symptoms of **bone marrow failure** become more obvious with the occurrence of pallor, fatigue, exercise intolerance, bruising, oral mucosal bleeding or epistaxis, and fever, which may be caused by infection or the leukemia. Organ infiltration can cause lymphadenopathy, hepatosplenomegaly, testicular enlargement, or central nervous system (CNS) involvement (cranial neuropathies, headache, seizures). Respiratory distress may be caused by severe anemia or mediastinal node compression of the airways.

On **physical examination,** findings of pallor, listlessness, purpuric and petechial skin lesions, or mucous membrane hemorrhage can reflect bone marrow failure (see Chapter 542). The proliferative nature of the disease may be manifested as lymphadenopathy, splenomegaly, or, less often, hepatomegaly. Patients with bone or joint pain may have exquisite tenderness over the bone or objective evidence of joint swelling and effusion. Nonetheless, with marrow involvement, deep bone pain may be present, but tenderness will not be elicited. Rarely, patients show signs of increased intracranial pressure that indicate leukemic involvement of the CNS. These include papilledema (see Fig. 542.3), retinal hemorrhages, and cranial nerve palsies. Respiratory distress usually is related to anemia but can occur in patients as the result of a large anterior mediastinal mass (e.g., in the thymus or nodes). This problem is most frequently seen in adolescent males with T-cell ALL (T-ALL). **T-ALL** also usually has a higher leukocyte count.

B-lymphoblastic leukemia is the most common immunophenotype, with onset at 1-10 years of age. The median leukocyte count at presentation is 33,000/μL, although 75% of patients have counts <20,000/μL; thrombocytopenia is seen in 75% of patients and hepatosplenomegaly in 30–40% of patients. In all types of leukemia, CNS symptoms are seen at presentation in 5% of patients. Leukemia cells can be seen in the cerebrospinal fluid (CSF) of 10–15% of patients, but only 3–5% are diagnosed with CNS leukemia, defined as >5 WBCs/μL with blasts present. Testicular involvement is rarely evident at diagnosis, but prior studies indicate occult involvement in 25% of males. There is no indication for testicular biopsy.

DIAGNOSIS

The diagnosis of ALL is strongly suggested by peripheral blood findings that indicate bone marrow failure. Anemia and thrombocytopenia are seen in most patients. Leukemic cells might not be reported in the peripheral blood in routine laboratory examinations. Many patients with ALL present with total leukocyte counts of <10,000/μL. In such cases, the leukemic cells often are reported initially to be "atypical lymphocytes," and it is only on further evaluation that the cells are

Table 544.2 Main Genetic Subtypes of B-Cell Acute Lymphoblastic Leukemia

	FREQUENCY	PATHOGENIC VARIANTS	PROGNOSIS
High hyperdiploid (gain of ≥5 chromosomes)	25% children; 3% AYAs and adults	RTK-RAS signaling pathway, histone modifiers	Favorable
Near-haploid (24-31 chromosomes)	2% children; <1% AYAs and adults	RAS-activating, *IKZF3*	Poor
Low-hypodiploid (32-39 chromosomes)	<1% children; 5% AYAs; >10% adults	*TP53, IKZF2, RB1*	Very poor
MLL (KMT2A) rearrangements	>80% infants; <1% children; 4% AYAs; 15% adults	*MLL (KMT2A)* rearrangement, few additional pathogenic variants (PI3K-RAS signaling pathway)	Very poor
ETV6-RUNX1 translocation, t(12;21)(q13;q22)	30% children; <5% AYAs and adults	*ETV6-RUNX1*	Favorable
TCF3-PBX1 translocation, t(1;19)(q23;p13)	5% children, AYAs and adults	*TCF3-PBX1*	Favorable
TCF3-HLF variant of t(1;19)(q23;p13)	<1% acute lymphoblastic leukemia	*TCF3-HLF*	Poor
BCR-ABL1 Philadelphia chromosome, t(9;22)(q34;q11)	2–5% children, 6% AYAs; >25% adults	*BCR-ABL1* fusion gene, common deletions of *IKZF1, CDKN2A, CDKN2B,* and *PAX5*	Poor (improved with tyrosine kinase inhibitors)
Philadelphia chromosome-like acute lymphoblastic leukemia	10% children; 25–30% AYAs; 20% adults	Rearrangements of *CRLF2* (about 50%), *ABL*-class tyrosine kinase genes (12%) and *JAK2* (10%); pathogenic variants of *EPOR* (3–10%); pathogenic variants activating JAK-STAT (10%) and RAS (2–8%) signaling pathways	Poor
DUX4 and *ERG*-deregulated acute lymphoblastic leukemia	5–10% acute lymphoblastic leukemia	*DUX4* rearrangement and overexpression, *ERG* deletions	Favorable, including if coexistence of *IKZF1* pathogenic variants (about 40% of patients)
MEF2D-rearranged acute lymphoblastic leukemia	4% children; 7% AYAs and adults	*MEF2D* is fused to *BCL9* (most frequent fusion event), *HNRNPUL1, SS18, FOXJ2, CSF1R,* or *DAZAP1*	Poor
ZNF384-rearranged acute lymphoblastic leukemia	5% children; 10% AYAs and adults	*ZNF384* rearranged with a transcriptional regulator or chromatin modifier (*EP300, CREBBP, TAF15, SYNRG,* EWSR1, *TCF3, ARID1B, BMP2K,* or *SMARCA2*)	Intermediate

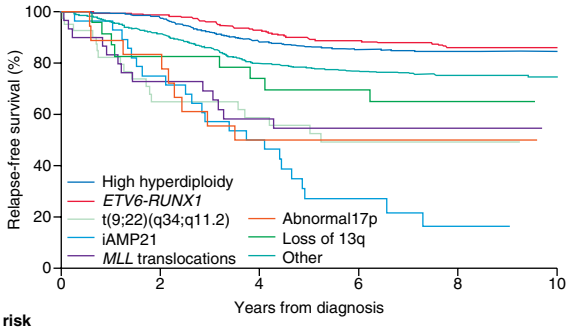
found to be part of a malignant clone. When the results of an analysis of peripheral blood suggest the possibility of leukemia, flow cytometry can rapidly facilitate the diagnosis. The bone marrow should be examined promptly to confirm the diagnosis. It is important that all studies necessary to confirm a diagnosis and adequately classify the type of leukemia be performed, including bone marrow aspiration and biopsy, flow cytometry, cytogenetics, and molecular studies.

ALL is diagnosed by a bone marrow evaluation that demonstrates >25% of the bone marrow cells as a homogeneous population of lymphoblasts. Initial evaluation also includes CSF examination. If lymphoblasts are found and the CSF leukocyte count is elevated, overt CNS or



Number at risk

Fig. 544.3 Kaplan-Meier analysis of relapse-free survival according to biologic subtype of leukemia. *(From Moorman AV, Ensor HM, Richards SM, et al. Prognostic effect of chromosomal abnormalities in childhood B-cell precursor acute lymphoblastic leukaemia: Results from the UK Medical Research Council ALL97/99 randomised trial. Lancet Oncol. 2010;11:429–438.)*

meningeal leukemia is present. This finding reflects a poorer stage and indicates the need for additional CNS and systemic therapies. The staging lumbar puncture (LP) may be performed in conjunction with the first dose of intrathecal chemotherapy, if the diagnosis of leukemia was previously established from bone marrow evaluation. An experienced proceduralist should perform the initial LP, because a traumatic LP is associated with an increased risk of CNS relapse.

DIFFERENTIAL DIAGNOSIS

The diagnosis of leukemia is readily made in the patient with typical signs and symptoms, anemia, thrombocytopenia, and elevated WBC count with blasts present on smear. Elevation of the lactate dehydrogenase (LDH) is often a clue to the diagnosis of ALL. When pancytopenia is present without peripheral blasts, aplastic anemia (congenital or acquired), marrow infiltration from metastatic disease, and hemophagocytic lymphohistiocytosis should be considered. Failure of a single cell line, as seen in transient erythroblastopenia of childhood, immune thrombocytopenia, and congenital or acquired neutropenia, is rarely the presenting feature of ALL. A high index of suspicion is required to differentiate ALL from infectious mononucleosis in patients with acute onset of fever and lymphadenopathy and from juvenile idiopathic arthritis in patients with fever, bone pain but often no tenderness, and joint swelling. These presentations also can require bone marrow examination.

ALL must be differentiated from AML and other malignant diseases that invade the bone marrow and can have clinical and laboratory findings similar to ALL, including neuroblastoma, rhabdomyosarcoma, Ewing sarcoma, and retinoblastoma.

TREATMENT

The single most important prognostic factor in ALL is the treatment: without effective therapy, the disease is fatal. Considerable progress has been made in overall survival for children with ALL through use of multiagent chemotherapeutic regimens, intensification of therapy, and selection of treatment based on relapse risk. Survival is also related to age (Fig. 544.2) and biologic subtype (Fig. 544.3).

Risk-stratified therapy is the standard of current ALL treatment and accounts for age at diagnosis, initial WBC count, immunophenotypic and cytogenetic characteristics of blast populations, rapidity of early treatment response (i.e., how quickly the leukemic cells can be cleared from the marrow or peripheral blood), and assessment of MRD at the end of induction therapy (Table 544.3). Different

Table 544.3 Prognostic Factors for Acute Lymphoblastic Leukemia

	FAVORABLE FACTOR	ADVERSE FACTOR
DEMOGRAPHIC AND CLINICAL FEATURES		
Age	1 year to <10 years	<1 year or ≥10 years
Sex	Female	Male
Ethnicity	White, Asian	Black, Hispanic
CLINICAL, BIOLOGIC, OR GENETIC FEATURES OF LEUKEMIA		
CNS involvement	No	Yes
Blood count at diagnosis	Low blood count; $<50 \times 10^9$ cells/L for B-cell acute lymphoblastic leukemia and $<100 \times 10^9$ cells/L for T-cell acute lymphoblastic leukemia	High blood count; $\geq 50 \times 10^9$/L for B-cell acute lymphoblastic leukemia and $\geq 100 \times 10^9$ cells/L for T-cell acute lymphoblastic leukemia
Immunophenotype	B-cell lineage	T-cell lineage
Cytogenetic features	Hyperdiploidy, *ETV6-RUNX*, *TCF3-PBX1*, and trisomy of chromosomes 4, 10, or 17	Hypodiploidy, *BCR-ABL1* Philadelphia chromosome-positive, *MLL* rearrangements, *TCF3-HLF*, and complex karyotype (≥5 chromosomal abnormalities)
Genomic features	*DUX4*-rearrangement (*ERG* deletion)	*IKZF1* deletions or pathogenic variants, Philadelphia chromosome-like, *MEF2D*-rearrangement
RESPONSE TO TREATMENT		
Minimal residual disease at specified time points	Low minimal residual disease $<10^{-3}$ nucleated cells or undetectable	Persistence of minimal residual disease $\geq 10^{-3}$ nucleated cells, the higher this value the worse the prognosis

From Malard F, Mohty M. Acute lymphoblastic leukaemia. *Lancet.* 2020;395:1146–1158. Table 2, p. 1150.

study groups use various factors to define risk, but age 1-10 years and a leukocyte count <50,000/μL are used by the National Cancer Institute (NCI) to define standard risk. Children who are younger than 1 year or older than 10 years or who have an initial leukocyte count of >50,000/μL are considered to be high risk. Additional characteristics that adversely affect outcome include T-cell immunophenotype or a slow response to initial therapy. Chromosomal abnormalities, including hypodiploidy, the Philadelphia chromosome, and *KMT2A (MLL)* gene rearrangements, portend a poorer outcome. Other genetic pathogenic variants, such as in the *IKZF1* gene, have been shown to be associated with a poor prognosis and may become important in treatment algorithms in the future. More favorable characteristics include a rapid response to therapy, hyperdiploidy, trisomy of specific chromosomes (4, 10, and 17), and rearrangements of the *ETV6-RUNX1* (formerly *TEL-AML1*) genes.

The outcome for patients at higher risk can be improved by administration of more intensive therapy despite the greater toxicity of such therapy. Infants with ALL, along with patients who present with specific chromosomal abnormalities, such as t(4;11), have an even higher risk of relapse despite intensive therapy. However, the poor outcome of Philadelphia chromosome–positive ALL with t(9;22) has been dramatically changed by the addition of imatinib to an intensive chemotherapy backbone. **Imatinib** is an agent specifically designed to inhibit the BCR-ABL kinase resulting from the translocation. With this approach, the event-free survival has improved from 30% to 70%. Clinical trials demonstrate that the prognosis for patients with a slower response to initial therapy may be improved by therapy that is more intensive than the therapy considered necessary for patients who respond more rapidly.

Most children with ALL are treated in clinical trials conducted by national or international cooperative groups. Standard treatment involves chemotherapy for 2-3 years, and most achieve remission at the end of the induction phase. Patients in clinical remission can have MRD that can only be detected with specific molecular probes to translocations and other DNA markers contained in leukemic cells or specialized flow cytometry. MRD can be quantitative and can provide an estimate of the burden of leukemic cells present in the marrow. Higher levels of MRD present at the end of induction suggest a poorer prognosis and higher risk of subsequent relapse. MRD of >0.01% on the marrow on day 29 of induction is a significant risk factor for shorter event-free survival for all risk categories, compared with patients with negative MRD. Therapy for ALL intensifies treatment in patients with evidence of MRD at the end of induction.

Initial therapy, termed **remission induction**, is designed to eradicate the leukemic cells from the bone marrow. During this phase, therapy is given for 4 weeks and consists of vincristine weekly, a corticosteroid such as dexamethasone or prednisone, and usually a single dose of a long-acting, pegylated asparaginase preparation. Patients at higher risk also receive daunorubicin at weekly intervals. With this approach, 98% of patients are in remission, as defined by <5% blasts in the marrow and a return of neutrophil and platelet counts to near-normal levels after 4-5 weeks of treatment. Intrathecal chemotherapy is always given at the start of treatment and at least once more during induction.

The second phase of treatment, **consolidation**, focuses on intensive CNS therapy in combination with continued intensive systemic therapy to prevent later CNS relapses. Intrathecal chemotherapy is given repeatedly by LP. The likelihood of later CNS relapse is thereby reduced to <5%, from historical incidence as high as 60%. A small percentage of patients with features that predict a high risk of CNS relapse may receive irradiation to the brain in later phases of therapy. This includes patients who at diagnosis have lymphoblasts in the CSF and either an elevated CSF leukocyte count or physical signs of CNS leukemia, such as cranial nerve palsy.

Subsequently, many regimens provide 14-28 weeks of therapy, with the drugs and schedules used varying depending on the risk group of the patient. This period of treatment is often termed **intensification** and includes phases of aggressive treatment **(delayed intensification)** as well as relatively less toxic phases of treatment **(interim maintenance)**. Multiagent chemotherapy, including such medications as cytarabine, methotrexate, asparaginase, and vincristine, is used during these phases to eradicate residual disease.

Finally, patients enter the **maintenance** phase of therapy, which lasts for 2-3 years, depending on the protocol used. Patients are given daily mercaptopurine and weekly oral methotrexate, usually with intermittent doses of vincristine and a corticosteroid.

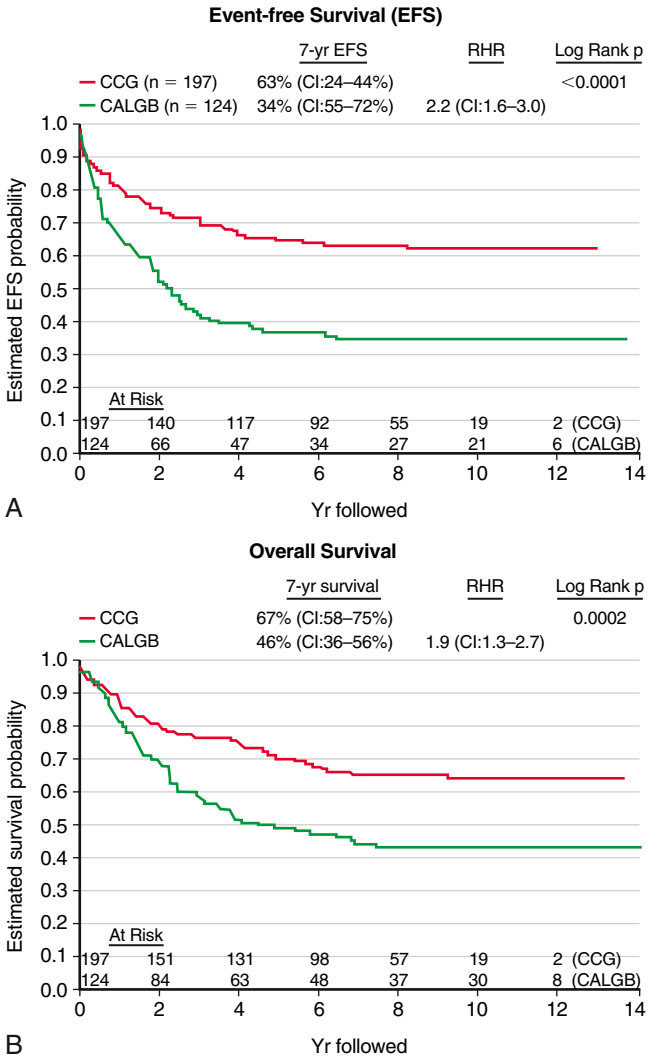

Fig. 544.4 Comparison of event-free survival (A) and overall survival (B) among Cancer and Leukemia Group B (CALGB) (adult protocol, *green line*) and Children's Cancer Group (CCG) (pediatric protocol, *red line*) patients. CI, Confidence interval; EFS, event-free survival; RHR, relative hazard rate. *(From Stock W, La M, Sanford B, et al. What determines the outcomes for adolescents and young adults with acute lymphoblastic leukemia treated on cooperative group protocols? A comparison of Children's Cancer Group and Cancer and Leukemia Group B studies. Blood. 2008;112:1646–1654.)*

A small number of patients with particularly poor prognostic features, such as those with induction failure or extreme hypodiploidy, may undergo bone marrow transplantation during the first remission.

Adolescents and **young adults** with ALL have a poor prognosis compared to children <15 years old. They often have adverse prognostic factors and require more intensive therapy. Patients in this age-group have a superior outcome when treated with pediatric rather than adult treatment protocols (Fig. 544.4). Although the explanation for these findings may be multifactorial, it is important that these patients be treated with pediatric treatment protocols, ideally in a pediatric cancer center.

Genetic polymorphisms of enzymes important in drug metabolism may impact both the efficacy and the toxicity of chemotherapeutic medications. **Pharmacogenetic testing** of the thiopurine *S*-methyltransferase *(TPMT)* gene, which encodes one of the metabolizing enzymes of mercaptopurine, can identify patients with varying levels of TPMT enzyme activity. Decreased TPMT enzyme activity results in accumulation of a toxic metabolite of mercaptopurine and severe myelosuppression, requiring dose reductions of the chemotherapy (see Chapter 543).

Treatment of Relapse

The major impediment to a successful outcome is **relapse** of the disease. Outcomes remain poor among those who relapse, with the most important prognostic indicators being time from diagnosis and site of relapsed disease. In addition, other factors, such as immunophenotype (T-ALL worse than B-ALL) and age at initial diagnosis, have prognostic significance.

Relapse occurs in the bone marrow in 15–20% of patients with ALL and has the most serious implications, especially if it occurs during or shortly after completion of therapy. Intensive chemotherapy with agents not previously used in the patient followed by allogeneic stem cell transplantation can result in long-term survival for some patients with bone marrow relapse (see Chapter 177). **Chimeric antigen receptor** (CAR) T-cell technology will have an increasing role in the treatment of patients who have experienced a relapse of ALL (see Chapter 543). In addition, therapy targeted to the possible underlying pathogenic pathways (tyrosine kinase inhibitors) or cell receptors (blinatumomab) have demonstrated promising results in patients with relapsed or refractory disease (Fig. 544.5)

The incidence of **CNS relapse** has decreased to <5% since introduction of preventive CNS therapy. CNS relapse may be discovered at a routine LP in the asymptomatic patient. Symptomatic patients with relapse in the CNS usually present with signs and symptoms of increased intracranial pressure and can present with isolated cranial nerve palsies. The diagnosis is confirmed by demonstrating the presence of leukemic cells in the CSF. The treatment includes intrathecal medication and cranial or craniospinal irradiation. Systemic chemotherapy also must be used, because these patients are at high risk for subsequent bone marrow relapse. Most patients with leukemic relapse confined to the CNS do well, especially those in whom the CNS relapse occurs longer than 18 months after initiation of chemotherapy.

Testicular relapse occurs in <2% of males with ALL, usually after completion of therapy. Such relapse occurs as painless swelling of one or both testes. The diagnosis is confirmed by biopsy of the affected testis. Treatment includes systemic chemotherapy and possibly local irradiation. A high proportion of males with a testicular relapse can be successfully retreated, and the survival rate of these patients is good.

The most current information on treatment of childhood ALL is available in the PDQ (Physician Data Query) on the NCI website (http://www.cancer.gov/cancertopics/pdq/treatment/childALL/healthprofessional/).

SUPPORTIVE CARE

Close attention to the medical supportive care needs of the patients is essential in successfully administering aggressive chemotherapeutic programs. Patients with high WBC counts are especially prone to **tumor lysis syndrome** as therapy is initiated. The kidney failure associated with very high levels of serum uric acid can be prevented or treated with allopurinol or urate oxidase. Chemotherapy often produces severe myelosuppression, which can require erythrocyte and platelet transfusion and always requires a high index of suspicion and aggressive empirical antimicrobial therapy for sepsis in febrile children with neutropenia. Patients must receive prophylactic treatment for *Pneumocystis jiroveci* pneumonia during chemotherapy and for several months after completing treatment.

The successful therapy of ALL is a direct result of intensive and often toxic treatment. However, such intensive therapy can incur substantial academic, developmental, and psychosocial costs for children with ALL and considerable financial costs and stress for their families. Both long-term and acute toxicity effects can occur. An array of cancer care professionals with training and experience in addressing the myriad of problems that can arise is essential to minimize the complications and achieve an optimal outcome.

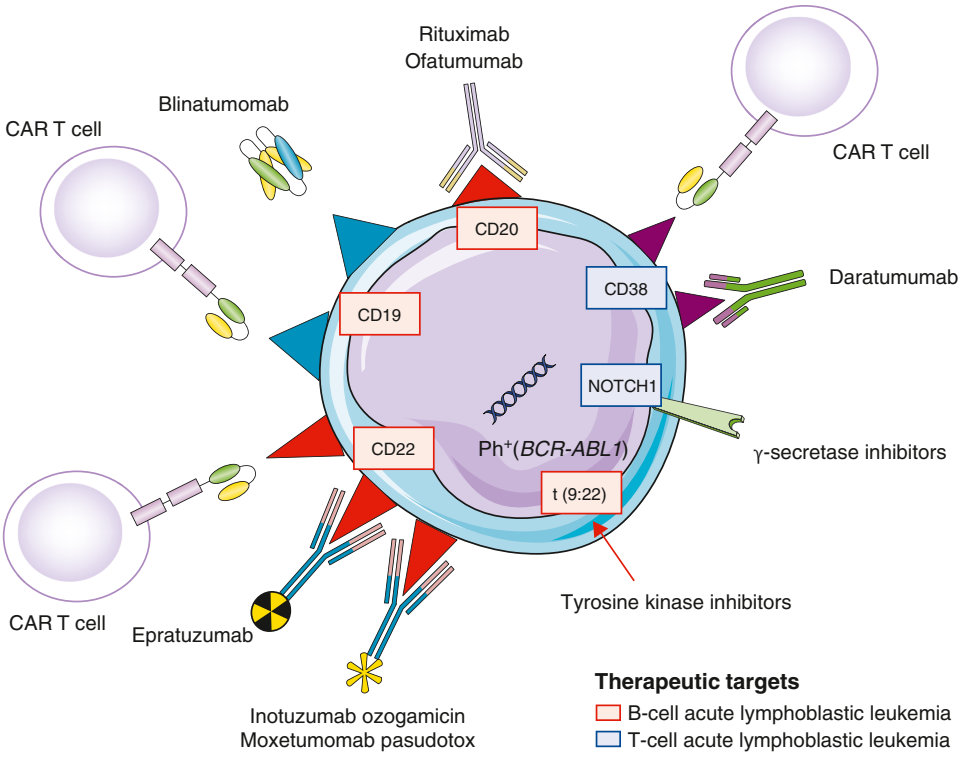

Fig. 544.5 New targeted therapy for acute lymphoblastic leukemia. CAR, Chimeric antigen receptor. *(From Malard F, Mohty M. Acute lymphoblastic leukaemia. Lancet. 2020;395:1146–1158. Fig. 2, p. 1153.)*

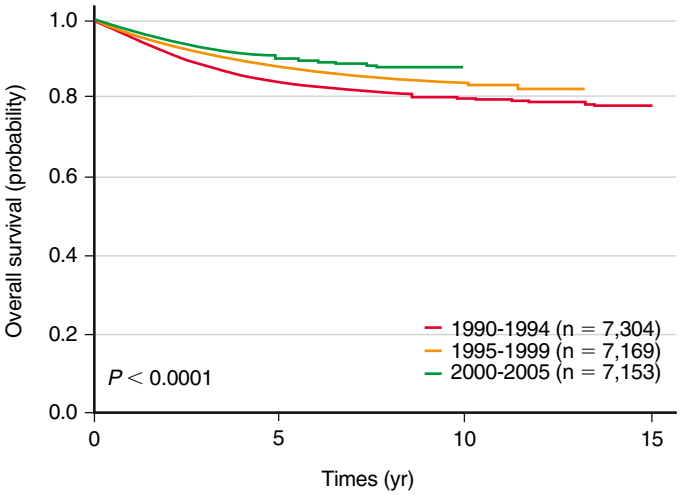

Fig. 544.6 Overall survival probabilities by treatment era for patients with acute lymphoblastic leukemia (ALL) in Children's Oncology Group trials in 1990–1994, 1995–1999, and 2000–2005. *(From Hunger SP, Lu X, Devidas M, et al. Improved survival for children and adolescents with acute lymphoblastic leukemia between 1990 and 2005: a report from the Children's Oncology Group. J Clin Oncol. 2012;30:1663–1669.)*

PROGNOSIS

Improvements in therapy and risk stratification have resulted in significant increases in survival rates, with current data showing overall 5-year survival of approximately 90% (Fig. 544.6). Although survivors are more likely to experience significant chronic medical conditions compared with siblings, including musculoskeletal, cardiac, and neurologic conditions, risk-adapted therapy has resulted in a decrease in late effects. Overall, long-term management following ALL should be conducted in a clinic where children and adolescents can be followed by a variety of specialists to address the challenges of these unique patients.

544.2 Acute Myelogenous Leukemia

Julia C. Meade, Erika D. Friehling, A. Kim Ritchey, David G. Tubergen, and Archie Bleyer

EPIDEMIOLOGY

AML accounts for 11% of the cases of childhood leukemia in the United States; it is diagnosed in approximately 370 children annually. The relative frequency of AML increases in adolescence, representing 36% of cases of leukemia in 15-19 year olds. **Acute promyelocytic leukemia (APL)** is a subtype that is more common in certain regions of the world, but the incidence of the other types is generally uniform. Environmental risk factors have been identified, including ionizing radiation, chemotherapeutic agents (e.g., alkylating agents, epipodophyllotoxin), and organic solvents (benzene). Approximately 10% of children with AML are found to have a germline pathogenic variant predisposing them to leukemia. Certain syndromes are also known to increase the risk of leukemia: Down syndrome, Fanconi anemia, Bloom syndrome, Kostmann syndrome, Shwachman-Diamond syndrome, Diamond-Blackfan syndrome, Li-Fraumeni syndrome, and neurofibromatosis type 1 (see Table 544.1).

CELLULAR CLASSIFICATION

The characteristic feature of AML is that >20% of bone marrow cells on bone marrow aspiration or biopsy touch preparations constitute a fairly homogeneous population of blast cells, with features similar to those that characterize early differentiation states of the myeloid-monocyte-megakaryocyte series of blood cells. Current practice requires the use of flow cytometry to identify cell surface antigens and use of chromosomal and molecular genetic techniques for additional diagnostic precision and to aid the choice of therapy. The WHO has proposed a new classification system that incorporates morphology, chromosome abnormalities, and specific gene pathogenic variants. This system provides significant biologic and prognostic information (Table 544.4).

CLINICAL MANIFESTATIONS

The production of symptoms and signs of AML is a result of replacement of bone marrow by malignant cells and caused by secondary bone

marrow failure. Patients with AML can present with any or all of the findings associated with marrow failure in ALL. In addition, patients with AML may present with signs and symptoms that are uncommon in ALL, including **subcutaneous nodules** or "blueberry muffin" lesions (especially in infants), infiltration of the gingiva (especially in monocytic subtypes), signs and laboratory findings of **disseminated intravascular coagulation** (especially indicative of APL), and discrete masses, known as **chloromas** or **granulocytic sarcomas**. These masses can occur in the absence of apparent bone marrow involvement and typically are associated with a t(8;21) translocation. Chloromas also may be seen in the orbit and epidural space.

DIAGNOSIS

Analysis of bone marrow aspiration and biopsy specimens of patients with AML typically reveals the features of a hypercellular marrow consisting of a monotonous pattern of cells. Flow cytometry and special stains assist in identifying myeloperoxidase-containing cells, thus confirming both the myelogenous origin of the leukemia and the diagnosis. Some chromosomal abnormalities and molecular genetic markers are characteristic of specific subtypes of disease (Table 544.5).

Table 544.4 WHO Classification of Acute Myeloid Neoplasms

Acute myeloid leukemia with recurrent genetic abnormalities
- AML with t(8;21)(q22;q22.1); *RUNX1-RUNX1T1*
- AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
- APL with *PML-RARA*
- AML with t(9;11)(p21.3;q23.3); *MLLT3-KMT2A*
- AML with t(6;9)(p23;q34.1); *DEK-NUP214*
- AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); *GATA2, MECOM*
- AML (megakaryoblastic) with t(1;22)(p13.3;q13.3); *RBM15-MKL1*
- *Provisional entity: AML with BCR-ABL1*
- AML with variant NPM1
- AML with biallelic pathogenic variants of CEBPA
- *Provisional entity: AML with variant RUNX1*

AML with myelodysplasia-related changes
Therapy-related myeloid neoplasms
Acute myeloid leukemia, not otherwise specified
- AML with minimal differentiation
- AML without maturation
- AML with maturation
- Acute myelomonocytic leukemia
- Acute monoblastic/monocytic leukemia
- Pure erythroid leukemia
- Acute megakaryoblastic leukemia
- Acute basophilic leukemia
- Acute panmyelosis with myelofibrosis

Myeloid sarcoma
Myeloid proliferations related to Down syndrome
- Transient abnormal myelopoiesis
- Myeloid leukemia associated with Down syndrome

Blastic plasmacytoid dendritic cell neoplasm

AML, Acute myelogenous leukemia; APL, acute promyelocytic leukemia.
Adapted from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood.* 2016;127:2391–2405.

PROGNOSIS AND TREATMENT

Aggressive multiagent chemotherapy is successful in inducing remission in approximately 85–90% of patients. Survival has increased dramatically since the 1970s, when only 15% of newly diagnosed patients survived, compared with a current survival rate of 60–70% with modern therapy (Fig. 544.7). Various induction chemotherapy regimens exist, typically including an anthracycline in combination with high-dose cytarabine. Targeting therapy to genetic markers may be beneficial (see Table 544.5). Up to 5% of patients die of either infection or bleeding before a remission can be achieved. Post-remission therapy is chosen based on a combination of cytogenetic and molecular markers of the leukemia as well as the response to induction chemotherapy (MRD assessment). Selected patients with favorable prognostic features [t(8;21); t(15;17); inv(16); *NPM1* pathogenic variants] and robust response to induction chemotherapy have improved outcomes with chemotherapy alone, with stem cell transplantation only recommended after a relapse. However, patients with unfavorable prognostic features (e.g., monosomies 7 and 5, 5q−, and 11q23 abnormalities) who have inferior outcomes with chemotherapy might benefit from stem cell transplant in first remission. With improvements in supportive care, there is no longer a substantial difference in mortality when comparing matched-related stem cell transplants to matched-unrelated stem cell transplants for AML.

Acute promyelocytic leukemia, characterized by a gene rearrangement involving the retinoic acid receptor [t(15;17); PML-RARA], is very responsive to **all-*trans*-retinoic acid (ATRA, tretinoin)** combined with anthracyclines and cytarabine. The success of this therapy makes marrow transplantation in first remission unnecessary for patients with this disease. Arsenic trioxide is an effective noncytotoxic therapy for APL. Data from trials in adults and children show that the use of combined ATRA and arsenic without cytotoxic drugs for initial therapy for selected patients is feasible and highly effective.

Increased **supportive care** is needed in patients with AML because the intensive therapy they receive produces prolonged bone marrow suppression with a very high incidence of serious infections, especially viridans streptococcal sepsis and fungal infection. These patients require prolonged hospitalization and prophylactic antimicrobials.

The most current information on treatment of AML is available in the PDQ (Physician Data Query) on the NCI website (http://www.cancer.gov/cancertopics/pdq/treatment/childAML/healthprofessional/).

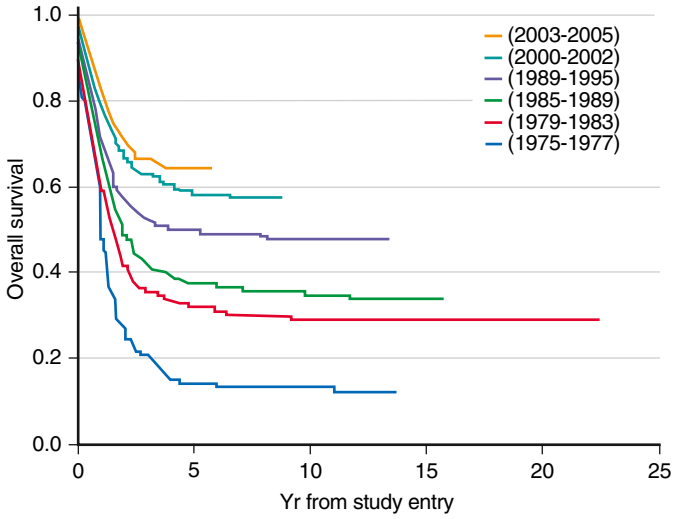

Fig. 544.7 Overall survival showing incremental improvements over the last 40 years in Children's Oncology Group and legacy trials in childhood acute myelogenous leukemia (AML). *(From Gamis AS, Alonzo TA, Perentesis JP, Meshinchi S. On behalf of the COG Acute Myeloid Leukemia Committee: Children's Oncology Group's 2013 blueprint for research: acute myeloid leukemia. Pediatr Blood Cancer. 2013;60:964–971.)*

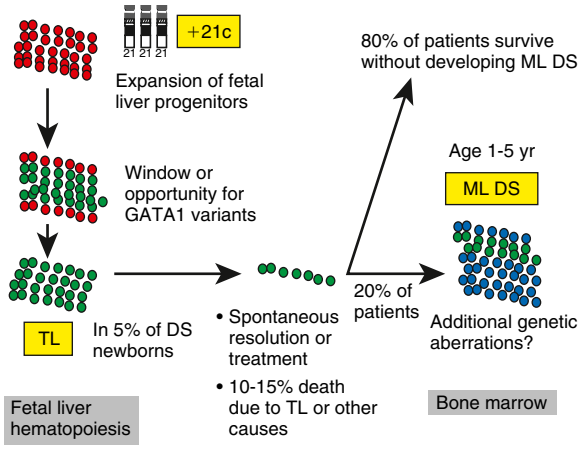

Fig. 544.8 Stepwise development of myeloid leukemia in Down syndrome (ML DS) following transient leukemia (TL). TL arises from expanded fetal liver progenitors as a result of constitutional trisomy 21, providing a window of opportunity for the occurrence of acquired mutations in the hematopoietic transcription factor GATA1. In most cases, TL spontaneously disappears, but some children need treatment because of severe TL-related symptoms. Approximately 20% of children with TL subsequently develop ML DS, which requires additional hits. *(From Zwaan MC, Reinhardt D, Hitzler J, Vyas P. Acute leukemias in children with Down syndrome. Pediatr Clin North Am. 2008;55:53–70.)*

544.3 Down Syndrome and Acute Leukemia and Transient Abnormal Myelopoiesis

A. Kim Ritchey, Julia C. Meade, Erika D. Friehling, David G. Tubergen, and Archie Bleyer

Acute leukemia occurs about 15-20 times more frequently in children with Down syndrome than in the general population (see Chapters 57 and 541). The ratio of ALL to AML in patients with Down syndrome is the same as that in the general population. The exception is during the first 3 years of life, when AML is more common. In children with Down syndrome who have ALL, the expected outcome of treatment has been slightly inferior to that for other children, a difference that can be partially explained by a lack of good prognostic characteristics, such as *ETV6-RUNX1* and trisomies, as well as the presence of genetic abnormalities associated with an inferior prognosis, such as *IKZF1*. However, studies of patients with Down syndrome and standard risk ALL show a 94% 10-year event-free survival. Patients with Down syndrome demonstrate a remarkable sensitivity to methotrexate and other antimetabolites, resulting in substantial toxicity if standard doses are administered. However, in the case of AML, patients with Down syndrome have much better outcomes than children without Down syndrome, with a >90% long-term survival rate. After induction therapy, these patients receive therapy that is less intensive to decrease toxicity while maintaining excellent cure rates.

Approximately 10% of neonates with Down syndrome develop a **transient abnormal myelopoiesis (TAM)**, a unique myeloproliferative disorder characterized by high leukocyte counts, blast cells in the peripheral blood, and associated anemia, thrombocytopenia, jaundice, and hepatosplenomegaly. Hydrops fetalis is an uncommon manifestation of TAM and is associated with pleural effusions, ascites, cardiac infiltration, hepatic dysfunction, and anemia. Mortality is rare from TAM but is associated with hyperleukocytosis, prematurity, ascites, coagulopathy, and renal or hepatic dysfunction. These features usually resolve within the first 3 months of life. Although these neonates can require temporary transfusion support, they usually do not require chemotherapy. Low-dose cytarabine has been used to decrease mortality in patients with high WBC counts and life-threatening complications. Patients who have Down syndrome and who develop TAM require close follow-up, because 20–30% will develop typical leukemia (often **acute megakaryocytic leukemia**) by 3 years of age (mean onset, 16 months). *GATA1* variants (a transcription factor that controls megakaryopoiesis) are present in blasts from patients with Down syndrome who have TAM and also in those with leukemia (Fig. 544.8). The presence of flow cytometry minimal residual disease at 3 months after a diagnosis of TAM is a risk factor for the development of myeloid leukemia.

544.4 Chronic Myelogenous Leukemia

Erika D. Friehling, Julia C. Meade, A. Kim Ritchey, David G. Tubergen, and Archie Bleyer

Chronic myelogenous leukemia (**CML**) is a clonal disorder of the hematopoietic tissue that accounts for 2–3% of all cases of childhood leukemia. Approximately 99% of the cases are characterized by a specific translocation, t(9;22)(q34;q11), known as the **Philadelphia chromosome**, resulting in a *BCR-ABL* fusion protein.

The presenting symptoms of CML are nonspecific and can include fever, fatigue, weight loss, and anorexia. Splenomegaly also may be present, resulting in pain in the left upper quadrant of the

abdomen. The diagnosis is suggested by a high WBC count with myeloid cells at all stages of differentiation in the peripheral blood and bone marrow. It is confirmed by cytogenetic and molecular studies that demonstrate the presence of the characteristic Philadelphia chromosome and the *BCR-ABL* gene rearrangement. This translocation, although characteristic of CML, is also found in a small percentage of patients with ALL.

The disease is characterized by an initial **chronic phase** in which the malignant clone produces an elevated leukocyte count with a predominance of mature forms but with increased numbers of immature granulocytes. In addition to leukocytosis, blood counts can reveal mild anemia and thrombocytosis. Typically, the chronic phase terminates 3-4 years after onset, when the CML moves into the **accelerated** or "blast crisis" **phase**. At this point, the blood counts rise dramatically, and the clinical picture is indistinguishable from acute leukemia. Additional manifestations can occur, including neurologic symptoms from hyperleukocytosis, which causes increased blood viscosity with decreased CNS perfusion.

Imatinib (Gleevec), an agent designed specifically to inhibit the *BCR-ABL* tyrosine kinase, has been used in adults and children and has shown an ability to produce major cytogenetic responses in >70% of patients (see Table 542.1). Experience in children suggests it can be used safely with results comparable to those seen in adults. Second-generation tyrosine kinase inhibitors, such as **dasatinib and nilotinib**, have improved remission rates in adults and are now included in the first-line therapy in that population. Both agents have been studied in children and have been found to be effective and safe. While waiting for a response to the tyrosine kinase inhibitor, disabling or threatening signs and symptoms of CML can be controlled during the chronic phase with hydroxyurea, which gradually returns the leukocyte count to normal. **Treatment with a tyrosine kinase inhibitor is the current standard for pediatric CML.** Although not considered curative at this time, prolonged responses can be seen, and studies in adults have shown that, in select cases, treatment with the tyrosine kinase inhibitor can be stopped. The role of potentially curative human leukocyte antigen (HLA)-matched family donor stem cell transplant in management of pediatric CML is debated.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

544.5 Juvenile Myelomonocytic Leukemia

Julia C. Meade, Erika D. Friehling, A. Kim Ritchey, David G. Tubergen, and Archie Bleyer

JMML, formerly termed **juvenile chronic myelogenous leukemia,** is a clonal proliferation of hematopoietic stem cells that typically affects children <2 years old. JMML is rare, constituting <1% of all cases of childhood leukemia. Patients with this disease do not have the Philadelphia chromosome characteristic of CML. Patients with JMML present with rashes, lymphadenopathy, splenomegaly, and hemorrhagic manifestations. Analysis of the peripheral blood often shows an elevated leukocyte count with increased monocytes, thrombocytopenia, and anemia with the presence of erythroblasts. The bone marrow shows a myelodysplastic pattern, with blasts accounting for <20% of cells. Most patients with JMML have been found to have pathogenic variants that lead to activation of the ***RAS* oncogene pathway**. About 90% have molecular changes in *NRAS, KRAS, NF1, CBL,* and *PTPN11*. Patients with **neurofibromatosis type 1** and **Noonan syndrome** have a predilection for this type of leukemia because they have germline mutations involved in *RAS* signaling. JMML in the setting of Noonan syndrome and CBL syndrome is unique, with most patients having a spontaneous resolution. However, for other patients with JMML, stem cell transplantation offers the best opportunity for cure, although outcomes are still poor.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

544.6 Infant Leukemia

A. Kim Ritchey, Erika D. Friehling, Julia C. Meade, David G. Tubergen, and Archie Bleyer

The incidence of infant acute leukemia is about 40 cases per million, or about 160 cases per year in the United States. Approximately 2% of cases of childhood leukemia occur before age 1 year. In contrast to the situation in older children, the ratio of ALL in infants to AML is 2:1. Leukemic clones have been noted in cord blood at birth before symptoms appear, and in one case, the same clone was noted in maternal cells (maternal-to-fetal transmission). Chromosome translocations can also occur in utero during fetal hematopoiesis, leading to malignant clone formation.

Several unique biologic features and a particularly poor prognosis are characteristic of ALL during infancy. Almost all are B cell with infrequent T cell. Seventy to 80% of the cases demonstrate rearrangements of the *KMT2A (MLL)* gene, found at the site of the 11q23 band translocation, the majority of which are the t(4;11). This subset of patients largely accounts for the very high relapse rate. These patients often present with hyperleukocytosis and extensive tissue infiltration producing organomegaly, including CNS disease. Subcutaneous nodules, known as **leukemia cutis**, and tachypnea caused by diffuse pulmonary infiltration by leukemic cells are observed more often in infants than in older children. The leukemic cell morphology is usually that of large, irregular lymphoblasts, with a phenotype negative for the CD10 (common ALL antigen) marker (pro-B), unlike most older children with B-ALL, who are $CD10^+$.

Very intensive chemotherapy programs, including stem cell transplantation, are being explored in infants with *KMT2A (MLL)* gene rearrangements, but none has yet proved satisfactory. Infants defined as high risk (*KMT2A*, age <6 months and WBC ≥300,000) have survival of only 30%, whereas infants with the *KMT2A* without other high-risk features have survival of 58%. Infants with leukemia who lack the *KMT2A* rearrangement have a prognosis somewhat inferior to that of older children with ALL.

Infants with AML often present with CNS or skin involvement and have a subtype known as **acute myelomonocytic leukemia.** The treatment may be the same as that for older children with AML, with similar outcome. Meticulous supportive care is necessary because of the young age and aggressive therapy needed in these patients.

Chapter 545

Lymphoma

Jessica Hochberg, Stanton C. Goldman, and Mitchell S. Cairo

INTRODUCTION

Lymphoma is the third most common cancer among U.S. children (≤14 years old), with an annual incidence of 15 cases per 1 million children. It is the most common cancer in adolescents, accounting for >25% of newly diagnosed cancers in those 15-19 years old. The two broad categories of lymphoma, Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL), have different clinical manifestations and treatments.*

545.1 Hodgkin Lymphoma

Stanton C. Goldman, Jessica Hochberg, and Mitchell S. Cairo

Hodgkin lymphoma (HL) is a malignant process involving the lymphoreticular system that accounts for 6% of childhood cancers. In the United States, HL accounts for approximately 5% of cancers in children ≤14 years old; it accounts for approximately 15% of cancers in adolescents (15-19 years), making HL the most common malignancy in this age-group.

EPIDEMIOLOGY

The worldwide incidence of HL is approximately 2-4 new cases per 100,000 population per year. There is a bimodal age distribution, with peaks at 15-35 years of age and again after 50 years. HL is the most common cancer seen in adolescents and young adults and the third most common in children <15 years old. In developing countries, the early peak tends to occur before adolescence. A male predominance is found among young children but lessens with age. Infectious agents may be involved, such as human herpesvirus 6, cytomegalovirus, and Epstein-Barr virus (EBV). The role of EBV is supported by prospective serologic studies. Infection with EBV confers a fourfold higher risk of developing HL and may precede the diagnosis by years. EBV antigens have been demonstrated in HL tissues, particularly type II latent membrane proteins 1 and 2. Some studies have suggested that elevated copies of EBV by polymerase chain reaction correspond to worse prognosis. The EBV antigens latent membrane protein 1 and 2 have been used as targets for cytotoxic T-lymphocyte therapy in patients with relapsed/refractory HL.

PATHOGENESIS

The **Reed-Sternberg (RS) cell,** a pathognomonic feature of HL, is a large cell (15-45 μm in diameter) with multiple or multilobulated nuclei. This cell type is considered the hallmark of HL, although similar cells are seen in infectious mononucleosis, NHL, and other conditions. The RS cell is clonal in origin and arises from the germinal center B cells but typically has lost most B-cell gene expression and function. There is no single simple genetic aberration that leads to malignant transformation of the RS cell; rather, a combination of somatic pathogenic variants, chromosomal instability, and complex chromosomal rearrangements has been reported with no particular pattern or frequency. This typically leads to cell regulation defects such as constitutive activation of the nuclear factor (NF)-κB pathway or abnormal regulation of the Bcl-2 family of proteins. HL is characterized by a variable number of RS cells surrounded by an inflammatory infiltrate of lymphocytes, macrophages, plasma cells, and eosinophils in different proportions, depending on the HL histologic subtype. The interaction between the RS cell and these background inflammatory cells with their associated cytokine release is important in the development and progression of HL. Reactive infiltration of eosinophils and $CD68^+$ macrophages and increased concentrations of cytokines, such as interleukin (IL)-1 and IL-6 and tumor necrosis factor, are all associated with an unfavorable prognosis. Other factors associated with a worse prognosis include advanced stage, the presence of systemic symptoms, decreased response to therapy, and slow response to therapy. In addition, evidence of $CD8^+$ T cells surrounding the RS cell offers evidence of an important role in T-cell promotion of malignant cell survival, perhaps through the CD30 and CD40 ligands found on RS cells as well as immune checkpoint inhibition pathways. Other features that distinguish the histologic subtypes include various degrees of fibrosis and the presence of collagen bands, necrosis, or malignant reticular cells (Fig. 545.1). The distribution of subtypes varies with age.

The **Revised World Health Organization Classification of Lymphoid Neoplasms** includes two modifications of the older Rye system. HL appears to arise in lymphoid tissue and spread to adjacent lymph node areas in a relatively orderly manner (Table 545.1). Hematogenous spread also occurs, leading to involvement of the liver, spleen, bone, bone marrow (BM), or brain, and is usually associated with systemic symptoms.

CLINICAL MANIFESTATIONS

Patients typically present with painless, nontender, firm, rubbery cervical or supraclavicular lymphadenopathy and usually some degree of mediastinal involvement. Clinically detectable hepatosplenomegaly may be encountered. Depending on the extent and location of nodal and extranodal disease, patients may present with symptoms and signs of airway obstruction (dyspnea, hypoxia, cough), pleural or pericardial effusion, hepatocellular dysfunction, or BM infiltration (anemia, neutropenia, or thrombocytopenia). Systemic symptoms, classified as **B symptoms**, that are considered important in staging are unexplained fever >38°C (100.4°F), weight loss >10% total body weight over 6 months, and drenching night sweats. Less common and not considered of prognostic significance are symptoms of pruritus, lethargy, anorexia, or pain. Patients also exhibit immune system deficiencies that often persist during and after therapy.

DIAGNOSIS

Any patient with persistent, unexplained lymphadenopathy unassociated with an obvious underlying inflammatory or infectious process should undergo chest radiography to identify the presence of a large mediastinal mass before undergoing lymph node biopsy (Fig. 545.2). Formal excisional biopsy is preferred over needle biopsy to ensure that adequate tissue is obtained, both for light microscopy and for appropriate immunohistochemical and molecular studies. Once the diagnosis of HL is established, extent of disease (stage) should be determined to allow selection of appropriate therapy (Table 545.2). Evaluation includes history, physical examination, and imaging studies, including chest radiograph; CT scans of the neck, chest, abdomen, and pelvis; and PET scan (Fig. 545.3). Laboratory studies should include a CBC to identify abnormalities that might suggest marrow involvement, ESR, and measurement of serum ferritin, which is of some prognostic significance and, if abnormal at diagnosis, serves as a baseline to evaluate the effects of treatment. A chest radiograph is particularly important for measuring the size of the mediastinal mass in relation to the maximal diameter of the thorax (see Fig. 545.2). This determines "bulk" disease and becomes prognostically significant. Chest CT more clearly defines the extent of a mediastinal mass if present and identifies hilar nodes and pulmonary parenchymal involvement, which may not be evident on chest radiographs (see Fig. 545.3). BM aspiration and biopsy should be performed to rule out advanced disease. Bone scans are performed in patients with bone pain and/or elevation of alkaline phosphatase. Fluorodeoxyglucose (FDG) PET imaging has advantages over traditional gallium scanning, with higher resolution, better dosimetry, less intestinal activity, and the potential to quantify disease (Table 545.3).

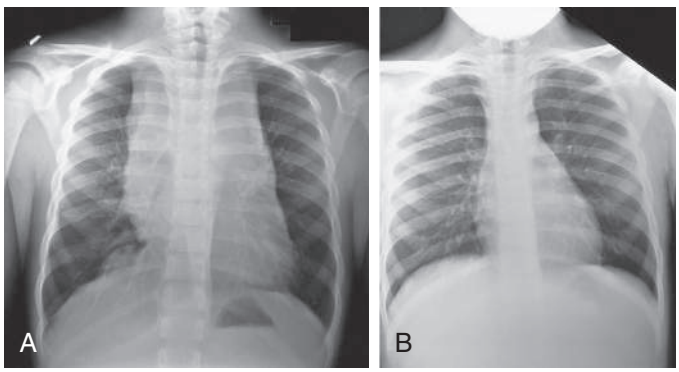

Fig. 545.2 **A,** Anterior mediastinal mass in a patient with Hodgkin disease before therapy. **B,** After 2 months of chemotherapy, the mediastinal mass has disappeared.

PET scans are essential as a prognostic tool in HL, enabling therapy to be reduced in those predicted to have a good outcome and identifying those at risk of relapse.

The staging classification currently used for HL was initially adopted at the **Ann Arbor Conference** in 1971 and was revised in 1989. The **Lugano classification** was developed in 2014 and incorporates standardized staging and response criteria for FDG-PET–avid lymphomas (see Table 545.2). HL can be subclassified into A or B categories: *A* is used to identify asymptomatic patients, and *B* is used for patients who exhibit any B symptoms. Extralymphatic disease resulting from direct extension of an involved lymph node region is designated by category *E*. A *complete response* in HL is defined as the complete resolution of disease on clinical examination and imaging studies, or at least 70–80% reduction of disease and a change from initial positivity to negativity on PET scanning, reflecting residual fibrosis, which is common.

Table 545.2 Lugano Classification for Hodgkin Lymphoma*

STAGE	INVOLVEMENT	EXTRANODAL STATUS
I	One node or group of adjacent nodes	Single extranodal lesions without nodal involvement
II	Two or more nodal groups on the same side of the diaphragm	Stage I or II by nodal extent with limited contiguous extranodal involvement
II bulky	II as above with "bulky" disease	Not applicable
III	Nodes on both sides of the diaphragm; nodes above the diaphragm with spleen involvement	Not applicable
IV	Additional noncontiguous extralymphatic involvement	Lung, liver, bone marrow, bone marrow, bone

*The absence or presence of fever >38°C (100.4°F) for 3 (some suggest 7) consecutive days, drenching night sweats, or unexplained loss of >10% of body weight in the 6 months preceding admission are to be denoted in all cases by the suffix letter A or B, respectively.

TREATMENT

Multiple agents allow different mechanisms of action to have nonoverlapping toxicities so that full doses can be given to each patient. Chemotherapy and radiation therapy are both effective in the treatment of HL. Treatment of HL in pediatric patients is **risk adapted** and involves the use of combined chemotherapy with or without low-dose involved-field radiation therapy based on response. Treatment is determined largely by disease stage, presence or absence of B symptoms, and the presence of *bulky nodal disease*. The development of effective multiagent combination **chemotherapy** and **immunotherapy** is a major milestone in the treatment of HL, resulting in a complete response rate of 70–80% and cure rate of 40–50% in patients with advanced-stage disease. However, this regimen also led to significant acute and long-term toxicity. The desire to reduce side effects and morbidity has stimulated attempts to reduce the intensity of chemotherapy, as well as radiation dose and volume. Combinations of chemotherapy have reduced the risk of secondary cancers. Also, current radiation therapy uses lower amounts of overall radiation in addition to narrowing the radiation treatment field to either involved-field or even involved-node irradiation. The current **Children's Oncology Group** and other trials are investigating whether radiation therapy can be eliminated altogether in patients who have a very good rapid early response to induction chemotherapy.

Chemotherapy agents used to treat children and adolescents with HL include cyclophosphamide, procarbazine, vincristine or vinblastine, prednisone or dexamethasone, doxorubicin, bleomycin, dacarbazine, etoposide, methotrexate, and cytosine arabinoside. The combination chemotherapy regimens in current use are based on **COPP** (cyclophosphamide, vincristine [Oncovin], procarbazine, and prednisone) or **ABVD** (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine), with the addition of prednisone, cyclophosphamide, and etoposide (**ABVE-PC** and **BEACOPP**) or **BAVD** (brentuximab vedotin, doxorubicin [Adriamycin], vincristine, dacarbazine) in various combinations for intermediate- and high-risk groups (Table 545.4). *Risk-adapted protocols* are based on both staging criteria and rapidity of response to initial chemotherapy. The aim is to reduce total drug doses and treatment duration and to eliminate radiation therapy, if possible.

Agents such as those that disrupt the NF-κB pathway or monoclonal antibodies (mAbs) that target RS tumor cells, as well as the benign reactive cells that surround them, are being investigated. Ongoing clinical trials report encouraging results with anti-CD20 antibody **(rituximab)**, particularly in nodular lymphocyte-predominant HL, for which trials in relapsed disease have shown an overall response rate of 94%. In addition, anti-CD30 agents are being used that target the RS cells themselves, where CD30 is abundantly expressed. **Brentuximab vedotin** is an antibody–drug conjugate approved by the U.S. Food and Drug Administration to treat HL. It combines the chimeric anti-CD30 antibody brentuximab linked to the antimitotic agent monomethyl auristatin E. This agent shows impressive efficacy as single-agent therapy in refractory HL and is being tested as part of up-front therapy combined with chemotherapy in patients with newly diagnosed disease where pediatric trials incorporating brentuximab to replace vincristine in the OEPA/COPDac backbone have demonstrated overall safety, tolerability, and efficacy with 97% event-free survival (EFS) and the ability to limit radiation to involved node radiation sites only. Furthermore, the combination of both brentuximab and rituximab, together with **AVD** chemotherapy in newly diagnosed patients, has shown 100% efficacy while allowing for the elimination of toxic alkylator agents, topoisomerase inhibitors, bleomycin, and any radiation in the majority of patients. **EBV-specific cytotoxic T lymphocytes (CTLs)** can also be generated from allogeneic donors for patients with advanced HL. In clinical trials, these cells show promising results, with enhanced antiviral activity and stabilization of disease. EBV-CTLs have been developed and are currently being investigated. These enhanced EBV-CTLs are designed to be latent membrane protein 1 and 2 specific and can be generated from second-party (in the case of BM transplant recipients) or even third-party donors for patients with refractory disease. These approaches represent an exciting direction in adoptive cellular tumor

Table 545.4 Chemotherapy Regimens for Children, Adolescents, and Young Adults with Hodgkin Lymphoma

CHEMOTHERAPY REGIMEN	CORRESPONDING AGENTS
ABVD	Doxorubicin (Adriamycin), bleomycin, vinblastine, dacarbazine
ABVD-Rituxan	Doxorubicin (Adriamycin), bleomycin, vinblastine, dacarbazine, rituximab
ABvVD	Doxorubicin (Adriamycin), brentuximab, vinblastine, dacarbazine
ABvVD-R	Doxorubicin (Adriamycin), brentuximab, vinblastine, dacarbazine, rituximab
AEPA/CAPDac	Brentuximab, etoposide, prednisone, and doxorubicin/cyclophosphamide, brentuximab, prednisone, and dacarbazine
ABVE (DBVE)	Doxorubicin (Adriamycin), bleomycin, vincristine, etoposide
VAMP	Vincristine, doxorubicin (Adriamycin), methotrexate, prednisone
OPPA ± COPP (females)	Vincristine (Oncovin), prednisone, procarbazine, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), prednisone, procarbazine
OEPA ± COPP (males)	Vincristine (Oncovin), etoposide, prednisone, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), prednisone, procarbazine
COPP/ABV	Cyclophosphamide, vincristine (Oncovin), prednisone, procarbazine, doxorubicin (Adriamycin), bleomycin, vinblastine
BEACOPP (advanced stage)	Bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), prednisone, procarbazine
COPP	Cyclophosphamide, vincristine (Oncovin), prednisone, procarbazine
CHOP	Cyclophosphamide, doxorubicin (Adriamycin), vincristine (Oncovin), prednisone
ABVE-PC (DBVE-PC)	Doxorubicin (Adriamycin), bleomycin, vincristine, etoposide, prednisone, cyclophosphamide
ICE ± (Brentuximab)	Ifosfamide, carboplatin, etoposide ± brentuximab
Ifos/Vino ± (Brentuximab)	Ifosfamide, vinorelbine ± brentuximab

immunology, and it remains to be determined whether CTLs will have improved cytotoxicity that can overcome inhibitory signals.

RELAPSE

Most relapses occur within the first 3 years after diagnosis, but relapses as late as 10 years have been reported. Relapse cannot be predicted accurately with this disease. Poor prognostic features include tumor bulk, stage at diagnosis, extralymphatic disease, and presence of B symptoms. Patients who achieve an initial chemosensitive response but relapse or progress before 12 months from diagnosis are candidates for myeloablative chemotherapy and autologous stem cell transplantation (SCT), with or without radiation therapy. Retrospective studies show a significant decrease in relapse in patients with HL following allogeneic vs autologous SCT. Reduced-intensity conditioning or nonmyeloablative regimens are successful at reducing regimen-related morbidity and mortality associated with myeloablative allogeneic SCT while still achieving a strong graft versus HL effect. For more difficult-to-treat refractory cases, radioimmunotherapy agents such as Zevalin and Bexxar are being trialed, often in combination with SCT strategies. Both are monoclonal anti-CD20 antibodies to which a radioactive isotope is directly linked. Clinical trials show each to be more effective than rituximab in NHL patients, and there is some interest in studying their use in the CD20 subpopulation of HL patients. Tumors can evade the host immune system by exploiting immune checkpoint pathways, such as the CTL-associated protein four (CTLA-4) and **programmed-death protein 1 (PD-1)** pathways. PD-1 is a negative co-stimulatory receptor with increased expression reported on T cells. PD-1 is critical for suppression of T-cell activation, with binding of **programmed-death ligand 1 (PD-L1)** resulting in "T-cell exhaustion." Blockade of this interaction renders previously anergic T cells responsive to antigen. Evidence has shown that antitumor immune responses can be improved by blocking immune checkpoint inhibitors in the tumor microenvironment. Phase I trials of the PD-1 blocking mAbs **nivolumab** and **pembrolizumab** have shown significant promise in refractory patients. Phase II clinical trials suggest that combining immunotherapy such as rituximab or brentuximab with PD-1 checkpoint blockade will be highly effective against relapsed lymphomas and well tolerated, without treatment-related adverse events. With the success seen in relapsed or refractory patients, PD-1 blockade likely will have a role in frontline therapy as well where studies have shown promise in combination with chemotherapy in adults, with pediatric trials currently under investigation.

PROGNOSIS

With the use of current therapeutic regimens, patients with favorable prognostic factors and early-stage disease have an EFS of 85–90% and an overall survival (OS) at 5 years of >95%. Patients with advanced-stage disease have slightly lower EFS (80–85%) and OS (90%), respectively, although OS has approached 100% with dose-intense chemotherapy (Table 545.5). Prognosis after relapse depends on the time from completion of treatment to recurrence, site of relapse (nodal vs extranodal), and presence of B symptoms at relapse. Patients whose disease relapses >12 months after chemotherapy alone or combined-modality therapy have the best prognosis, and their relapses usually respond to additional standard therapy, resulting in a long-term survival of 60–70%. A myeloablative autologous SCT in patients with refractory disease or relapse within 12 months of therapy results in a long-term survival rate of only 40–50%. Allogeneic SCT has shown promise in patients with poor-risk features at relapse/progression.

545.2 Non-Hodgkin Lymphoma

Stanton C. Goldman, Jessica Hochberg, and Mitchell S. Cairo

Non-Hodgkin lymphoma (**NHL**) accounts for approximately 60% of lymphomas in children and is the second most common malignancy between ages 15 and 35 years. The annual incidence of pediatric NHL in the United States is 750-800 cases per year. In contrast to adult NHL, which is predominantly indolent, pediatric NHL is usually *high grade*. Although >70% of patients present with advanced disease, the prognosis has improved dramatically, with survival rates of 90–95% for localized disease and 80–95% for advanced disease.

EPIDEMIOLOGY

Although most children and adolescents with NHL present with de novo disease, a small number of patients have NHL secondary to specific etiologies, including inherited or acquired immunodeficiencies (e.g., severe combined immunodeficiency syndrome, Wiskott-Aldrich syndrome), virus-associated malignancy (e.g., HIV, EBV), and as part of genetic syndromes (e.g., ataxia-telangiectasia, Bloom syndrome).

However, most children in North America and Europe in whom NHL develops have no obvious genetic or environmental etiology.

PATHOGENESIS

Three most prevalent subtypes of childhood and adolescent NHL with different treatment approaches are **lymphoblastic lymphoma (LBL), mature B-cell lymphoma**, and **anaplastic large cell lymphoma** (**ALCL**; Figs. 545.4 and 545.5). LBL arises from precursor T lymphocytes and less often from precursor B lymphocytes, with biology and treatment approaches similar to acute lymphoblastic leukemia. Mature B-cell lymphomas comprise two main pathologies, **Burkitt lymphoma (BL)** and **diffuse large B-cell lymphoma (DLBCL)**. DLBCL is further divided into several subtypes: the *germinal center B-cell–like* subtype, which carries a favorable prognosis and accounts for most pediatric cases of DLBCL, and the subtypes with poorer prognosis, including *activated B-cell–like* and *primary mediastinal B-cell* subtypes. Primary mediastinal B-cell subtype of DLBCL shares molecular signature more akin to HL then germinal center–derived DLBCL. Most cases of ALCL are of mature T-cell origin, with a smaller percentage of null-cell and B-cell origin. Cellular surface markers can aid in differentiating NHL subtypes and present opportunities for specific antibody-targeted treatments. BL and DLBCL express the mature B-cell antigens CD20 (the target of rituximab) and CD22, whereas ALCL expresses the CD30 antigen (the target of the antibody conjugate brentuximab vedotin). Some pathologic subtypes have specific cytogenetic aberrations. Children with BL frequently have a driver genetic change involving the *MYC* gene juxtaposed to an immunoglobulin chain in the form of translocations: t(8;14) (90%) or, less often, a t(2;8) or t(8;22) translocation (10%). Children with BL who have additional chromosomal aberrations such as 13q deletion or complex karyotype have a poorer prognosis. Unlike adult DLBCL, a higher proportion of pediatric DLBCL may also have c-myc dysregulation with t(8;14) translocation (30%) and often have a complex (80%) and aneuploid (80%) karyotype. In recent years a Burkitt morphology lymphoma (Burkitt-like) that lacks a c-myc driver has been categorized by findings of 11q aberrations and several target genes such as chromatin remodeling complex pathogenic variants (INO80) that likely contribute to lymphomagenesis (Fig. 545.6). Patients with ALCL usually have a driver t(2;5) translocation (90%), which results in the formation of a fusion gene encoding the constitutively active nucleophosmin–anaplastic lymphoma kinase (ALK) tyrosine kinase and can be targeted by the oral agent, crizotinib. T-cell LBL harbors many of the same cytogenetic abnormalities as T-cell acute lymphoblastic leukemia (T-ALL), including rearrangements with breakpoints at 14q11.2 involving the T-cell receptor and multiple other rearranged genes. Loss of heterozygosity at chromosome 6q defines a poor-risk subgroup of T-LBL patients.

Genomic studies have offered insights into NHL pathogenesis as well as elucidated potential targets for novel therapies. Gene expression profiling of T-LBL and T-ALL has implicated the activation of oncogenic transcription factors as a result of aberrant T-cell receptor gene rearrangement. One of the most frequently activated signaling pathways is NOTCH1, which may be amenable to therapeutic targeting with γ-secretase inhibitors. In BL and DLBCL, extensive genomic work has identified unique gene expression signatures that

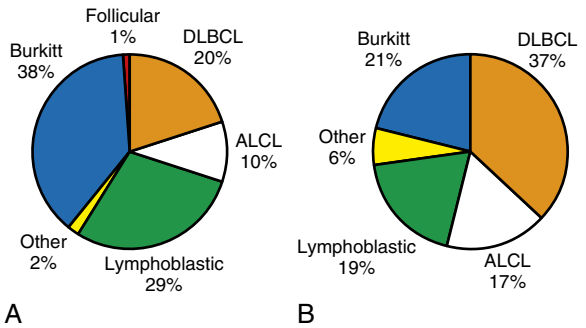

Fig. 545.4 Incidence of non-Hodgkin lymphoma subtypes. **A,** In 0- to 14-yr-old children. **B,** In 15- to 19-yr-old adolescents. Fig. 545.6 Germinal center–derived B-cell lymphomagenesis. *Diffuse large B-cell lymphoma (DLBCL), recently subclassified as MCD, BNS, N1, and EZB subgroups. *(From Cairo, MS. A new Burkitt "look-alike" lymphoma. Blood. 2019;133[9]:889–891.)*

differentiate these two mature B-cell neoplasms. In addition, next-generation sequencing of BL has identified genetic lesions in *TCF3* and *ID3,* which lead to activation of the AKT/PI3 kinase pathway. Other genetic lesions that have been described in BL include loss of function of the chromatin remodeling genes *ARID1A* and *SMARCA4.* Importantly, many of these alterations are potentially targetable by agents that are in development.

CLINICAL MANIFESTATIONS

The clinical manifestations of childhood and adolescent NHL depend primarily on pathologic subtype and sites of involvement. The current revised staging system used for NHL is the **International Pediatric Non-Hodgkin Lymphoma Staging System (IPNHLSS),** which reflects our increasing ability to diagnose lower levels of organ involvement with disease. For instance, the older staging system (St. Jude/Murphy classification) did not account for molecular or flow cytometry involvement of BM, which is now reflected in the new system (Tables 545.6 and 545.7). Patients are further classified based on risk categories according to pediatric international cooperative group trials. Approximately 70% of patients with NHL present with advanced disease (stage III or IV), including extranodal disease with BM and CNS involvement. B symptoms of fever, weight loss, and night sweats can be seen, particularly in ALCL, but unlike HL, are not prognostic.

The primary site of tumor involvement and the pattern of metastasis vary by pathologic subtype. LBL typically manifests as a symptomatic mediastinal mass and also has a predilection for spreading to the BM, CNS, and testes in males. BL commonly manifests as a diffuse leukemia presentation or massive abdominal (*sporadic* type) or head and neck (*endemic* type) tumor and can metastasize to the BM or CNS. DLBCL usually manifests as either an abdominal or a mediastinal primary tumor and, rarely, disseminates to the BM or CNS. ALCL manifests either as a primary cutaneous manifestation (10%) or as systemic disease (90%) with dissemination to liver, spleen, lung, or mediastinum. BM or CNS disease is rare in ALCL. Site-specific manifestations of NHL include painless, rapid lymph node enlargement; cough or dyspnea with thoracic involvement; superior mediastinal syndrome; ascites, increased abdominal girth or intestinal obstruction with an abdominal mass; nasal congestion, earache, hearing loss, or tonsil enlargement with Waldeyer ring involvement; and localized bone pain.

NHL can present as a life-threatening **oncologic emergency**. These manifestations are important to recognize because these patients require intensive supportive care and, in some cases, alternative treatment. **Superior mediastinal syndrome** can occur as a consequence of a large mediastinal mass causing obstruction of blood flow or respiratory airways. Spinal cord tumors can cause cord compression and acute paraplegias requiring emergent radiation therapy. **Tumor lysis syndrome** (TLS) can occur from rapid cell turnover, which is especially common in BL. TLS can result in severe metabolic abnormalities, including hyperuricemia, hyperphosphatemia, hyperkalemia, and

Table 545.6 International Pediatric Non-Hodgkin Lymphoma Staging System (IPNHLSS)*

STAGE I
- A single tumor with the exclusion of the mediastinum and abdomen (N: nodal; EN: extranodal; bone (B) or skin (S): EN-B, EN-S)

STAGE II
- A single extranodal tumor with regional node involvement
- Two or more nodal areas on the same side of the diaphragm
- A primary gastrointestinal tract tumor (usually in the ileocecal area), with or without involvement of associated mesenteric nodes, that is completely resectable (if malignant ascites or extension of the tumor to adjacent organs, it should be regarded as stage III)

STAGE III
- Two or more extranodal tumor(s) (including bone or skin: EN-B, EN-S) above and/or below the diaphragm
- Two or more nodal areas above and below the diaphragm
- Any intrathoracic tumor (mediastinal, hilar, pulmonary, pleural, or thymic)
- Intraabdominal and retroperitoneal disease, including liver, spleen, kidney, and/or ovary localizations, regardless of degree of resection (except a primary gastrointestinal tract tumor [usually in the ileocecal region], with or without involvement of associated mesenteric nodes, that is completely resectable)
- Any paraspinal or epidural tumor, whether or not other sites are involved
- Single bone lesion with concomitant involvement of extranodal and/or nonregional nodal sites

STAGE IV
- Any of the previous findings with initial involvement of the central nervous system (stage IV CNS), bone marrow (stage IV BM), or both (stage IV combined) based on conventional methods, see Table 545.7
- For each stage, type of examination and degree of BM and CNS involvement should be specified, using the abbreviations listed in Table 545.7 to identify involvement

*Based on the classification proposed by Murphy (Murphy SB. Classification, staging and end results of treatment of childhood non-Hodgkin's lymphomas: dissimilarities from lymphomas in adults. *Semin Oncol*. 7:332–339, 1980.)
From Rosolen A, Perkins SL, Pinkerton CR, et al. Revised International Pediatric Non-Hodgkin Lymphoma Staging System. *J Clin Oncol*. 2015;33(18):2112–2118.

Table 545.7 Additional IPNHLSS Information*

BONE MARROW (BM) INVOLVEMENT

Stage IV disease, caused by BM involvement, is currently defined by morphologic evidence of ≥5% blasts or lymphoma cells by bone marrow aspiration. This applies to any histologic subtype and will be maintained in the IPNHLSS.

However, for each stage, type and degree of BM involvement (by bone marrow aspiration) should be specified, using the abbreviations below to identify involvement:
- BMm = BM positive by morphology (specify % lymphoma cells).
- BMi = BM positive by immunophenotypic methods (immunohistochemical/flow cytometry analysis) (specify % lymphoma cells).
- BMc = BM positive by cytogenetic/FISH analysis (specify % lymphoma cells).
- BMmol = BM positive by molecular techniques (PCR based) (specify level of involvement).

Same approach should be used for peripheral blood (PB) involvement (i.e., PBm, PBi, PBc, PBmol).

Note: Definition of BM involvement should be obtained from analysis of bilateral BM aspirates and BM biopsy.

CENTRAL NERVOUS SYSTEM (CNS) INVOLVEMENT

CNS is considered involved in case of:
1. Any CNS tumor mass (identified by imaging techniques; i.e., CT, MRI).
2. In case of cranial nerve palsy that cannot be explained by extradural lesions.
3. In case of blasts morphologically identified in the cerebrospinal fluid (CSF).

Condition that defines CNS positivity should be specified: CNS positive/mass; CNS positive/palsy; CNS positive/blasts.

CSF status: CSF positivity is based on morphologic evidence of lymphoma cells.

CSF should be considered positive when any number of blasts is detected.

CSF unknown (e.g., not performed, technical difficulties).

Similar to BM, type of CSF involvement should be described whenever possible:
- CSFm = CSF positive by morphology (specify the number of blasts per microliter).
- CSFi = CSF positive by immunophenotype methods (immunohistochemical/flow cytometry analysis) (specify % lymphoma cells).
- CSFc = CSF positive by cytogenetic/FISH analysis (specify % lymphoma cells).
- CSFmol = CSF positive by molecular techniques (PCR based) (specify level of involvement).

*Until sufficient data are available, PET should be used with caution for staging, and PET results should be compared and discussed in light of other, more consolidated imaging approaches.
IPNHLSS, International Pediatric Non-Hodgkin Lymphoma Staging System Information; FISH, fluorescence in situ hybridization; PCR, polymerase chain reaction.
From Rosolen A, Perkins SL, Pinkerton CR, et al. Revised International Pediatric Non-Hodgkin Lymphoma Staging System. *J Clin Oncol*. 2015;33(18):2112–2118.

hypocalcemia. This can rapidly lead to renal insufficiency/failure, as well as cardiac abnormalities, if not aggressively treated.

LABORATORY FINDINGS

Recommended laboratory and radiologic testing includes CBC; measurements of electrolytes, lactate dehydrogenase, uric acid, calcium, phosphorus, BUN, creatinine, bilirubin, alanine aminotransferase, and aspartate aminotransferase; BM aspiration and biopsy; lumbar puncture with cerebrospinal fluid cytology, cell count, and protein; chest radiographs; and abdominal ultrasound for initial diagnosis. Staging relies on more detailed anatomic imaging, with CT for neck, chest, abdomen, and pelvic imaging and MRI the preferred modality for suspected CNS disease of brain and spine (Fig. 545.7). PET scan, usually with radioactive FDG for functional imaging, is more sensitive and has replaced gallium imaging. It is also an excellent modality for judging treatment response to therapy. Tumor tissue (i.e., biopsy, BM, cerebrospinal fluid, pleurocentesis/paracentesis fluid) should be tested by flow cytometry for immunophenotypic origin (T, B, or null) and cytogenetics (karyotype). Additional tests might include fluorescent in situ hybridization (FISH) or quantitative reverse-transcription polymerase chain reaction (RT-PCR) for specific genetic translocations, T- and B-cell gene rearrangement studies, and molecular profiling by oligonucleotide microarray or next-generation sequencing.

TREATMENT

The primary modality of treatment for childhood and adolescent NHL is *multiagent systemic chemotherapy and/or immunotherapy with intrathecal chemotherapy* (see Table 545.5). An international pediatric NHL response classification has been developed (IPNHLRC) (Tables 545.8 and 545.9). Surgery is used mainly for diagnosis. Radiation therapy is used only in special circumstances, such as CNS involvement in LBL or the presence of acute superior mediastinal syndrome or paraplegias. Newly diagnosed patients, especially those with BL or LBL, are at high risk for TLS. These patients require vigorous hydration, frequent electrolyte monitoring, and either a xanthine oxidase inhibitor (e.g., allopurinol, 10 mg/kg/day orally in three divided doses daily) or a recombinant urate oxidase (e.g., rasburicase, 0.2 mg/kg/day intravenously once daily for up to 5 days). Recombinant urate oxidase is preferred in patients with a high risk of tumor lysis but is *contraindicated* in patients with a history of G6PD deficiency.

Burkitt Lymphoma and Diffuse Large B-Cell Lymphoma

Pediatric BL and DLBCL (except mediastinal primary B cell) are treated with the same mature B-cell NHL chemoimmunotherapy regimens

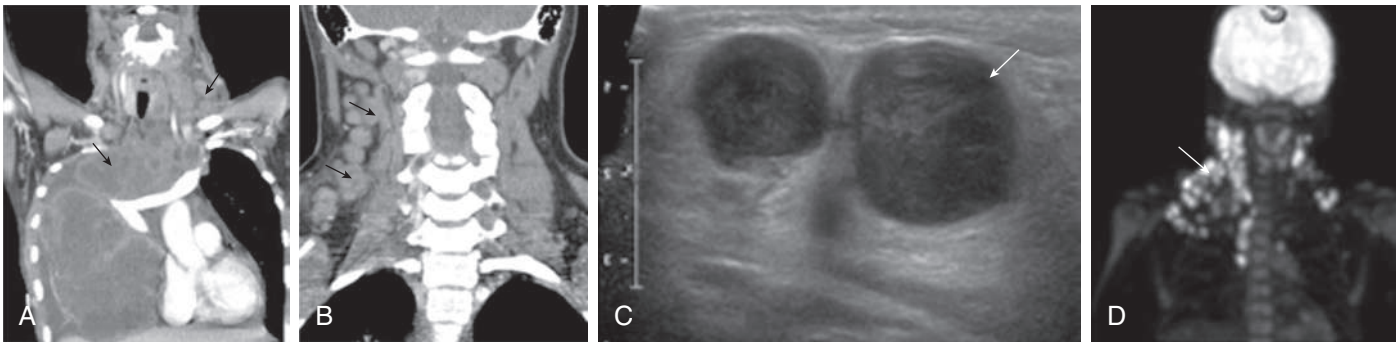

Fig. 545.7 Lymphoma. Coronal postcontrast CT images demonstrate extensive cervical (**A**) and mediastinal (**B**) lymphadenopathy *(arrows)*. **C,** Sonographic image demonstrates two enlarged lymph nodes with abnormal internal morphology *(arrow)*. **D,** PET scan demonstrates metabolically active conglomeration of right-sided cervical lymph nodes *(arrow)*. *(From Haaga JR, Boll DT, et al., eds. CT and MRI of the Whole Body (Vol. 1). Philadelphia: Elsevier; 2017: Fig. 26-15, p. 768.)*

Table 545.8 International Pediatric Non-Hodgkin Lymphoma Response Criteria (IPNHLRC)

Complete Response (CR): disappearance of all disease (three designations)

1. Complete (CR):
   a. CT or MRI reveals no residual disease or new lesions.
   b. Resected residual mass that is pathologically (morphologically) negative for disease (detection of disease with more sensitive techniques, as described in "supporting data," Table 545.9).
   c. Bone marrow (BM) and cerebrospinal fluid (CSF) morphologically free of disease (detection of disease with more sensitive techniques, as described in Table 545.9).
2. Complete Response, biopsy negative (CRb):
   a. Residual mass has no morphologic evidence of disease from limited or core biopsy (detection of disease with more sensitive techniques, as described in Table 545.9) with no new lesions by imaging examination.
   b. BM and CSF morphologically free of disease (detection of disease with more sensitive techniques, as described in Table 545.9).
   c. No new and/or progressive disease elsewhere.
3. Complete Response, unconfirmed (CRu):
   a. Residual mass is negative by FDG-PET; no new lesions by imaging examination.
   b. BM and CSF morphologically free of disease (detection of disease with more sensitive techniques, as described in Table 545.9).
   c. No new and/or progressive disease elsewhere.

Partial Response (PR): 50% decrease in the sum of the product of the greatest perpendicular diameters (SPD) on CT or MRI. FDG-PET may be positive (Deauville score of 4 or 5 with reduced lesional uptake compared with baseline). No new and/or PD. Morphologic evidence of disease may be present in the BM or CSF if present at diagnosis (detection of disease with more sensitive techniques, as described in Table 545.9); however, there should be a 50% reduction in the percentage of lymphoma cells.

Minor Response (MR): Decrease in SPD is >25% but <50% on CT or MRI. No new and/or PD. Morphologic evidence of disease may be present in the BM or CSF if present at diagnosis (detection of disease with more sensitive techniques, as described in Table 545.9); however, there should be a 25–50% reduction in the percentage of lymphoma cells.

No Response (NR): For those who do not meet CR, PR, MR, or PD criteria.

Progressive Disease (PD): For those with >25% increase in the SPD on CT or MRI, Deauville score 4 or 5 on FDG-PET with an increase in lesional uptake from baseline, or the development of new morphologic evidence of disease in the BM or CSF.

FDG-PET, Fluorodeoxyglucose positron emission tomography.
From Sandlund JT, Guillerman RP, Perkins SL, et al. International Pediatric Non-Hodgkin Lymphoma Response Criteria. *J Clin Oncol.* 2015;33(18):2106–2111.

Table 545.9 Supporting IPNHLRC Data

BONE MARROW (BM) INVOLVEMENT

BM involvement is currently defined by morphologic evidence of lymphoma cells. This applies to any histologic subtypes.
Type and degree of BM involvement should be specified, using the following abbreviations:
- BMm = BM positive by morphology (specify % lymphoma cells).
- BMi = BM positive by immunophenotypic methods (histochemical/flow cytometry analysis) (specify % lymphoma cells).
- BMc = BM positive by cytogenetic/FISH analysis (specify % lymphoma cells).
- BMmol= BM positive by molecular techniques.

Same approach should be used for peripheral blood (PB) involvement (i.e., PBm, PBi, PBc, PBmol).

CENTRAL NERVOUS SYSTEM (CNS) INVOLVEMENT

Cerebrospinal fluid (CSF) status: CSF positivity is based on morphologic evidence of lymphoma cells.
CSF should be considered positive when any number of blasts is detected.
CSF unknown (e.g., not performed, technical difficulties).
Similar to BM, type of CSF involvement should be described whenever possible:
- CSFm = CSF positive by morphology (specify the number of blasts/μL).
- CSFi = CSF positive by immunophenotypic methods (histochemical/flow cytometry analysis) (specify % lymphoma cells).
- CSFc = BM positive by cytogenetic/FISH analysis (specify % lymphoma cells).
- CSFmol = CSF positive by molecular techniques.

RESIDUAL MASS (RM)

RMm = Tumor detected by standard morphologic evaluation.
RMi = Tumor detected by immunophenotypic methods (immunohistochemical or flow cytometry analysis).
RMc = Tumor detected by cytogenetic/FISH analysis.
RMmol = Tumor detected by molecular techniques.

FISH, Fluorescence in situ hybridization.
From Sandlund JT, Guillerman RP, Perkins SL, et al. International Pediatric Non-Hodgkin Lymphoma Response Criteria. *J Clin Oncol.* 2015;33(18):2106–2111.

based on stage and risk stratification. For patients with localized disease, multiagent chemotherapy is given over 6 weeks, and the prognosis is excellent. In the international French-American-British Lymphoma, mature B cell [FAB/LMB 96] trial, patients with localized, completely resected disease received two cycles of COPAD (cyclophosphamide, vincristine, prednisone, and doxorubicin), resulting in a 4-year OS of 99%. Advanced disease is usually treated with a 4- to 6-month regimen of multiagent chemoimmunotherapy, such as FAB/LMB 96 protocol therapy or

NHL-Berlin-Frankfurt-Mulnster-95 (BFM 95) protocol therapy with the addition of rituximab, with an OS of 79–90%. A subset of patients who likely require a different treatment approach have **primary mediastinal B-cell lymphoma (PMBCL)**. PMBCL is a histologic subtype that represents 2% of mature B-NHLs. Pediatric patients with PMBCL had an inferior outcome when treated with standard mature B-NHL protocols (EFS of only 66%). Alternative treatment strategies, including prolonged infusional chemotherapy, rituximab, and chimeric antigen receptor T cells expressing anti-CD19 mAbs, may benefit this group (see Chapter 543).

Rituximab is a mAb directed at CD20 that, when combined with standard chemotherapy, improves outcomes in adult patients with aggressive B-NHL (usually DLBCL). A window study of rituximab given to pediatric patients with newly diagnosed BL and DLBCL demonstrated its activity as a single agent with a response rate of 41%. Additionally, a Children's Oncology Group study examined the safety and pharmacokinetics of rituximab when added to standard chemotherapy for intermediate-risk patients. Rituximab was found to be safe, and survival in this cohort was the best reported to date (3-year OS of 95%). In a similar cohort of CNS-positive patients, the addition of rituximab to the chemotherapy backbone resulted in a 93% EFS. Based on this pilot data, an international randomized study of rituximab added to standard multiagent chemotherapy in advanced-stage pediatric patients enrolled over 300 patients. The randomized trial demonstrated that the addition of rituximab markedly prolonged EFS and OS. The EFS at 3 years was 94% compared to 82% in patients who received chemotherapy alone. As expected with an antibody to a protein on the surface of normal mature B cells, there was a higher incidence of low immunoglobulin levels in rituximab-treated patients up to 1 year poststudy entry. Rituximab is standard-of-care therapy for pediatric mature B-NHL with advanced disease at presentation. These patients make up roughly ~30% of all mature B-NHL. A study of dose substitution of anthracycline (doxorubicin) intensity with rituximab in children and adolescents with good-risk mature B-cell lymphoma noted reduction of anthracycline dramatically reduced mucositis and febrile admissions during the intensive induction phases of therapy and was associated with 100% EFS and OS. With the success of rituximab in pediatric mature B-NHL and the poor outcome of recurrent or refractory disease, there is interest in improving immunotherapy in up-front patients. Polatuzumab vedotin is a CD79b-directed antibody conjugated to an antimitotic agent. The therapy has been approved in conjunction with rituximab and chemotherapy for adult refractory DLBCL. A study to determine the feasibility and safety of the addition of polatuzumab vedotin in combination with rituximab and FAB chemotherapy in patients with intermediate and high-risk mature B-NHL is in progress.

Lymphoblastic Lymphoma

Localized or advanced LBL requires 12-24 months of therapy, including chemotherapy, intrathecal therapy, and cranial radiation in CNS-positive lymphomas. The best results in advanced LBL have been obtained using therapeutic approaches mirroring those for childhood acute leukemia, including induction, consolidation, interim maintenance, and reinduction (advanced disease only) phases, as well as a year-long maintenance phase with 6-mercaptopurine and methotrexate. For patients with relapsed disease, the outcome is poor (OS of 10%), and novel treatments are needed. *Nelarabine,* a purine analog with significant T-lymphocyte toxicity, has completed testing in primary therapy for T-LBL in conjunction with a much larger cohort of T-ALL patients. Nelarabine was demonstrated in the trial to improve disease-free survival at 4 years and to reduce the risk of CNS relapses. The smaller subset of patients with advanced LBL did not have a benefit demonstrated to nelarabine, but this subset was underpowered, and most U.S. centers are now including nelarabine in the up-front treatment of all T-LBL patients.

Anaplastic Large Cell Lymphoma

For patients who present with localized disease, surgical resection alone is sufficient. The majority of patients, however, have advanced disease, which requires multiagent chemotherapy. Various chemotherapy regimens have been studied, with similar outcomes and survival of 70–79%. CNS prophylaxis consists of intrathecal chemotherapy, although this may be omitted with the substitution of high-dose methotrexate.

Two novel targeted agents have shown substantial promise in early-phase trials in ALCL. The CD30 antibody–drug conjugate **brentuximab vedotin** and the ALK inhibitor **crizotinib** both have impressive activity and minimal toxicity in patients with relapsed ALCL. A trial piloted the addition of brentuximab vedotin in newly diagnosed advanced ALCL patients with impressive 2-year EFS of 79% and OS of 97% among ~70 patients. There were no toxic deaths with combination brentuximab and chemotherapy and no severe neurotoxicity.

Relapsed Non-Hodgkin Lymphoma

Patients with NHL in whom progressive or relapsed disease develops require reinduction chemotherapy and may require either allogeneic or autologous SCT. A notable exception is ALCL, where low-dose approaches such as prolonged vinblastine have been efficacious for some patients. The specific reinduction regimen or transplantation type depends on the pathologic subtype, previous therapy, site of reoccurrence, and stem cell donor availability. Novel reinduction approaches are being investigated, including a type II CD20 antibody, *obinutuzumab,* alone and in combination with chemotherapy, *ibrutinib,* a BTK inhibitor alone and in combination with chemotherapy, and *idelalisib,* a PI3K delta inhibitor alone and in combination with chemotherapy. Although there are no randomized trials examining autologous versus allogeneic SCT for relapsed NHL, data from retrospective studies suggest that outcomes are similar, with the exception of LBL and ALCL, for which allogeneic SCT is superior, perhaps because of a graft versus lymphoma effect.

Native (autologous) patient T cells have been genetically manipulated to produce a T-cell vs leukemia or lymphoma response. Tisagenlecleucel (Kymriah) is a CD19-directed genetically modified autologous T-cell immunotherapy first approved for patients under 25 years with precursor B-ALL. The immunotherapy has been approved in adults with relapsed mature DLBCL after two prior lines of systemic therapy. An additional CD19-directed immunotherapy, axicabtagene ciloleucel, has been approved for recurrent adult mature B-NHL. The responses have been less impressive in adult DLBL to those seen in childhood adolescent and young adult ALL, but continued work with different target antigens and genetic manipulation of the constructs is ongoing. These T-cell–modified products, although autologous, can lead to a cytokine release syndrome and CNS toxicities that can be severe.

Because relapsed NHL can be difficult to treat, efforts have been made to identify patients at higher risk of relapse to tailor initial therapy. The measurement of **minimal residual disease** may serve as a prognostic marker and aid in risk stratification. Minimal residual disease is prognostic in ALCL and LBL. In ALCL, there is also evidence that a humoral response to the ALK kinase can be used to predict outcome, with a superior outcome in patients who mount an antibody titer to ALK.

COMPLICATIONS

Patients receiving multiagent chemotherapy for advanced disease are at acute risk for mucositis, infections, cytopenias that require red blood cell and platelet blood product transfusions, electrolyte imbalances, and poor nutrition. Long-term complications include the risk of growth retardation, cardiac toxicity, gonadal toxicity with infertility, and secondary malignancies.

PROGNOSIS

The prognosis is excellent for most forms of childhood and adolescent NHL (see Table 545.5). Patients with localized disease have a 90–100% survival rate, and those with advanced disease have an 80–95% survival rate. Because outcomes for pediatric patients with NHL have improved substantially, the focus has now shifted to minimizing the *long-term toxicity of therapy.* Novel targeted agents are desirable because they have the potential to improve outcomes and decrease the reliance on toxic conventional chemotherapy. An ongoing multi-institutional study is testing the reduction of anthracycline to decrease short-term (mucositis) and long-term (cardiac health) complications of therapy by incorporation of immunotherapy in mature B-NHL, with promising results to date.

545.3 Late Effects in Children and Adolescents with Lymphoma

Jessica Hochberg, Stanton C. Goldman, and Mitchell S. Cairo

The majority of patients with newly diagnosed HL and NHL have OS rates >90%. There are approximately 270,000 survivors of childhood cancer in the United States, or about one of every 640 adults between ages 20 and 40. However, this survival has often been achieved at the expense of an increased relative risk of long-term complications, including solid tumors, leukemia, cardiac disease, pulmonary complications, thyroid disease, and infertility. An analysis of >1,000 long-term childhood NHL survivors found increased rates of death >20 years after treatment. A review of the National Cancer Institute Surveillance, Epidemiology, and End Results data over a 25-year follow-up demonstrates that the relative survival curves do not plateau after 10 years following diagnosis of HL, but rather accelerate. This finding highlights the importance of late morbidity and mortality among survivors of lymphoma. The incidence of Grade 3-5 adverse health conditions is >15% in adult survivors of childhood HL treated with chemoradiotherapy regimens. Radiation therapy has been shown to further compound the risk for late mortality, obesity, and organ dysfunction with worsening effects on cardiovascular, pulmonary, and thyroid function. The first **Childhood Cancer Survivor Study**, a retrospective cohort study of 10,397 cancer survivors, shows that 62.3% of survivors report at least one chronic condition, with 27.5% reporting severe or life-threatening conditions. The survivor's adjusted relative risk of a severe or life-threatening chronic condition, compared with that of a sibling, was 8.2 (95% confidence interval, 6.9-9.7). Studying disease-specific health outcomes, both HL and NHL were found to be associated with a cumulative incidence of chronic health conditions **approaching 70–80%, with severe conditions reported in ~50% of HL survivors** (Fig. 545.8).

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

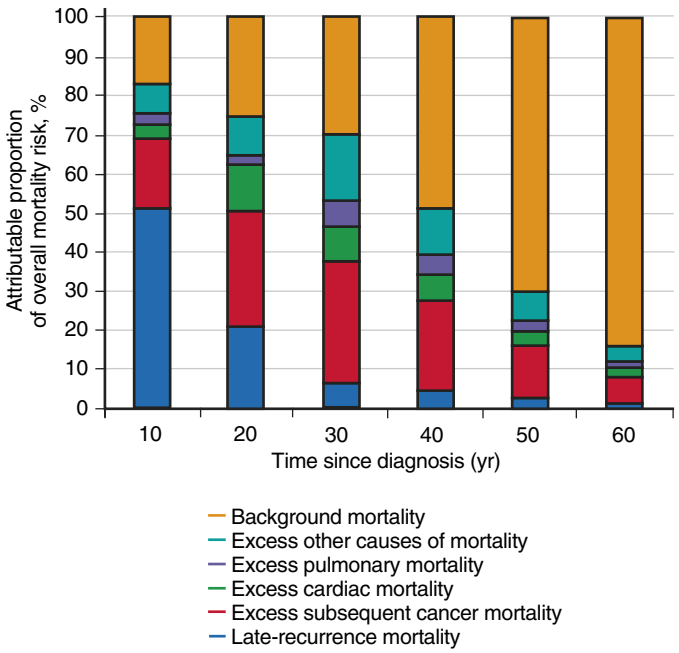

Fig. 545.8 Percentage of attributable proportions of overall mortality risk in survivors of childhood cancer. *(Adapted from Yeh JM, Nekhlyudov L, Goldie SJ, et al. A model-based estimate of cumulative excess mortality in survivors of childhood cancer. Ann Intern Med. 2010;152[7]:409– 417.)*

Chapter 546

Central Nervous System Tumors in Childhood

Wafik Zaky

Primary central nervous system (CNS) tumors are a heterogeneous group of diseases that are, collectively, the most common malignancy in childhood and adolescence. The overall mortality among this group approaches 30%. Patients with CNS tumors have the highest morbidity, primarily neurologic, of all children with malignancies. Outcomes have improved with innovations in neurosurgery, imaging, and radiation therapy as well as the introduction of chemotherapy and biologic agents as a therapeutic modality. The treatment approach for the majority of these tumors is multimodal. Surgery with complete resection, if feasible, is the foundation, with radiation therapy and chemotherapy utilized according to the diagnosis, patient age, and other factors.

ETIOLOGY

The etiology of pediatric CNS tumors is not well defined. An overall female predominance exists in the incidence of CNS tumors, but male predominance is noted in the incidence of high-grade tumors like glioblastoma multiforme, medulloblastoma, and ependymoma. Familial syndromes associated with an increased incidence of brain tumors account for approximately 5% of cases (Table 546.1). Cranial exposure to ionizing radiation also is associated with a higher incidence of CNS tumors. There are sporadic reports of CNS tumors within families without evidence of a heritable syndrome.

EPIDEMIOLOGY

Approximately 5,550 primary brain tumors are diagnosed each year in children and adolescents in the United States, with an average annual age adjusted incidence rate of 5.65 per 100,000 population. It is the most common cancer in patients 0-14 years of age and the leading cause of cancer-related death in this age-group.

PATHOGENESIS

More than 100 histologic categories and subtypes of primary brain tumors are described in the World Health Organization (WHO) classification of tumors of the CNS. In children 0-14 years of age, the most common tumors are pilocytic astrocytomas (PAs) and embryonal tumors (i.e., medulloblastoma/primitive neuroectodermal tumors [PNETs]). In adolescents (15-19 years), the most common tumors are pituitary/craniopharyngeal tumors and PAs (Fig. 546.1).

There is a slight predominance of infratentorial tumor location (43.2%), followed by the supratentorial region (40.9%), spinal cord (4.9%), and multiple sites (11%) (Fig. 546.2, Table 546.2). There are age-related differences in the primary location of tumor. During the first year of life, supratentorial tumors predominate and include, most commonly, choroid plexus complex tumors and germ cell tumors. In children 1-10 years of age, infratentorial tumors predominate, due to the high incidence of juvenile PA and medulloblastoma. After 10 years of age, supratentorial tumors predominate, with diffuse astrocytomas (DAs) most common. Tumors of the optic pathway and hypothalamus region, the brainstem, and the pineal–midbrain region are more common in children and adolescents than in adults. Additionally, some tumors are more common in males (astrocytic and germ cell tumors), whereas meningioma and craniopharyngiomas are more common in females. Malignant tumors are more common in White children (embryonal and astrocytic neoplasms), whereas low-grade tumors are more common in Black children (meningiomas and craniopharyngiomas).

545.3 Late Effects in Children and Adolescents with Lymphoma

Jessica Hochberg, Stanton C. Goldman, and Mitchell S. Cairo

The majority of patients with newly diagnosed HL and NHL have OS rates >90%. There are approximately 270,000 survivors of childhood cancer in the United States, or about one of every 640 adults between ages 20 and 40. However, this survival has often been achieved at the expense of an increased relative risk of long-term complications, including solid tumors, leukemia, cardiac disease, pulmonary complications, thyroid disease, and infertility. An analysis of >1,000 long-term childhood NHL survivors found increased rates of death >20 years after treatment. A review of the National Cancer Institute Surveillance, Epidemiology, and End Results data over a 25-year follow-up demonstrates that the relative survival curves do not plateau after 10 years following diagnosis of HL, but rather accelerate. This finding highlights the importance of late morbidity and mortality among survivors of lymphoma. The incidence of Grade 3-5 adverse health conditions is >15% in adult survivors of childhood HL treated with chemoradiotherapy regimens. Radiation therapy has been shown to further compound the risk for late mortality, obesity, and organ dysfunction with worsening effects on cardiovascular, pulmonary, and thyroid function. Cranial exposure to ionizing radiation also is associated with a higher incidence of CNS tumors. There are sporadic reports of CNS tumors within families without evidence of a heritable syndrome.

EPIDEMIOLOGY

Approximately 5,550 primary brain tumors are diagnosed each year in children and adolescents in the United States, with an average annual age adjusted incidence rate of 5.65 per 100,000 population. It is the most common cancer in patients 0-14 years of age and the leading cause of cancer-related death in this age-group.

PATHOGENESIS

More than 100 histologic categories and subtypes of primary brain tumors are described in the World Health Organization (WHO) classification of tumors of the CNS. In children 0-14 years of age, the most common tumors are pilocytic astrocytomas (PAs) and embryonal tumors (i.e., medulloblastoma/primitive neuroectodermal tumors [PNETs]). In adolescents (15-19 years), the most common tumors are pituitary/craniopharyngeal tumors and PAs (Fig. 546.1).

There is a slight predominance of infratentorial tumor location (43.2%), followed by the supratentorial region (40.9%), spinal cord (4.9%), and multiple sites (11%) (Fig. 546.2, Table 546.2). There are age-related differences in the primary location of tumor. During the first year of life, supratentorial tumors predominate and include, most commonly, choroid plexus complex tumors and germ cell tumors. In children 1-10 years of age, infratentorial tumors predominate, due to the high incidence of juvenile PA and medulloblastoma. After 10 years of age, supratentorial tumors predominate, with diffuse astrocytomas (DAs) most common. Tumors of the optic pathway and hypothalamus region, the brainstem, and the pineal–midbrain region are more common in children and adolescents than in adults. Additionally, some tumors are more common in males (astrocytic and germ cell tumors), whereas meningioma and craniopharyngiomas are more common in females. Malignant tumors are more common in White children (embryonal and astrocytic neoplasms), whereas low-grade tumors are more common in Black children (meningiomas and craniopharyngiomas).

Table 546.1 Familial Syndromes Associated with Pediatric Brain Tumors

SYNDROME	CENTRAL NERVOUS SYSTEM MANIFESTATIONS	CHROMOSOME	GENE
Neurofibromatosis type 1 (autosomal dominant)	Optic pathway gliomas, astrocytoma, malignant peripheral nerve sheath tumors, neurofibromas	17q11	*NF1*
Neurofibromatosis type 2 (autosomal dominant)	Vestibular schwannomas, meningiomas, spinal cord ependymoma, spinal cord astrocytoma, hamartomas	22q12	*NF2*
von Hippel-Lindau (autosomal dominant)	Hemangioblastoma	3p25-26	*VHL*
Tuberous sclerosis (autosomal dominant)	Subependymal giant cell astrocytoma, cortical tubers	9q34 16q13	*TSC1* *TSC2*
Li-Fraumeni (autosomal dominant)	Astrocytoma, primitive neuroectodermal tumor	17q13	*TP53*
Cowden (autosomal dominant)	Dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos disease)	10q23	*PTEN*
Turcot (autosomal dominant)	Medulloblastoma	5q21	*APC*
	Glioblastoma	3p21 7p22	*hMLH1* *hPSM2*
Nevoid basal cell carcinoma Gorlin (autosomal dominant)	Medulloblastoma	9q31	*PTCH1*

ATRT, Atypical teratoid rhabdoid tumor; NOS, not otherwise specified; PNET, primitive neuroectodermal tumor. *(From Ostrom QT, Patil N, Cioffi G, et al. CBTRUS Statistical Report: Primary Brain and Other Central Nervous System Tumors Diagnosed in the United States in 2013-2017. Neuro Oncol. 2020;30;22:iv1–iv96.)*

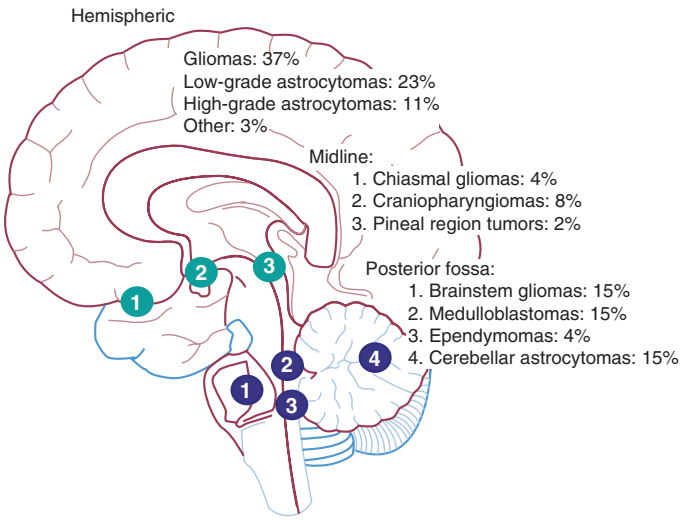

Fig. 546.2 Childhood brain tumors occur at any location within the central nervous system. The relative frequency of brain tumor histologic types and the anatomic distribution are shown. *(Redrawn from Albright AL. Pediatric brain tumors. CA Cancer J Clin 1993;43:272–288.)*

CLINICAL MANIFESTATIONS

The clinical presentation of the patient with a brain tumor depends on the tumor location, the tumor type, and the age of the child. Signs and symptoms are related to obstruction of cerebrospinal fluid (CSF) drainage paths by the tumor, leading to **increased intracranial pressure (ICP)** or causing focal brain dysfunction. In young children, the diagnosis of a brain tumor may be delayed because the symptoms are similar to those of more common illnesses, such as gastrointestinal disorders, with associated vomiting. Infants with open cranial sutures may present with signs of increased ICP, such as vomiting, lethargy, and irritability, as well as the later finding of macrocephaly. The **classic triad** of headache, nausea, and vomiting as well as papilledema is associated with midline or infratentorial tumors. Disorders of equilibrium, gait, and coordination occur with infratentorial tumors. **Torticollis** may occur in cases of cerebellar tonsil herniation. Blurred vision, diplopia, and nystagmus also are associated with infratentorial tumors. Tumors of the brainstem region may be associated with gaze palsy, multiple cranial nerve palsies, and upper motor neuron deficits (e.g., hemiparesis, hyperreflexia, and clonus). **Supratentorial tumors** are more commonly associated with focal motor weakness, focal sensory changes, language disorders, focal seizures, and reflex asymmetry. Infants with supratentorial tumors may present

Table 546.2 Posterior Fossa Tumors of Childhood

TUMOR	RELATIVE INCIDENCE (%)	PRESENTATION	DIAGNOSIS	PROGNOSIS
Medulloblastoma	35-40	2-3 mo of headaches, vomiting, truncal ataxia	Heterogeneously or homogeneously enhancing fourth ventricular mass; may be disseminated	65–85% survival; dependent on stage/type; poorer (20–70%) in infants
Cerebellar astrocytoma	35-40	3-6 mo of limb ataxia; secondary headaches, vomiting	Cerebellar hemisphere mass, usually with cystic and solid (mural nodule) components	90–100% survival in totally resected pilocytic type
Brainstem glioma	10-15	1-4 mo of double vision, unsteadiness, weakness, and cranial nerve dysfunction, including facial weakness, swallowing dysfunction, and oculomotor abnormalities	Diffusely expanded, minimally or partially enhancing mass in 80%; 20% more focal tectal or cervicomedullary lesion	>90% mortality in diffuse tumors; better in localized
Ependymoma	10-15	2-5 mo of unsteadiness, headaches, double vision, and facial asymmetry	Usually enhancing, fourth ventricular mass with cerebellopontine predilection	>75% survival in totally resected lesions
Atypical teratoid/rhabdoid	5–10% of infantile malignant tumors	As in medulloblastoma, but primarily in infants; often associated facial weakness and strabismus	As in medulloblastoma, but often more laterally extended	≤20% survival in infants

Modified from Packer RJ, MacDonald T, Vezina G. Central nervous system tumors. *Pediatr Clin North Am.* 2008;55:121–145.

with premature hand preference. **Optic pathway tumors** manifest as visual and/or afferent oculomotor disturbances, such as decreased visual acuity, Marcus Gunn pupil (afferent pupillary defect), nystagmus, and/or visual field defects. Suprasellar region tumors and third ventricular region tumors may manifest initially as **neuroendocrine deficits,** such as subacute development of obesity, abnormal linear growth velocity, diabetes insipidus, galactorrhea, precocious puberty, delayed puberty, and hypothyroidism. In fact, signs of endocrine dysfunction preceded symptoms of neuroophthalmologic dysfunction by an average of 1.9 years, and their recognition as a possible sign of hypothalamic or pituitary neoplasm can hasten diagnosis and improve outcome. The **diencephalic syndrome,** which manifests as failure to thrive but normal linear growth, emaciation despite normal caloric intake, and inappropriately normal or happy (euphoric) affect, occurs in infants and young children with tumors (most often low-grade hypothalamic or thalamic glioma). **Parinaud syndrome** is seen with pineal region tumors and is manifested by paresis of upward gaze, pupillary caliber reactive to accommodation but not to light (pseudo-Argyll Robertson pupil), nystagmus to convergence or retraction, and eyelid retraction. **Spinal cord tumors** and spinal cord dissemination of brain tumors may manifest as long nerve tract motor and/or sensory deficits often localized to below a specific spinal level, bowel and bladder deficits, resistance to back flexion, scoliosis, bowel and bladder dysfunction, and back or radicular pain. The signs and symptoms of meningeal metastatic disease from brain tumors or leukemia include head or back pain and symptoms referable to compression of cranial nerves or spinal nerve roots.

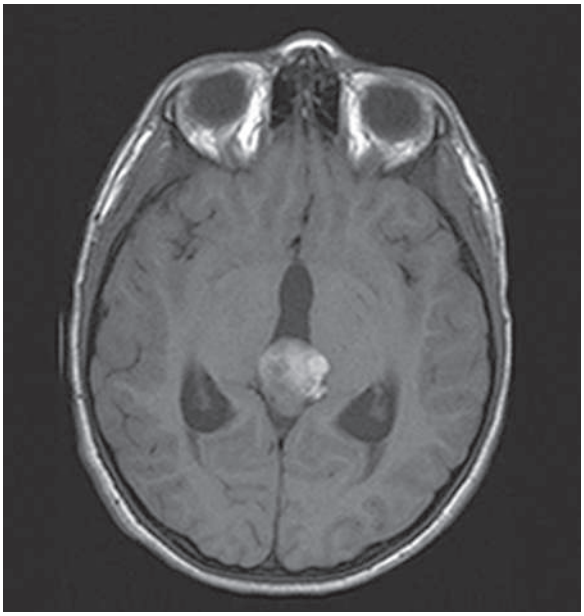

Fig. 546.3 Axillary T1 weighted MR image with gadolinium of a 10-yr-old male presenting with **mixed germ cell tumor** of the pineal region, with early onset of puberty, headaches, and elevated α-fetoprotein and β-human chorionic gonadotropin in the spinal fluid and serum.

DIAGNOSIS

The evaluation of a patient when a CNS tumor is suspected is an emergency. Initial evaluation should include a complete history (including endocrine), physical (including ophthalmic) examination, and full neurologic assessment with neuroimaging. For primary brain tumors, **MRI** with and without gadolinium is the neuroimaging standard. Tumors in the pituitary/suprasellar region, optic pathway, and infratentorium are better delineated with MRI than with CT. Patients with tumors of the midline and the pituitary/suprasellar/optic chiasmal region should undergo evaluation for **neuroendocrine dysfunction.** Formal ophthalmologic examination is beneficial in patients with optic path region tumors to document the impact of the disease on oculomotor function, visual acuity, and fields of vision. The suprasellar and pineal regions are preferential sites for germ cell tumors (Fig. 546.3). Both serum and CSF measurements of β-**human chorionic gonadotropin** and α-**fetoprotein** can assist in the diagnosis of germ cell tumors. In tumors with a propensity for spreading to the leptomeninges, such as medulloblastoma/PNET, ependymoma, and germ cell tumors, lumbar puncture with cytologic analysis of the CSF is indicated; lumbar puncture is contraindicated in individuals with newly diagnosed hydrocephalus secondary to CSF flow obstruction, in tumors that cause supratentorial midline shift, and in individuals with

infratentorial tumors. Lumbar puncture in these individuals may lead to brain herniation, resulting in neurologic compromise and death. Therefore, in children with newly diagnosed intracranial tumors and signs of increased ICP, the lumbar puncture usually is delayed until surgery or shunt placement.

SPECIFIC TUMORS

Astrocytoma

Astrocytomas are a heterogeneous group of tumors that account for approximately 40% of pediatric CNS malignancies. These tumors occur throughout the CNS.

Low-grade astrocytomas (LGAs), the predominant group of astrocytomas in childhood, are characterized by an indolent clinical course. **PA** is the most common astrocytoma in children, accounting for approximately 15.2% of all brain tumors (Fig. 546.4). Based on clinicopathologic features using the WHO Classification System, PA is classified as a WHO grade I tumor. Although PA can occur anywhere in the CNS, the classic sites are the **cerebellum followed by the optic pathway region** (Fig. 546.5A-B). The classic but not exclusive neuroradiologic finding in PA is the presence of a contrast-enhancing nodule within the wall of a cystic mass (Fig. 546.5A). The microscopic findings include the biphasic appearance of bundles of compact fibrillary tissue interspersed with loose microcystic, spongy areas. The presence of **Rosenthal fibers,** which are condensed masses of glial filaments occurring in the compact areas, with low mitotic potentials helps establish the diagnosis. A small proportion of these tumors can progress and develop leptomeningeal spread, particularly in the optic path region and very rarely transform to higher grade aggressive type. A PA of the optic nerve and chiasmal region is a relatively common finding in patients with neurofibromatosis type 1 (15% incidence). Molecularly, PA has activation of the **MAPK** pathway in the form of **BRAF** fusion or duplication and less commonly BRAF pathogenic variant (V600E) (see Fig. 546.4). Other low-grade tumors occurring in the pediatric age-group with clinic pathologic characteristics similar to PA include pleomorphic xanthoastrocytoma, pilomyxoid astrocytoma, and subependymal giant cell astrocytoma.

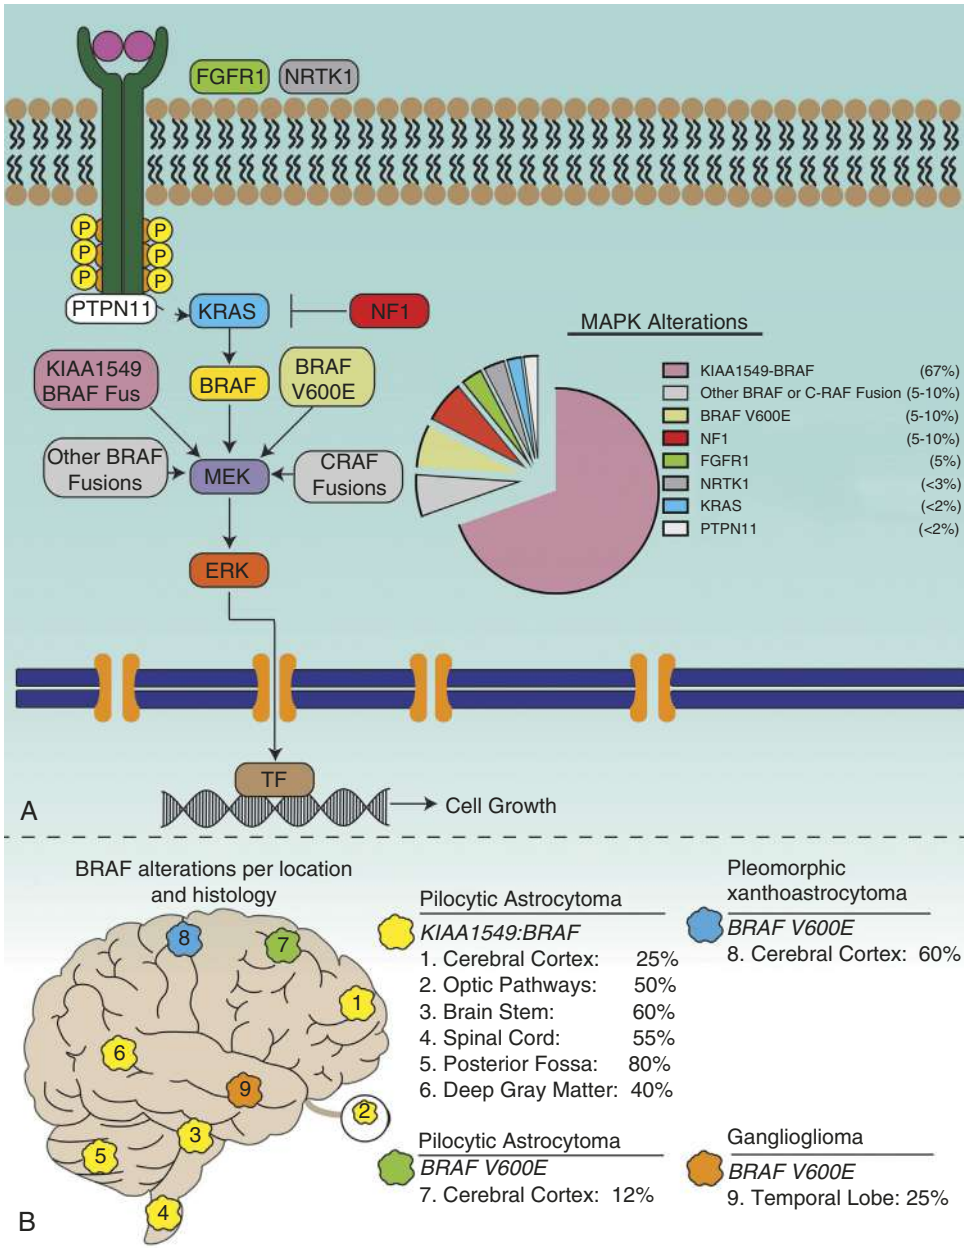

Fig. 546.4 A, Schematic of the frequency of MAPK pathway alterations detected by biopsy of pilocytic astrocytomas. This underestimates the frequency of NF1 pathogenic variants among children with low-grade gliomas (LGGs) because the tumors in patients affected by NF1 often do not undergo biopsy. Although BRAF fusions (BRAF Fus) constitute the majority of alterations in pilocytic astrocytoma, BRAF pathogenic variants are more commonly observed in pleomorphic xanthoastrocytomas and gangliogliomas. B, Frequency of the different BRAF abnormalities as a function of tumor location and histological diagnosis. *(From Pollack IF, Agnihotri S, Broniscer A. Childhood brain tumors: current management, biological insights, and future directions. J Neurosurg Pediatr. 2019;23:261–273. Fig. 1.)*

The second most common astrocytoma is **DA,** which consists of a group of tumors characterized by a pattern of diffuse infiltration of tumor cells amidst normal neural tissue. Histologically, these low-grade tumors demonstrate greater cellularity, with few mitotic figures, nuclear pleomorphism, and microcysts. They occur anywhere in the CNS with predilection to supratentorial location. The characteristic MRI finding is a lack of enhancement after contrast agent infusion. Molecular genetic abnormalities found in DA include pathogenic variants of *P53* and overexpression of platelet-derived growth factor receptor-α. Evolution of DA into malignant astrocytoma is associated with cumulative acquisition of multiple molecular abnormalities. Overactivation of the MAPK pathway has been detected in DA in the form of the ***BRAF V600E*** pathogenic variant and **FGFR1** duplication.

Pilomyxoid astrocytoma occurs most commonly in the hypothalamic/optic chiasmic region and carries a high risk of local as well as cerebrospinal spread. This astrocytoma affects young children and infants. It is classified as a WHO grade II tumor.

The clinical management of LGAs focuses on a multimodal approach incorporating surgery if feasible as the primary treatment as well as radiation therapy and chemotherapy. With complete surgical resection, the overall survival approaches 80–100%. In patients with partial resection, overall survival varies from 50–95%, depending on the anatomic location of the tumor. In the patient who has undergone partial tumor resection and has stable neurologic status, the current approach is to follow the patient closely by examination and imaging. With evidence of progression, a second surgical resection should be considered. In patients in whom a second procedure was less than complete or is not feasible, radiation therapy is beneficial. Radiation therapy is delivered to the tumor bed at a total cumulative dose ranging from 50-55 Gy. Modern surgical techniques and innovative radiation therapy methodology, *including proton-beam radiation,* may have a positive impact on the survival and clinical outcome of these patients. Chemotherapy for LGAs has become the standard of care for progressive LGAs. Because of concerns regarding morbidity from radiation therapy in young children, several chemotherapy approaches have been evaluated, especially in children younger than 10 years of age. Complete response to chemotherapy is uncommon; however, these approaches have yielded durable control of disease in 70–100% of patients with clinical improvement. Patients with midline tumors in the hypothalamic/optic chiasmatic region (see Fig. 546.5B) have tended to do less well. The chemotherapy approaches have permitted delay and, potentially, avoidance of radiation therapy. Chemotherapy agents given singly or in combination for LGA include carboplatin, vincristine, lomustine, procarbazine, temozolomide, and vinblastine. Observation is the primary approach in clinical management of selected patients with LGAs that are biologically indolent (neurofibromatosis type 1 and tectal gliomas and indolent LGA variants like angiocentric gliomas). *Astrocytomas associated with tuberous sclerosis have responded to everolimus, a mammalian target of rapamycin inhibitor.*

Malignant astrocytomas are less common in children and adolescents than in adults, accounting for 7–10% of all childhood brain tumors. Among this group, **anaplastic astrocytoma** (WHO grade III; Fig. 546.6) is more common than **glioblastoma multiforme** (WHO grade IV). The histopathology of anaplastic astrocytomas demonstrates greater cellularity than that of LGA, with cellular and nuclear atypia, and the presence of mitoses. Characteristic histopathologic findings in glioblastoma multiforme include dense cellularity, high mitotic index, microvascular proliferation, and foci of tumor necrosis with pseudopalisading. Genome-wide DNA methylation patterns have identified five molecular subgroups of pediatric high-grade glioma. These subgroups appear to have distinct cellular origins and biological drivers. Common genetic alterations include gene pathogenic variants in ***histone H3.3*** or ***H3.1, p53,*** and ***BRAF*** in addition to focal amplifications of oncogene (***PDGFRA*** and ***EGFR***) and deletions of tumor-suppressor genes ***(CDKN2A, CDKN2B, PTEN).***

Optimal therapeutic approaches for malignant astrocytomas have yet to be defined. Standard therapy continues to be surgical resection followed by involved-field radiation therapy with evolving role of maintenance alkylator chemotherapy (temozolomide ± lomustine). A study of adult glioblastoma showed significantly better survival with temozolomide during and after irradiation than with irradiation alone. Current therapeutic approaches incorporate novel chemotherapeutic agents with radiation therapy.

Oligodendrogliomas are uncommon tumors of childhood. These infiltrating tumors occur predominantly in the cerebral cortex and originate in the white matter. Histologically, oligodendrogliomas consist of rounded cells with little cytoplasm and microcalcifications. Observation of a **calcified cortical mass** on CT in a patient presenting with a seizure is suggestive of oligodendroglioma. The definition of oligodendroglioma requires two diagnostic genotypic features: pathogenic gene variants in isocitrate dehydrogenase (IDH) and the co-deletions of the short arm of chromosome 1 (1p) and the long arm of chromosome 19 (19q). Treatment approaches are similar to those for infiltrating astrocytomas.

Ependymal Tumors

Ependymal tumors are derived from the ependymal lining of the ventricular system. Cellular ependymoma (WHO grade II) is the most common of these neoplasms, accounting for 5% of childhood CNS tumors. Approximately 70% of ependymomas in childhood occur in the posterior fossa. The mean age of patients is 6 years, with approximately

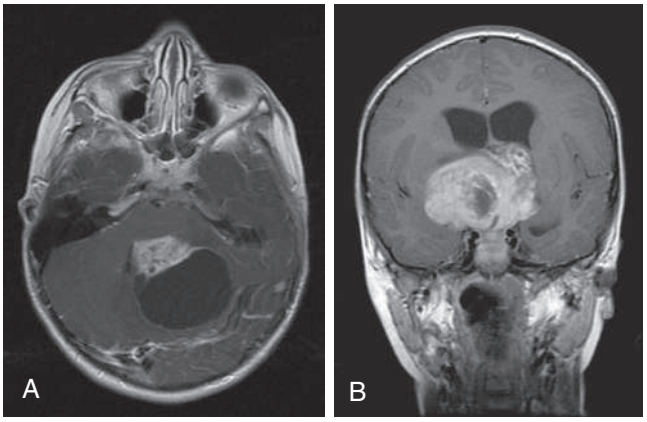

Fig. 546.5 A, Gadolinium-enhanced axial T1-weighted MR image in a 4-yr-old child with cerebellar **pilocytic astrocytoma** presenting with headaches, emesis, and ataxia demonstrates a predominantly cystic mass with enhancement of the solid component and enhancement of the capsule. B, Gadolinium-enhanced coronal view of a cystic juvenile pilocytic astrocytoma of the suprasellar region from a 4-yr-old child presenting with visual loss and headaches.

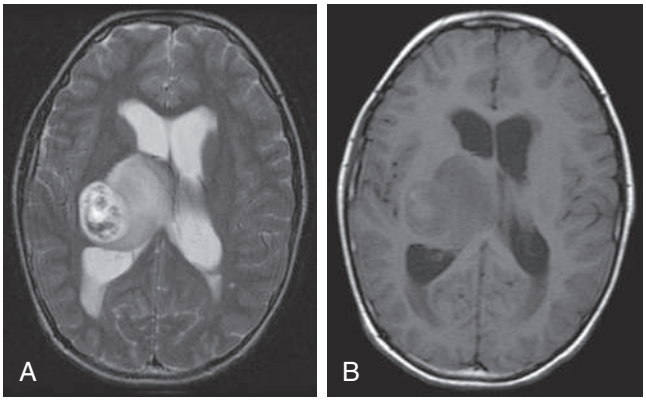

Fig. 546.6 A, Nonenhanced axial T2-weighted MR image of **grade III astrocytoma** of the right thalamus demonstrating diffuse hyperintensity and area of necrotic cyst formation. B, Gadolinium-enhanced sagittal T1-weighted MR image showing slight enhancement and hypodensity of **grade III astrocytoma** of the thalamus. This 14-yr-old child presented with left arm and leg numbness and weakness and right-sided headaches.

40% of cases occurring in children younger than 4 years of age. The incidence of leptomeningeal spread approaches 10% overall. Clinical presentation can be insidious and often depends on the anatomic location of the tumor. MRI demonstrates a well-circumscribed tumor with variable and complex patterns of gadolinium enhancement, with or without cystic structures (Fig. 546.7). These tumors usually are noninvasive, extending into the ventricular lumen and/or displacing normal structures, sometimes leading to significant obstructive hydrocephalus. Histologic characteristics include perivascular pseudorosettes, ependymal rosettes, monomorphic nuclear morphology, and occasional nonpalisading foci of necrosis. Other histologic subtypes include **anaplastic ependymoma** (WHO grade III), which is much less common in childhood and is characterized by a high mitotic index and histologic features of microvascular proliferation and pseudopalisading necrosis. **Myxopapillary ependymoma** (WHO grade II) is a slow-growing tumor arising from the filum terminale and conus medullaris and appears to be a biologically different subtype. Preliminary studies suggest that there are genetically distinct subtypes of ependymoma, exemplified by an association between alterations in the ***NF2*** gene and spinal ependymoma. Surgery is the primary treatment modality, with extent of surgical resection a major prognostic factor. Two other major prognostic factors are age, with younger children having poorer outcomes, and tumor location, with localization in the posterior fossa, which often is seen in young children, associated with poorer outcomes. Surgery alone is rarely curative. Multimodal therapy incorporating irradiation with surgery has resulted in long-term survival in approximately 40% of patients with ependymoma undergoing gross total resection. Recurrence is predominantly local. The role of chemotherapy in multimodal therapy of ependymoma is still unclear. Current investigations are directed toward identification of optimal radiation dose, surgical questions addressing the use of second-look procedures after chemotherapy, and further evaluation of classic as well as novel chemotherapeutic agents. Genome-wide DNA methylation patterns have identified nine molecular subgroups in these tumors across three anatomic compartments including supratentorial (ST), posterior fossa (PF), and the spinal locations (Fig. 548.8). Two subgroups (group A and B) of PF ependymoma have been identified with distinct molecular and clinical characteristics, and the use of targeted chemotherapy against these subtypes is being evaluated.

Choroid Plexus Tumors

Choroid plexus tumors account for 2–4% of childhood CNS tumors. They are the most common CNS tumors in children younger than 1 year of age and account for 10–20% of CNS tumors in infants. These tumors are intraventricular epithelial neoplasms arising from the choroid plexus. Children present with signs and symptoms of increased ICP. Infants may present with macrocephaly and focal neurologic deficits. In children, these tumors predominantly occur supratentorially in the lateral ventricles. The group of choroid plexus tumors is made up of **choroid plexus papillomas** (WHO grade I), **atypical choroid plexus papillomas** (WHO grade II), and **choroid plexus carcinomas** (WHO grade III). Choroid plexus papilloma, the *most common of this group*, is a well-circumscribed lesion with focal calcification on neuroimaging. *Choroid plexus carcinoma* is a malignant tumor with metastatic potential to seed into the CSF pathways. This malignancy has the following histologic characteristics: nuclear pleomorphism, high mitotic index, necrosis, and increased cell density. MRI typically demonstrates a large, hyperdense, contrast-enhancing, intraventricular mass with peritumoral edema, hemorrhage, and hydrocephalus. The tumor suppressor p53 is crucially involved in the biology of this cancer and may contribute to aggressive tumor behavior. Molecular data subclassify choroid plexus tumors into three distinct subgroups with different molecular aberrations and clinical outcomes. These tumors are associated with the Li-Fraumeni syndrome. After complete surgical resection, the frequency of cure for choroid plexus *papilloma* approaches 100%, whereas the frequency of cure for choroid plexus *carcinoma* approaches 20–40%. Reports suggest that radiation therapy and/or chemotherapy may lead to better disease control for choroid plexus carcinoma.

Embryonal Tumors

Embryonal tumors or **primitive neuroectodermal tumors (PNETs)** are one of the most common groups of *malignant* CNS tumors of childhood, accounting for approximately 9% of pediatric CNS tumors. They have the potential to metastasize to the neuraxis and extracranial tissues. The group includes medulloblastoma, supratentorial PNET, atypical teratoid/rhabdoid tumor, and other rare embryonal tumors, all of which are histologically classified as WHO grade IV tumors.

Medulloblastoma, which accounts for ~62% of embryonal CNS tumors, is a cerebellar tumor occurring predominantly in males and at a median age of 5-7 years. CT and MRI demonstrate a solid, homogeneous, contrast medium–enhancing mass in the PF causing fourth ventricular obstruction and hydrocephalus (Fig. 546.9). Up to 30% of patients with medulloblastoma present with neuroimaging evidence of leptomeningeal spread. Among a variety of diverse histologic patterns of this tumor, the most common is a monomorphic sheet of undifferentiated cells classically noted as small, blue round cells. Neuronal differentiation is more common among these tumors and is characterized

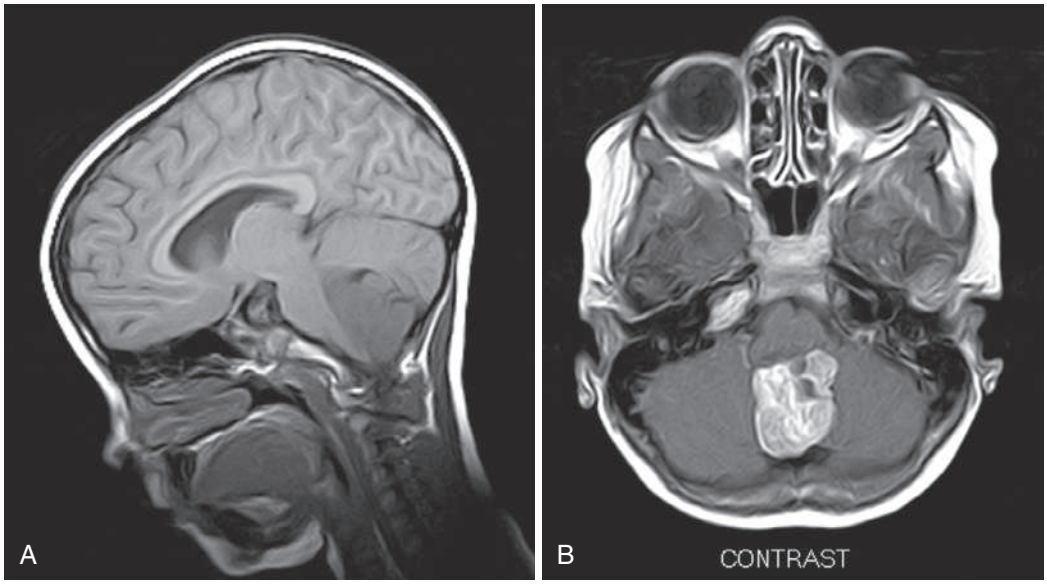

Fig. 546.7 A, Sagittal T1-weighted MR image of a 6-yr-old patient with **ependymoma**, demonstrating a hypointense mass within the fourth ventricle compressing the brainstem. B, Gadolinium-enhanced axial T1-weighted image of an ependymoma showing an enhancing mass within the fourth ventricle.

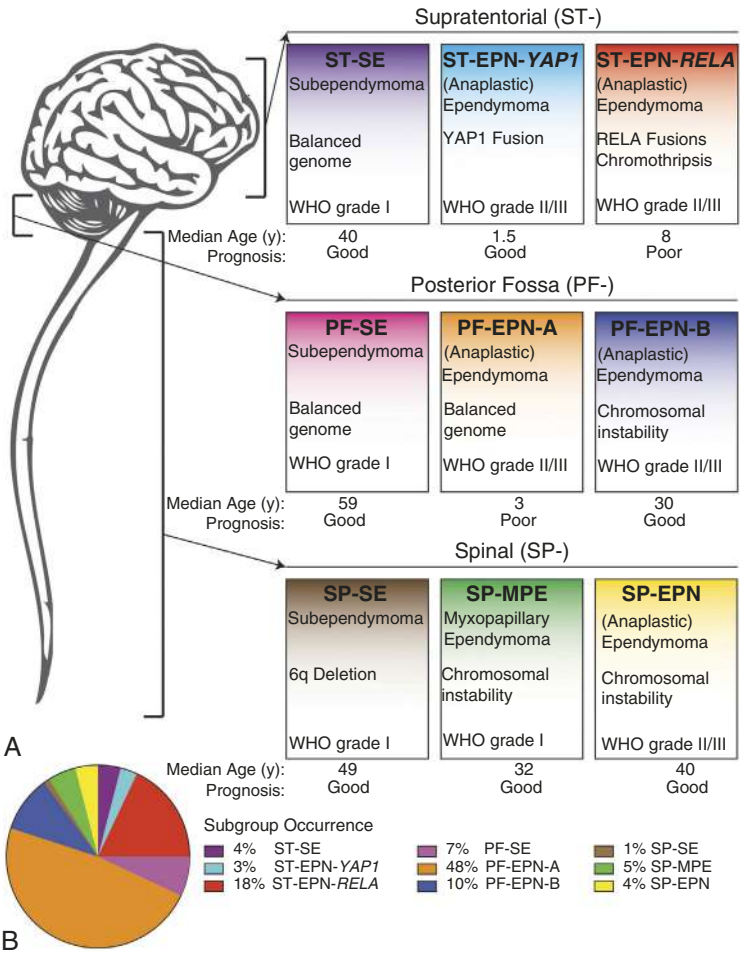

Fig. 546.8 A, Illustration of the nine recognized subsets of **ependymomas**. Only four of these subsets (ST-EPN-YAP1, ST-EPN-RELA, PF-EPN-A, and PF-EPN-B) typically occur during the childhood years. The subependymoma (SE) groups typically affect middle-age or older adults, and the spinal lesions, although occasionally encountered in children, are largely seen in adults. B, Estimate of the overall frequency of the different subtypes of ependymomas. *(From Pollack IF, Agnihotri S, Broniscer A. Childhood brain tumors: current management, biological insights, and future directions. J Neurosurg Pediatr. 2019;23:261–273. Fig. 3.)*

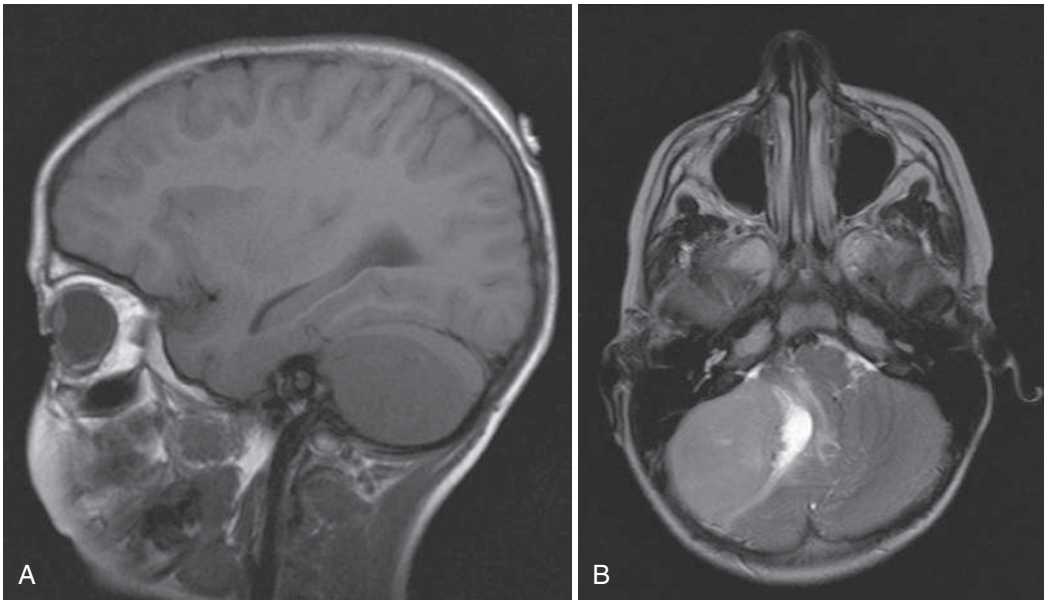

Fig. 546.9 A, Sagittal T1-weighted MR image shows hypointense mass involving the cerebellar hemisphere in a 6-yr-old child with desmoplastic variant of **medulloblastoma**. B, Axial T2-weighted image of the same child shows hyperintense mass involving the cerebellar hemisphere.

histologically by the presence of Homer Wright rosettes and by immunopositivity for synaptophysin. An anaplastic variant is often more aggressive and may be associated with poorer prognosis. Patients present with signs and symptoms of increased ICP (i.e., headache, nausea, vomiting, blurring of vision, mental status changes, and hypertension) and cerebellar dysfunction (i.e., ataxia, poor balance, dysmetria, dysarthria). Clinical staging evaluation includes MRI of the brain and spine, both preoperatively and postoperatively, as well as lumbar puncture after the increased ICP has resolved. Clinical features that have consistently demonstrated prognostic significance include age at diagnosis,

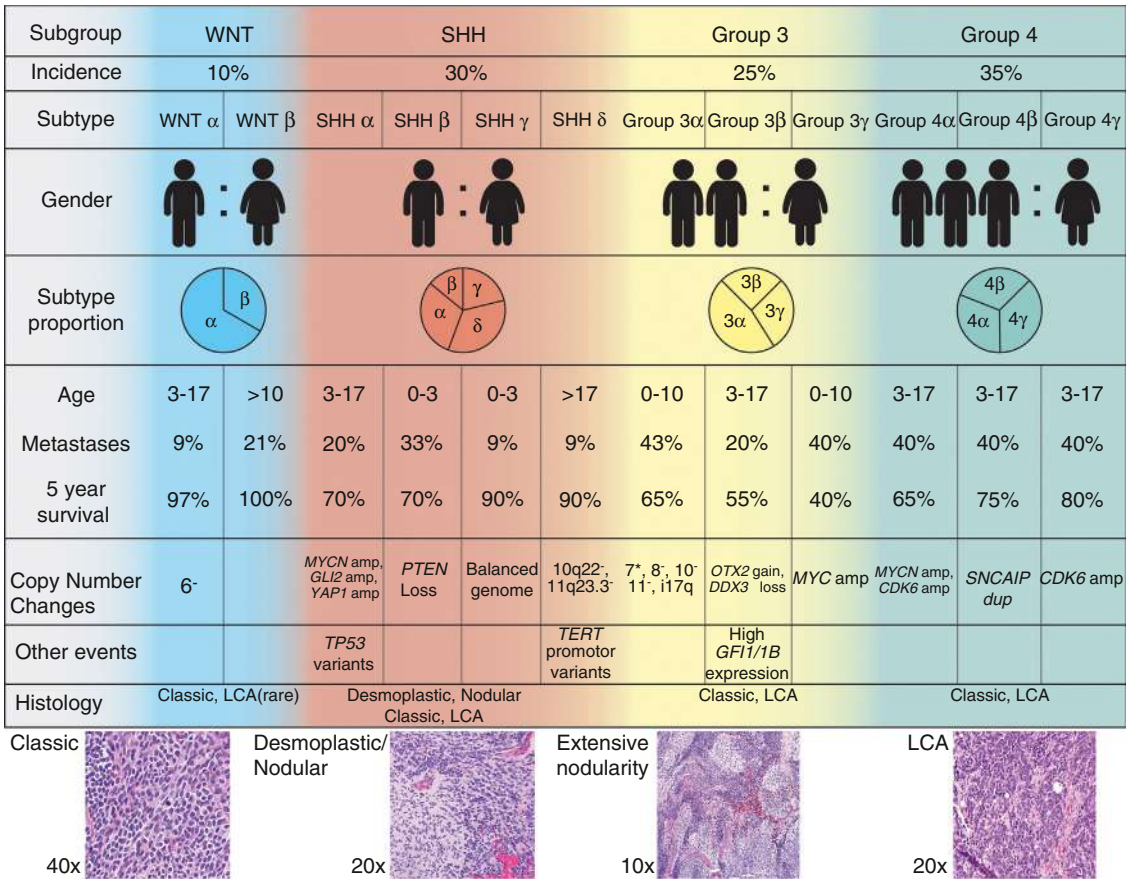

Fig. 546.10 Schematic *(upper)* depicting the four WHO-recognized subgroups of medulloblastoma, as well as the additional subtypes noted more recently and their distinguishing characteristics in terms of amplifications (amp) and duplications (dup). The figure *(lower)* also depicts the histological diversity of medulloblastomas: WNT tumors most commonly have a classic histology, whereas SHH tumors have desmoplastic histology with varying degrees of nodularity. Large cell/anaplastic (LCA) histology is most commonly seen in group 3 and less commonly in group 4 tumors. *(From Pollack IF, Agnihotri S, Broniscer A. Childhood brain tumors: current management, biological insights, and future directions. J Neurosurg Pediatr. 2019;23:261–273. Fig. 2.)*

extent of disease, and extent of surgical resection. Patients younger than 4 years of age have a poor outcome, partly as the result of a higher incidence of disseminated disease on presentation and past therapeutic approaches that have used less intense therapies. Patients with disseminated disease at diagnosis (M > 0), including positive CSF cytologic result alone (M1), have a markedly poorer outcome than those patients with no dissemination (M0). Similarly, patients with gross residual disease after surgery have poorer outcomes than those in whom surgery achieved gross total resection of disease.

Cytogenetic and molecular genetic studies have demonstrated multiple abnormalities in medulloblastoma (Fig. 546.10). The most common abnormality involves chromosome 17p deletions, which occur in 30–40% of all cases. Several signaling pathways have been shown to be active in medulloblastomas, including the sonic hedgehog **(SHH)** pathway, predominately associated with the desmoplastic variants, and the **WNT** pathway, which can occur in up to 15% of cases and has been associated with improved survival. Integrative genomic studies have identified at least four distinct molecular subgroups of medulloblastoma—**WNT**, **SHH**, **group 3**, and **group 4**—that exhibit highly discriminate transcriptional, cytogenetic, and mutational spectra, in addition to divergent patient demographics and clinical behavior (see Fig. 546.10). These prognostic groups still must be validated in larger prospective studies, though the WNT subgroup is known to have the most favorable outcome. A multimodal treatment approach is pursued in medulloblastoma, with surgery as the starting point of treatment. Medulloblastoma is sensitive to both chemotherapy and radiation therapy. With technologic advances in neurosurgery, neuroradiology, and radiation therapy, as well as identification of chemotherapy as an effective modality, the overall outcome among all patients approaches 60–70%. Standard radiation treatment in standard risk medulloblastoma incorporates craniospinal radiation at a total cumulative dose of 24 Gy, with a cumulative dose of 50-55 Gy to the tumor bed. Craniospinal radiation at this dose in children younger than 3 years of age results in severe late neurologic sequelae, including microcephaly, learning disabilities, cognitive impairment, neuroendocrine dysfunction (growth failure, hypothyroidism, hypogonadism, and absence/delay of puberty), and/or second malignancies. Similarly, in older children, late sequelae, such as learning disabilities, neuroendocrine dysfunction, and/or second malignancies, can occur. These observations have resulted in stratification of treatment approaches into the following three strata: (1) patients younger than 3 years of age, (2) standard-risk patients older than 3 years of age with surgical total resection and no disease dissemination (M0), and (3) high-risk patients older than 3 years of age with disease dissemination (M > 0) and/or bulky residual disease after surgery. With the risk-based approach to treatment, children with high-risk medulloblastoma receive high-dose cranial–spinal radiation (36 Gy) with chemotherapy during and after radiation therapy. As the dose of radiation depends on the risk stratification, complete staging with MRI of the spine before starting treatment is essential for the best chance of survival. Approaches in young children (usually younger than 3 years of age) incorporate high-dose chemotherapy with peripheral stem cell reinfusion to avoid radiation therapy.

Overall survival in children with nonmetastatic medulloblastoma and gross total tumor resection approaches 85%. The presence of bulky residual tumor (56% survival) or metastases (38% survival) confers a poor prognosis. The molecular classification is being evaluated to stratify risk groups and tailor therapy accordingly. The WNT subgroup and nonmetastatic group 4 tumors are recognized as low-risk tumors that may qualify for reduced therapy. High-risk groups were defined as patients with metastatic SHH or group 4 tumors, where intensification of therapy is being profiled.

Supratentorial primitive neuroectodermal tumors (SPNETs) account for approximately 1% of childhood CNS tumors, primarily in children within the first decade of life. These tumors are similar histologically to medulloblastoma and are composed of undifferentiated or poorly differentiated neuroepithelial cells. Historically, patients with SPNETs have had poorer outcomes than those with medulloblastoma after combined-modality therapy. Children with SPNETs are considered among the high-risk group and receive dose-intense chemotherapy with craniospinal radiation therapy.

Atypical teratoid/rhabdoid tumor is a very aggressive embryonal malignancy that occurs predominantly in children younger than 5 years of age and can occur at any location in the neuraxis. The histology demonstrates a heterogeneous pattern of cells, including rhabdoid cells that express epithelial membrane antigen and neurofilament antigen. The characteristic cytogenetic pattern is partial or complete deletion of chromosome 22q11.2 that is associated with pathogenic variants in the *INI1* gene. The relation between this variant and tumorigenesis is unclear. Though the overall prognosis remains poor, intensive chemotherapy, focal radiation, and high-dose chemotherapy with stem cell rescue have shown a trend toward improved survival. This is noted more in patients who undergo complete resection of tumor and focal radiation.

Pineal Parenchymal Tumors

The pineal parenchymal tumors are the most common malignancies after germ cell tumors that occur in the pineal region. These include **pineoblastoma**, occurring predominantly in childhood, **pineocytoma**, and the **mixed pineal parenchymal tumors**. The therapeutic approach in this group of diseases is multimodal. There was significant concern regarding the location of these masses and the potential complications of surgical intervention. With developments in neurosurgical technique and surgical technology, the morbidity and mortality associated with these approaches have markedly decreased. Stereotactic biopsy of these tumors may be adequate to establish diagnosis; however, consideration should be given to total resection of the lesion before institution of additional therapy. Pineoblastoma, the more malignant variant, is considered a subgroup of childhood PNETs. Chemotherapy regimens incorporate cisplatin, cyclophosphamide (Cytoxan), etoposide (VP-16), and vincristine and/or lomustine. The survival outcome of combined chemotherapy and radiation therapy in pineal-region PNETs approaches 70% at 5 years. Pineocytoma usually is approached with surgical resection.

Craniopharyngioma

Craniopharyngioma (WHO grade I) is a common tumor of childhood, accounting for 3–10% of all CNS childhood tumors. Two histological subtypes have been identified, adamantinomatous and papillary craniopharyngiomas (CP), each with specific origin and genetic alterations. ***BRAFV600E*** pathogenic variants are solely found in the papillary CP subgroup, which is the common type in adults, whereas ***CTNNB1*** pathogenic variants are exclusively detected in adamantinomatous CP, which is common in children. Children with CP often present with endocrinologic abnormalities (growth failure and delayed sexual maturation) and/or visual changes (decreased acuity or visual field abnormalities). These tumors are often large and heterogeneous, displaying both solid and cystic components, and occur within the suprasellar region. They are minimally invasive, adhere to adjacent brain parenchyma, and engulf normal brain structures. MRI demonstrates the solid tumor with cystic structures containing fluid of intermediate density, and CT may show calcifications. Surgery is the primary treatment modality, with gross total resection being curative. Controversy exists regarding the relative roles of surgery and radiation therapy in large, complex tumors. Significant morbidity (panhypopituitarism, growth failure, visual loss) is associated with these tumors and their therapy, owing to the anatomic location.

Germ Cell Tumors

Germ cell tumors of the CNS are a heterogeneous group of tumors that are primarily tumors of childhood, arising predominantly in midline structures of the pineal and suprasellar regions (see Fig. 546.3). They account for 3–5% of pediatric CNS tumors. The peak incidence of these tumors is in children 10-12 yr of age. Overall, there is a male preponderance, although there is a female preponderance for suprasellar tumors. Germ cell tumors occur multifocally in 5–10% of cases. This group of tumors is much more prevalent in Asian populations than European populations. Delays in diagnosis can occur because these tumors have a particularly insidious course; the initial presenting symptoms may be subtle. Similar to peripheral germ cell tumors, the analysis of protein markers, **α-fetoprotein,** and **β-human chorionic gonadotropin** may be useful in establishing the diagnosis and monitoring treatment response. Surgical biopsy is recommended to establish the diagnosis; however, secreting **germinomas** and **nongerminomatous germ cell tumors** may be diagnosed based on protein marker elevations. Therapeutic approaches to germinomas and nongerminomatous germ cell tumors are different. The survival proportion among patients with pure germinoma exceeds 90%. The postsurgical treatment of pure germinomas is somewhat controversial in defining the relative roles of chemotherapy and radiation therapy. Clinical trials have investigated the use of chemotherapy and reduced-dose radiation and field after surgery in pure germinomas. The therapeutic approach to nongerminomatous germ cell tumors is more aggressive, combining more intense chemotherapy regimens with craniospinal radiation therapy. Survival rates among patients with these tumors are markedly lower than those noted in patients with germinoma, ranging from 70–80% at 5 years. Trials have shown the benefit of the use of high doses of chemotherapy with peripheral blood stem cell rescue specially at metastatic and relapse groups.

Tumors of the Brainstem

Tumors of the brainstem are a heterogeneous group of tumors that account for 10.9% of childhood primary CNS tumors. Outcome depends on tumor location, imaging characteristics, and the patient's clinical status. Patients with these tumors may present with motor weakness, cranial nerve dysfunction, cerebellar dysfunction, and/or signs of increased ICP. On the basis of MRI evaluation and clinical findings, tumors of the brainstem can be classified into four types: focal (5–10% of patients), dorsally exophytic (5–10%), cervicomedullary (5–10%), and diffuse intrinsic pontine glioma **(DIPG)** (70–85%) (Fig. 546.11). Surgical resection is the primary treatment approach for focal and dorsally exophytic tumors and leads to a favorable outcome. Histologically, these two groups usually are low-grade gliomas. *Cervicomedullary tumors, because of their location, may not be amenable to surgical resection but are sensitive to radiation therapy*. DIPG, characterized by the diffuse infiltrating grade II-IV glioma, is associated with a very poor outcome independent of histologic diagnosis. These tumors are not amenable to surgical resection. Biopsy in children in whom MRI shows DIPG is controversial and is not recommended unless there are atypical radiographic findings suspicious for another diagnosis, such as infection, vascular malformation, myelination disorder, or metastatic tumor. Studies have identified the unique genetic makeup of this fatal brain cancer, with nearly 80% found to harbor pathogenic variants in histone ***H3.3*** or ***H3.1 (H3-K27M)*** and 20% pathogenic variants affecting the activin receptor gene ***(ACVR1);*** three molecularly distinct subgroups have been identified (H3-K27M, silent and MYCN).

The standard treatment approach has been palliative radiation therapy, and median survival with this treatment is 12 months, at best. Use

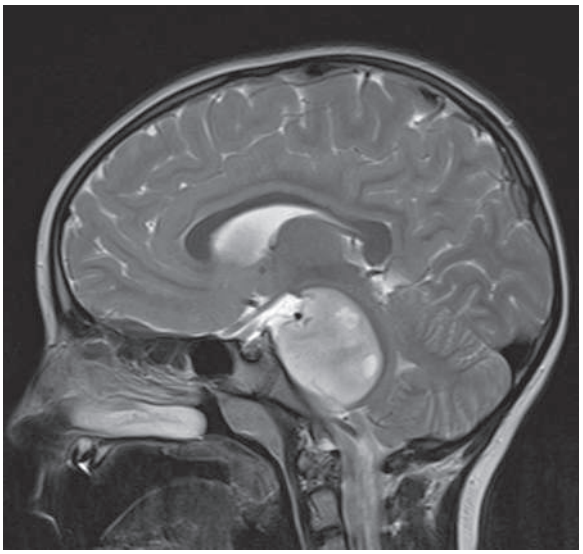

Fig. 546.11 T2-weighted sagittal MR image of a diffuse infiltrating pontine glioma in a 5-yr-old child presenting with headaches, left facial droop, and lethargy.

of chemotherapy, including high-dose chemotherapy with peripheral blood stem cell rescue, has not yet been of survival benefit in this group of patients. Experimental approaches have included the use of immunotherapy with oncolytic herpes simplex virus (HSV) or adenoviruses.

Metastatic Tumors

Metastatic spread of other childhood malignancies to the brain is uncommon. Childhood acute lymphoblastic leukemia and non-Hodgkin lymphoma can spread to the leptomeninges, causing symptoms of communicating hydrocephalus. **Chloromas,** which are collections of myeloid leukemia cells, can occur throughout the neuraxis. Rarely, brain parenchymal metastases occur from lymphoma, neuroblastoma, rhabdomyosarcoma, Ewing sarcoma, osteosarcoma, and clear cell sarcoma of the kidney. Therapeutic approaches are based on the specific histologic diagnosis and may incorporate radiation therapy, intrathecal administration of chemotherapy, and/or systemic administration of chemotherapy. Medulloblastoma is the childhood brain tumor that most commonly metastasizes extraneurally. Less commonly, extraneural metastases from malignant glioma, PNET, and ependymoma can occur. Ventriculoperitoneal shunts have been known to allow extraneural metastases, primarily within the peritoneal cavity but also systemically.

COMPLICATIONS AND LONG-TERM MANAGEMENT

Data from the National Cancer Institute Surveillance, Epidemiology, and End Results Program indicate that more than 70% of patients with childhood brain tumors will be long-term survivors. At least 50% of these survivors will experience chronic problems as a direct result of their tumors and treatment. These problems include chronic neurologic deficits such as focal motor and sensory abnormalities, seizure disorders, neurocognitive deficits (e.g., developmental delays, learning disabilities), and neuroendocrine deficiencies (e.g., hypothyroidism, growth failure, delay or absence of puberty). These patients are also at significant risk for secondary malignancies, hearing deficit, and early cataract from radiation therapy. Supportive multidisciplinary interventions for children with brain tumors both during and after therapy may help improve the ultimate outcome. Optimal seizure management, physical therapy, endocrine management with timely growth hormone and thyroid replacement therapy, tailored educational programs, and vocational interventions may enhance the childhood brain tumor survivor's quality of life.

Chapter 547

Neuroblastoma

Fiorela N. Hernandez Tejada and Douglas J. Harrison

Neuroblastomas are embryonal cancers of the peripheral sympathetic nervous system with heterogeneous clinical presentation and course, ranging from tumors that undergo spontaneous regression to very aggressive tumors unresponsive to very intensive multimodal therapy. The causes of most cases remain unknown. Advances have been made in the treatment of children with these tumors, which have improved outcomes, although many with aggressive forms of neuroblastoma still succumb to their disease despite intensive therapy.

EPIDEMIOLOGY

Neuroblastoma is the most common extracranial solid tumor in children and is the most commonly diagnosed malignancy in the first year of life. Approximately 600 new cases are diagnosed each year in the United States, accounting for 8–10% of childhood malignancies and one-third of cancers in infants. Neuroblastoma accounts for >15% of the mortality from cancer in children. The median age of children at diagnosis of neuroblastoma is 18 months, and 90% of cases are diagnosed in children who are <10 years of age. The incidence is slightly higher in males and in the White population.

PATHOLOGY

Neuroblastoma tumors, which are derived from primordial neural crest cells, form a spectrum with variable degrees of neural differentiation, ranging from tumors with primarily undifferentiated small round cells (neuroblastoma) to tumors consisting of mature and maturing Schwannian stroma with ganglion cells (ganglioneuroblastoma or ganglioneuroma). The tumors may resemble other **small, round blue cell tumors,** such as rhabdomyosarcoma, Ewing sarcoma, and non-Hodgkin lymphoma. The prognosis of children with neuroblastoma varies with the histologic features of the tumor as dictated by the presence and amount of Schwannian stroma, the degree of tumor cell differentiation, and the mitosis-karyorrhexis index.

PATHOGENESIS

The etiology of neuroblastoma in most cases remains unknown. Familial neuroblastoma is rare but accounts for 1–2% of all cases, is associated with a younger age at diagnosis, and is linked to germline gain-of-function pathogenic variants in the *ALK* gene. The *BARD1* gene has also been identified as a major genetic contributor to neuroblastoma risk. Germline gain-of-function pathogenic variants in *PHOX2B* predisposes to most of the syndromic neuroblastoma cases, including Hirschsprung disease and central congenital hypoventilation syndrome. Neuroblastoma is associated with other neural crest disorders, such as neurofibromatosis type 1, and potentially congenital cardiovascular malformations (Table 547.1). Children with Beckwith-Wiedemann syndrome and hemihypertrophy also have a higher incidence of neuroblastoma. Increased incidence of neuroblastoma is associated with some maternal and paternal occupational chemical exposures, maternal drug use, farming, and work related to electronics, although no single environmental exposure has been shown to directly cause neuroblastoma.

Genetic characteristics of neuroblastoma tumors that are of prognostic importance include amplification of the *MYCN (N-myc)* protooncogene and tumor cell DNA content, or ploidy (Tables 547.2-547.4). Amplification of *MYCN* is strongly associated with advanced tumor stage and poor outcomes. Other genetic alterations have been identified

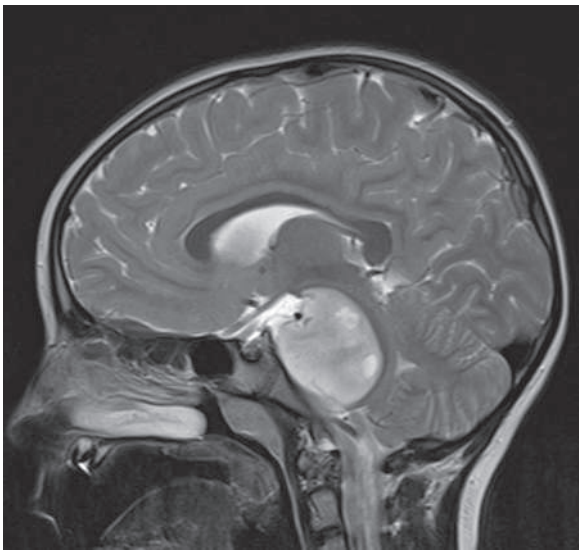

Fig. 546.11 T2-weighted sagittal MR image of a diffuse infiltrating pontine glioma in a 5-yr-old child presenting with headaches, left facial droop, and lethargy.

of chemotherapy, including high-dose chemotherapy with peripheral blood stem cell rescue, has not yet been of survival benefit in this group of patients. Experimental approaches have included the use of immunotherapy with oncolytic herpes simplex virus (HSV) or adenoviruses.

Amplification of *MYCN* is strongly associated with advanced tumor stage and poor outcomes. Other genetic alterations have been identified

Table 547.1 Syndromes Due to or Associated with Neuroblastoma

EPONYM	FEATURES
SYNDROMES CAUSED BY NEUROBLASTOMA	
Pepper syndrome	Massive involvement of the liver with metastatic disease with or without respiratory distress
Horner syndrome	Unilateral ptosis, myosis, and anhidrosis associated with a thoracic or cervical primary tumor; symptoms do not resolve with tumor resection
Hutchinson syndrome	Limping and irritability in young child associated with bone and bone marrow metastases
Opsoclonus-myoclonus-ataxia syndrome	Myoclonic jerking and random conjugate eye movements with or without cerebellar ataxia; often associated with a biologically favorable and differentiated tumor; the condition is likely immune mediated, may not resolve with tumor removal, and often exhibits progressive neuropsychologic sequelae
Kerner-Morrison syndrome	Intractable secretory watery diarrhea due to tumor secretion of vasointestinal peptides; tumors are generally biologically favorable
ROHHAD	Approximately 40% may have neural crest-derived tumors. Obesity and neurologic issues may be part of a paraneoplastic syndrome
SYNDROMES PREDISPOSING TO NEUROBLASTOMA	
Neurocristopathy syndrome	Neuroblastoma associated with other neural crest disorders, including congenital hypoventilation syndrome or Hirschsprung disease; germline pathogenic variants in the paired homeobox gene *PHOX2B* have been identified in a subset of patients with this disease
Beckwith-Wiedemann syndrome	Macrosomia, hyperinsulinemic hypoglycemia, omphalocele
Costello syndrome (faciocutaneo-skeletal syndrome)	Autosomal dominant, pathogenic variant in *HRAS*, intellectual disability, delayed development, cardiomyopathy
Familial pheochromocytoma/paraganglioma syndrome	Autosomal dominant, pathogenic variant in *MAX* and other genes
Fanconi anemia	Autosomal recessive, congenital anomalies, aplastic anemia, pathogenic variants in *FANCA*, *FANCC*, *FANCG*
Neurofibromatosis type 1	*NF1* pathogenic variants
Noonan syndrome	Ras-MAPK pathway (RASopathies) pathogenic variant
Turner syndrome	Partial or complete deletion of X chromosome, short-webbed neck, short stature

ROHHAD, Rapid-onset obesity, hypothalamic dysfunction, hypoventilation, autonomic dysregulation.

Table 547.3 International Neuroblastoma Staging System

STAGE	DEFINITION	INCIDENCE (%)	SURVIVAL AT 5 YR* (%)
1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive)	5	≥90
2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically	10	70-80
2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor; enlarged contralateral lymph nodes must be negative microscopically	10	70-80
3	Unresectable unilateral tumor infiltrating across the midline,† with or without regional lymph node involvement; *or* localized unilateral tumor with contralateral regional lymph node involvement; *or* midline tumor with bilateral extension by infiltration (resectable) or by lymph node involvement	25	40-70
4	Any primary tumor with dissemination to distant lymph nodes; bone, bone marrow, liver, skin, and other organs (except as defined for stage 4S)	60	85-90¶ 30-40#
4S	Localized primary tumor (as defined for stage 1, 2A, or 2B), with dissemination limited to skin, liver, and bone marrow‡ (limited to infants <1 yr of age)	5	>80

*Survival is influenced by other characteristics, such as *MYCN* amplification. Percentages are approximate.
†The *midline* is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the other side of the vertebral column.
‡Marrow involvement in stage 4S should be minimal (i.e., <10% of total nucleated cells identified as malignant on bone marrow biopsy or on marrow aspirate). More extensive marrow involvement would be considered stage 4. Results of the metaiodobenzylguanidine (MIBG) scan (if performed) should be negative in the marrow.
¶If age at diagnosis is <18 mo.
#If age at diagnosis is >18 mo.

Revisions of the international criteria for neuroblastoma diagnosis, staging, and response to treatment. *J Clin Oncol*. 1993;11:1466–1477.

Table 547.4 Phenotypic and Genetic Features of Neuroblastoma, Treatment, and Survival According to Prognostic Category

	PROGNOSTIC CATEGORY*			
VARIABLE	LOW RISK	INTERMEDIATE RISK	HIGH RISK	TUMOR STAGE 4S
Pattern of disease	Localized tumor	Localized tumor with locoregional lymph node extension; metastases to bone marrow and bone in infants	Metastases to bone marrow and bone (except in infants)	Metastases to liver and skin (with minimal bone marrow involvement) in infants
Tumor genomics	Whole-chromosome gains	Whole-chromosome gains	Segmental chromosomal aberrations	Whole-chromosome gains
Treatment	Surgery†	Moderate-intensity chemotherapy; surgery†	Dose-intensive chemotherapy, surgery, and external-beam radiotherapy to primary tumor and resistant metastatic sites; myeloablative chemotherapy with autologous hematopoietic stem cell rescue; isotretinoin with anti-ganglioside GD2 immunotherapy	Supportive care‡
Survival rate	>98%	90–95%	40–50%	>90%

*Patients are assigned to prognostic groups according to risk, as described by the Children's Oncology Group, with the level of risk defining the likelihood of death from disease. Stage 4S disease is considered separately here because of the unique phenotype of favorable biologic features and relentless early progression but ultimately full and complete regression of the disease.
†The goal of surgery is to safely debulk the tumor mass and avoid damage to surrounding normal structures while obtaining sufficient material for molecular diagnostic studies. Some localized tumors may spontaneously regress without surgery.
‡Low-dose chemotherapy or radiation therapy, or both, is used in patients with life-threatening hepatic involvement, especially in infants <2 mo of age, who are at much higher risk for life-threatening complications from massive hepatomegaly.
From Maris JM. Recent advances in neuroblastoma. *N Engl J Med*. 2010;362:2202–2210.

in patients with neuroblastoma using whole genome sequencing such as loss of function in *ATRX* and *TERT*. Hyperdiploidy confers better prognosis if the child is younger than 18 months of age at diagnosis if amplification of *MYCN* is not present. Other chromosomal abnormalities, including loss of heterozygosity of 1p, 11q, and 14q, and gain of 17q, may be found in neuroblastoma tumors and have been associated with worse outcomes. In addition, many other biologic factors are associated with neuroblastoma outcomes, including tumor vascularity and the expression levels of nerve growth factor receptors (TrkA, TrkB), ferritin, lactate dehydrogenase, ganglioside GD2, neuropeptide Y, chromogranin A, CD44, multidrug resistance–associated protein, and telomerase.

CLINICAL MANIFESTATIONS

Neuroblastoma may develop at any site of sympathetic nervous system tissue. Approximately half of neuroblastoma tumors arise in the adrenal glands, and most of the remainder originate in the paraspinal sympathetic ganglia. Metastatic spread, which is more common in children older than 1 year of age at diagnosis, occurs via local invasion or distant hematogenous or lymphatic routes. The most common sites

of metastasis are the regional or distant lymph nodes, long bones and skull, bone marrow, liver, and skin. Lung and brain metastases are rare, occurring in less than 3% of cases.

The signs and symptoms of neuroblastoma reflect the tumor site and extent of disease and may mimic other disorders, which can result in a delayed diagnosis. Metastatic disease can cause a variety of signs and symptoms, including fever, irritability, failure to thrive, bone pain, cytopenias, bluish subcutaneous nodules, orbital proptosis, and periorbital ecchymoses (Fig. 547.1). Localized disease can manifest as an asymptomatic mass or can cause symptoms due to mass effect, which can in certain cases result in spinal cord compression, bowel obstruction, and superior vena cava syndrome.

Children with neuroblastoma can also present with associated neurologic signs and symptoms (see Table 547.1). Neuroblastoma originating in the superior cervical ganglion can result in **Horner syndrome.** Paraspinal neuroblastoma tumors can invade the neural foramina, causing spinal cord and nerve root compression. Neuroblastoma can also be associated with a paraneoplastic syndrome of autoimmune origin, termed **opsoclonus-myoclonus-ataxia syndrome**, in which patients experience rapid, uncontrollable jerking eye and body movements, poor coordination, and cognitive dysfunction. Some tumors produce catecholamines that can cause increased sweating and hypertension, and some release vasoactive intestinal peptide, causing a profound secretory diarrhea. Children with extensive tumors can also experience tumor lysis syndrome and disseminated intravascular coagulation. Infants younger than 18 months of age also can present in unique fashion, termed *stage MS* (previously 4S; see later), with widespread subcutaneous tumor nodules, massive liver involvement, limited bone marrow disease, and a small primary tumor without bone involvement or other metastases. The stage MS disease can spontaneously regress. The enigmatic characteristics of neuroblastoma with paraneoplastic syndromes and spontaneous regression under some circumstances have led some researchers to suggest that neuroblastoma may originate as a neurodevelopmental disorder.

Fig. 547.1 Neuroblastoma. Periorbital ecchymosis, proptosis, and subconjunctival hemorrhage of the left eye. *(From Mota EB, Penna CRR, Marchiori E. Metastatic dissemination of a neuroblastoma. J Pediatr. 2017;189:232–232.e1. Fig. 1.)*

DIAGNOSIS

Neuroblastoma is usually discovered as a mass or multiple masses on plain radiography, CT, or MRI (Fig. 547.2A). The mass often contains calcification and hemorrhage that can allow it to be appreciated on plain radiography or CT (Fig. 547.3). Prenatal diagnosis of perinatal neuroblastoma on maternal ultrasound scans is sometimes possible. Tumor markers, including catecholamine metabolites homovanillic acid and vanillylmandelic acid, are elevated in the urine of approximately 95% of cases and help to confirm the diagnosis. A pathologic diagnosis is established from tumor tissue obtained by biopsy. Neuroblastoma can be confirmed without a primary tumor biopsy if small, round, blue tumor cells are observed in bone marrow samples (Fig. 547.4) and the levels of vanillylmandelic acid or homovanillic acid are elevated in the urine.

Evaluations for metastatic disease should include CT or MRI of the chest and abdomen, bone scans to detect cortical bone involvement, and at least two independent bone marrow aspirations and biopsies to evaluate for marrow disease. **Iodine-123 metaiodobenzylguanidine (^{123}I-MIBG)** studies should be used when available to better define the extent of disease. Some centers use gallium-68 dotatate PET/MRI or CT scans, especially if the MIBG scan is negative (Fig. 547.5). MRI of the spine should be performed in cases with suspected or potential spinal cord compression, but imaging of the brain with

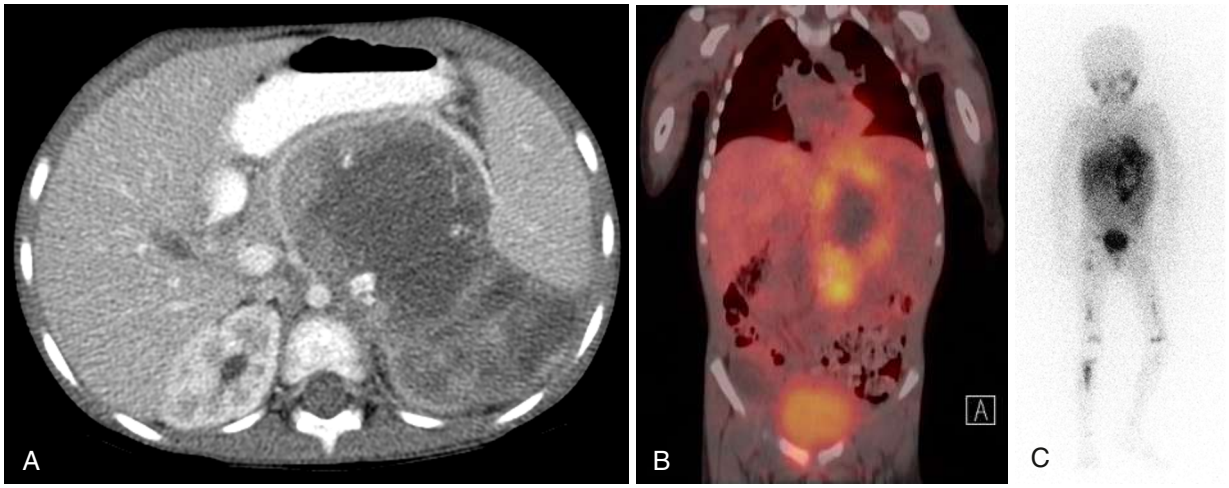

Fig. 547.2 A, CT scan of an abdominal neuroblastoma with central necrosis at diagnosis. B, Coronal fused CT and metaiodobenzylguanidine (MIBG) image of the same child with extensive retroperitoneal mass and central necrosis, probably an adrenal primary with extensive lymph node involvement. C, MIBG avid neuroblastoma with increased uptake of radiolabeled tracer can be detected in multiple sites of disease, including bone and soft tissue.

either CT or MRI is not routinely performed unless dictated by the clinical presentation.

The **International Neuroblastoma Risk Group (INRG) Staging System (INSS)** is currently used to stage patients with neuroblastoma and is based on the extent of disease as determined by imaging at diagnosis. Extent of locoregional disease is based on specific local image-defined risk factors (IDRFs) (see Table 547.3). L1 tumors (previously classified as INSS stage 1) are localized and confined to one body compartment without any IDRFs. L2 tumors (previously classified as INSS stages 2 and 3) refer to localized tumors with the presence of IDRFs. Disseminated tumors with metastases to bones, bone marrow, liver, distant lymph nodes, and/or other organs are staged as M (previously classified as INSS stage 4). Stage MS (previously stage 4S) refers to neuroblastoma in children younger than 18 months of age with dissemination to liver, skin, and/or bone marrow without bone involvement and with a primary tumor that would otherwise be staged as L1 or L2. This new INSS was recently developed to allow for more effective comparisons of treatments and outcomes worldwide.

TREATMENT

Treatment strategies for neuroblastoma have changed with significant reduction in treatment intensity for children who have localized low-risk tumors and with continued increased treatment intensity and the addition of novel agents for treatment of children who have high risk or recurrent disease. The patient's age and tumor stage are combined with cytogenetic and molecular features of the tumor to determine the treatment risk group and estimated prognosis for each patient (see

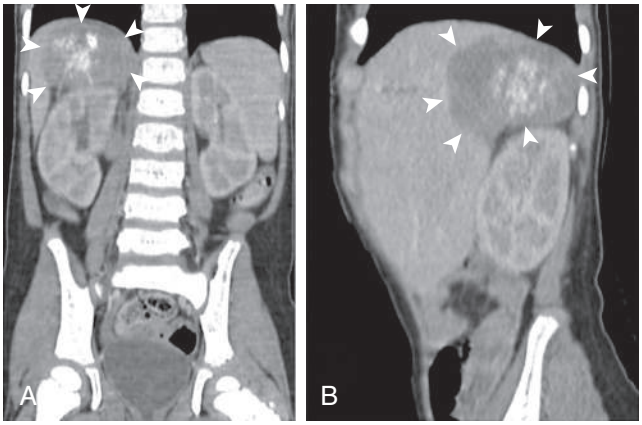

Fig. 547.3 Neuroblastoma. CT images of the abdomen with coronal (**A**) and sagittal (**B**) reconstructions showing a large low-density tumor in the right suprarenal region *(arrowheads)*. Note the neoplastic calcifications inside the mass. *(From Mota EB, Penna CRR, Marchiori E. Metastatic dissemination of a neuroblastoma. J Pediatr. 2017;189:232–232.e1. Fig. 3.)*

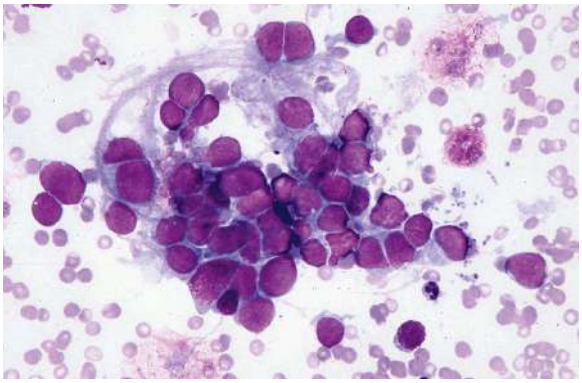

Fig. 547.4 Neuroblastoma cells aspirated from the bone marrow. Clumps of cells often contain ≥3 cells with or without evidence of rosette formation. Rosettes of cells surrounding an inner mass of fibrillary material are characteristic of neuroblastoma.

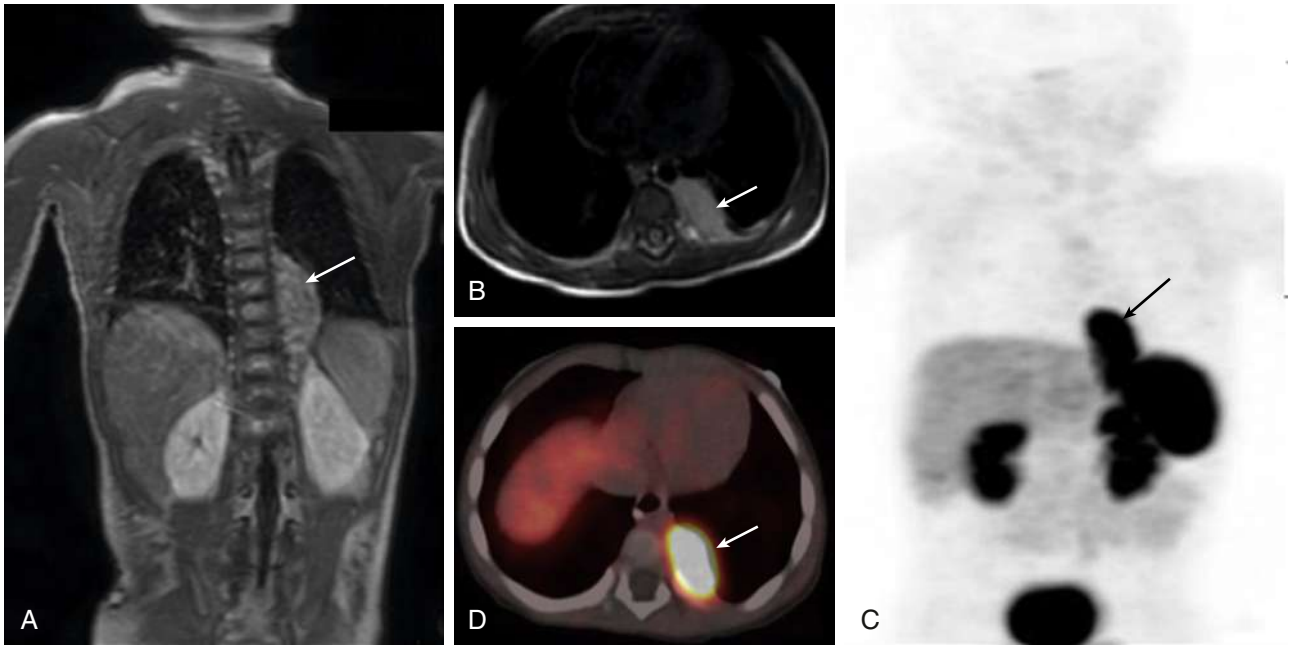

Fig. 547.5 Neuroblastoma. MRI and gallium-68 DOTANOC PET/CT scan of chest and abdomen reveal a mass in left posterior mediastinum (likely neuroblastoma). **A**, Coronal T1-weighted postcontrast image (**A**) and axial T2-weighted image (**B**) reveal a well-defined isointense lesion (42 × 26 × 27 mm) in the left posterior mediastinum extending from D7-D11 vertebrae. **C**, PET/CT maximum intensity projection image shows increased uptake in left lower thoracic paraspinal region. **D**, Axial fused PET-CT image shows somatostatin-receptor expressing mass (maximum standardized uptake value, 21; *arrow in A–D*) in the same location. *(From Kaur A, Bhagwat C, Madaan P, et al. Dancing eyes. J Pediatr. 2019;214:231.)*

Tables 547.2-547.4). Treatment for children with low-risk neuroblastoma typically includes surgery for stages L1 and L2 and observation for asymptomatic stage MS with cure rates generally >90% without further therapy. Treatment with chemotherapy or radiation for the rare child with local recurrence can still be curative. Children with spinal cord compression at diagnosis may require urgent treatment with chemotherapy, surgery, or radiation to avoid neurologic damage. Stage MS neuroblastomas have a very favorable prognosis, and many regress spontaneously without therapy. Chemotherapy or resection of the primary tumor does not improve survival rates, but for infants with massive liver involvement and respiratory compromise, chemotherapy or radiation is used to alleviate symptoms. For children with stage 4S neuroblastoma who require treatment for symptoms, the survival rate is 81%.

Treatment of intermediate-risk neuroblastoma includes surgery, chemotherapy, and, in some cases, radiation therapy. The chemotherapy usually includes moderate doses of cisplatin or carboplatin, cyclophosphamide, etoposide, and doxorubicin given over several months. Radiation therapy is used for tumors with incomplete response to chemotherapy. Children with intermediate-risk neuroblastoma, including children with L2 disease and infants with M disease both with favorable characteristics, have an excellent prognosis and >90% survival with this moderate treatment. In this intermediate-risk group, obtaining adequate diagnostic material for determination of the underlying biologic features of the tumor, such as the Shimada pathologic classification and *MYCN* gene amplification, is critical, so that children with unfavorable characteristics can receive more-aggressive treatment and those with favorable features can be spared excessive toxic therapy.

Children with high-risk neuroblastoma historically have had poor long-term survival rates of 25–35% despite intensive treatment consisting of induction chemotherapy, high-dose chemotherapy with autologous stem cell rescue, surgery, radiation, and 13-*cis*-retinoic acid. Induction chemotherapy for children with high-risk neuroblastoma includes combinations of cyclophosphamide, topotecan, doxorubicin, vincristine, cisplatin, and etoposide. After completion of induction chemotherapy, resection of the residual primary tumor is followed by high-dose chemotherapy with autologous stem cell rescue and focal radiation therapy to tumor sites. A national cooperative group trial demonstrated significantly better survival with chemotherapy plus autologous stem cell rescue than with chemotherapy alone. The further addition of the differentiating agent, 13-*cis*-retinoic acid, following autologous stem cell transplantation, resulted in further improvements in survival rates. In addition, a national clinical trial has demonstrated an increase in short-term survival rates with the addition of the monoclonal antibody ch14.18 **(dinutuximab)** to 13-*cis*-retinoic acid therapy. This monoclonal antibody targets a disialoganglioside, GD2, which has ubiquitous expression on neuroblastoma cells. In this large, randomized, clinical trial of high-risk neuroblastoma patients sponsored by the Children's Oncology Group, incorporation of the antibody into consolidative therapy following autologous stem cell transplant improved the 2-year event-free survival from 46.5–66.5%. The incorporation of tandem autologous stem cell transplant (two separate autologous stem cell transplants with differing conditioning regimens) may further improve outcomes for patients with high-risk disease.

Cases of high-risk neuroblastoma are associated with frequent relapses, and children with recurrent neuroblastoma have a <50% response rate to alternative chemotherapy regimens. New treatment strategies and agents are needed for children with both high-risk and recurrent neuroblastoma. Therapies currently under investigation include new chemotherapeutic agents as well as novel therapies directed against critical intracellular signaling pathways, radiolabeled targeted agents (such as *therapeutic* ^{131}I-MIBG), immunotherapy, and antitumor vaccines.

Chapter 548
Neoplasms of the Kidney

548.1 Wilms Tumor

Najat C. Daw and Dristhi S. Ragoonanan

Wilms tumor **(nephroblastoma)** is the most common primary malignant *renal* tumor of childhood. It is the second most common malignant abdominal tumor in childhood after neuroblastoma. The most common sites of metastases are the lungs, regional lymph nodes, and liver. Histologically, the classic Wilms tumor is made up of varying proportions of blastemal, stromal, and epithelial cells, recapitulating stages of normal renal development. The use of multimodality treatment and multi-institutional cooperative group trials has dramatically improved the cure rate of Wilms tumor from <30% to >90% (Table 548.1).

EPIDEMIOLOGY

Wilms tumor accounts for 6% of pediatric malignancies and >95% of kidney tumors in children. In the United States, incidence of Wilms tumor is approximately 7 cases per 1 million children <15 years of age per year, and about 650 new cases are diagnosed each year. Approximately 75% of the cases occur in children <5 years old, with a peak incidence at 2-3 years. It can arise in one or both kidneys; the incidence of bilateral Wilms tumors is 7%. The male/female ratio is 0.92 to 1 in unilateral disease and 0.6 to 1 in bilateral disease. Most cases are sporadic, but approximately 2% of patients have a family history. In 8–10% of patients, Wilms tumor is observed in the context of hemihypertrophy, aniridia, genitourinary anomalies, and a variety of rare syndromes, including **Beckwith-Wiedemann syndrome (BWS)** and **Denys-Drash syndrome** (Table 548.2). An earlier age at diagnosis and an increased incidence of bilateral disease are generally observed in syndromic and familial cases.

ETIOLOGY: GENETICS AND MOLECULAR BIOLOGY

Wilms tumor is thought to be derived from incompletely differentiated renal mesenchyme, and tumors are typically composed of cells reminiscent of the undifferentiated and partially differentiated cells that normally arise from renal mesenchyme. Foci of benign, undifferentiated mesenchyme **(nephrogenic rests)** that persist abnormally in the kidney into postnatal life are observed in approximately 1% of children in the general population but are present in up to 90% of children who have a family history of Wilms tumor, develop bilateral tumors, or display features of Wilms tumor–related syndromes. Nephrogenic rests usually regress or differentiate, but those that persist can become malignant.

Wilms tumor has been associated with genetic abnormalities. The first identified Wilms tumor gene, *WT1*, located at 11p13, is a homozygous gene variant in 10–15% of tumors, resulting in loss of function of the encoded zinc finger transcription factor. The majority of *WT1* pathogenic variants are somatic; however, *WT1* pathogenic variants can also be germline. The type of WT1 pathogenic variant affects the disease phenotype. Germline truncating variants are usually associated with Wilms tumor in the context of genitourinary anomalies or the **WAGR syndrome** (Wilms tumor, aniridia, genitourinary anomalies, mental retardation) as it involves the deletion of several contiguous genes at 11p13. Missense germline variants are usually observed in children with Denys-Drash syndrome, resulting in early-onset renal failure. In instances of germline variant, the wild-type allele present in the germline is altered or lost in the tumor, resulting in loss of *WT1* function.

Tables 547.2-547.4). Treatment for children with low-risk neuroblastoma typically includes surgery for stages L1 and L2 and observation for asymptomatic stage MS with cure rates generally >90% without further therapy. Treatment with chemotherapy or radiation for the rare child with local recurrence can still be curative. Children with spinal cord compression at diagnosis may require urgent treatment with chemotherapy, surgery, or radiation to avoid neurologic damage. Stage MS neuroblastomas have a very favorable prognosis, and many regress spontaneously without therapy. Chemotherapy or resection of the primary tumor does not improve survival rates, but for infants with massive liver involvement and respiratory compromise, chemotherapy or radiation is used to alleviate symptoms. For children with stage 4S neuroblastoma who require treatment for symptoms, the survival rate is 81%.

Treatment of intermediate-risk neuroblastoma includes surgery, chemotherapy, and, in some cases, radiation therapy. The chemotherapy usually includes moderate doses of cisplatin or carboplatin, cyclophosphamide, etoposide, and doxorubicin given over several months. Radiation therapy is used for tumors with incomplete response to chemotherapy. Children with intermediate-risk neuroblastoma, including children with L2 disease and infants with M disease both with favorable characteristics, have an excellent prognosis and >90% survival with this moderate treatment. In this intermediate-risk group, obtaining adequate diagnostic material for determination of the underlying biologic features of the tumor, such as the Shimada pathologic classification and *MYCN* gene amplification, is critical, so that children with unfavorable characteristics can receive more-aggressive treatment and those with favorable features can be spared excessive toxic therapy.

Children with high-risk neuroblastoma historically have had poor long-term survival rates of 25–35% despite intensive treatment consisting of induction chemotherapy, high-dose chemotherapy with autologous stem cell rescue, surgery, radiation, and 13-*cis*-retinoic acid. Induction chemotherapy for children with high-risk neuroblastoma includes combinations of cyclophosphamide, topotecan, doxorubicin, vincristine, cisplatin, and etoposide. After completion of induction chemotherapy, resection of the residual primary tumor is followed by high-dose chemotherapy with autologous stem cell rescue and focal radiation therapy to tumor sites. A national cooperative group trial demonstrated significantly better survival with chemotherapy plus autologous stem cell rescue than with chemotherapy alone. The further addition of the differentiating agent, 13-*cis*-retinoic acid, following autologous stem cell transplantation, resulted in further improvements in survival rates. In addition, a national clinical trial has demonstrated an increase in short-term survival rates with the addition of the monoclonal antibody ch14.18 **(dinutuximab)** to 13-*cis*-retinoic acid therapy. This monoclonal antibody targets a disialoganglioside, GD2, which has ubiquitous expression on neuroblastoma cells. In this large, randomized, clinical trial of high-risk neuroblastoma patients sponsored by the Children's Oncology Group, incorporation of the antibody into consolidative therapy following autologous stem cell transplant improved the 2-year event-free survival from 46.5–66.5%. The incorporation of tandem autologous stem cell transplant (two separate autologous stem cell transplants with differing conditioning regimens) may further improve outcomes for patients with high-risk disease.

Chapter 548
Neoplasms of the Kidney

548.1 Wilms Tumor

Najat C. Daw and Dristhi S. Ragoonanan

Wilms tumor **(nephroblastoma)** is the most common primary malignant *renal* tumor of childhood. It is the second most common malignant abdominal tumor in childhood after neuroblastoma. The most common sites of metastases are the lungs, regional lymph nodes, and liver. Histologically, the classic Wilms tumor is made up of varying proportions of blastemal, stromal, and epithelial cells, recapitulating stages of normal renal development. The use of multimodality treatment and multi-institutional cooperative group trials has dramatically improved the cure rate of Wilms tumor from <30% to >90% (Table 548.1).

EPIDEMIOLOGY

Wilms tumor accounts for 6% of pediatric malignancies and >95% of kidney tumors in children. In the United States, incidence of Wilms tumor is approximately 7 cases per 1 million children <15 years of age per year, and about 650 new cases are diagnosed each year. Approximately 75% of the cases occur in children <5 years old, with a peak incidence at 2-3 years. It can arise in one or both kidneys; the incidence of bilateral Wilms tumors is 7%. The male/female ratio is 0.92 to 1 in unilateral disease and 0.6 to 1 in bilateral disease. Most cases are sporadic, but approximately 2% of patients have a family history. In 8–10% of patients, Wilms tumor is observed in the context of hemihypertrophy, aniridia, genitourinary anomalies, and a variety of rare syndromes, including **Beckwith-Wiedemann syndrome (BWS)** and **Denys-Drash syndrome** (Table 548.2). An earlier age at diagnosis and an increased incidence of bilateral disease are generally observed in syndromic and familial cases.

ETIOLOGY: GENETICS AND MOLECULAR BIOLOGY

Wilms tumor is thought to be derived from incompletely differentiated renal mesenchyme, and tumors are typically composed of cells reminiscent of the undifferentiated and partially differentiated cells that normally arise from renal mesenchyme. Foci of benign, undifferentiated mesenchyme **(nephrogenic rests)** that persist abnormally in the kidney into postnatal life are observed in approximately 1% of children in the general population but are present in up to 90% of children who have a family history of Wilms tumor, develop bilateral tumors, or display features of Wilms tumor–related syndromes. Nephrogenic rests usually regress or differentiate, but those that persist can become malignant.

Wilms tumor has been associated with genetic abnormalities. The first identified Wilms tumor gene, *WT1*, located at 11p13, is a homozygous gene variant in 10–15% of tumors, resulting in loss of function of the encoded zinc finger transcription factor. The majority of *WT1* pathogenic variants are somatic; however, *WT1* pathogenic variants can also be germline. The type of WT1 pathogenic variant affects the disease phenotype. Germline truncating variants are usually associated with Wilms tumor in the context of genitourinary anomalies or the **WAGR syndrome** (Wilms tumor, aniridia, genitourinary anomalies, mental retardation) as it involves the deletion of several contiguous genes at 11p13. Missense germline variants are usually observed in children with Denys-Drash syndrome, resulting in early-onset renal failure. In instances of germline variant, the wild-type allele present in the germline is altered or lost in the tumor, resulting in loss of *WT1* function.

Table 548.2 Wilms Tumor Predisposing Conditions

SYNDROME	GENETIC LESION	ESTIMATED WT RISK	PHENOTYPE
WT1-ASSOCIATED WILMS TUMOR PREDISPOSITION SYNDROMES			
Denys-Drash syndrome (DDS)	*WT1* pathogenic variant affecting exon 8 or 9	~75%	Ambiguous genitalia, diffuse mesangial sclerosis
Frasier syndrome	*WT1* pathogenic variant affecting intron 9 donor splice site	Low; 1 case reported	Ambiguous genitalia, streak gonads, focal segmental glomerulosclerosis
WAGR syndrome (Wilms tumor, aniridia, genital anomalies, retardation)	Deletion of 11p13 containing *WT1*	~50%	Aniridia, genitourinary anomalies, delayed-onset renal failure
WT1-associated WT predisposition	*WT1* pathogenic variant	~30%	Median age at WT diagnosis is 1.3 yr (range: 0.6-4.5)
OTHER SYNDROMES THAT PREDISPOSE TO WILMS TUMOR			
Beckwith-Wiedemann syndrome (BWS)	LOM at maternal IC2 at 11p15.5 GOM at maternal IC1 at 11p15.5 Paternal UPD at 11p15.5 Pathogenic variant in *CDKN1C* Negative molecular test	~0.2% ~24% ~8% ~1.4% ~4%	Organomegaly, large birth weight, macroglossia, omphalocele, hemihypertrophy, ear pits and creases, neonatal hypoglycemia
Bloom syndrome	Biallelic *BLM* pathogenic variants	~3%	Short stature, microcephaly, growth deficiency, immune abnormalities, sensitivity to sunlight

Continued

Table 548.2 Wilms Tumor Predisposing Conditions—cont'd

SYNDROME	GENETIC LESION	ESTIMATED WT RISK	PHENOTYPE
Fanconi anemia	Biallelic *BRCA2* or *PALB2* pathogenic variants	20–40%	Short stature, abnormal skin pigmentation, skeletal malformations, microcephaly, bone marrow failure
Hyperparathyroid-jaw tumor syndrome	*CDC73* pathogenic variant	~3%	Primary hyperparathyroidism, ossifying fibroma of the maxilla and/or mandible
Mosaic variegated aneuploidy	Biallelic *BUB1B* or *TRIP13* pathogenic variants	>85%	Microcephaly, growth deficiency, developmental delay, eye anomalies, mild dysmorphism
Perlman syndrome	Biallelic *DIS3L2* pathogenic variants	~65%	Organomegaly, large birth weight, developmental delay
Simpson-Golabi-Behmel syndrome	*GPC3* pathogenic variant	4–9%	Overgrowth, congenital heart defects
CLOVES syndrome	*PIK3CA* pathogenic variant	<5%	Congenital lipomatous overgrowth, vascular malformations, epidermal nevi, scoliosis/skeletal/spine anomalies
Sotos syndrome	*NSD1* pathogenic variant	<5%	Cerebral giantism, macrocephaly, intellectual disability, advanced bone age, poor coordination
Trisomy 18	Trisomy 18	<5%	Cognitive impairment, hypertonia, overlapping fingers, congenital heart disease, micrognathia
GENETIC VARIANTS THAT PREDISPOSE TO NONSYNDROMIC WILMS TUMOR			
CTR9-associated WT predisposition	*CTR9* pathogenic variant	4 families reported; 9/14 individuals with a pathogenic *CTR9* variant developed WT	Median age at WT diagnosis is 1.3 yr (range: 0.6-3.3). All reported variants are paternally inherited
DICER1 syndrome	*DICER1* pathogenic variant	Low; 5 families in which 6/22 individuals with a pathogenic *DICER1* variant developed WT	Lung cysts, cystic nephroma, nodular hyperplasia of the thyroid, nasal chondromesenchymal hamartoma, ciliary body medulloepithelioma and increased cancer risks including pleuropulmonary blastoma (PPB), ovarian sex cord-stromal tumors, pineoblastoma, and pituitary blastoma
Li-Fraumeni syndrome (LFS)	*TP53* pathogenic variant	Low; 12 cases reported	Around 50% of individuals with LFS develop cancer by the age of 30 yr, with a lifetime risk of >70% The tumors most closely associated with LFS include soft tissue sarcomas, osteosarcoma, premenopausal breast cancer, brain tumors, and adrenocortical carcinoma
REST-associated WT predisposition	*REST* pathogenic variant	4 families reported; 7/14 individuals with a pathogenic *REST* variant developed WT Ten presumed sporadic cases reported	Median age at WT diagnosis is 3 yr (range: 0.5-6) Other clinical features reported include primary ovarian failure, café-au-lait macules, and mild developmental delay
TRIM28-associated WT predisposition	*TRIM28* pathogenic variant	9 families reported; 18/24 individuals with a pathogenic *TRIM28* variant developed WT; however, few unaffected family members were tested 17 presumed sporadic cases reported	Median age at WT diagnosis is 1.1 yr (range: 0.4-9.8) All reported variants are maternally inherited Histology is frequently epithelial type

GOM, Gain of methylation; IC, imprinting center; LOM, loss of methylation; UPD, uniparental disomy; WT, Wilms tumor.
Modified from Maciaszek JL, Oak N, Nichols KE. Recent advances in Wilms' tumor predisposition. *Hum Mole Genetics.* 2020;29(R2):R138–R149. Table 1, p. R139–R140.

Consistent with the etiology of Wilms tumor being grounded in aberrant kidney development, genes that regulate the proliferation and differentiation of kidney progenitors have been identified to be mutated in tumors. One class of genes that encodes proteins essential for the biogenesis of mature miRNAs are altered in one fifth to one third of Wilms tumors. These include *DROSHA* missense variants that occur in approximately 10% of tumors, and *DICER, DGCR8, XPO5*, and *TARBP2* variants. Of note, germline *DICER1* variants are observed, albeit infrequently, in Wilms tumor families and, more frequently, in families with pleuropulmonary blastoma (see Table 548.2).

The **Wnt signaling pathway** plays a critical role in regulating the differentiation of the fetal kidney. Somatic pathogenic variants in *CTNNB1* and *WTX*, both of which play a role in the Wnt pathway regulation, are observed in approximately 15% and 20% of Wilms tumors,

Table 548.3 Differential Diagnosis of Abdominal and Pelvic Tumors in Children

TUMOR	PATIENT AGE	CLINICAL SIGNS	LABORATORY FINDINGS
Wilms tumor	Preschool	Unilateral flank mass, aniridia, hemihypertrophy	Hematuria, polycythemia, thrombocytosis, elevated partial thromboplastin time
Neuroblastoma	Preschool	Gastrointestinal/genitourinary obstruction, raccoon eyes, myoclonus-opsoclonus, diarrhea, skin nodules	Increased urinary vanillylmandelic acid, homovanillic acid, or ferritin; stippled calcification in the mass
Non-Hodgkin lymphoma	>1 yr	Intussusception in >2 yr old	Increased lactate dehydrogenase; blood cytopenia caused by bone marrow involvement
Rhabdomyosarcoma	All	Gastrointestinal/genitourinary obstruction, abdominal pain, vaginal bleeding, paratesticular mass	Hypercalcemia; blood cytopenia caused by bone marrow involvement
Germ cell tumor/ teratoma	Preschool, teenage	*Females:* Abdominal pain, vaginal bleeding *Males:* Testicular mass, new-onset hydrocele, sacrococcygeal mass/dimple	Increased β-human chorionic gonadotropin, increased α-fetoprotein
Hepatoblastoma	Birth-3 yr	Right upper quadrant mass, jaundice Early puberty in males	Increased α-fetoprotein
Hepatocellular carcinoma	School age, teenage	Right upper quadrant mass, jaundice, hepatitis B, cirrhosis	Increased α-fetoprotein

respectively. Somatic variants in genes that are critical for regulating progenitor proliferation and differentiation (*MYCN, SIX1,* and *SIX2*) are observed in approximately 10% of tumors. Other somatic variants, including *MLLT1, ARID1A,* and *SMARCA4,* occur at a frequency of approximately 4–5% each. Importantly a somatic variant of the p53 gene, *TP53*, is observed in approximately 5% of tumors and is associated with **anaplastic tumor** histology, a poor prognostic feature of Wilms tumor.

Loss of heterozygosity (LOH; usually copy number neutral) or loss of imprinting at imprinted loci at 11p15 is observed in approximately 70% of Wilms tumors. This epigenetic alteration often results in biallelic expression of *IGF2,* a normally imprinted gene that encodes insulin-like growth factor 2, in addition to the loss of imprinting of other 11p15 genes. BWS, a somatic overgrowth syndrome with predisposition to embryonal tumors (including Wilms tumor), has been linked to 11p15, and microdeletions within the *IGF2* imprinting control region are present in BWS families in whom Wilms tumor is observed.

Allelic imbalances have been identified in Wilms tumors, particularly LOH at 1p and 16q, which has been associated with increased risk of recurrence. Gain of chromosome 1q was found to be associated with inferior survival in unilateral favorable-histology Wilms tumor.

In patients with a family history of Wilms tumor, predisposition is inherited as an autosomal dominant trait with incomplete penetrance. Predisposition to other tumor types or other phenotypes is not observed in most of these families. Germline pathogenic variants have been identified in a minority of families, and each of those genes identified (e.g., *WT1, DICER1, MYCN, REST, BRCA2*) is altered in <5% of Wilms tumor families.

CLINICAL PRESENTATION

The most common initial clinical presentation for Wilms tumor is the incidental discovery of an asymptomatic **abdominal mass** by parents while bathing or clothing an affected child or by a physician during a routine physical examination (Table 548.3). At presentation, the mass can be quite large, because retroperitoneal masses can grow unhampered by strict anatomic boundaries. Functional defects in paired organs such as the kidney, with good functional reserve, are also unlikely to be detected early. Physical exam findings include a firm, nontender, smooth abdominal mass that rarely crosses the midline. Care should be taken to avoid vigorous palpation to prevent the risk of renal capsule rupture. Children with direct access to pediatricians vs generalists as primary caregivers are more likely to be diagnosed early and to have smaller tumors and less advanced stage at diagnosis. Hypertension is present in about 25% of patients at presentation and has been attributed to increased renin activity. Abdominal pain (40%), gross painless hematuria (18%), and constitutional symptoms such as fever, anorexia, and weight loss are other findings at diagnosis. Occasionally, rapid abdominal enlargement and anemia occur because of bleeding into the renal parenchyma or pelvis. Wilms tumor thrombus extends into the inferior vena cava (IVC) in 4–10% of patients and rarely into the right atrium; dislodgment of the intravascular tumor may produce a fatal occlusive **pulmonary embolism**. Patients might also have microcytic anemia from iron deficiency or anemia of chronic disease, polycythemia, elevated platelet count, and acquired deficiency of von Willebrand factor or factor VII deficiency.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

An abdominal mass in a child should be considered malignant until diagnostic imaging, laboratory findings, and pathology can define its true nature (see Table 548.3). Imaging studies include plain abdominal radiography, abdominal ultrasonography (US), and CT of the abdomen to define the intrarenal origin of the mass and differentiate it from adrenal masses (e.g., neuroblastoma) and other masses in the abdomen. Abdominal US helps differentiate solid from cystic masses. Wilms tumor might show focal areas of necrosis or hemorrhage and hydronephrosis because of obstruction of the renal pelvis by the tumor. US with Doppler imaging of renal veins and the IVC is a useful first study to identify Wilms tumor, evaluate the collecting system, and demonstrate tumor thrombi in the renal veins and IVC. However, its routine use after CT has been performed is not required.

CT is useful to define the extent of the disease, integrity of the contralateral kidney, and metastasis (Figs. 548.1 and 548.2). MRI requires sedation in young children and is not routinely used. However, MRI may be helpful in defining an extensive tumor thrombus that extends up to the level of the hepatic veins, or even into the right atrium, and to distinguish Wilms tumor from nephrogenic rests. Chest CT is more sensitive than chest radiography to screen for pulmonary metastasis and is preferably performed before surgery because effusions and atelectasis can confound the interpretation of postoperative imaging studies. A bone scan is performed if the histologic diagnosis confirms clear cell sarcoma of the kidney (CCSK) or rhabdoid tumor of the kidney, to look for bone metastasis. Brain imaging with CT or MRI is also obtained in cases of clear cell sarcoma or rhabdoid tumor of the kidney because these tumors can spread to the brain.

Wilms tumor lesions are metabolically active and concentrate fluorodeoxyglucose (FDG). Regional spread and metastatic lesions can

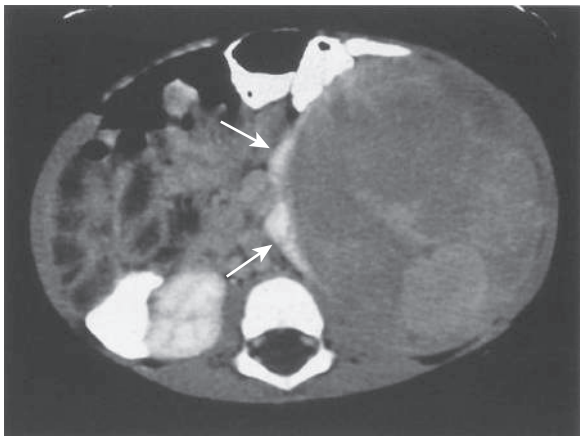

Fig. 548.1 Large heterogeneous Wilms tumor in left kidney. The residual renal parenchyma is displaced medially *(arrows). (From Haaga JR, Boll DT, eds. CT and MRI of the Whole Body. 6th ed. Philadelphia: Elsevier; 2017: Fig. 54-84, p. 1816.)*

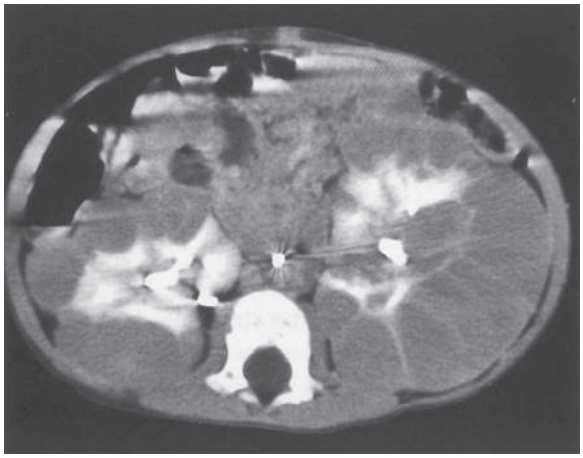

Fig. 548.2 Multicentric and bilateral Wilms tumors. The tumors have a low density and compress residual enhancing renal tissue. *(From Haaga JR, Boll DT, eds. CT and MRI of the Whole Body. 6th ed. Philadelphia: Elsevier; 2017: Fig. 54-86, p. 1817.)*

be visualized on PET/CT scanning. The diagnosis is usually made by imaging studies and confirmed by histology at the time of nephrectomy. Although biopsy is a reliable diagnostic tool, it is discouraged because it results in disease upstaging according to the Children's Oncology Group (COG) staging system. A core needle biopsy obtained through a posterior approach (to limit contamination of the peritoneal cavity) should be performed in cases of unusual presentation (>10 years old, signs of infection, inflammation) or unusual imaging findings (significant adenopathy, no renal parenchyma seen, intratumoral calcification).

Patients with Wilms tumor associated syndromes should undergo routine screening with serial abdominal US to allow for early detection and treatment.

TREATMENT

The COG protocols and the **International Society of Pediatric Oncology (SIOP)** protocols differ in their initial treatment approach. *COG advocates upfront surgery* prior to initiating treatment, whereas *SIOP recommends preoperative chemotherapy.* Each approach has advantages and limitations, but they have similar outcomes. Early surgery provides accurate diagnosis and staging and can facilitate *risk-adapted therapy*. Preoperative chemotherapy can make surgery easier and reduces the risk of intraoperative tumor rupture and hemorrhage. Surgery entails a radical nephrectomy, with meticulous dissection to avoid rupture of the tumor capsule, and lymph node sampling despite the absence of abnormal nodes on preoperative imaging studies or intraoperative assessment. Partial nephrectomy is performed in patients with bilateral disease or those with unilateral Wilms tumor and predisposing syndrome such as the Denys-Drash and WAGR syndromes to minimize the risk of future renal failure.

Table 548.4 Children's Oncology Group Staging of Wilms Tumor

STAGE	DESCRIPTION
I	Tumor *confined to the kidney* and completely resected Renal capsule or sinus vessels not involved Tumor not ruptured or biopsied Regional lymph nodes examined and negative
II	Tumor extends *beyond the kidney* but is completely resected with negative margins and lymph nodes At least one of the following has occurred: (a) penetration of renal capsule, (b) invasion of renal sinus vessels
III	*Residual tumor* present following surgery confined to the abdomen, including gross or microscopic tumor; spillage of tumor preoperatively or intraoperatively; biopsy prior to nephrectomy, regional lymph node metastases; tumor implants on the peritoneal surface; extension of tumor thrombus into the inferior vena cava, including thoracic vena cava and heart
IV	*Hematogenous metastases* (lung, liver, bone, brain, etc.) or lymph node metastases outside the abdominopelvic region
V	*Bilateral* renal involvement by tumor

Prognostic factors for risk-adapted therapy include age, stage, histology, tumor weight, LOH at chromosomes 1p and 16q, and metastatic lung nodule response (Table 548.4). Histology plays a major role in risk stratification of Wilms tumor. Absence of anaplasia is considered a favorable histologic finding. Presence of anaplasia is further classified as focal or diffuse, both of which are unfavorable histologic findings.

The COG has very specific drug dose and schedule recommendations for risk-adapted treatment of Wilms tumor. Patients with *favorable-histology* Wilms tumor have a good outcome and are generally treated in the outpatient setting. Nephrectomy alone is sufficient for patients with very low risk disease (<2 years old with stage I disease and a tumor weight <550 g), resulting in a 4-year event-free survival of 90% and a 4-year overall survival of 100%. Patients with stage I and II disease receive chemotherapy with two drugs, vincristine and actinomycin D (also called dactinomycin), every 1-3 weeks for a total of 18 weeks (regimen **EE4A**). Patients with stage III or stage IV disease receive chemotherapy with three drugs (vincristine, doxorubicin, and actinomycin D) every 1-3 weeks for a total of 24 weeks (regimen **DD4A**) and radiation therapy. Patients with regional lymph node metastases, residual disease after surgery, or tumor rupture receive radiation therapy to the flank or abdomen, and those with lung metastases receive radiation therapy to the lungs. Rapid response of lung metastases to chemotherapy may eliminate the need for lung radiation. In patients with stage III or stage IV disease and LOH at both 1p and 16q or in those with lung metastases only who have incomplete response at 6 weeks of DD4A, therapy is augmented by adding cyclophosphamide/etoposide to DD4A (Regimen M). The LOH of both 1p and 16q and gain of 1q confers an adverse prognosis and deserves treatment intensification.

For patients with bilateral Wilms tumor, three-drug preoperative chemotherapy, surgical resection within 12 weeks of diagnosis, and histology-based postoperative therapy improves survival outcomes and feasibility of nephron-sparing surgery.

Anaplastic histology (focal and diffuse) accounts for approximately 11% of Wilms tumor cases. Patients with *diffuse anaplasia* have worse outcome than patients with favorable histology and receive more

intensive therapy. Patients with stage 1 anaplastic Wilms tumor treated with regimen DD4A and flank radiation had excellent survival outcomes. Patients with stage II-IV disease are treated more intensively with multiagent chemotherapy including vincristine, cyclophosphamide, doxorubicin, etoposide, carboplatin, and irinotecan, in addition to radiotherapy. Despite some improvement in survival outcomes, patients with stage IV disease continue to fare poorly.

RECURRENT DISEASE

Approximately 15% of favorable-histology and 50% of anaplastic-histology Wilms tumors relapse; most relapses occur early (within 2 years of diagnosis). Factors associated with a favorable outcome after relapse include low stage (I/II) at diagnosis, treatment with vincristine and actinomycin D only, no prior radiotherapy, favorable histology, relapse to lung only, and interval from nephrectomy to relapse ≥12 months. Patients with recurrent Wilms tumor who previously received only vincristine and actinomycin D had a 4-year survival of approximately 80%, whereas those who previously received the three-drug regimen of vincristine, actinomycin D, and doxorubicin had a 4-year survival of only 50%. Other agents used to treat recurrent Wilms tumor include doxorubicin, carboplatin, cyclophosphamide, ifosfamide, etoposide, irinotecan, and topotecan. *Metachronous* Wilms tumor may not represent tumor relapse but development of a new tumor in the opposite kidney.

PROGNOSIS

Despite some adverse risk factors that decrease prognosis (presence of metastasis, unfavorable histology, recurrent disease, incomplete lung nodule response at 6 weeks of chemotherapy, LOH of both 1p and 16q and gain of 1q), most children with Wilms tumor have a very favorable prognosis. Overall survival of children with Wilms tumor exceeds 90%, with some prognostic factors (low stage, favorable histology, young age, low tumor weight) conferring even better outcomes. Wilms tumor tops the list of common pediatric solid tumors in terms of favorable outcome.

LATE EFFECTS

Current strategies are successful with relatively few long-term effects of therapy. Generally, late complications are a consequence of treatment type and intensity; the use of radiotherapy and anthracyclines increase the risk of these complications. Clinically significant late sequelae include musculoskeletal effects, cardiac toxicity, pulmonary disease, reproductive problems, renal dysfunction, and development of second malignant neoplasms such as leukemia and cancer of the digestive organs and breast (in females).

548.2 Other Pediatric Renal Tumors

Najat C. Daw and Dristhi S. Ragoonanan

MESOBLASTIC NEPHROMA

Mesoblastic nephroma is the most common solid renal tumor identified in the *neonatal period* and the most frequent benign renal tumor in childhood. It represents approximately 5% of all pediatric renal tumors. ETV6-NTRK3 fusion pathogenic variant is the most common molecular alteration seen in these tumors. Many cases are diagnosed with prenatal US and can manifest as polyhydramnios, hydrops, and premature delivery. Most patients are diagnosed before 3 months of age, whereas Wilms tumor is *rarely diagnosed* before 6 months. Male/female ratio is 1.5:1. Radical nephrectomy is the treatment of choice and may be sufficient by itself. Local recurrence is uncommon. Although rare, malignant variants do occur, marked by metastases to the lung, liver, heart, and brain.

CLEAR CELL SARCOMA OF THE KIDNEY

CCSK is an uncommon renal neoplasm of childhood, with approximately 20 new cases diagnosed each year in North America. Peak incidence is between 1 and 4 years of age with a male/female ratio of 2:1. It usually presents with abdominal distention, abdominal mass, or gross hematuria. Gene expression profiles of CCSK suggest the cell of origin to be a renal mesenchymal cell with neural markers, and *BCOR* gene duplication is the most common molecular alteration seen. Bone is the most common site of distant metastasis, followed by lung, abdomen, retroperitoneum, brain, and liver. Therefore the staging workup should include a bone scan. With modern therapy, patients with stage I and II disease have an excellent prognosis (4-year overall survival of 97–100%), whereas those with stage III and IV disease have a 4-year overall survival of 89% and 45%, respectively.

RHABDOID TUMOR OF THE KIDNEY

Malignant rhabdoid tumor of the kidney **(MRTK)** has rhabdomyoblast-like morphology and is a rare but aggressive cancer. The median age of presentation is 11 months, and hematuria is a common presenting feature. Both rhabdoid tumor of the kidney and central nervous system (CNS) atypical teratoid/rhabdoid tumors have deletions and pathogenic variants of the *SMARCB1/hSNF5/INI1* gene and are considered related. Germline pathogenic variants in *SMARCA4* or *SMARCB1* have been linked to rhabdoid tumor predisposition syndrome, an autosomal dominant disorder that results in the increased risk of developing rhabdoid tumors predominantly in infants and children younger than 3 years of age. MRTKs tend to metastasize to the lungs and brain. Prognosis is poor with current therapeutic protocols. Younger age at diagnosis, advanced-stage disease, and CNS involvement are associated with a worse prognosis. The outcome of patients with MRTK is poor. Both the 4-year relapse-free survival and overall survival for patients treated on the National Wilms Tumor Study-5 (NWTS-5) were 50% for stage I, 33% for stages II and III, and 21% for stage IV.

RENAL CELL CARCINOMA

Although renal cell carcinoma **(RCC)** is the most prevalent renal tumor in adults, it is extremely rare in children, accounting for <10% of pediatric renal tumors. The annual incidence rate is approximately four cases per 1 million children. Although Wilms tumor is the predominant renal tumor in childhood, it is rare past early childhood, and RCC is the most prevalent renal malignancy during the second decade of life. Several **genetic disorders** are associated with a predisposition to RCC, including von Hippel-Lindau disease, tuberous sclerosis, and hereditary leiomyomatosis. The most common subtype of RCC in children, the **translocation-type RCC**, is characterized by translocations most frequently involving the *TFE3* gene on chromosome Xp11.2 or the *TFEB* gene on chromosome 6p21. *Renal medullary carcinoma is seen typically in young patients with sickle cell trait.*

Children with RCC may present with frank hematuria, flank pain, and/or a palpable mass, although RCC can be asymptomatic and detected incidentally. RCC has a propensity to metastasize to the lungs, liver, and bone. Although local lymph node involvement is a poor prognostic indicator in adult RCC, the importance of nodal status in pediatric RCC is controversial. Nephrectomy alone may be adequate for early-stage RCC. Along with surgery, there is no established optimal treatment for childhood RCC; neither chemotherapy nor radiation therapy has demonstrated significant activity. Localized pediatric RCC has an excellent outcome without adjuvant therapy; however, the outcomes remain poor for metastatic RCC and renal medullary carcinoma.

Chapter 549

Soft Tissue Sarcomas

Wendy A. Allen-Rhoades and Carola A.S. Arndt

The annual incidence of soft tissue sarcomas is 11 cases per 1 million children younger than 14 years of age and 17.4 cases per 1 million adolescents age 15-19 years. Rhabdomyosarcoma accounts for more than 50% of soft tissue sarcomas. The prognosis most strongly correlates with age and extent of disease at diagnosis, primary tumor site and histology, and presence of translocations involving the *FOXO1* and *PAX* genes.

RHABDOMYOSARCOMA

Epidemiology

The most common pediatric soft tissue sarcoma, rhabdomyosarcoma, accounts for approximately 3.5% of childhood cancers. These tumors may occur at any anatomic site (Table 549.1) including the head and neck, orbit, genitourinary tract, and extremities; retroperitoneal and other sites account for the remainder of primary sites. The incidence at each anatomic site is related to both patient age and tumor type. Extremity lesions are more likely to occur in older children and to have alveolar histology and harbor a fusion oncoprotein. Rhabdomyosarcoma occurs with increased frequency in patients with neurofibromatosis, Costello syndrome, and other family cancer predisposition syndromes such as Li-Fraumeni syndrome (Table 549.2).

Table 549.1 Common Presenting Signs and Symptoms by Primary Site

PRIMARY SITE (%)	SYMPTOMS AND SIGNS
Head and neck (40%)	Painless or painful swelling Proptosis Ptosis Ophthalmoplegia Headache Vomiting Cranial nerve palsy Other cranial nerve palsies Nasal discharge Nasal/sinus congestion Trismus Systemic hypertension
Limbs/trunk (30%)	Asymptomatic swelling
Genitourinary tract/pelvis (20%)	Painless scrotal lesions Hematuria Urinary retention/dribbling Vulval nodule Polypoid vaginal lesions Vaginal bleeding/discharge Constipation
Abdomen/liver/biliary (~10%)	Asymptomatic swelling Abdominal pain Intestinal obstruction Jaundice Cholangitis
Metastatic disease (20% at diagnosis) Bone Bone marrow Lung Lymph nodes	Otherwise unexplained: Poor feeding Seizures Pain Irritability Pancytopenia

Modified from Rogers TN, Dasgupta R. Management of rhabdomyosarcoma in pediatric patients. *Surg Oncol Clin N Am.* 2021;30(2):339–353. Table 2.

Pathogenesis

Rhabdomyosarcoma is thought to arise from the same embryonic mesenchyme as striated skeletal muscle although a large percentage of these tumors arise in areas lacking skeletal muscle (e.g., bladder, prostate, vagina). On the basis of light microscopic appearance, it belongs to the general category of small, round, blue cell tumors that includes Ewing sarcoma, neuroblastoma, and non-Hodgkin lymphoma. Definitive diagnosis of a pathologic specimen requires immunohistochemical studies using antibodies to skeletal muscle (desmin, muscle-specific actin, myogenin) and reverse transcription polymerase chain reaction, next generation sequencing, or fluorescent in situ hybridization for *FOXO1* rearrangements.

Determination of the specific histologic subtype and fusion status is important in treatment planning and assessment of prognosis. There are four recognized histologic subtypes. The **embryonal type** accounts for approximately 60% of all cases and does not typically harbor a genetic translocation. The rare **spindle/sclerosing** subtype that accounts for approximately 3–4% of all children with rhabdomyosarcoma. It is characterized by a sclerosing (microalveolar) pattern that can mimic the alveolar subtype, but it does not harbor the characteristic PAX/FOXO translocation seen in the alveolar subtype. The **alveolar type** accounts for approximately 25–40% of cases and is characterized by the presence of a chromosomal translocation. Over 80% of *FOXO1* translocations in the alveolar subtype involve a translocation between *FOXO1* and *PAX3*, but other rare variants exist such as *PAX3-NCOA2*. The tumor cells tend to grow in nests that often have cleft-like spaces resembling alveoli. Alveolar tumors occur most often in the trunk and extremities and carry the poorest prognosis. The **pleomorphic type** (adult form) is rare in childhood, accounting for <1% of cases.

Table 549.2 Genetic Disorders Associated with Rhabdomyosarcoma

DISORDER	GENETIC VARIANTS
Beckwith-Wiedemann syndrome	Deletions and loss of heterozygosity at chromosome 11p15, particularly affecting *IGF2, CDKAIC, H19,* and/or *LIT1*
Gorlin syndrome (basal cell nevus syndrome)	*PTCH*
Costello syndrome	*H-RAS*
Neurofibromatosis 1	*NF1*
Li-Fraumeni syndrome	*TP53*
Mosaic variegated aneuploidy syndrome	*BUB1B*
Nijmegen breakage syndrome (ataxia-telangiectasis syndrome variant 1)	*NBS*
Rubinstein-Taybi syndrome	*CREBBP*
Constitutional mismatch-repair/deficiency syndrome	*PSM2*
Adenomatous polyposis coli	*APC*
Hereditary retinoblastoma	*RB1*
Familial pleuropulmonary blastoma syndrome	*DICER1*
Noonan syndrome	*PTPN11*
Werner syndrome	*RECOL2*

From Parham DM, Alaggio R, Coffin CM. Myogenic tumors in children and adolescents. *Pediatr Dev Pathol.* 2012;15(1):S211–S236. Table 3.

Clinical Manifestations

The most common presenting feature of rhabdomyosarcoma is a mass that may or may not be painful. Symptoms are caused by displacement or obstruction of normal structures. Origin in the **nasopharynx** may be associated with nasal congestion, mouth breathing, epistaxis, and difficulty with swallowing and chewing. Regional extension into the cranium can produce cranial nerve paralysis, blindness, and signs of increased intracranial pressure with headache and vomiting. When the tumor develops in the face or cheek, there may be swelling, pain, trismus, and, as extension occurs, paralysis of cranial nerves. Tumors in the **neck** can produce progressive swelling with neurologic symptoms after regional extension. **Orbital** primary tumors are usually diagnosed early in their course because of associated proptosis, periorbital edema, ptosis, change in visual acuity, and local pain. When the tumor arises in the **middle ear**, the most common early signs are pain, hearing loss, chronic otorrhea, or a mass in the ear canal; extensions of the tumor produce cranial nerve paralysis and signs of an intracranial mass on the involved side. An unremitting croupy cough and progressive stridor can accompany rhabdomyosarcoma of the **larynx**. Because most of these signs and symptoms also are associated with common childhood conditions, clinicians must be alert to the possibility of tumor.

Rhabdomyosarcoma of the trunk or extremities often is first noticed after trauma and initially may be regarded as a hematoma. If the swelling does not resolve or increases, malignancy should be suspected. Involvement of the genitourinary tract can produce hematuria, obstruction of the lower urinary tract, recurrent urinary tract infections, incontinence, or a mass detectable on abdominal or rectal examination. Paratesticular tumor usually manifests as a painless, rapidly growing mass in the scrotum. Vaginal rhabdomyosarcoma may manifest as a grapelike mass of tumor tissue bulging through the vaginal orifice, known as **sarcoma botryoides**, and can cause urinary tract or large bowel symptoms. Vaginal bleeding or obstruction of the urethra or rectum may occur. Similar findings can be noted with tumors arising from the uterus.

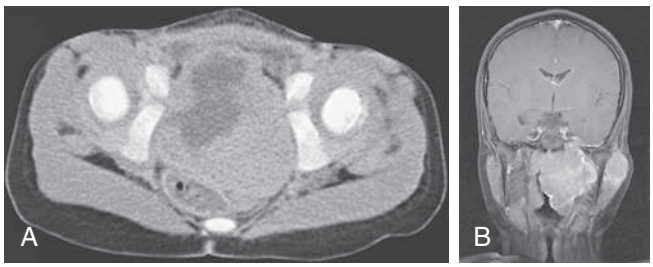

Fig. 549.1 A, Pelvic CT scan of a child with a bladder rhabdomyosarcoma. B, MR image of a child with a parameningeal rhabdomyosarcoma.

Tumors in any location may disseminate early and cause symptoms of pain or respiratory distress associated with pulmonary metastases. Extensive bone involvement can produce symptomatic hypercalcemia or bony pain. In such cases, it may be difficult to identify the primary lesion.

Diagnosis

Early diagnosis of rhabdomyosarcoma requires a high index of suspicion. The microscopic appearance is that of a small, round blue cell tumor. Neuroblastoma, lymphoma, and Ewing sarcoma also are **small, round blue cell tumors** from which suspected rhabdomyosarcomas must be differentiated. The differential diagnosis depends on the site of presentation. Definitive diagnosis is established by biopsy, microscopic appearance, and results of immunohistochemical stains and analysis of *PAX/FOXO1* expression. A lesion in an extremity may be thought to be a hematoma or hemangioma, an orbital lesion resulting in proptosis may be treated as an orbital cellulitis, or bladder-obstructive symptoms may be missed. Adolescents may ignore or be embarrassed to mention paratesticular lesions for a long time. Unfortunately, several months often elapse between initial symptoms and biopsy. Diagnostic procedures are determined mainly by the area of involvement. CT or MRI is necessary for evaluation of the primary tumor site. With signs and symptoms in the head and neck area, MRI should be performed to identify intracranial extension or meningeal involvement and also to reveal bony involvement or erosion at the base of the skull. For abdominal and pelvic tumors, CT with a contrast agent or MRI can help delineate the tumor (Figs. 549.1 and 549.2). A radionuclide bone or fluorodeoxyglucose PET (FDG-PET) scan, chest CT, and bilateral bone marrow aspiration and biopsy should be performed to evaluate the patient for the presence of metastatic disease and to plan treatment. Some low-risk patients may not need bone marrow evaluation. The most critical element of the diagnostic workup is examination of tumor tissue by an experienced sarcoma pathologist, which includes the use of special histochemical stains and immunostains along with molecular genetics to detect fusion transcripts as described earlier. Lymph nodes also should be sampled for the presence of disease spread, especially in tumors of the extremities and in males older than 10 years of age with paratesticular tumors.

Treatment

Treatment is multidisciplinary and includes the pediatric oncologist, pediatric surgeon or other surgical subspecialist, and often a radiation oncologist. Only if the tumor is able to be completely resected, with negative margins, without loss of function or major cosmetic deformity, should this be attempted initially. Unfortunately, most rhabdomyosarcomas are not completely resectable at initial diagnosis. Treatment is based on risk classification of the tumor, which is determined by the stage of tumor, the tumor histology and/or fusion status, and the amount of tumor that was surgically resected prior to chemotherapy ("surgical group"). Stage is dependent on primary site

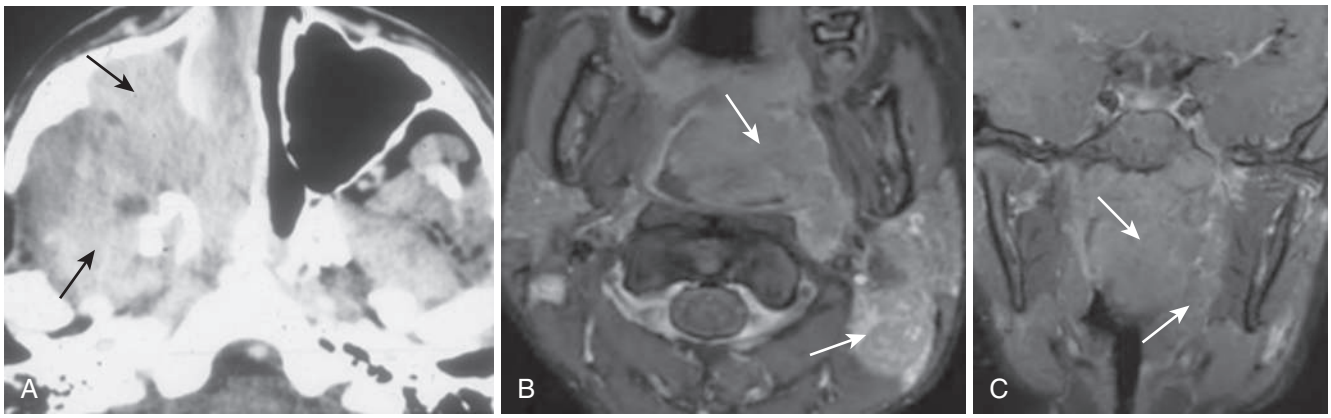

Fig. 549.2 Rhabdomyosarcoma. A, Axial contrast-enhanced CT scan at the level of the nasal cavity demonstrates a large, enhancing aggressive soft tissue mass involving the right maxillary sinus and the infratemporal fossa *(arrows)*. Axial MR image (B) and coronal contrast-enhanced T1-weighted MR image (C) demonstrate an infiltrative mass involving the pharyngeal mucosal space, left infratemporal masticator space, skull base, and sphenoid sinus *(arrows)*. *(From Haaga JR, Boll DT, eds. CT and MRI of the Whole Body. 6th ed. Philadelphia: Elsevier; 2017: Fig. 26-16, p. 769.)*

(favorable vs unfavorable), tumor invasiveness (T1 or T2), lymph node status, tumor size, and presence of metastasis. Favorable sites include female genital, paratesticular, and head and neck (nonparameningeal) regions; all other sites are considered unfavorable. Table 549.3 shows the Children's Oncology Group staging system for rhabdomyosarcoma.

Patients should be offered enrollment in clinical trials. Table 549.4 shows current risk stratification and outcome based on results of recent studies. Patients with low-risk disease can be cured with minimal therapy consisting of vincristine and actinomycin with or without lower doses of cyclophosphamide; radiation therapy can be used in the case of residual disease after initial surgery. Treatment for patients with intermediate-risk disease consists of vincristine, actinomycin, and cyclophosphamide along with radiation. The addition of irinotecan has recently been studied in intermediate risk rhabdomyosarcoma, and the current trial for patients with intermediate risk disease is exploring the role of maintenance chemotherapy. For patients with high-risk disease, approaches using intensive multiagent chemotherapy have not improved the outcome and new approaches are being investigated.

Prognosis

Prognostic factors include age, stage, histology/fusion status, and primary site. Among patients with resectable tumor and favorable histology, 80–90% have prolonged disease-free survival. Unresectable tumor localized to certain favorable sites, such as the orbit, also has a high likelihood of cure. Approximately 65–70% of patients with incompletely resected tumor also achieve long-term disease-free survival. Patients with disseminated disease have a poor prognosis; only approximately 50% achieve remission, and fewer than 50% of these are cured. Older children have a poorer prognosis than younger children. For all patients, surveillance for late effects of cancer treatment is extremely important. Some examples of late effects include infertility from cyclophosphamide, late effects in the radiation field such as bladder dysfunction, infertility, cataracts, impaired bone growth, and secondary malignancies.

OTHER SOFT TISSUE SARCOMAS

The nonrhabdomyosarcoma soft tissue sarcomas constitute a heterogeneous group of tumors that account for 3% of all childhood malignancies (Table 549.5). Because they are relatively rare in children, much of the information about their natural history and treatment has been derived from studies in adult patients. In children, the median age at diagnosis is 12 years, with a male:female ratio of 2.3:1. These tumors commonly arise in the trunk or lower extremities. The most common histologic types are synovial sarcoma (42%), fibrosarcoma (13%), malignant fibrous histiocytoma (12%), and neurogenic tumors (10%). Molecular genetic studies often prove useful in diagnosis, because several of these tumors have characteristic chromosomal translocations. Tumor size, stage (clinical group), invasiveness, and histologic grade correlate with survival.

Surgery remains the mainstay of therapy, but a careful search for lung and bone metastases should be undertaken before surgical excision. Chemotherapy and radiation therapy should be considered for large, high-grade, and/or unresectable tumors. The role of chemotherapy for nonrhabdomyosarcoma soft tissue sarcomas is not as well defined as for rhabdomyosarcoma. Patients with large (>5 cm) high-grade, or unresectable or metastatic disease are treated with multiagent chemotherapy in addition to irradiation and/or surgery. Patients with completely resected small (<5 cm) tumors are generally treated with surgery alone and can be expected to have an excellent outcome regardless of whether the tumor is high or low grade.

Neoplasms of Bone

550.1 Malignant Tumors of Bone

Wendy A. Allen-Rhoades and Carola A.S. Arndt

The annual incidence of malignant bone tumors in the United States is approximately 8.2 cases per 1 million children younger than 14 years and 14.7 per 1 million for adolescents age 15-19. **Osteosarcoma** is the most common primary malignant bone tumor in children and adolescents, followed by **Ewing sarcoma** (Table 550.1, Fig. 550.1). In children <10 years old, Ewing sarcoma is more common than osteosarcoma. Both tumor types are most likely to occur in the second decade of life.

OSTEOSARCOMA

Epidemiology

The annual incidence of osteosarcoma in the United States is 5.7 cases per 1 million children 0-19 years old. The highest risk period for development of osteosarcoma is during the adolescent growth spurt, suggesting an association between rapid bone growth and malignant transformation. Patients with osteosarcoma are taller than their peers of similar age.

Pathogenesis

Although the cause of osteosarcoma is unknown, certain genetic or acquired conditions predispose patients to development of osteosarcoma. Patients with **hereditary retinoblastoma** have a significantly increased risk for development of osteosarcoma. The sites of osteosarcoma in these patients include previously irradiated areas but also sites far from the original retinoblastoma radiation field. Predisposition to development of osteosarcoma in these patients may be related to loss of heterozygosity of the *RB* gene. Osteosarcoma also occurs in **Li-Fraumeni syndrome**, which is a familial cancer syndrome associated with germline pathogenic variants of the *P53* gene. Kindreds with Li-Fraumeni syndrome have a spectrum of malignancies in first-degree relatives, including carcinoma of the breast, soft tissue sarcomas, brain tumors, leukemia, adrenocortical carcinoma, and other malignancies. **Rothmund-Thomson syndrome** is a rare condition associated with short stature, skin telangiectasia, small hands and feet, hypoplasticity or absence of the thumbs, and a high risk of osteosarcoma. **Diamond-Blackfan anemia** is also a risk factor for osteosarcoma. Osteosarcoma can also be induced by irradiation for Ewing sarcoma, craniospinal irradiation for brain tumors, or high-dose irradiation for other malignancies. Other benign conditions that can be associated with malignant transformation to osteosarcoma include Paget disease, enchondromatosis, multiple hereditary exostoses, and fibrous dysplasia (see Chapter 550.2).

The pathologic diagnosis of osteosarcoma is made by demonstration of a highly malignant, pleomorphic, spindle cell neoplasm associated with the formation of malignant osteoid and bone. There are four pathologic subtypes of conventional high-grade osteosarcoma: osteoblastic, fibroblastic, chondroblastic, and telangiectatic. No significant differences in outcome are associated with the various subtypes, although the chondroblastic component of that subtype may not respond as well to chemotherapy.

Telangiectatic osteosarcoma may be confused with aneurysmal bone cyst (ABC) because of its lytic appearance on radiography. High-grade osteosarcoma typically arises in the diaphyseal region of long bones and invades the medullary cavity. It also may be associated with a soft tissue mass. Two variants of osteosarcoma, parosteal and periosteal, should be distinguished from conventional osteosarcoma because of their characteristic clinical features. **Parosteal osteosarcoma** is a low-grade, well-differentiated tumor that does not invade the medullary cavity and most frequently is found in the posterior aspect of the distal femur. Surgical resection alone often is curative in this lesion, which has a low propensity for metastatic spread. **Periosteal osteosarcoma** is a rare variant that arises on the surface of the bone but has a higher rate of metastatic spread than the parosteal type and an intermediate prognosis.

Clinical Manifestations

Pain, limp, and swelling are the most common presenting manifestations of osteosarcoma. Because these tumors occur most often in active

Table 550.1 Comparison of Features of Osteosarcoma and the Ewing Family of Tumors

FEATURE	OSTEOSARCOMA	EWING FAMILY OF TUMORS*
Age	Second decade	Second decade
Ethnicity	All	Primarily Whites
Sex (M:F)	1.5:1	1.5:1
Predisposition	Retinoblastoma, Li-Fraumeni syndrome, Rothmund-Thomson syndrome, Paget disease, radiotherapy	None known
Site	Metaphyses of long bones	Diaphyses of long bones, flat bones, soft tissues
Presentation	Local pain and swelling; often history of injury; pathologic fracture	Local pain and swelling; fever, palpable mass, pathologic fracture
Radiographic findings	Sclerotic destruction (less often lytic); sunburst pattern, Codman triangle	Primarily lytic, multilaminar periosteal reaction ("onion-skinning"), "moth-eaten," Codman triangle
Differential diagnosis	Ewing sarcoma, osteomyelitis, hematoma	Osteomyelitis, eosinophilic granuloma, lymphoma, neuroblastoma, rhabdomyosarcoma, FUO
Metastasis	Lungs, bones	Lungs, bones, bone marrow
Treatment	Chemotherapy	Chemotherapy
	Ablative surgery of primary tumor	Radiotherapy and/or surgery of primary tumor
Outcome	Without metastases, 70% cured; with metastases at diagnosis, ≤20% survival	Without metastases, 65–75% cured; with metastases at diagnosis, 20–30% survival

FUO, Fever of unknown origin.
*Ewing family of tumors includes: (1) Ewing sarcoma of bone; (2) extraosseous (extraskeletal) Ewing tumor; (3) peripheral primitive neuroectodermal tumor (PPNET). A PPNET arising from the chest wall is an Askin tumor.

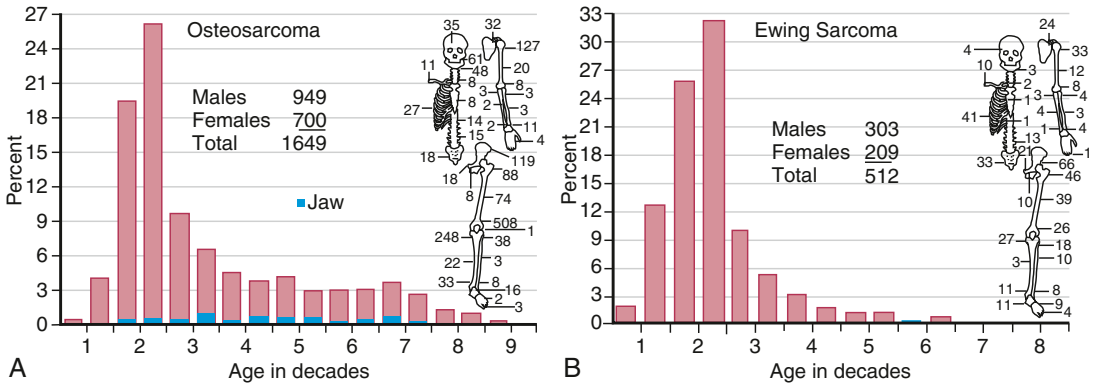

Fig. 550.1 A, Age and skeletal distribution of 1,649 cases of osteosarcoma in the Mayo Clinic files. B, Age and skeletal distribution of 512 cases of Ewing sarcoma in the Mayo Clinic files. *(From Unni KK, ed. Dahlin's Bone Tumors: General Aspects and Data on 11,087 Cases. 5th ed. Philadelphia: Lippincott-Raven; 1996. Reprinted by permission of the Mayo Foundation.)*

adolescents, initial complaints may be attributed to a sports injury or sprain; any bone or joint pain not responding to conservative therapy within a reasonable time should be investigated thoroughly. Additional clinical findings may include limitation of motion, joint effusion, tenderness, and warmth. Results of routine laboratory tests, such as a complete blood cell count and chemistry panel, are usually normal, although alkaline phosphatase or lactate dehydrogenase values may be elevated.

Diagnosis

Bone tumor should be suspected in a patient who presents with deep bone pain, often causing nighttime awakening, and has a palpable mass with radiographs that demonstrate a lesion. The lesion may be mixed lytic and blastic in appearance, but new bone formation is usually visible. The classic radiographic appearance of osteosarcoma is the *sunburst pattern* (Fig. 550.2). When osteosarcoma is suspected, the patient should be referred to a center with experience in managing bone tumors. The biopsy and the surgery should be performed by the same surgeon so that the incisional biopsy site can be placed in a manner that will not compromise the definitive surgical procedure. Tissue usually is obtained for molecular and biologic studies at the time of the initial biopsy. Before biopsy, MRI of the primary lesion and the entire bone should be performed to evaluate the tumor for its proximity to nerves and blood vessels, soft tissue and joint extension, and skip lesions. The metastatic workup includes CT of the chest and radionuclide bone scanning or positron emission tomography (PET) scan to evaluate for lung and bone or soft tissue metastases, respectively. The **differential diagnosis** of a lytic bone lesion includes histiocytosis, Ewing sarcoma, lymphoma, and bone cyst.

Fig. 550.2 Radiograph of an osteosarcoma of the femur with typical sunburst appearance of bone formation.

Treatment

With chemotherapy and surgery, 5-year disease-free survival of patients with nonmetastatic extremity osteosarcoma is 65–75%. Complete surgical resection of the tumor is important for cure. The current approach is to treat patients with preoperative chemotherapy in an attempt to facilitate limb salvage operations and to treat micrometastatic disease immediately. Up to 80% of patients are able to undergo limb salvage operations after initial chemotherapy. It is important to resume chemotherapy as soon as possible after surgery. Lung metastases present at diagnosis should be resected by thoracotomies at some time during treatment. Active agents in use in multidrug chemotherapy regimens for conventional osteosarcoma include doxorubicin, cisplatin, methotrexate, and ifosfamide.

One of the most important prognostic factors in osteosarcoma is the *histologic response to chemotherapy;* a poor histologic response is ≥10% viable tumor (<90% necrosis in resected tissue). **MAP** (methotrexate, doxorubicin, cisplatin) is the standard chemotherapy regimen for osteosarcoma. After limb salvage surgery, intensive rehabilitation and physical therapy are necessary to ensure maximal functional outcome. Intensification of therapy by addition of ifosfamide and etoposide in patients with poor histologic response after induction chemotherapy with MAP has not improved outcome.

For patients who require amputation, early prosthetic fitting and gait training are essential to enable patients to resume normal activities as soon as possible. Before definitive surgery, patients with tumors on weight-bearing bones should be instructed to use crutches to avoid stressing the weakened bones and causing pathologic fracture. The role of chemotherapy in parosteal and periosteal osteosarcomas is not well defined, and chemotherapy is generally reserved for use in patients with tumors that have a high-grade microscopic appearance.

Prognosis

Surgical resection alone is curative only for patients with low-grade parosteal osteosarcoma. Conventional high-grade osteosarcoma requires multiagent chemotherapy. Up to 75% of patients with nonmetastatic extremity osteosarcoma are cured with current multiagent treatment protocols. The prognosis is not as favorable for patients with pelvic tumors as for those with primary tumors in the extremities. From 20–30% of patients who have limited numbers of pulmonary metastases also can be cured with aggressive chemotherapy and resection of lung nodules. Patients with bone metastases and those with widespread lung metastases have an extremely poor prognosis. Long-term follow-up of patients with osteosarcoma is important to monitor for late effects of chemotherapy, such as cardiotoxicity from anthracycline and hearing loss from cisplatin. Patients in whom late, isolated lung metastases develop may be cured with surgical resection of the metastatic lesions alone.

EWING SARCOMA

Epidemiology

The incidence of Ewing sarcoma in the United States is 3.1 cases per 1 million children ages 0-19 years. It is rare among Black children. Ewing sarcoma, an undifferentiated sarcoma of bone, also may arise from soft tissue. Treatment protocols for these tumors are the same whether the tumors arise in bone or soft tissue. Anatomic sites of primary tumors arising in bone are distributed evenly between the extremities and the central axis (pelvis, spine, and chest wall). Primary tumors arising in the chest wall are often referred to as **Askin tumors**.

Pathogenesis

Immunohistochemical staining assists in the diagnosis of Ewing sarcoma to differentiate it from **small, round, blue cell tumors** such as lymphoma, rhabdomyosarcoma, and neuroblastoma. Histochemical stains may react positively with certain neural markers on tumor cells (neuron-specific enolase and S-100), especially in peripheral primitive neuroectodermal tumors. Reactivity with muscle markers (e.g., desmin, actin) is absent. Additionally, MIC-2 (CD99) staining is usually positive. A specific chromosomal translocation, t(11;22) (q24;q12), or a variant is found in most of the Ewing sarcoma family of tumors. Analysis for the translocation by next generation sequencing, fluorescence in situ hybridization (FISH), or polymerase chain reaction (PCR) analysis for the chimeric fusion gene products *EWS*/*FLI1* or *EWS*/*ERG* (or other variants) are used routinely in diagnosis.

Clinical Manifestations

Symptoms of Ewing sarcoma are similar to those of osteosarcoma. Pain, swelling, limitation of motion, and tenderness over the involved bone or soft tissue are common presenting symptoms. Patients with large chest wall primary tumors may present with respiratory distress. Patients with paraspinal or vertebral primary tumors may present with symptoms of cord compression. Ewing sarcoma often is associated with **systemic manifestations**, such as fever and weight loss, and may be accompanied by elevated inflammatory markers; patients may have undergone treatment for a presumptive diagnosis of osteomyelitis or a fever of unknown origin. Patients also may have a delay in diagnosis when their pain or swelling is attributed to a sports injury. Biopsy and tissue diagnosis should be considered for patients presenting with suspicious bone lesions, because even the gross appearance of Ewing sarcoma can appear similar to infection and the time course can be rapid. Surgical procedures for treatment of infection can contaminate the surgical field and impact treatment outcomes.

Diagnosis

The diagnosis of Ewing sarcoma should be suspected in a patient who presents with pain and swelling, with or without systemic symptoms, and with a radiographic appearance of a primarily lytic bone lesion with periosteal reaction, the characteristic **onion-skinning** (Fig. 550.3). A large, associated soft tissue mass often is visualized on MRI or CT (Fig. 550.4). The **differential diagnosis** includes osteosarcoma,

Fig. 550.3 Radiograph of tibial Ewing sarcoma showing periosteal elevation or "onion-skinning."

Fig. 550.4 MR image of tibial Ewing sarcoma showing a large associated soft tissue mass.

osteomyelitis, Langerhans cell histiocytosis, primary lymphoma of bone, metastatic neuroblastoma, or rhabdomyosarcoma in the case of a pure soft tissue lesion. Patients should be referred to a center with experience in managing bone tumors for evaluation and biopsy. Thorough evaluation for metastatic disease includes CT of the chest, radionuclide bone scan, or PET scan. Bone marrow aspiration and biopsy specimens from at least two sites are generally required but can be omitted for certain lower risk patients. MRI of the tumor and the entire length of involved bone should be performed to determine the exact extension of the soft tissue and bony mass and the proximity of tumor to neurovascular structures. Studies are also using fluorodeoxyglucose (FDG) PET to evaluate response to therapy.

To avoid compromising an ultimate potential for limb salvage by a poorly planned biopsy incision, the same surgeon should perform the biopsy and the surgical procedure. CT-guided biopsy of the lesion often provides diagnostic tissue. It is important to obtain adequate tissue for special stains and molecular studies.

Treatment

Tumors of the Ewing sarcoma family are best managed with a comprehensive multidisciplinary approach in which the surgeon, chemotherapist, and radiation oncologist plan therapy. Multiagent chemotherapy is important because it can shrink the tumor rapidly and is usually given before local control is attempted. In North America, standard **chemotherapy** for nonmetastatic Ewing sarcoma includes vincristine, doxorubicin, cyclophosphamide, etoposide, and ifosfamide. Chemotherapy usually causes dramatic shrinkage of the soft tissue mass and rapid, significant pain relief. Patients with nonmetastatic Ewing sarcoma have a better outcome when treated on a 14-day rather than on a 21-day schedule. An international cooperative group trial found that myeloablative chemotherapy and stem cell rescue was not superior to chemotherapy with lung irradiation for patients with pulmonary metastases.

Ewing sarcoma is considered a radiosensitive tumor, and local control may be achieved with **irradiation** or **surgery**. Radiation therapy is associated with a risk of radiation-induced second malignancies, especially osteosarcoma, as well as failure of bone growth in skeletally immature patients. It is important to provide the patient with crutches if the tumor is in a weight-bearing bone to avoid a pathologic fracture before definitive local control. Many centers prefer surgical resection, if possible, to achieve local control. Chemotherapy should be resumed as soon as possible after surgery.

Prognosis

Patients with small, nonmetastatic, distally located extremity tumors have the best prognosis, with a cure rate of up to 75%. Patients with pelvic tumors have, until recently, had a much worse outcome. Patients with metastatic disease at diagnosis, especially bone or bone marrow metastases, have a poor prognosis, with <30% surviving long term.

Long-term follow-up of patients with Ewing sarcoma is important because of the potential for late effects of treatment, such as anthracycline-induced cardiotoxicity, infertility, and second malignancies, especially in the radiation field, and late relapses, even as long as 10 years after initial diagnosis.

550.2 Benign Tumors and Tumor-Like Processes of Bone

Carola A.S. Arndt and A. Noelle Larson

Benign bone lesions in children are common compared with the relatively rare malignant neoplasms of bone. A broad range of diagnostic possibilities must be considered when the physician is confronted with an undiagnosed bone lesion (Table 550.2). Some, although histologically benign, can be life-threatening, while others can be locally destructive to bone. Many represent an incidental finding that, if asymptomatic, can be observed. A group of benign characteristic lesions including osteochondroma, nonossifying fibroma, unicameral bone cyst, and enchondroma may occur in 19% of children in a historic cohort of children and can readily be diagnosed on standard radiographs without additional imaging studies. Other conditions require further study to determine a diagnosis where no single element in the history or diagnostic test is sufficient to rule out malignancy. Benign lesions are usually painless but may be painful, especially if the lesion is causing local bone destruction or there is an impending pathologic fracture. Night pain that awakens a child suggests malignancy, but relief of such pain with aspirin is common with osteoid osteomas. Rapidly enlarging lesions usually are associated with malignancy, but several benign lesions, such as ABCs, can enlarge faster than most malignancies. Several conditions, such as osteomyelitis, can simulate the appearance of bone tumors.

Many benign bone tumors are diagnosed incidentally or after pathologic fracture. Initial management of these fractures is similar to that of nonpathologic fractures in the same location. It is unusual for benign bone tumors to interfere with fracture healing, but the area of weakness typically remains, and refracture is common. Fractures rarely result in resolution of the tumor, which usually is treated after the fracture has healed. Fractures around the hip, however, frequently require immediate treatment to stabilize the femoral neck and restore anatomic alignment.

Radiographs of any suspected bone lesion should always be obtained in two planes. Additional studies may be necessary to help arrive at the correct diagnosis and to guide treatment. Although these lesions are benign, selected lesions require intervention. If biopsy is performed, both microbiology and pathology evaluations should always be obtained.

Osteochondroma (exostosis) is one of the most common benign bone tumors in children. Because many are completely asymptomatic and unrecognized, the true incidence of this lesion is unknown. Osteochondromas develop in childhood, arising from the metaphysis of a long bone, particularly the distal femur, proximal humerus, and proximal tibia. The lesion enlarges with the child until skeletal maturity. Children commonly present at 5-15 years of age, when the child or parent notices a bony, nonpainful mass. Some are discovered because they are irritated by soft tissues rubbing over the lesion during athletic or other activities. Fracture is rare. Osteochondromas appear radiographically as stalks or broad-based projections from the surface of the bone, usually in a direction away from the adjacent joint (Fig. 550.5A). The bone is in continuity with the medullary canal. Invariably, the lesion is radiographically smaller than suggested by palpation because the cartilage cap covering the lesion is not seen. This cartilage cap may be up to 1 cm thick. Both the cortex of the bone and the marrow space of the involved bone are continuous with the lesion. Malignant degeneration of a chondrosarcoma is rare in children but occurs in as many as 1% of adults. Routine removal is not performed unless the lesion is large enough to cause symptoms, such as pain or nerve compression, most commonly presenting as foot drop. Osteochondromas can be diagnosed by radiographs alone, and unless patients present with unusual symptoms such as night pain, further studies such as CT or MRI are not typically indicated. Patients should be referred to an orthopedic practice for counseling, but routine radiographic follow-up and treatment should be based on symptoms.

Multiple hereditary osteochondrosis (exostoses) is a related but rare condition characterized by the presence of multiple osteochondromas (see Fig. 550.5B). This is an autosomal dominant disorder due to pathogenic variants in *EXT1* or *EXT2*. Severely involved children can have short stature, limb-length inequality, premature partial physeal arrests, deformity of both the upper and lower extremities including genu valgum, dislocation of the radial head at the elbow, and neurovascular impingement or entrapment in areas adjacent to the tumor and neurovascular compartments. These children must be monitored carefully during growth by a pediatric orthopedist. Malignant transformation may occur but is rare. Screening MRI of the entire spine is recommended during childhood to detect bony lesions growing into the

Table 550.2 Features of Pediatric Benign Bone Tumors

LESION	TYPICAL COURSE	MOST COMMON WORKUP TO CONFIRM DIAGNOSIS
Fibroma (nonossifying fibroma, fibrous cortical defect, metaphyseal fibrous defect)	Observation; surgery to treat fracture/impending fracture (rare, large lesions)	Radiographs
Enchondroma	Observation; treat if symptomatic	Radiographs, occasionally MRI
Osteochondroma	Observation; excise if symptomatic	Radiographs
Subungual exostosis	Symptoms warrant excision for most patients	Radiographs
Unicameral/simple bone cyst	Observation; treat if fracture occurs to prevent further fractures	Radiographs, occasionally MRI
Osteoid osteoma	NSAIDs; but symptoms warrant percutaneous ablation for most patients	Radiographs, CT
Heterotopic ossification	Observation; if symptomatic, excise after bone is mature (>6 mo)	Radiographs, ± MRI, CT
Fibrous dysplasia	Observation; treat if pain or bony deformities	Radiographs, ± MRI, ± biopsy
Chronic regional multifocal osteomyelitis (reactive bone condition)	Observation; medical treatment available if symptomatic; pathology is identical to osteomyelitis	Radiographs, MRI; bone scan to look for other lesions; antibiotics to rule out osteomyelitis; biopsy
Langerhans cell histiocytosis	Variable; depends on extent of disease	Skeletal survey, MRI, biopsy, workup to rule out systemic disease
Infection	Treat with prolonged antibiotics, typically some intravenously; surgery for joint/growth plate involvement, abscess, and chronic disease	CRP, sedimentation rate, CBC with differential, blood cultures, radiographs, ± MRI, ± biopsy
Osteoblastoma	Locally aggressive, treat	Radiographs, CT, MRI, biopsy
Aneurysmal bone cyst	Locally aggressive, treat	Radiographs, MRI, biopsy
Chondroblastoma	Locally aggressive, treat	Radiographs, MRI, biopsy
Chondromyxoid fibroma	Locally aggressive, treat	Radiographs, MRI, biopsy
Osteofibrous dysplasia	Possibly locally aggressive; variable	Radiographs, MRI, biopsy
Adamantinoma	Malignant, treat	Radiographs, MRI, biopsy

CBC, Complete blood count; CRP, C-reactive protein; CT, computed tomography; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal antiinflammatory drugs.

canal, which can result in spinal cord compression which may occur in up to 20–30% of patients (see Fig. 550.5C).

SUBUNGUAL EXOSTOSIS

This lesion is an osteochondroma that forms underneath the nailbed in an otherwise healthy child. The nailbed may become discolored or raised, and the condition is typically painful (Fig. 550.6). It can be differentiated from a paronychia or ingrown toenail by findings of an osteochondroma on radiographs. Radiographs should be taken, which will show a bony protuberance under the nailbed. Treatment should be nailbed removal and surgical excision with nailbed repair. Despite surgical excision, recurrence can occur up to 5% of the time.

Enchondroma is a benign lesion of hyaline cartilage that occurs centrally in the bone. These lesions are asymptomatic and frequently occur in the hands. Most are discovered incidentally, although pathologic fractures often lead to the diagnosis. Radiographically, the lesions occupy the medullary canal, are radiolucent, and are sharply marginated. Punctate or stippled calcification may be present within the lesion, but this is much more common in adults than in children. Almost all enchondromas in children are solitary and small. Most can simply be observed, with curettage and bone grafting reserved for lesions that are symptomatic or large enough to weaken the bone structurally. Large lesions with extensive involvement may represent low-grade chondrosarcoma. Multifocal involvement is referred to as **Ollier disease** and can result in bone dysplasia, short stature, limb-length inequality, and joint deformity. Surgery may be necessary to correct or prevent such deformities. When multiple enchondromas are associated with angiomas of the soft tissue, the condition is referred to as **Maffucci syndrome**. A high rate of malignant transformation has been reported in both of these multifocal conditions.

Chondromyxoid fibroma is an uncommon benign bone tumor in children. This metaphyseal lesion usually causes pain and local tenderness. The lesion occasionally is asymptomatic. Chondromyxoid fibroma appears radiographically as eccentric, lobular metaphyseal radiolucency with sharp, sclerotic, and scalloped margins. The lower extremity is involved most often. Treatment usually consists of curettage and bone grafting or en bloc resection.

Osteoid osteoma is a small benign bone tumor typically found in the proximal tibia and femur and the posterior elements of the spine. Most of these tumors are diagnosed between 5 and 20 years of age. The clinical pattern is characteristic, consisting of unremitting and gradually increasing pain that often is worst at night and is relieved by NSAIDs. Boys are affected more often than girls. Vertebral lesions can cause scoliosis or symptoms that mimic a neurologic disorder. Examination can reveal a limp, atrophy, and weakness when the lower extremity is involved. Palpation and range of motion do not alter the discomfort. Radiographs may show cortical thickening, and CT shows distinctive findings, with a round or oval metaphyseal or diaphyseal lucency (0.5-1.0 cm in diameter) surrounded by dense sclerotic bone (Fig. 550.7). The central lucency, or nidus, shows intense uptake on bone scan. Approximately 25% of osteoid osteomas are not visualized on plain radiographs but can be identified with CT. Because of the small size of the lesion and its location adjacent to thick cortical bone, MRI is poor at diagnosing osteoid osteomas, revealing only extensive T2

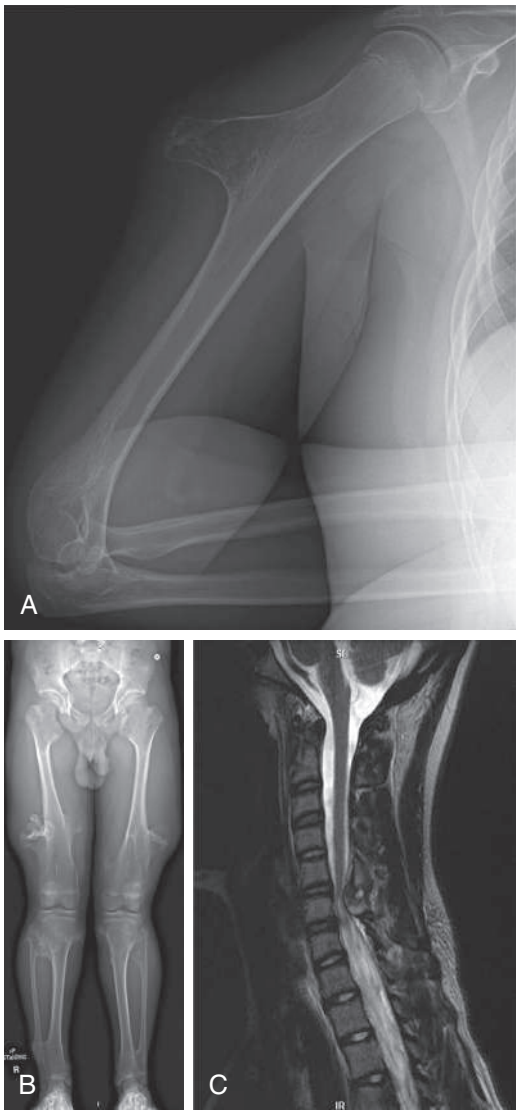

Fig. 550.5 A, Lateral radiograph of the right humerus showing isolated osteochondroma. Bone lesion is in continuity with the medullary canal and points away from the growth plate. B, Hip-to-ankle radiograph in a child with multiple hereditary exostoses (MHE) showing many osteochondromas about the knees and ankles. C, Sagittal T2 weighted MR image of the cervical spine in a 15-yr-old female with MHE who underwent routine cervical screening MRI, which detected asymptomatic spinal stenosis caused by C6 osteochondroma. She underwent urgent decompression.

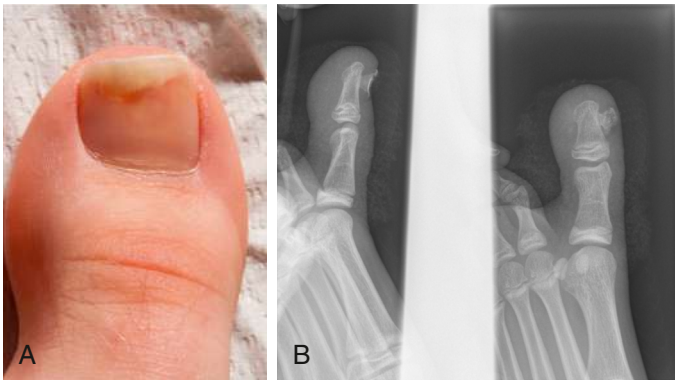

Fig. 550.6 A, Photograph of the great toe showing nailbed abnormality. B, Lateral and oblique views of the left great toe showing subungual exostosis. These lesions are typically painful and require surgical removal.

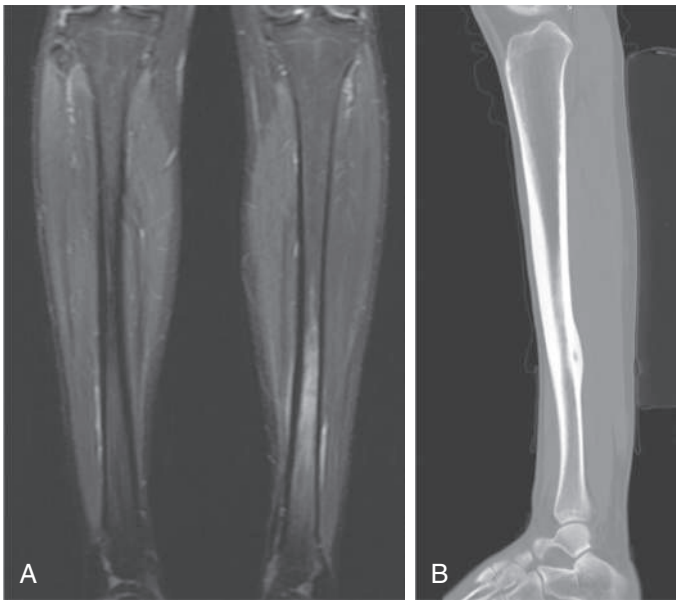

Fig. 550.7 MRI and CT in 15-yr-old female with left tibial night pain. A, Coronal T2 weighted MR of the bilateral tibias shows increased T2 signal change in the left tibia diaphysis. B, Sagittal CT scan shows cortically based lesion <1 cm typical for osteoid osteoma. Patient was treated with percutaneous radiofrequency ablation.

signal change throughout the region. Treatment is directed at removing the lesion. Patients may be treated with NSAIDs, and the symptoms typically resolve within 1-2 years. Most patients and families elect for treatment. Percutaneous treatments such as radiofrequency ablation and cryoablation have become the standard of care for routine lesions. There is still an occasional role for open surgical resection, if there is concern for osteomyelitis (Brodie's abscess), or the lesion is in close proximity to articular cartilage or neurovascular structures.

Osteoblastoma is a locally destructive, progressively growing lesion of bone with a predilection for the vertebrae, although almost any bone may be involved. Most patients note the insidious onset of dull aching pain, which may be present for months before patients seek medical attention. Spinal lesions can cause neurologic symptoms or deficits. The radiographic appearance is variable and less distinctive than that of other benign bone tumors. CT or MRI is indicated. Approximately 25% show features suggesting a malignant neoplasm, making biopsy necessary in many cases. Expansile spinal lesions often involve the posterior elements. Treatment involves curettage and bone grafting or en bloc excision; care must be taken to preserve nerve roots when treating spinal lesions. Surgical stabilization of the spine may be necessary.

Fibromas (nonossifying fibroma, fibrous cortical defect, metaphyseal fibrous defect) are fibrous lesions of bone that occur in up to 40% of children older than 2 years of age. They most likely represent a defect in ossification rather than a neoplasm and usually are asymptomatic. Most are discovered incidentally when radiographs are taken for other reasons, usually to rule out a fracture after trauma. Occasional pathologic fractures can occur through large lesions. Physical examination usually is unrevealing. Radiographs show a sharply marginated eccentric lucency in the metaphysis or metaphyseal cortex (Fig. 550.8). Lesions may be multilocular and expansile, with extension from the cortex into the medullary bone. The long axis of the lesion runs parallel to that of the bone. Approximately 50% are bilateral or multiple. Because of the characteristic radiographic appearance, most lesions do not require axial imaging, biopsy, or treatment. If the child is asymptomatic, no further monitoring is needed for characteristic lesions. Spontaneous regression can be expected after skeletal maturity. Curettage and bone grafting may be considered for symptomatic lesions or lesions occupying >50% of the bone diameter due to the risk of a pathologic fracture.

Fig. 550.8 Anteroposterior radiograph of the knee showing nonossifying fibroma, which was discovered incidentally.

Fig. 550.9 External rotation view of the left humerus in a 9-yr-old female who presented with pain after falling off her bicycle. Imaging is consistent with simple bone cyst.

Unicameral bone cysts can occur at any age in childhood but are rare in children younger than 3 years of age and after skeletal maturity. The cause of these fluid-filled lesions is unknown. Spontaneous resolution after skeletal maturity is expected, although pathologic fracture can be a significant problem in the interim. Diagnosis usually follows a pathologic fracture (Fig. 550.9). Such fractures can occur with relatively minor trauma, such as with throwing or catching a ball. Unicameral bone cysts appear radiographically as solitary, centrally located lesions within the medullary portion of the bone. These cysts are most common in the proximal humerus or femur. They often extend to (but not through) the physis and are sharply marginated. The cortex expands, but that does not exceed the width of the adjacent physis. Treatment involves allowing the pathologic fracture to heal. Subsequently, humerus lesions can be observed or treated. Proximal femoral lesions are typically treated due to the risk of pathologic fracture. Treatments include aspiration and injection with methylprednisolone or calcium phosphate. A randomized controlled trial (RCT) showed 42% healing rate with steroid injections (1-3, mean 1.7 injections) compared with injection of bone marrow aspirate (23% healing rate, 1-3 injections, 2.1 mean). Open biopsy and bone grafting with or without internal fixation can also be performed. Recurrence is common despite surgical treatment. Repeat injections are frequently necessary to treat recurrent lesions. Healing rates are higher with injection or surgical treatment compared with observation, and internal fixation is recommended for proximal femoral lesions given the high risk of fracture.

Fibrous dysplasia is a developmental abnormality characterized by fibrous replacement of cancellous bone. Lesions may be solitary or multifocal (polyostotic). Lesions may progress over time or may be stable. Some children are asymptomatic, although others have bone pain. Those with skull involvement might have swelling or exophthalmos. Pain and limp are characteristic of proximal femoral involvement, which also may indicate impending pathologic fracture. Limb-length discrepancy, bowing of the tibia or femur, and pathologic fractures may be presenting complaints. The triad of polyostotic disease, precocious puberty, and cutaneous pigmentation is known as McCune-Albright syndrome. Radiographic features of fibrous dysplasia include a lytic or ground-glass expansile lesion of the metaphysis or diaphysis. The lesion is sharply marginated and often is surrounded by a thick rim of sclerotic bone. Bowing, especially of the proximal femur, may be present. Treatment usually involves observation for asymptomatic lesions. Surgery is indicated for patients with progressive deformity, pain, or impending pathologic fractures. Bone grafting is not as successful in the treatment of fibrous dysplasia, because the lesion recurs within the grafted bone. Reconstructive surgical techniques with metal implants often are necessary to provide stability and treat pain, particularly in the proximal femur. In addition to surgical stabilization, bisphosphonate therapy has been used to treat bone pain, although a recent RCT showed improvement in regional bone mineral density but no change in pain scores.

LOCALLY AGGRESSIVE LESIONS

Aneurysmal bone cyst (ABC) is a reactive lesion of bone seen in persons younger than 20 years of age. The lesion is characterized by cavernous spaces filled with blood and solid aggregates of tissue. Although the femur, tibia, and spine are commonly involved, this progressively growing, expansile lesion can develop in any bone. Radiographs show eccentric lytic destruction and expansion of the metaphysis surrounded by a thin sclerotic rim of bone. Expansion of the bone frequently extends beyond the diameter of the physis. Pain and swelling are common. Spinal involvement can lead to cord or nerve root compression and associated neurologic symptoms, including paralysis. Posterior elements of the spine are involved more commonly than the vertebral body. Unlike most other benign bone tumors, which usually are confined to a single bone, ABCs can involve adjacent vertebrae. Spinal lesions can require stabilization after excision. As with other benign tumors, attempts are made to preserve nerve roots and other vital structures. Rapid growth is characteristic and can lead to confusion with malignant neoplasms (Fig. 550.10). ABCs can occur with concomitantly with neoplasms, confounding pathology results from biopsy. Treatment consists of percutaneous injection, curettage and bone grafting, or excision. Recurrence after surgical treatment occurs in 20–30% of patients, is more common in younger than older children, and usually occurs in the first 1-2 years after treatment. Treatment approaches also include percutaneously treatment with polidocanol or doxycycline, which targets the specific matrix metalloproteinase upregulation pathway seen in ABCs and has shown promising results.

CHARACTERISTIC LESIONS OF THE TIBIA

Osteofibrous dysplasia affects the tibia in children. Most children present with anterior swelling or enlargement of the leg. Radiographs show solitary or multiple lucent cortical diaphyseal lesions surrounded by sclerosis. Anterior bowing of the tibia often is present, and pathologic fracture can occur. The radiographic appearance closely resembles that

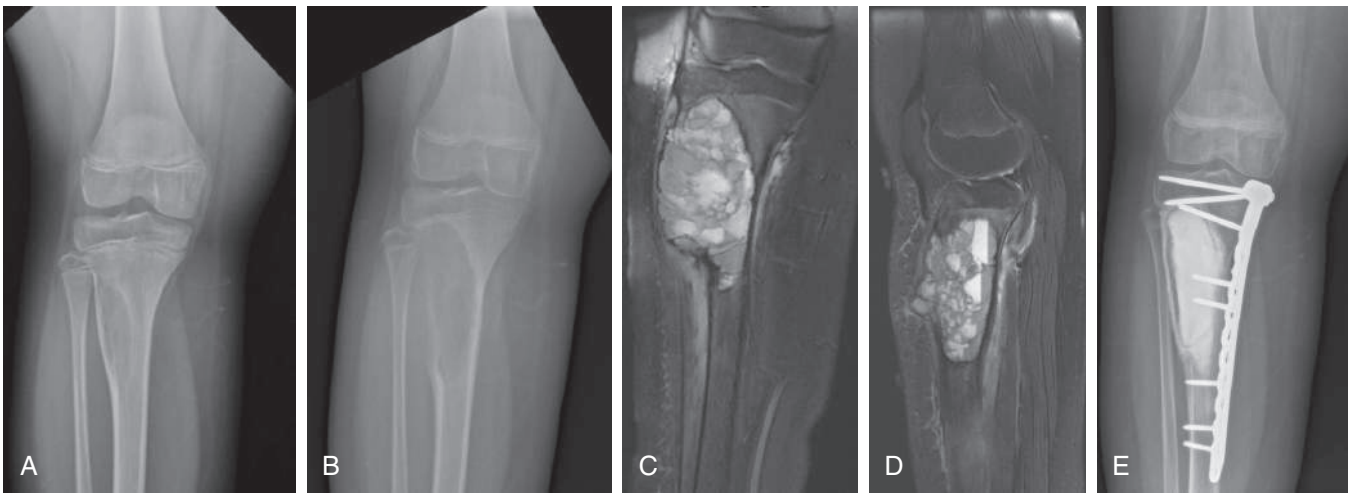

Fig. 550.10 Aneurysmal bone cyst. **A**, A 10-yr-old female presents with right tibia pain after playing softball. PA radiograph of the right proximal tibia reveals an eccentric, lytic lesion. **B**, Repeat imaging 4 months later shows rapid expansion. **C**, Coronal T2 MR image. **D**, Sagittal T2 MR image shows fluid-fluid levels classically seen with aneurysmal bone cysts. **E**, The patient was treated with curettage, bone grafting, and plate fixation to prevent fracture.

Table 550.3 Summary of Prognosis and Treatment of Vascular Bone Tumors

CLASSIFICATION	ENTITY	PROGNOSIS	TREATMENT
Benign	Hemangioma	100% survival, 0% metastasis	Treat symptoms
Intermediate	Epithelioid hemangioma	100% survival, 2% metastases, 9% local recurrence	Curettage or marginal excision
	Pseudomyogenic hemangioendothelioma	Limited follow-up, stable or progressive osseous disease	
Malignant	Epithelioid hemangioendothelioma	85% survival, 25% metastases	Wide resection
	Angiosarcoma	30% survival	Wide resection, consider systemic therapy

From van IJzendoorn DGP, Bovee JVMG. Vascular tumors of bone: the evolvement of a classification based on molecular developments. *Surg Pathol Clin.* 2017;10:621–635. Table 1.

of adamantinoma, a malignant neoplasm, making biopsy more common than with other benign bone tumors. Some believe osteofibrous dysplasia is a precursor lesion to adamantinoma. Treatment options include observation, excision and bone grafting, or wide resection.

Adamantinoma is a rare malignancy, typically found in adults, but occasionally in children. In contrast to osteofibrous dysplasia, the lesion involves the medullary canal. Resection is indicated, as there are no known benefits to radiation or chemotherapy for this slow-growing tumor.

Langerhans cell histiocytosis is a monostotic or polyostotic disease that can also involve the skin, liver, or other organs. Single-site disease should be distinguished from the other forms of Langerhans cell histiocytosis (Hand-Schüller-Christian or Letterer-Siwe variants), which can have a less favorable prognosis (see Chapter 556.1). Langerhans cell histiocytosis usually occurs during the first 3 decades of life and is most common in males 5-10 years of age. The skull is commonly affected, but any bone may be involved. Patients usually present with local pain and swelling. Marked tenderness and warmth often are present in the area of the involved bone. Spinal lesions can cause pain, stiffness, and occasional neurologic symptoms. Vertebra plana with uniform compression or flattening of the vertebral body is commonly but not always associated with Langerhans cell histiocytosis. The radiographic appearance of the skeletal lesions is similar in all forms of Langerhans cell histiocytosis but is variable enough to mimic many other benign and malignant lesions of bone as well as infection. The radiolucent lesions have well-defined or irregular margins with expansion of the involved bone and periosteal new bone formation. A skeletal survey is warranted as lesions may not be apparent on bone scan. Polyostotic involvement and the typical skull lesions strongly suggest the diagnosis of eosinophilic granuloma. Biopsy often is necessary to confirm the diagnosis because of the broad radiographic differential diagnosis. Treatment for isolated bone lesions includes curettage and bone grafting, or observation for asymptomatic lesions because most osseous lesions heal spontaneously and do not recur. All children with bone lesions should be evaluated for visceral involvement because multisystem organ disease may exist with the bone lesion and may not be obvious. Treatment of multisystem disease is more complex and often systemic and may require chemotherapy. For multisystem disease, bone lesions frequently improve with systemic chemotherapy, and operative treatment may not be necessary.

VASCULAR TUMORS OF BONE

There is a wide spectrum of vascular bone tumors (Table 550.3), which, depending on severity, may produce local sclerosis or osteopenia (see also Chapter 554). More severe lesions are locally aggressive and result in cortical destruction.

Chapter 551

Retinoblastoma

Cynthia E. Herzog

Retinoblastoma is an embryonal malignancy of the retina and the most common intraocular tumor in children. Although the survival rate of children with retinoblastoma in the United States and developed countries is extremely high, retinoblastoma progresses to metastatic disease and death in >40% of children in low income countries. Furthermore, the associated loss of vision and side effects of therapy are significant problems that remain to be addressed.

EPIDEMIOLOGY

Approximately 200-300 new cases of retinoblastoma are diagnosed each year in the United States, with no known racial or gender predilection. The cumulative lifetime incidence of retinoblastoma is approximately 1 in 20,000 live births, and retinoblastoma accounts for 2% of all pediatric malignancies. The median age at diagnosis is approximately 2 years, and >90% of cases are diagnosed in children <5 years old. Overall, 66–75% of children with retinoblastoma have unilateral tumors, with the remainder having bilateral retinoblastoma. Bilateral involvement is more common in younger children, particularly in those diagnosed before age 1 year, and is always heritable. Risk of retinoblastoma may be increased in children conceived by in vitro fertilization.

Retinoblastoma can be either hereditary or sporadic. **Hereditary** cases usually are diagnosed at a younger age and are multifocal and bilateral, whereas **sporadic** cases are usually diagnosed in older children who tend to have unilateral, unifocal involvement. The hereditary form is associated with loss of function of the **retinoblastoma gene *(RB1)*** via a pathogenic variant or deletion. *RB1* is located on chromosome 13q14 and encodes the retinoblastoma protein, a tumor-suppressor protein that controls cell cycle phase transition and has roles in apoptosis and cell differentiation. Children with **13q deletion syndrome** are at increased risk to develop retinoblastoma. Many different causative pathogenic variants have been identified, including translocations, deletions, insertions, point pathogenic variants, and epigenetic modifications such as gene methylation. The nature of the predisposing pathogenic variant can affect the penetrance and expressivity of retinoblastoma development.

According to Knudson's "2-hit" model of oncogenesis, two pathogenic variant events are required for retinoblastoma tumor development (see Chapter 541). In the hereditary form of retinoblastoma, the first pathogenic variant in *RB1* is inherited through germinal cells, and a pathogenic variant occurs subsequently in somatic retinal cells. Second pathogenic variants that lead to retinoblastoma often result in the loss of the normal allele and concomitant loss of heterozygosity. Parents and siblings of a child with a germline pathologic genetic variant should be referred to a genetic specialist for testing; most children with hereditary retinoblastoma have spontaneous new germinal pathogenic variants, and both parents have wild-type retinoblastoma genes. All first-degree relatives of children with known or suspected hereditary retinoblastoma should have retinal examinations to identify retinomas or retinal scars, which may suggest hereditary retinoblastoma even though malignant retinoblastoma did not develop. In the sporadic form of retinoblastoma, the two pathogenic variants occur in somatic retinal cells. Heterozygous carriers of oncogenic *RB1* pathogenic variants demonstrate variable phenotypic expression.

PATHOGENESIS

Histologically, retinoblastoma appears as a small, round blue cell tumor with rosette formation **(Flexner-Wintersteiner rosettes)**. It may arise in any of the nucleated layers of the retina and exhibit various degrees of differentiation. Retinoblastoma tumors tend to outgrow their blood supply, resulting in necrosis and calcification.

Endophytic tumors arise from the inner surface of the retina and grow into the vitreous and can also grow as tumors suspended within the vitreous itself, known as **vitreous seeding**. *Exophytic* tumors grow from the outer retinal layer and can cause retinal detachment. Diffuse infiltrating tumors grow intraretinally and remain flat; these are less common and can cause iris neovascularization. Tumors can also be both endophytic and exophytic. These tumors can also spread by direct extension to the choroid or along the optic nerve beyond the lamina cribrosa to the central nervous system, or by hematogenous or lymphatic spread to distant sites, including bones, bone marrow, and lungs.

SCREENING

Children with a positive family history of retinoblastoma should undergo a dilated eye examination under general anesthesia early in life and at regular intervals until genetic testing is performed and results are available. Infants with a negative genetic test require no further screening; infants with a positive genetic test require regular screening ophthalmologic examinations until age 7 years.

CLINICAL MANIFESTATIONS

Retinoblastoma classically presents with **leukocoria,** a *white pupillary reflex*, which often is first noticed when a red reflex is not present at a routine newborn or well-child examination or in a flash photograph of the child (Fig. 551.1). Strabismus often is an initial presenting complaint. Decreased vision, orbital inflammation, hyphema, and pupil irregularity can occur with advancing disease. Pain can occur if secondary glaucoma is present. Only about 10% of retinoblastoma cases are detected by routine ophthalmologic screening in the context of a positive family history.

DIAGNOSIS

The diagnosis is established by the characteristic ophthalmologic findings of a chalky, white-gray retinal mass with a soft, friable consistency. Imaging studies are not diagnostic, and biopsies are contraindicated. Indirect ophthalmoscopy with slit-lamp evaluation can detect retinoblastoma tumors, but a complete evaluation requires an examination

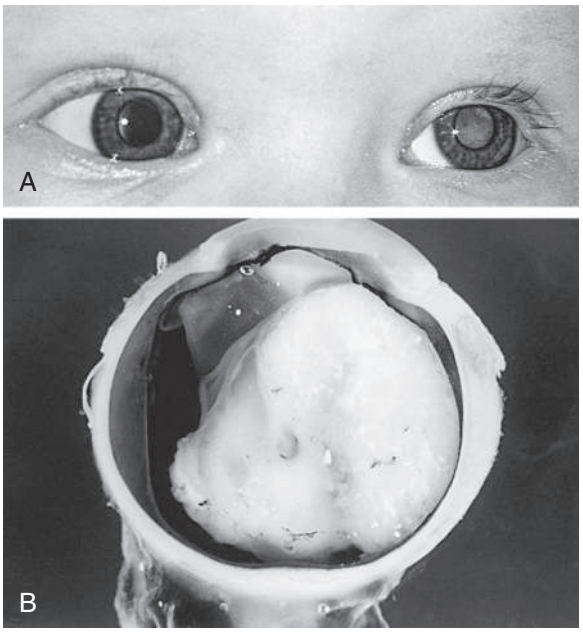

Fig. 551.1 A, Leukocoria noted in the left eye of a child presenting with retinoblastoma. B, A large white tumor mass noted within the posterior chamber of the enucleated eye. *(From Shields JA, Shields CL. Current management of retinoblastoma. Mayo Clin Proc. 1994;69:50–56.)*

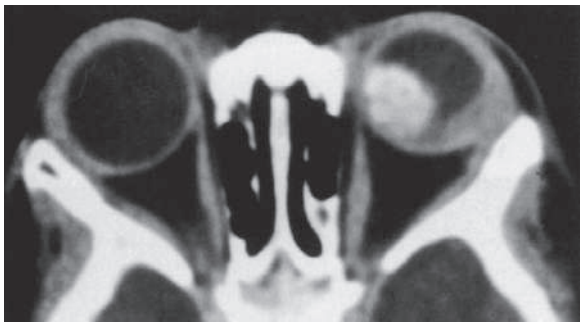

Fig. 551.2 Axial contrast-enhanced CT scan shows calcified retinoblastoma of the left eye. *(From Haaga JR, Boll DT, eds. CT and MRI of the Whole Body. 6th ed. Philadelphia: Elsevier; 2017. Fig. 20-32.)*

under general anesthesia by an experienced ophthalmologist to obtain complete visualization of both eyes, which also facilitates photographing and mapping of the tumors. Retinal detachment or vitreous hemorrhage can complicate the evaluation.

Orbital ultrasonography, CT, or MRI is used to evaluate the extent of intraocular disease and extraocular spread (Fig. 551.2). In approximately 5% of cases, a pineal area (primitive neuroectodermal) tumor is detected in a child with hereditary and bilateral retinoblastoma, a phenomenon known as **trilateral retinoblastoma**. MRI allows for better evaluation of optic nerve involvement. Metastatic disease is rarely present at diagnosis; evaluation of the cerebrospinal fluid and bone marrow for tumor metastasis and radionuclide bone scan are required only if indicated by other clinical, laboratory, or imaging findings.

The **differential diagnosis** of retinoblastoma includes other causes of leukocoria, including persistent hyperplastic primary vitreous, Coats disease, vitreous hemorrhage, cataract, endophthalmitis from *Toxocara canis*, choroidal coloboma, retinopathy of prematurity, and familial exudative vitreoretinopathy.

TREATMENT

Treatment is determined by the size and location of the tumors, if the disease is localized to the eye or has spread either to the brain or to the rest of the body, and whether the child has hereditary or sporadic disease. The primary goal of treatment is always cure; the secondary goals include preserving vision and the eye itself and decreasing the risk of late side effects, mainly secondary malignancies. With current modalities for local control of intraocular tumors and more effective systemic chemotherapy, primary enucleation is being performed less often.

Most unilateral disease presents with a solitary, large tumor. **Enucleation** is performed if useful vision cannot be salvaged. With bilateral disease, chemoreduction in combination with **focal therapy** (laser photocoagulation or cryotherapy) has replaced the traditional approach of enucleation of the more severely affected eye and irradiation of the remaining eye. If feasible, small tumors can be treated with focal therapy with careful follow-up for recurrence or new tumor growth. Larger tumors often respond to multiagent **chemotherapy**, including carboplatin, vincristine, and etoposide given intravenously. However, systemic therapy is generally reserved for patients with unilateral disease when high-risk features are noted after enucleation, or in very young patients with bilateral disease that are at higher risk of complications with intraarterial chemotherapy. The delivery of chemotherapy via the ophthalmic artery is becoming more common, as is delivery of intravitreal chemotherapy. If these approaches fail, **external-beam irradiation** should be considered, although this approach may result in significant orbital deformity and increased incidence of second malignancies in patients with germline *RB1* pathologic genetic variants. **Brachytherapy**, or *episcleral plaque radiotherapy,* is an alternative with less morbidity. Enucleation may be required for unresponsive or recurrent tumors. Intense multiagent chemotherapy with autologous stem cell rescue may be used for patients with metastatic disease.

PROGNOSIS

Approximately 95% of U.S. children with retinoblastoma are cured with modern treatment. Current efforts using chemotherapy in combination with focal therapy are intended to preserve useful vision and avoid external-beam radiation or enucleation. Unfortunately, the diagnosis of retinoblastoma in many children from resource-poor countries is delayed, resulting in spread of the tumor outside the orbit. The prognosis for children with retinoblastoma that has spread outside the eye is poor. Trilateral retinoblastoma, disease involving both eyes and the pineal region, is almost universally fatal.

Children with germline *RB1* pathologic genetic variants are at significant risk for development of *second malignancies*, especially osteosarcoma, as well as soft tissue sarcomas and malignant melanoma. The risk of second malignancies is further increased by the use of radiation therapy. Other radiation-related late adverse effects include cataracts, orbital growth deformities, lacrimal dysfunction, and late retinal vascular injury.

Chapter 552

Gonadal and Germ Cell Neoplasms

Cynthia E. Herzog and Winston W. Huh

EPIDEMIOLOGY

Malignant **germ cell tumors (GCTs)** and gonadal tumors are rare, with an incidence of 12 cases per 1 million persons younger than 20 years. Most malignant tumors of the gonads in children are GCTs. The incidence varies according to age and sex, although the incidence of GCTs in adolescent males has increased over time. **Sacrococcygeal** tumors occur predominantly in infant females. **Testicular** GCTs occur predominantly before age 4 years and after puberty. Klinefelter syndrome is associated with an increased risk of **mediastinal** GCTs. Trisomy 21, undescended testes, infertility, testicular atrophy, testicular microlithiasis, testicular dysgenesis syndrome, and inguinal hernias are associated with an increased risk of **testicular cancer**. The risk of testicular cancer in patients with cryptorchidism is reduced but not eliminated if orchiopexy is performed before 13 years of age. The risk of testicular GCT is increased in first-degree relatives and is highest among monozygotic twins.

PATHOGENESIS

The GCTs and non-GCTs arise from primordial germ cells and coelomic epithelium, respectively. Testicular and sacrococcygeal GCTs arising during early childhood characteristically have deletions at chromosome arms 1p and 6q and gains at 1q, and they lack the isochromosome 12p that is highly characteristic of malignant GCTs of adults. Testicular GCTs also may demonstrate loss of imprinting. Ovarian GCTs from older females characteristically have deletions at 1p and gains at 1q and 21. Dysregulation of microRNAs have been linked to GCTs. Because GCTs may contain benign and mixed malignant elements in different areas of the tumor, extensive sectioning is essential to confirm the correct diagnosis. The many histologically distinct subtypes of GCTs include **teratoma** (mature and immature), endodermal sinus tumor, and embryonal carcinoma (Fig. 552.1). Non-GCTs of the

NONINVASIVE GERM CELL NEOPLASIA
Germ cell neoplasia in situ (GCNIS; previous synonyms: carcinoma in situ testis, intratubular germ cell neoplasia unclassified)
Gonadoblastoma (in patients with disorders of sex development; tumor also contains sex cord–stromal elements)
GERM CELL TUMORS DERIVED FROM GCNIS
Seminoma
Nonseminoma (nonseminomatous germ cell tumors)
Embryonal carcinoma
Teratoma (postpubertal type)
Yolk sac tumor (postpubertal type)
Choriocarcinoma and other trophoblastic tumors
GERM CELL TUMORS UNRELATED TO GCNIS
Childhood tumors
Teratoma (prepubertal type)
Yolk sac tumor (prepubertal type)
Spermatocytic tumor (median age at diagnosis: approximately 50 yr)

*Based on updated WHO classification of tumors of the testis and paratesticular tissue. Adapted from Raypert-De Meyts E, McGlynn KA, Okamoto, et al. Testicular germ cell tumours, *Lancet* 2016;387:1762–1770.

ovary include epithelial (serous and mucinous) and sex cord–stromal tumors; non-GCTs of the testicle include sex cord–stromal (e.g., Leydig cell, Sertoli cell) tumors. *DICER1* pathogenic variants have been observed in nonepithelial ovarian cancers, especially in Sertoli-Leydig tumors. Table 552.1 provides a histologic classification of testicular GCTs.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical presentation of germ cell neoplasms depends on location (Table 552.2). Ovarian tumors often are quite large by the time they are diagnosed (Fig. 552.2). Extragonadal GCTs occur in the midline, including the suprasellar region, pineal region, neck, mediastinum, and retroperitoneal and sacrococcygeal areas (Fig. 552.3). Symptoms relate to mass effect, but the intracranial GCTs often present with anterior and posterior pituitary deficits (see Chapter 546).

The serum α-fetoprotein **(AFP)** level is elevated with endodermal sinus tumors and may be minimally elevated with teratomas (Table 552.3). Infants normally have higher levels of AFP, which usually falls to normal adult levels by about age 8 months; consequently, high AFP levels must be interpreted with caution in this age-group. Elevation of the β subunit of human chorionic gonadotropin (β-**hCG**), which is secreted by syncytiotrophoblasts, is seen with choriocarcinoma and germinomas. Lactate dehydrogenase, although nonspecific, may be a useful marker. If elevated, these markers provide important confirmation of the diagnosis and provide a means for risk stratification and to monitor the patient for tumor response and recurrence. Both serum and cerebrospinal fluid (CSF) should be assayed for these markers in patients with intracranial lesions. MicroRNA-371 is a superior tumor marker in GCT, but its use is still limited.

Diagnosis begins with physical examination and imaging studies, including plain radiographs of the chest and ultrasonography of the abdomen. CT or MRI can further delineate the primary tumor. If germ cell malignancy is strongly suggested, preoperative staging with CT of the chest and bone scan is appropriate. Primary surgical resection is indicated for tumors deemed resectable. For older patients with testicular tumors, ipsilateral retroperitoneal lymph node sampling may be required to determine extent of the disease and aid in treatment planning. Ovarian tumors also require detailed surgical evaluation, including lymph node removal and pelvic washings for cytologic analysis for peritoneal spread. Diagnosis of intracranial lesions can be established with imaging and AFP or β-hCG determinations of serum and CSF.

Gonadoblastomas often occur in patients with gonadal dysgenesis and all or parts of a Y chromosome. **Gonadal dysgenesis** is characterized by failure to fully masculinize the external genitalia. If this syndrome is diagnosed, imaging of the gonad with ultrasonography or CT is performed, and surgical resection of the tumor usually is curative. Prophylactic resection of dysgenetic gonads at the time of diagnosis is recommended, because gonadoblastomas, some of which contain malignant GCT elements, often develop. Gonadoblastomas may produce abnormal amounts of estrogen.

Table 552.2 Clinical Features of Germ Cell Tumors

CLINICAL FEATURES		
TUMOR TYPE	**FEMALE**	**MALE**
Mature/immature teratoma	Abdominal pain, abdominal mass 10% bilateral Gliomatosis peritonei does not affect prognosis	Nontender scrotal mass Excellent survival with surgery alone in prepubertal males
Dysgerminoma/seminoma	Rapidly developed intraabdominal mass 20% bilateral 14–25% mixed with other germ cell elements	Virtually not seen in children, most common testicular tumor in adult males. Most patients present in their 30s
YST	Most common malignant histology 75% stage I	Most common malignant histology, most pediatric tumors are pure YST 85% stage I
Embryonal carcinoma	Associated with precocious puberty, amenorrhea, and hirsutism	Higher incidence of metastatic disease at presentation, patients can present with retroperitoneal mass
Choriocarcinoma	Rare in children, when present in infants related to maternal metastatic disease	Frequent pulmonary metastatic disease at presentation, patients can present with hemoptysis due to hemorrhage of metastases
Gonadoblastoma	Associated with gonadal dysgenesis Presents mostly in phenotypical females with a Y chromosome	Very rare

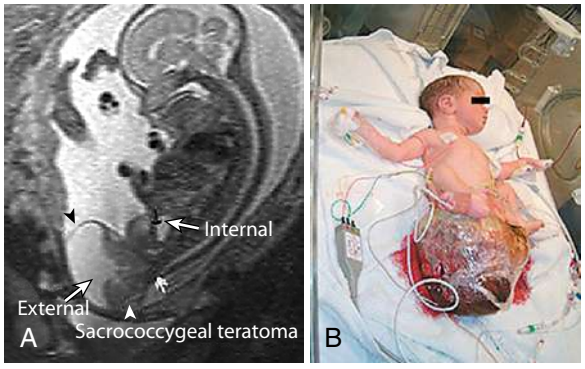

Fig. 552.3 A, Prenatal MR image showing sacrococcygeal teratoma with a small internal and large external component. B, Postnatal large, bleeding sacrococcygeal teratoma. *(From Lakhoo K. Neonatal teratomas. Early Hum Dev. 2010;86:643–647.)*

Teratomas occur in many locations, presenting as masses. They are not associated with elevated markers unless malignancy is present. The sacrococcygeal region is the most common site for teratomas. Sacrococcygeal teratomas occur most commonly in infants and may be diagnosed in utero or at birth, with most found in girls. The rate of malignancy in this location varies, ranging from <10% in children younger than 2 months to >50% in children older than 4 months.

Germinomas occur intracranially, in the mediastinum, and in the gonads. In the ovary, they are called **dysgerminomas,** and in the testis, they are called **seminomas.** They usually are tumor-marker–negative masses despite being malignant. Endodermal sinus or yolk sac tumor and choriocarcinoma appear highly malignant by histologic criteria. Both occur at gonadal and extragonadal sites. Embryonal carcinoma most often occurs in the testes. Choriocarcinoma and embryonal carcinoma rarely occur in the pure form and are usually found as part of a mixed malignant GCT.

Non–germ cell gonadal tumors are very uncommon in pediatrics and occur predominantly in the ovary. Epithelial carcinomas (usually an adult tumor), Sertoli-Leydig cell tumors, and granulosa cell

tumors may occur in children. Carcinomas account for ~30% of ovarian tumors in females <20 years old; most of these occur in older teens and are of the serous or mucinous subtype. **Sertoli-Leydig cell tumors** and **granulosa cell tumors** produce hormones that can cause virilization, feminization, or precocious puberty, depending on pubertal stage and the balance between Sertoli cells (estrogen production) and Leydig cells (androgen production). Diagnostic evaluation usually focuses on the chief complaint of inappropriate sex steroid effect and includes hormone measurements, which reflect gonadotropin-independent sex steroid production. Appropriate imaging also is performed to rule out a functioning gonadal tumor. Surgery usually is curative. No effective therapy for nonresectable disease has been found.

TREATMENT

Complete surgical excision of the tumor usually is indicated, except for patients with intracranial tumors, for whom the primary therapy consists of radiation therapy and chemotherapy. For testicular tumors, an inguinal approach is indicated, and complete resection should include the entire spermatic cord. When complete excision cannot be accomplished, preoperative chemotherapy is indicated, with second-look surgery, especially if retroperitoneal lymph node enlargement persists. For teratomas, both mature and immature, and completely resected malignant tumors of the testes and ovary, surgery alone is the treatment. For ovarian tumors, unless the contralateral ovary is obviously also involved by tumor, a fertility-sparing surgery should be performed. Cisplatin-based chemotherapy regimens usually are curative in GCTs that cannot be completely resected, even if metastases are present. However, sex cord–stromal tumors tend to be refractory to chemotherapy. Except for GCTs of the central nervous system, radiation therapy is limited to those tumors that are not amenable to complete excision and are refractory to chemotherapy. High-dose chemotherapy followed by autologous stem cell rescue is an option in those with refractory disease.

PROGNOSIS

The overall cure rate for children with GCTs is >80%. Age is the most predictive factor of survival for extragonadal GCTs. Children >12 years old have a fourfold higher risk of death and a sixfold higher risk if the tumor is thoracic. Histology has minimal effect on prognosis. Patients with nonresected extragonadal GCTs have a slightly worse prognosis.

Chapter 553

Neoplasms of the Liver

Fiorela N. Hernandez Tejada and Cynthia E. Herzog

Hepatic tumors are rare in children. Primary tumors of the liver account for approximately 1% of malignancies in children younger than 15 years, with an annual incidence of 1.5 cases per 1 million children in the United States (Table 553.1). Between 50% and 60% of hepatic tumors in children are malignant, with >65% of these malignancies being **hepatoblastomas** and most of the remainder being **hepatocellular carcinomas (HCCs)**. Rare **hepatic malignancies** include embryonal sarcoma, angiosarcoma, malignant germ cell tumor, rhabdomyosarcoma of the liver, and undifferentiated sarcoma. More common childhood malignancies, such as neuroblastoma, Wilms tumor, and lymphoma, can metastasize to the liver. **Benign liver tumors**, which usually present in the first 6 months of life, include hemangiomas, hamartomas, and hemangioendotheliomas.

Table 553.1 Pediatric Liver Tumors Consensus Classification

Epithelial tumors Hepatocellular	**Benign:** Hepatocellular adenoma, focal nodular hyperplasia (FNH), regenerative nodules, and dysplastic nodules **Malignant:** Hepatoblastoma (various types), hepatocellular carcinoma (classic HCC and fibrolamellar HCC), hepatocellular malignant neoplasm not otherwise specified (NOS)
Biliary	**Benign:** Bile duct adenoma, biliary hamartoma **Malignant:** Cholangiocarcinoma, combined HCC-cholangiocarcinoma
Mesenchymal tumors	**Benign:** Hemangioma, mesenchymal hamartoma **Malignant:** Embryonal sarcoma, rhabdomyosarcoma, malignant vascular tumors (epithelioid hemangioendothelioma, angiosarcoma)
Other rare malignancies	Malignant rhabdoid tumor, germ cell tumors, desmoplastic small round cell tumor, peripheral primitive neuroectodermal tumor
Metastases (and secondary)	From solid tumors: neuroblastoma, Wilms, acute myeloid leukemia, Langerhans cell histiocytosis, hemophagocytic lymphohistiocytosis

Modified from Chavhan GB, Siddiqui I, Ingley KM, Gupta AA. Rare malignant liver tumors in children. *Pediatr Radiol*. 2019;49:1404–1421. Table 1.

HEPATOBLASTOMA

Epidemiology

Approximately 100 new cases of hepatoblastoma are diagnosed each year in the United States. The incidence of hepatoblastoma has increased over the last 30 years by as much as 2.7% per year, probably related to increasing survival of very low birthweight premature infants. Hepatoblastoma occurs predominantly in children <3 years old, and the median age of diagnosis is 1 year. The etiology is unknown. Hepatoblastomas are associated with **familial adenomatous polyposis**. Alterations in the antigen-presenting cell/β-catenin pathway have been found in most of the tumors evaluated. Hepatoblastomas are also associated with **Beckwith-Wiedemann syndrome** (BWS), **hemihyperplasia**, and other somatic overgrowth syndromes. Increased expression of insulin-like growth factor 2 secondary to genetic pathogenic variants or epigenetic changes is implicated in hepatoblastoma development in patients with BWS. All children with BWS or hemihyperplasia should be routinely screened with α-fetoprotein (AFP) levels and abdominal ultrasounds. Prematurity/low birthweight is associated with increased incidence of hepatoblastoma, with the risk increasing as birthweight decreases. Aicardi syndrome, trisomy 18, other trisomies, Li-Fraumeni syndrome, Prader-Willi syndrome, Alagille syndrome, glycogen storage disease (type 1), Simpson-Golabi-Behmel syndrome, and fetal alcohol syndrome have also been associated with increased risk of hepatoblastoma.

Pathogenesis

Hepatoblastoma arises from precursors of hepatocytes and is histologically classified as *whole epithelial* type, containing fetal or embryonal malignant cells (either as a mixture or as pure elements), and *mixed* type, containing both epithelial and mesenchymal elements. Histologic classification has a direct correlation with clinical outcome. *Pure fetal histology* and low mitotic activity predicts the best outcome, and the *small cell undifferentiated* subtype associated with normal AFP levels predicts the worse outcome.

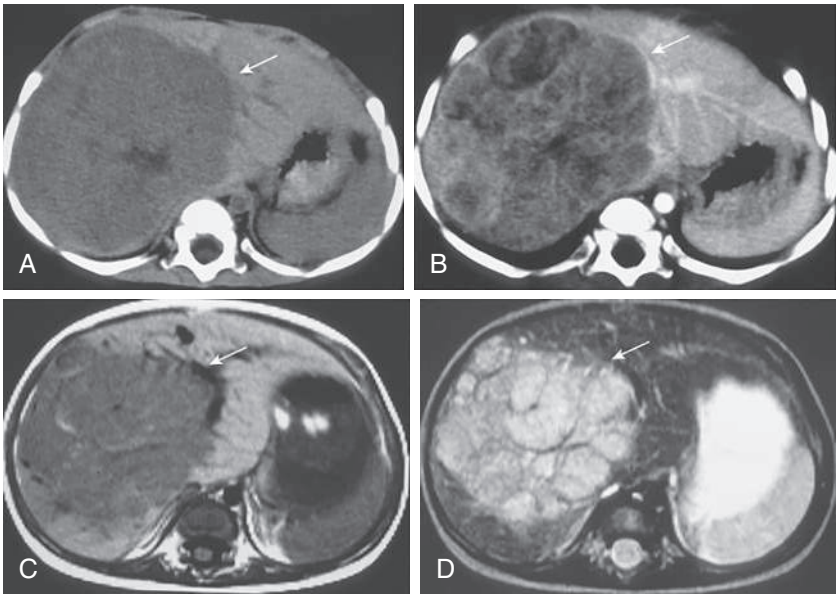

Fig. 553.1 Hepatoblastoma in a 3-yr-old child. **A,** Precontrast CT scan shows well-demarcated, heterogeneous hypodense mass *(arrow).* **B,** Postcontrast CT scan shows heterogeneous internal enhancement *(arrow).* **C** and **D,** The mass *(arrow)* demonstrates heterogeneous hypointensity on T1-weighted **(C)** and hyperintensity on T2-weighted **(D)** MR images.

Clinical Manifestations

Hepatoblastoma usually presents as a large, asymptomatic abdominal mass, with no associated systemic symptoms. Jaundice is uncommon. It arises from the right lobe three times more often than the left and usually is unifocal. When the disease progresses, fatigue, fever, weight loss, anorexia, vomiting, and abdominal pain may ensue. Rarely, hepatoblastoma presents with hemorrhage secondary to trauma or spontaneous rupture. Metastatic spread of hepatoblastoma most often involves regional lymph nodes and the lungs.

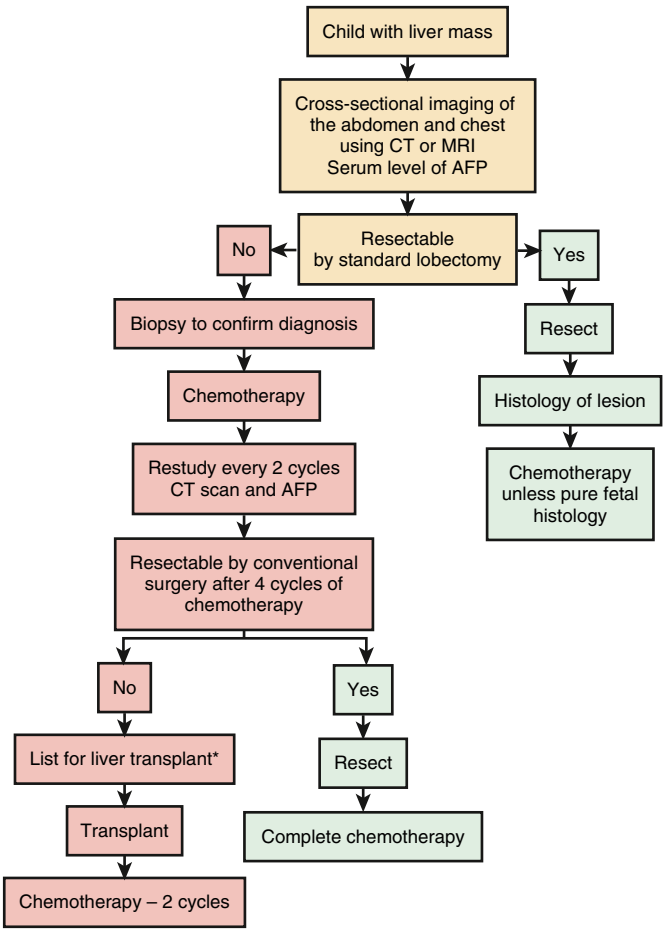
Diagnosis

A biopsy of liver tumors is necessary to establish the diagnosis. A valuable serum tumor marker, AFP, is used in the diagnosis and monitoring of hepatic tumors. AFP is normally elevated in the newborn period and then declines to <10 ng/mL by 1 year of age. The AFP levels are elevated in almost all hepatoblastomas. Bilirubin and liver enzymes usually are normal. Anemia is common, and thrombocytosis occurs in approximately 30% of patients. Serologic testing for hepatitides B and C should be performed, but the results usually are negative in hepatoblastoma.

Diagnostic imaging should include plain radiographs and ultrasonography of the abdomen to characterize the hepatic mass. US can differentiate malignant hepatic masses from benign vascular lesions. Either CT or MRI is an accurate method of defining the extent of intrahepatic tumor involvement and the potential for surgical resection. Evaluation for metastatic disease should include CT of the chest (Fig. 553.1).

Treatment

Treatment is guided by the degree of local tumor burden determined by the pre- and posttreatment extent of disease. In general, the cure of malignant hepatic tumors in children depends on complete resection of the primary tumor (Fig. 553.2); as much as 85% of the liver can be resected, with hepatic regeneration noted within 3-4 months after surgery. Treatment of hepatoblastoma is based on surgery and **systemic chemotherapy** using cisplatin in combination with vincristine and 5-fluorouracil (5-FU), and for intermediate- and high-risk patients, doxorubicin is also used. The role of **radiation therapy** is questionable, because the effective antitumor dose exceeds the hepatic tolerance. Radiation therapy may have a role in shrinking unresectable disease or managing incompletely resected tumors. In 30% of cases, tumors are resectable at diagnosis; a safe attempt for initial gross total resection should be made, followed by adjuvant chemotherapy. Unresectable tumors with or without metastatic disease at presentation usually respond to chemotherapy; preresection chemotherapy is indicated, and excision of the primary tumor and



*Consider continuation of chemotherapy or living-related liver transplantation if cadaveric liver transplant not available in a timely fashion

Fig. 553.2 Algorithm for the management of a child who presents with a hepatoblastoma. AFP, α-Fetoprotein. *(From Tiao GM, Bobey N, Allen S, et al. The current management of hepatoblastoma: a combination of chemotherapy, conventional resection, and liver transplantation. J Pediatr. 2005;146:204–211.)*

extrahepatic disease should be attempted as soon as it becomes feasible, followed by additional chemotherapy. Orthotopic **liver transplant** is a viable option for unresectable primary hepatic malignancies and results in good long-term survival. The pretransplant medical condition is an important predictor of outcome, and thus transplant is much more effective as the primary surgery than as salvage therapy. Alternative treatment options currently under investigation include other systemic chemotherapy agents such as carboplatin, ifosfamide, etoposide, irinotecan, and temsirolimus. Other treatment approaches include transarterial chemoembolization, cryoablation, and radiofrequency ablation (RFA).

Prognosis

In low-stage tumors, survival rates >90% can be achieved with multimodal treatment, including surgery and adjuvant chemotherapy. With tumors unresectable at diagnosis, survival rates of approximately 60% can be obtained. Metastatic disease further reduces survival, but complete regression of disease often can be obtained with chemotherapy and surgical resection of the primary tumor and isolated pulmonary metastatic disease, resulting in survival rates of approximately 25%. Treatment-related long-term adverse effects include cardiac toxicity with doxorubicin and renal and ototoxicity with cisplatin.

HEPATOCELLULAR CARCINOMA

Epidemiology

HCC occurs mostly in adolescents and often is associated with perinatal acquired hepatitis B infection and tyrosinemia. It is more common in East Asia and other areas where hepatitis B is endemic; the incidence has decreased following the introduction of hepatitis B vaccination. In these areas, HCC also tends to occur in a bimodal pattern, with the younger age peak overlapping the age of hepatoblastoma presentation. HCC also occurs in the chronic form of glycogen storage disease, α_1-antitrypsin deficiency, biliary atresia, progressive familial intrahepatic cholestasis, Alagille syndrome, congenital portosystemic shunts, Budd-Chiari syndrome, status postirradiation for liver metastatic Wilms tumor, and with other liver diseases producing chronic inflammation or cirrhosis (Fig. 553.3).

Pathogenesis

Pediatric HCC arises in cirrhotic and noncirrhotic backgrounds and presents as a multicentric, invasive tumor consisting of large pleomorphic cells of epithelial origin. Compared to adults, cirrhosis in children is less common, and congenital liver disorders are more common. HCCs are classified as **classical** or **fibrolamellar**. The fibrolamellar variant occurs more often in adolescent and young adult patients, is not associated with cirrhosis, and represents one fourth of the pediatric

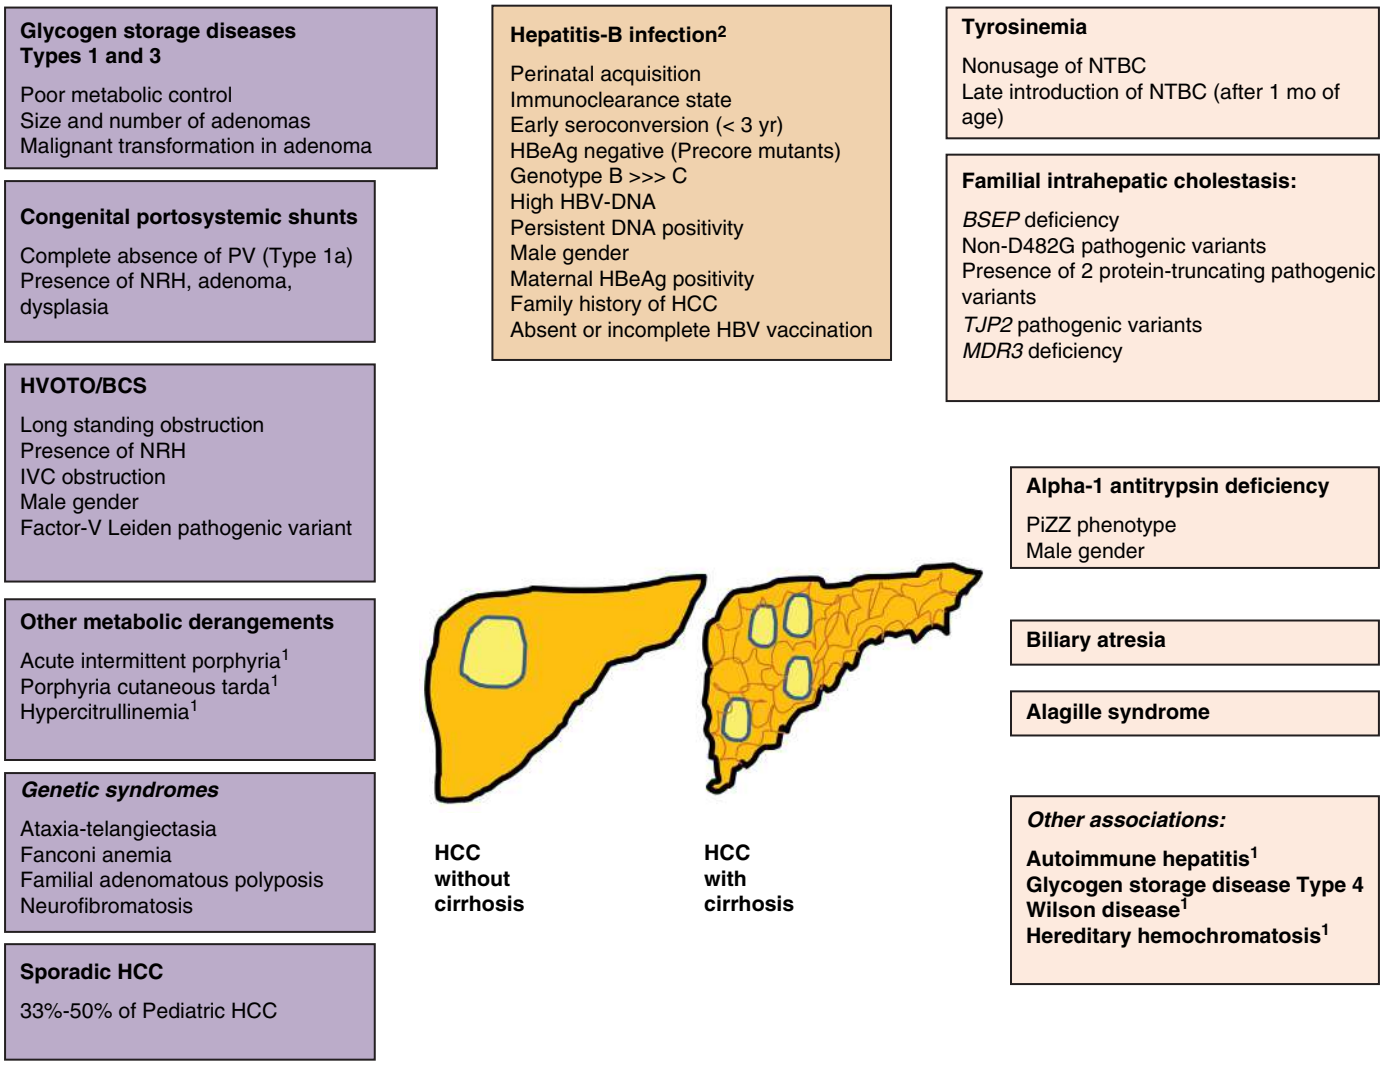


Fig. 553.3 Risk factors for pediatric hepatocellular carcinoma (HCC). [1]Conditions cause HCC in adults, and very rarely in children; [2]Hepatitis B virus (HBV)-related HCC may occur in the presence or absence of cirrhosis. BCS, Budd-Chiari syndrome; HVOTO, hepatic venous outflow tract obstruction; IVC, inferior vena cava; NRH, nodular regenerative hyperplasia; BSEP, bile salt export pump; MDR3, multidrug resistance protein-3; NTBC, [2-(2-nitro4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (Nitisinone); PiZZ, homozygous PiZ phenotype of α_1-antitrypsin; PV, Portal vein; TJP: tight junction protein. *(From Khanna R, Verma SK. Pediatric hepatocellular carcinoma. World J Gastroenterol. 2018;24[35]:3980–3999. Fig. 1.)*

HCC cases. This variant has been reported to have a distinct translocation, *DNAJB1-PRKACA*. A rare subtype called **transitional liver tumor** occurs in older children and has clinical and histopathologic findings of both hepatoblastoma and HCC.

Clinical Manifestations

HCC usually presents as a hepatic mass with abdominal distention and symptoms of anorexia, weight loss, jaundice, and abdominal pain. HCC can present as an acute abdominal crisis with rupture of the tumor and hemoperitoneum. Metastatic spread usually involves regional lymph nodes and the lungs. The AFP level is elevated in approximately 60% of children with conventional HCC, but not in the fibrolamellar variant. Evidence of hepatitis B usually is found in endemic areas but not in Western countries or with the fibrolamellar type. Liver enzymes may be abnormal.

Diagnostic imaging should include plain radiographs and US of the abdomen to characterize the hepatic mass. US can differentiate malignant hepatic masses from benign vascular lesions. Either CT or MRI is an accurate method of defining the extent of intrahepatic tumor involvement and the potential for surgical resection. Evaluation for metastatic disease should include CT of the chest.

Treatment

Complete tumor resection is crucial for curative treatment. Because of the multicentric origin of HCC and underlying liver disease, complete resection is accomplished in only 20–30% of cases. A gross total resection should be attempted at diagnosis when possible; if not, neoadjuvant chemotherapy should be given to convert nonresectable tumors into resectable ones. Combination chemotherapy following surgery is necessary. For unresectable tumors, **chemotherapy** followed by surgical assessment is essential, and **liver transplant** should be decided individually for each patient with HCC. Chemotherapy, including cisplatin, carboplatin, doxorubicin, and etoposide, has shown activity against this tumor, but improved long-term outcome has been difficult to achieve if tumor is not completed resected. **Sorafenib**, a small inhibitor of several tyrosine protein kinase showed antitumoral activity in adult patients with HCC, and initial studies have been published in the pediatric population with encouraging results. Other techniques are under study in adults, including cryosurgery, RFA, transarterial chemoembolization, and radiation therapy.

Chapter 554

Complex Vascular Anomalies

Alexandra J. Borst and Denise M. Adams

Vascular anomalies in children encompass a spectrum of disorders that may be divided into **vascular malformations** and vascular tumors (Tables 554.1-554.4; see Chapter 691). **Vascular malformations** are developmental disorders of blood vessel formation. Malformations do not regress; rather, they slowly enlarge. They should be named after the predominant vessel(s) forming the lesion: arterial, capillary, lymphatic, or venous, or combinations of these (see Table 554.1). Vascular tumors exhibit endothelial cell hyperplasia and proliferation. The International Society for the Study of Vascular Anomalies (ISSVA) continues to update the classification structure for vascular disorders as new disorders are identified and as the biology and genetic causes for established disorders are found. The complete classification, associated syndromes, and causative pathogenic variants can be found at www.issva.org. The discovery of the molecular basis of many **vascular malformations** and tumors has allowed for improved understanding of the etiology of these disorders as well as new **targeted therapeutic approaches** for management.

GENETIC BASIS FOR VASCULAR ANOMALIES

Two key intracellular signaling pathways have been implicated in the pathogenesis of most **vascular malformations**, syndromes, and tumors. The RAS/MAPK and PI3K/AKT/mTOR pathways are crucial for cell cycle regulation, proliferation, and migration (Fig. 554.1). Pathogenic, *somatic* variants in the *PIK3CA* gene have been identified in patients with **venous malformations**, **lymphatic malformations**, and several vascular anomalies and overgrowth syndromes (see Table 554.4). Pathogenic variants in the RAS/MAPK pathway have been identified in **capillary and arteriovenous malformations (AVMs)**, central conducting lymphatic anomalies, as well as many of the vascular tumors.

Discovery of the molecular basis for **vascular malformations** and tumors has led to the ability to find **targeted therapies** for management of these conditions. **Sirolimus** has been utilized successfully in vascular malformations and tumors. The identification of the crucial role of *PIK3CA* pathogenic variants in vascular anomalies has led to the investigation of **PI3K inhibitors** as important targeted therapies. Agents that target the RAS/MAPK pathway, such as **MEK inhibitors**, have also been trialed in complicated AVMs as well as Kaposiform lymphangiomatosis (KLA).

COMPLEX LYMPHATIC ANOMALIES

Lymphatic anomalies represent a rare disease entity, with an estimated incidence of 1:10,000 for the most common form of lymphatic malformations, but with only a few hundred case reports in the literature for *complex* lymphatic anomalies. Lymphatic anomalies arise from developmental defects in lymphangiogenesis. They carry significant risk for comorbidities, including pain, infection, disfigurement, and life-threatening organ dysfunction. Lymphatic anomalies encompass a broad range of developmental and functional defects in lymphatic vessels that range from discrete malformations to complex anomalies (generalized lymphatic anomaly [GLA], KLA, and Gorham-Stout disease [GSD]) and primary lymphedema syndromes.

Most lymphatic anomalies are thought to arise from *somatic* pathogenic variants in genes involved in lymphangiogenesis, but germline predispositions also exist. Pathogenic variants in the PIK3CA/AKT/mTOR and VEGFC/VEGFR3 pathways have been found in many isolated lymphatic malformations; variants in the RAS/MAPK pathway have been identified in patients with *complex lymphatic anomalies* (Fig. 554.2). However, most patients remain without a genetic diagnosis.

Generalized Lymphatic Anomaly

Previously known as lymphangiomatosis, GLA is characterized by a nonneoplastic, multicentric proliferation of dilated lymphatic vessels, with multiple sites resembling common lymphatic malformations (Fig. 554.3). The lesions are present since birth but generally become clinically apparent within the first 2 decades of life. The lesions can affect the bones, liver, spleen, mediastinum, lung, and soft tissues. Bone involvement is typically osteolytic, with punched out lesions and intact cortex. Clinical response depends on location and extent of disease, with thoracic involvement having the poorest prognosis. Patients with GLA most commonly have pathogenic somatic variants in *PIK3CA* leading to overactivity in the PI3K/AKT/mTOR pathway and disrupted lymphatic development and growth. Many patients have been successfully managed with sirolimus.

Gorham-Stout Disease

GSD (also known as *vanishing bone disease*) has significant clinical overlap with GLA but tends to involve a single site or adjacent sites. Patients may present with adjacent soft tissue mass or small areas of

microcystic lymphatic malformation. The upper axial skeleton is commonly affected, and there is osteolysis of both the medullary and cortical bone (Fig. 554.4). This osteolysis can be profound and result in significant morbidity, including dysfunction of an appendage or even spinal column instability. Some molecular findings in patients with GSD have suggested that somatic activating variants in *KRAS* and dysfunction of the RAS/MAPK signaling pathway drive the pathogenesis of GSD. Many patients have been treated with sirolimus with adjunctive bisphosphonate therapy.

Kaposiform Lymphangiomatosis

KLA has been considered an aggressive subtype of GLA but is histologically and molecularly distinct. Many patients with KLA harbor *somatic* activation variants in the RAS pathway, rather than the PI3K/AKT/mTOR pathway identified as causative in GLA. KLA presents with distinct foci of spindled endothelial cells on a background of malformed lymphatic vessels. KLA can affect multiple organs and sites but primarily affects the thoracic cavity with patients presenting with life-threatening, and frequently hemorrhagic, pleural effusions (Fig. 554.5). Patients often have a coagulopathy at presentation due to the same **Kasabach-Merritt phenomenon (KMP)** seen in patients with **Kaposiform hemangioendothelioma**. Patients typically present at a younger age than those with GLA or GSD; the mortality has been reported as high as 50–60% prior to the introduction of sirolimus.

Central Conducting Lymphatic Anomaly

Central conducting lymphatic anomaly (CCLA), also known as *lymphangiectasia*, is classified as a channel-type lymphatic anomaly. CCLA is caused by lymphatic channel dysmotility and distal obstruction/malformation affecting lymphatic drainage and leading to recurrent effusions (Fig. 554.6). Patients with other complex lymphatic anomalies may have a component of CCLA. Pathogenic variants in *EPHB4* and *ARAF* have been identified in patients with CCLA and both mTOR and MEK inhibition have been used in its management with mixed success. Patients frequently needed targeted interventional procedures to embolize abnormal lymphatic vessels.

Treatment of Complex Lymphatic Anomalies

Management of complex lymphatic anomalies is principally aimed at control, not cure. This can include a variety of medical, surgical, and interventional procedures to control symptoms and prevent morbidity. Sirolimus, an mTOR inhibitor, has been shown to decrease symptoms of lymphatic leak such as lymphatic blebs, decrease the size of macrocystic and microcystic malformations, decrease chylous production, and may slow the pathologic dissolution of bone by lymphatic malformation. MEK inhibition has shown promise in the management of KLA and CCLA, both found to be driven more by perturbations affecting RAS/MAPK signaling. Adjunctive therapy with bisphosphonates is often used in GSD and in patients with GLA and KLA with bony vertebral lesions.

COMPLEX VENOUS ANOMALIES

Venous anomalies are slow-flow lesions that represent abnormal or excessive growth of venous structures. **Venous malformations** are the most common vascular malformations with an incidence of 1 in 5,000 to 10,000. Due to the slow and sometimes turbulent flow, they commonly are associated with pain, swelling, and intralesional thrombosis. Venous malformations have been found to have *somatic* pathogenic variants in both *PIK3CA* and *TIE2/TEK*, an endothelial cell–specific tyrosine kinase receptor that functions through the PI3K/AKT/mTOR pathway (see Fig. 554.1).

Blue Rubber Bleb Nevus Syndrome

Blue rubber bleb nevus syndrome (BRBNS) is characterized by multiple cutaneous and internal venous malformations, primarily hepatic and intestinal (Fig. 554.7). Many cases have been found to be due to gain-of-function

Table 554.3 Vascular Malformations Associated with Other Anomalies

SYNDROME	LESIONS	GENES

Table 554.4 PIK3CA-Related Overgrowth Spectrum

PIK3CA-related overgrowth spectrum (PROS) group lesions with heterogeneous segmental overgrowth phenotypes with or without vascular anomalies due to somatic PIK3CA activating variants.

This spectrum includes:

- Fibroadipose hyperplasia or overgrowth (FAO)
- Hemihyperplasia multiple lipomatosis (HHML)
- Congenital lipomatous overgrowth, vascular malformations, epidermal nevi, scoliosis/skeletal, and spinal (CLOVES) syndrome
- Macrodactyly
- Fibroadipose infiltrating lipomatosis/facial infiltrative lipomatosis
- Megalencephaly-capillary malformation (MCAP or M-CM)
- Dysplastic megalencephaly (DMEG)
- Klippel-Trenaunay syndrome

From ISSVA Classification for Vascular Anomalies (Approved at the 20th ISSVA Workshop, Melbourne, April 2014, last revision May 2018) https://www.issva.org/UserFiles/file/ISSVA-Classification-2018.pdf

TIE2/TEK pathogenic variants; both sporadic and autosomal dominant inheritance have been described. Significant morbidity can arise due to intestinal venous malformations, which can lead to severe bleeding and secondary iron deficiency anemia. Patients must be monitored closely for signs and symptoms of bleeding. The mainstay of management is control of disease with sirolimus and supportive care for anemia.

Glomuvenous Malformation (Glomangioma)

Glomuvenous malformations, also known as *glomangiomas* or *glomus tumors*, are one of the rare germline conditions in vascular anomalies. Glomuvenous malformations result from an autosomal dominant loss-of-function variant in the *GLMN* gene, which encodes a protein essential for normal vascular development. Patients present with multiple superficial cutaneous lesions with a cobblestone appearance (Fig. 554.8). There is 100% penetrance but variable expressivity. Painful lesions can be treated with surgical resection, laser, or sclerotherapy.

SYNDROMES ASSOCIATED WITH VASCULAR ANOMALIES

PIK3CA-Related Overgrowth Spectrum Disorders

PIK3CA-related overgrowth spectrum (PROS) encompasses a group of disorders caused by somatic mosaic mutations in the PI3K/AKT/mTOR pathway (see Table 554.4). The *PIK3CA* (phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit α) gene encodes a group of lipid kinases (PI3 kinases) that are key to regulating cell proliferation and survival via the PI3K/AKT/mTOR pathway. Patients with PROS present with a wide spectrum of clinical phenotypes, but progressive segmental overgrowth and vascular malformations are key components.

Klippel-Trenaunay Syndrome

Klippel-Trenaunay syndrome (KTS) is characterized by overgrowth of one lower extremity in combination with combined slow-flow vascular malformation (capillary, venous, and/or lymphatic). Complications include lymphatic overgrowth, infection, oozing and/or bleeding from lymphatic blebs, and thromboembolism (Fig. 554.9). Patients with KTS have an anomalous venous return system composed of dilated and incompetent veins, often with a larger marginal vein. The deep venous system may also be poorly developed. Patients can have lymphatic involvement of the skin, musculature, and intestinal tract. Venous malformation may affect the bladder and urethra. Due to variability in diagnostic criteria and identification of KTS over the years, the genetic etiology of KTS is not completely confirmed, but many patients have been identified to have a *somatic* variants in *PIK3CA*; KTS is considered part of PROS disorders. Surgical and interventional procedures may be important for some patients with KTS. Medical management currently includes sirolimus and anticoagulation therapy.

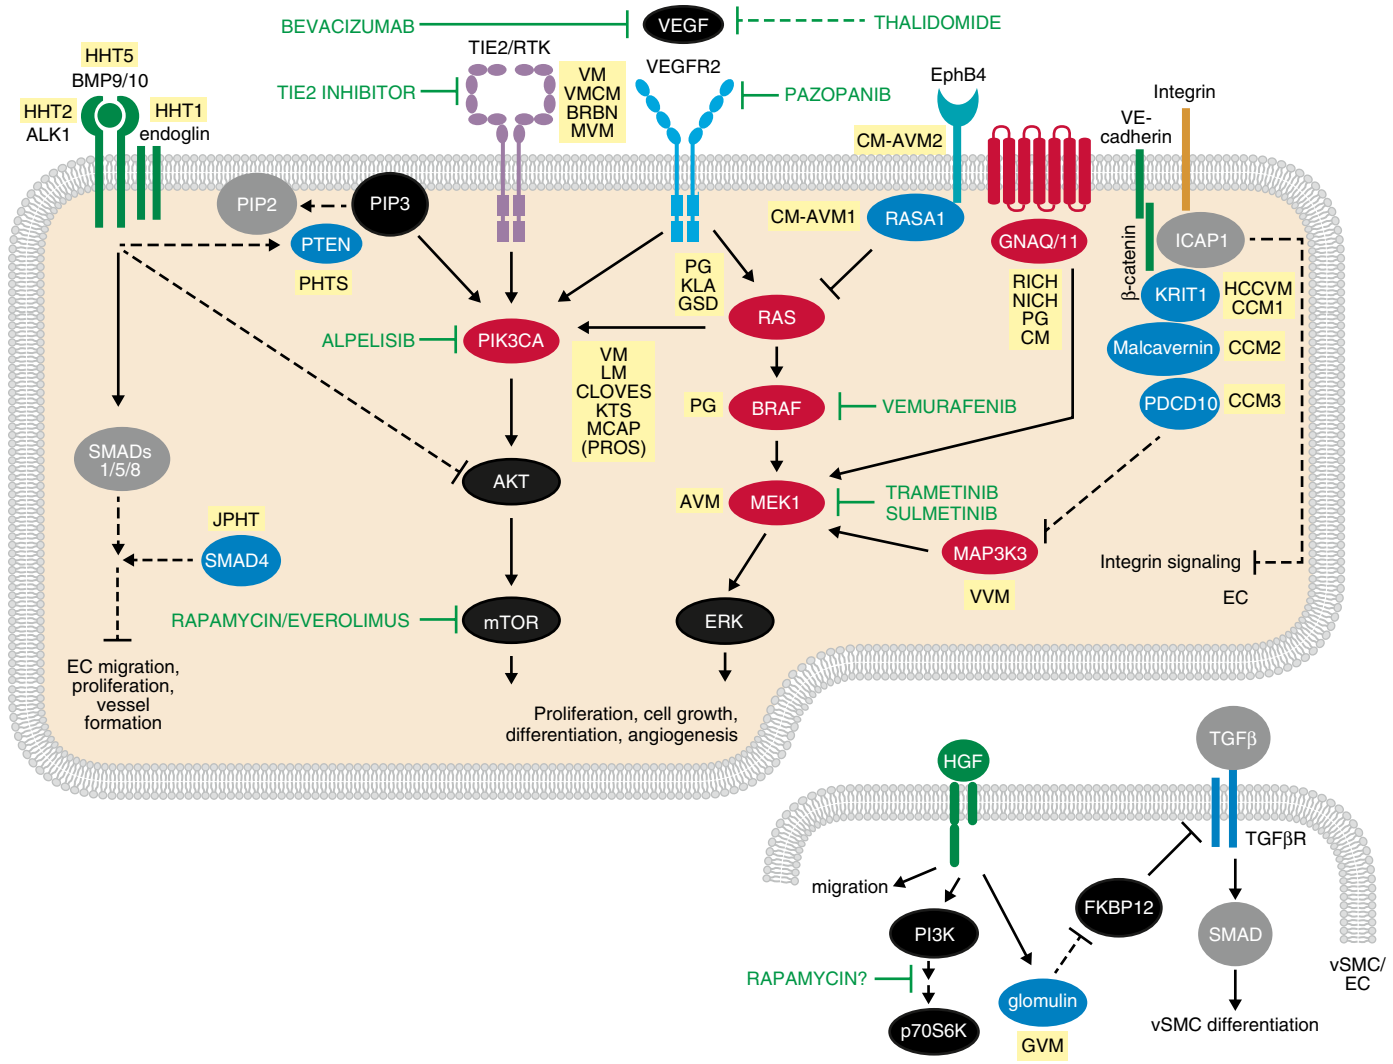

Fig. 554.1 PI3K/AKT/mTOR signaling and RAS/MAPK signaling in vascular anomalies. Red, gain of function; blue, loss of function; black, enhanced signaling; gray, decreased signaling. *(From Queisser A, Seront E, Boon LM, Vikkula M. Genetic basis and therapies for vascular anomalies. Circ Res. 2021;129[1]:155–173. Fig. 3.)*

CLOVES

CLOVES, or congenital lipomatous overgrowth, vascular malformations, epidermal nevi, and scoliosis/spinal/skeletal anomalies, is a disorder that results from an early embryonic pathogenic variant in *PIK3CA*. In addition to extremity hypertrophy, patients can have significant fatty lipomatous overgrowth (Fig. 554.10). Spinal involvement is common. Patients with vascular malformations usually have a combination of capillary, venous, and lymphatic malformations. AVMs are less common but have been reported with spinal involvement. Deep venous anomalies increase the risk for venous thromboembolism. Patients with CLOVES have an increased risk of Wilms tumor and require serial monitoring with abdominal ultrasonography in early childhood. Patients may require sclerotherapy, surgery, and other interventional procedures depending on symptoms. Patients have also been successfully managed with sirolimus.

Macrocephaly-Capillary Malformation

Macrocephaly-capillary malformation (M-CM) syndrome is a PROS disorder characterized by macrocephaly, brain abnormalities, CM (often in a reticular pattern), overgrowth, and developmental delays (Fig. 554.11). Neurologic manifestations can include hydrocephalus, cortical dysplasia, polymicrogyria, and posterior fossa crowding with cerebellar tonsillar herniation. Patients require supportive care for overgrowth and other vascular anomalies, as well as close monitoring of brain growth and development.

AKT-RELATED OVERGROWTH SPECTRUM

Proteus Syndrome

Proteus is an overgrowth disorder caused by a *somatic* mosaic pathogenic variant in the PI3K/AKT/mTOR pathway. Clinical features include overgrowth (including lipomatous), bony abnormalities, cerebriform connective tissue nevus, vascular malformations (capillary, venous, lymphatic), epidermal nevi, cerebral abnormalities and accompanying intellectual disability, and increased risk for secondary neoplasms and venous thromboembolism. Management of proteus disorders has primarily been supportive, although use of AKT1 inhibition is currently being evaluated.

RASopathies

RASopathies refers to a group of medical conditions caused by pathogenic variants in the RAS/MAPK pathway. It includes both germline conditions, as well as *somatic* variants. The RAS/MAPK pathway is important in cell cycle regulation, proliferation, migration, and stress response. RAS/MAPK pathway pathogenic variants have been identified in patients with solitary CMs and AVMs, GLA, KLA, verrucous venous malformation, cerebral CM, pyogenic granuloma (PG), and congenital hemangiomas.

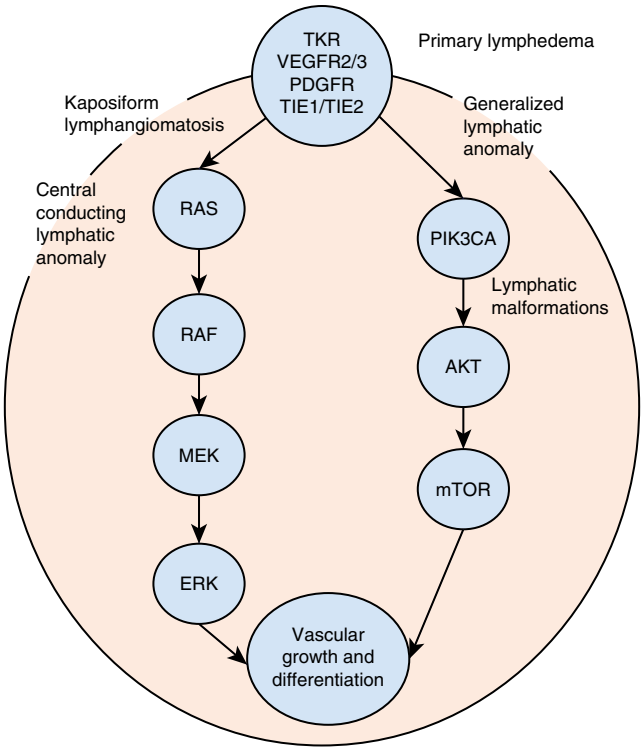

Fig. 554.2 Molecular pathways identified in lymphatic anomalies.

Capillary Malformation-Arteriovenous Malformation Syndrome

Capillary malformation-arteriovenous malformation (CM-AVM) is an autosomal dominant disorder characterized by diffuse, circumscribed CMs and increased risk for intra- or extracranial AVMs. AVMs are found in ~80% of patients. The CMs have a distinct appearance with a round or ovoid shape and surrounding pale halo. Most cases of CM-AVM are caused by a loss-of-function pathogenic variant in *RASA1*, but variants in *EPHB4* have also been reported (CM-AVM type 2). Familial penetrance is high, and screening is important due to the high risk for life-threatening complications from AVMs. AVMs may require treatment with a combination of interventional and surgical procedures.

Parkes-Weber Syndrome

Parkes-Weber syndrome (PKWS) is associated with pathogenic variants in *RASA1*. The syndrome includes multiple microscopic arteriovenous fistulae in association with a CM. PKWS is also associated with soft tissue and bony overgrowth of an extremity.

KAPOSIFORM HEMANGIOENDOTHELIOMA

Kaposiform hemangioendothelioma (KHE) is a rare and potentially life-threatening vascular tumor. KHE classically presents as a red to purple firm plaque on the lateral neck, axilla, trunk, or extremities. Visceral tumors occur as well. Lesions may occasionally get smaller over time but rarely resolve completely. **Tufted angioma,** once thought to be a separate tumor on the same clinical spectrum as KHE, is considered under the umbrella term of KHE (Fig. 554.12). The main complication of these tumors is the development of **KMP**, which may be fatal; therefore early diagnosis and treatment is important. Retroperitoneal or intrathoracic lesions in the absence of cutaneous lesions are uncommon but are often associated with KMP.

Kasabach-Merritt Phenomenon

KMP is a life-threatening combination of a rapidly enlarging KHE, thrombocytopenia, microangiopathic hemolytic anemia, and an acute or chronic consumption coagulopathy. The clinical manifestations are usually evident during early infancy. The vascular lesion is usually cutaneous and is only

Fig. 554.7 Multiple **venous malformations** on the tongue (A) and subcutaneous tissues of the foot (B) in a patient with blue rubber bleb nevus syndrome (BRBNS).

rarely located in viscera. The associated thrombocytopenia may lead to precipitous hemorrhage accompanied by ecchymoses, petechiae, and a rapid increase in the size of the vascular lesion. Severe anemia from hemorrhage or microangiopathic hemolysis may ensue. The thrombocytopenia has been attributed to sequestration or increased destruction of platelets within the lesion. Hypofibrinogenemia and decreased levels of consumable clotting factors are relatively common (see Chapter 533.6). KMP is seen in KHE or tufted angioma, as well as to a milder extent in very large congenital and hepatic hemangiomas *but not* in infantile hemangiomas.

Treatment includes surgical excision of small lesions, although this is often difficult because of coagulopathy and the infiltrative nature of the tumor. Additional pharmacologic treatments include systemic steroids with or without vincristine as first-line therapy in most cases. mTOR inhibition with sirolimus has been found to be successful as an alternative first-line treatment for KHE. The optimal initial combination of medical therapies is not yet known. Antiplatelet, antifibrinolytic, and other chemotherapeutic agents have been used with mixed results. The mortality rate overall once patients have KMP is high.

OTHER RARE VASCULAR TUMORS

Benign Tumors (Other Than Infantile Hemangiomas) (see Chapter 691)

Epithelioid Hemangiomas

Epithelioid hemangioma (EH) is a very rare vascular tumor, usually occurring in the skin or subcutaneous tissues, but occasionally occurring

Fig. 554.8 Cobblestoned appearance of a patient with a glomangioma, or glomuvenous malformation, caused by a germline pathogenic variant in the glomulin gene *(GLMN)*. Family members all with similar appearing lesions.

Fig. 554.9 Overgrown right lower extremity with **capillary-venous-lymphatic malformation** in a patient with Klippel-Trenaunay syndrome.

in other sites such as bone. They may be mistaken for infantile hemangiomas or PGs and can be reactive due to trauma or infection. EHs are well-circumscribed proliferations of capillaries that stain for endothelial cell and lymphatic markers but are without any cytologic atypia or mitoses. Primary treatment is with surgical excision, though they can recur locally. *FOS* gene rearrangements have been identified in some EHs.

Pyogenic Granuloma (Lobular Capillary Hemangioma)

A PG is a small red, glistening, sessile, or pedunculated papule that often has a discernible epithelial collarette (see Fig. 691.16). The surface may be weeping and crusted or completely epithelialized. PGs initially grow rapidly, may ulcerate, and bleed easily when traumatized because they consist of exuberant granulation tissue. They are relatively common in children, particularly on the face, arms, and hands. Such a lesion located on a finger or hand may appear as a subcutaneous nodule. PGs may arise at sites of injury, but a history of trauma often cannot be elicited.

PGs are benign but a nuisance because they bleed easily with trauma and may recur if incompletely removed. Numerous satellite papules have developed after surgical excision of PGs from the back, particularly in the interscapular region. Small lesions may regress after cauterization with silver nitrate; larger lesions require excision and electrodesiccation of the base of the granuloma. Small (<5 mm) lesions may be treated successfully with **pulsed dye laser** therapy.

Spider Angioma

A vascular spider (nevus araneus) consists of a central feeder artery with many dilated radiating vessels and a surrounding erythematous flush, varying from a few millimeters to several centimeters in diameter (see Fig. 691.17). Pressure over the central vessel causes blanching; pulsations visible in larger nevi are evidence for the arterial source of the lesion. Spider angiomas are associated with conditions in which there are increased levels of circulating estrogens, such as cirrhosis and pregnancy, but they also occur in up to 15% of normal preschool-age children and 45% of school-age children. Sites of predilection in children are the dorsum of the hand, forearm, nose, infraocular region, lips, and ears. Lesions often regress spontaneously after puberty. If removal is desired, pulsed dye laser therapy is the mode of choice; resolution is achieved in 90% of cases with a single treatment.

Maffucci Syndrome

The association of spindle cell hemangiomas with nodular enchondromas in the metaphyseal or diaphyseal cartilaginous portion of long bones is known as Maffucci syndrome. Maffucci syndrome is caused by *somatic* mosaic pathogenic variants in the *IDH1* and *IDH2* genes. Vascular lesions are typically soft, compressible, asymptomatic blue to purple subcutaneous masses that grow in proportion to a child's growth and stabilize by adulthood. Mucous membranes or viscera may also be involved. Onset occurs during childhood. Bone lesions may produce limb deformities and pathologic fractures. Malignant transformation of enchondromas (chondrosarcoma, angiosarcoma) or primary malignancies (ovarian, fibrosarcoma, glioma, pancreatic) may be a complication (see Chapter 550).

LOCALLY AGGRESSIVE RARE VASCULAR TUMORS

Retiform Hemangioendothelioma

Retiform hemangioendothelioma (RHE) is an intermediate, or rarely metastasizing, vascular tumor. They usually present as a slow-growing mass with plaque-like or nodular appearance. They can involve the entire dermis and extend into the subcutaneous tissue. Histologically, hobnail endothelial cells are found, but only variably lymphatic endothelial cell markers. Treatment is with surgical excision, though local recurrence is common and regional lymph node metastases have been reported.

Papillary Intralymphatic Angioendothelioma

Papillary intralymphatic angioendothelioma (PILA), also referred to as *Dabska tumor,* is a locally aggressive hemangioendothelioma. PILA occur within the dermis and superficial soft tissues of the head, neck, trunk, or extremities. On occasion they have been reported to arise from preexisting lymphatic or venolymphatic malformations, or within an extremity affected by lymphedema. They appear as violaceous nodules similar to RHE but histologically appear similar to lymphatic malformations and contain hobnail endothelial cells. Primary treatment is with excision, but regional lymph node metastasis and even death due to distant metastasis have been reported. Systemic chemotherapy based on sarcoma treatment may be used in recurrent or refractory cases.

Composite Hemangioendothelioma

Composite hemangioendotheliomas (CHE) contain overlapping histologic features with epithelioid, retiform, and spindle-cell hemangioendotheliomas. Some also contain angiosarcoma-like features within the same tumor. Fewer than 40 cases have been reported in the literature, and they can present at any age and in association with other vascular anomalies. Treatment options include surgical excision, chemotherapy, and radiation therapy.

Fig. 554.10 A, Soft tissue and bony overgrowth of the digits of the bilateral hands in a patient with CLOVES. Also noted is overlying capillary malformation (CM). B, Overgrowth of digits of the feet and right sandal-toe gap deformity in a patient with CLOVES. Also noted are CM and dilated venous pattern from underlying bilateral **venous malformation** of the lower extremities.

Fig. 554.11 Infant with macrocephaly, prominent forehead, depressed nasal bridge, short neck, bluish white iris, and reticulated port-wine stains over body, consistent with macrocephaly-capillary malformation (M-CM). *(From Panigrahi I, Bhushan M, Yadav M, Khandelwal N, Singhi P. Macrocephaly-capillary malformation syndrome: three new cases. J Neurol Sci. 2012;313:178–181. Fig. 5.)*

Pseudomyogenic Hemangioendothelioma (Epithelioid Sarcoma-Like Hemangioendothelioma)

Pseudomyogenic hemangioendothelioma (PMH) is a rare vascular tumor that presents more commonly in males than females (4:1 predominance) and usually in young adulthood (<40 years). The typical presentation is multifocal presentation within one extremity, and it does frequently have bony involvement. Histologically, it shares some features with epithelioid sarcoma, with myoid-appearing spindle cells, but has very low metastatic potential. Primary treatment is with surgical resection, but local recurrence is common, and mTOR inhibition with sirolimus has shown promise in its management.

MALIGNANT TUMORS

Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma (EHE) is variant of *angiosarcoma,* which is locally aggressive and has metastatic potential. It usually occurs in middle-age adults and presents as a solitary mass in the soft tissues, viscera, or bone, with liver as the most common site. Thirty

Fig. 554.12 A, Patient with **Kaposiform hemangioendothelioma** (KHE) of the thigh who presented with **Kasabach-Merritt phenomenon** (KMP) with thrombocytopenia and hypofibrinogenemia unresponsive to all therapy until introduction of sirolimus. B, Premature infant with KHE of the arm who presented with KMP.

percent present with metastases, and occasionally patients present with hemolytic anemia or consumptive coagulopathy. EHE is characterized by the WWTR1/CAMTA1 translocation, with some also expressing a *YAP1-TFE3* gene fusion. Histologically, EHE are epithelioid tumors arranged in nests or cords. They may contain spindle endothelial cells and express Fli-1 and CD31. Treatment depends on location and metastatic pattern but includes surgery, radiotherapy, and chemotherapy. Overall survival for those with progressive disease is quite poor.

Angiosarcoma

Angiosarcomas account for ~2% of all soft tissue sarcomas, occur mostly in adults, and very rarely affect children. In children, they may be cutaneous or in the deep tissues or viscera. Angiosarcomas present as rapidly enlarging purplish plaques or nodules that ulcerate and can leak serosanguinous fluid. Necrosis and hemorrhage within the tumor are common. Due to risk for rapid progression and metastasis, multimodal therapy including resection and intensive chemotherapy is generally pursued. Combined treatment with mTOR and MEK inhibition has shown some promise, but progression-free and overall survival remain very poor.

Hepatic angiosarcomas appear to be a distinct subtype of angiosarcoma, presenting in earlier childhood, usually between age 1 and 5 years (Fig. 554.13). There is sometimes a history of infantile hepatic hemangioma, although cutaneous infantile hemangiomas do not appear to progress to angiosarcoma. Patients can present with anemia and thrombocytopenia due to intratumoral bleeding. Liver function tests may be abnormal, but α-fetoprotein is normal or only minimally elevated. Risk of local invasion and metastasis is quite high, so rapid diagnosis, surgical resection, and initiation of sarcoma-based chemotherapy is important. Unfortunately, complete cure is very rare.

Lymphangiosarcoma is a distinct subtype of angiosarcoma arising from the lymphatic endothelium of a site of lymphedema. Lymphangioma resembles angiosarcoma both clinically and histologically and appears to harbor the same c-myc amplification seen in postradiation angiosarcoma of the breast. Similar to the "hemangiosarcoma" form of angiosarcoma, lymphangiosarcomas are managed similarly and have similar overall poor prognosis.

Chapter 555
Rare Tumors

555.1 Thyroid Tumors

Jonathan D. Wasserman

See Chapter 607.

BENIGN THYROID TUMORS

Benign thyroid tumors represent approximately 75% of all thyroid nodules presenting in the pediatric population and generally require no treatment unless they result in compressive symptoms or thyroid hormone hypersecretion. The workup of a suspected thyroid nodule includes the laboratory assessment of thyroid function (thyroid-stimulating hormone [TSH]), ultrasound (US) to assess characteristics of the nodule(s) and regional lymph nodes, and US-guided fine-needle aspiration biopsy (of the primary nodule and suspicious lymph nodes) for cytopathologic diagnosis if imaging is suspicious for malignancy. Nuclear scintigraphy using radioactive iodine (^{123}I) or technetium 99m (^{99m}Tc)-pertechnetate are not recommended in the initial diagnostic evaluation, except in the event of a suppressed TSH level.

MALIGNANT THYROID TUMORS

Pediatric thyroid malignancies are rare tumors that include medullary thyroid carcinoma (MTC) and the differentiated thyroid carcinomas (DTCs), namely, papillary thyroid carcinoma (PTC) and follicular thyroid carcinoma. Findings suggestive of a thyroid malignancy are noted in Table 555.1.

PTC represents the majority of thyroid cancers in children. The incidence of pediatric thyroid cancer has been rising, with the highest rate in adolescence, and a female predominance emerges around the time of puberty. With few exceptions, children with PTC have a highly favorable prognosis, with anticipated survival over decades, even in the presence of distally metastatic disease at diagnosis. *The major established risk factor for development of PTC is exposure to ionizing radiation, typically in the context of antineoplastic therapy.*

MTC is an uncommon disease in childhood that usually occurs in the context of **multiple endocrine neoplasia type 2a (MEN2A) or type 2b (MEN2B),** autosomal dominant, hereditary endocrine tumor syndromes that arise secondary to activating variants in the *RET* proto-oncogene. In addition to the almost complete penetrance of MTC in patients with the most common *RET* variants, patients with MEN2A and MEN2B have up to a 50% lifetime risk of developing pheochromocytomas (PHEOs). Up to 20% of MEN2A patients also develop primary hyperparathyroidism. Patients with MEN2B do not develop hyperparathyroidism but have a distinct clinical phenotype that includes a characteristic facial appearance, marfanoid body habitus, aerodigestive tract ganglioneuromatosis, and **oral and ocular mucosal neuromas** (Fig. 555.1). The diagnosis of MEN2B is often delayed (usually after the MTC has already metastasized) because its pathognomonic features are not apparent in very early childhood, although an inability to cry tears (alacrimia) and constipation represent the earliest clues to diagnosis. MTC may be sporadic or familial without features of MEN 2A or 2B; it may also be associated with **Hirschsprung disease**.

Children with sporadic **DTC** typically present with an asymptomatic thyroid mass and/or cervical lymphadenopathy. Lymph node metastases are present in most PTC cases, and lung metastases are identified in up to 20% of patients, primarily in those children with a high burden of neck disease. In contrast, children with MEN2-related **MTC** are often diagnosed only after a positive genetic test result or, in the case of MEN2B, after the clinical phenotype is recognized. When

Table 555.1	Clinical Findings Associated with Malignant Thyroid Nodules
HISTORIC FEATURES	
Neck irradiation during childhood or adolescence	
Rapid growth	
Recent, persistent changes in speaking, breathing, or swallowing	
Family history of multiple endocrine neoplasia type 2	
PHYSICAL EXAMINATION	
Firm, fixed, and irregular consistency of nodule	
Vocal cord paralysis or hoarseness	
Persistent regional lymph adenopathy

Fig. 555.1 Classic appearance of oral mucosal neuromas on the tongue in a boy with multiple endocrine neoplasia type 2b (MEN2B) secondary to the typical M918T variant in the *RET* protooncogene.

a family history is known, presymptomatic surveillance may identify MTC at earlier stages. As with PTC, MTC also frequently metastasizes to cervical lymph nodes.

There are well-documented genotype-phenotype correlations in MEN2, and the biologic aggressiveness of MTC depends on the hereditary setting in which it develops. With the availability of genetic testing for *RET* variants, MTC has become one of the few malignancies that can be prevented by *prophylactic thyroidectomy*.

The age at which prophylactic thyroidectomy is recommended is determined based on the specific *RET* variant, serum calcitonin levels, and parent and child preference.

The **primary therapy** for thyroid cancer, regardless of histologic type, is thyroidectomy and, if there is evidence of lymph node metastasis, a compartment-oriented lymph node dissection performed by a highly experienced thyroid cancer surgeon. In **DTC**, adjuvant radioactive iodine (^{131}I) may be used postoperatively to treat iodine-avid distant metastasis and unresectable residual neck disease. The use of ^{131}I is limited to children at higher risk for residual or recurrent disease who are most likely to benefit from treatment. Children with **MTC** do not require ^{131}I therapy.

In children with DTC, the TSH level is initially suppressed by giving supraphysiologic levothyroxine, because TSH may stimulate DTC tumor growth; the TSH level is kept normal in MTC.

Oral multikinase inhibitors and oncogene-targeted therapy (for children with tumors driven by *BRAF*, *RET*, or *NTRK* substitutions or oncogenic fusions) have demonstrated benefit for the treatment of advanced MTC and DTC in adults. These are rarely indicated in pediatric patients but may be considered for symptomatic and/or progressive disease.

Long-term follow-up of thyroid cancer survivors involves monitoring of tumor markers (thyroglobulin/thyroglobulin antibody in DTC, calcitonin/carcinogenic embryonic antigen in MTC) and routine imaging, primarily neck US.

555.2 Nasopharyngeal Carcinoma

Cynthia E. Herzog

Nasopharyngeal carcinoma is rare in the pediatric population, but it is one of the most common nasopharyngeal tumors in pediatric patients. In adults, the incidence is highest in South China, but it is also high among the Inuit people and in North Africa and Northeast India. In China, this diagnosis is rare in the pediatric population, but in other populations, a substantial proportion of cases occur in the pediatric age-group, primarily in adolescents. It occurs in males twice as often as in females and is more common in Black people. In the pediatric population, the tumors are more frequently of undifferentiated histology and associated with **Epstein-Barr virus (EBV)**. Nasopharyngeal carcinoma is associated with specific human leukocyte antigen (HLA) types; other genetic factors may play a role, especially in low-incidence populations.

Most pediatric patients present with advanced locoregional disease manifesting as cervical lymphadenopathy. Epistaxis, trismus, and cranial nerve deficits also may be present. The diagnosis is established from biopsy of the nasopharynx or cervical lymph nodes. In most cases the lactate dehydrogenase level is elevated, but this finding is nonspecific. CT or MRI evaluation of the head and neck is performed to determine the extent of locoregional disease. Chest radiography, CT, bone scan, and liver scan are used to evaluate for metastatic disease. PET scans appear to be useful for monitoring primary disease and looking for metastases. EBV DNA levels correlate with disease stage, have prognostic value, and can be used to monitor for recurrence.

Treatment is a combination of chemotherapy and irradiation. Cisplatin, given concurrently with radiation, with either neoadjuvant or adjuvant cisplatin-based chemotherapy, is the standard treatment. The outcome depends on the extent of disease; patients with distant metastases have a very poor prognosis. Using intensity-modulated radiation therapy improves local control and reduces the late adverse effects associated with radiation therapy, including hormonal dysfunction, dental caries, fibrosis, and second malignancies. Use of proton therapy may result in further reduction of adverse effects.

555.3 Adenocarcinoma of the Colon and Rectum

Cynthia E. Herzog and Winston W. Huh

Colorectal carcinoma (CRC) is rare in the pediatric population, with an estimated incidence rate of approximately one case per 1 million. Even in patients with predisposing conditions, CRC usually does not present until late adolescence or adulthood; only 35–40% of CRC in this age-group are association with a known predisposition factor. **Hereditary nonpolyposis colon cancer (HNPCC) (Lynch Syndrome)** is an autosomal dominant disorder, with germline pathogenic variants in DNA mismatch repair genes *(MMR)* causing DNA repair errors and microsatellite instability (MSI). *MYH*-associated polyposis, Peutz-Jeghers syndrome, and juvenile polyposis also predispose to CRC.

Genetic testing is available, and screening for cancer in HNPCC and familial adenomatous polyposis (FAP) should begin during childhood or adolescence. Likewise, genetic evaluation for these conditions should be pursued in young patients presenting with colon cancer, even when there is no history of predisposing genetic conditions.

Presenting symptoms include bloody stools or melena, abdominal pain, weight loss, and changes in bowel patterns. In many cases, signs are vague, often resulting in a delay in diagnosis, sometimes not until the disease has reached an advanced stage. The histologic subtype differs from that seen in adults, with most pediatric tumors being either mucinous adenocarcinoma or signet ring cell carcinoma. Pediatric patients tend to have tumors with MSI and tend to present with more advanced disease. Treatment is based on guidelines used in adults with CRC and consists of surgical resection when possible with chemotherapy for unresectable tumors. Adequate lymph node removal should be performed at surgical resection of primary tumor. Radiation therapy is useful in select cases. Pediatric patients have a worse overall prognosis compared with adult patients, but the reasons for this discrepancy are not clear.

555.4 Adrenal Tumors

Jonathan D. Wasserman

See Chapters 617-621.

The adrenal gland is comprised of two embryologically distinct layers, the steroid-secreting outer cortex and the catecholamine-secreting inner medulla. **Adrenocortical tumors (ACTs)** arise from the cortex, whereas pheochromocytomas (**PHEOs**) derive from the chromaffin cells of the adrenal medulla. Additionally, catecholaminergic tumors arising from the parasympathetic and sympathetic ganglia *outside* the adrenal medulla are called **paragangliomas (PGLs)**. Both ACTs and PHEOs are strongly associated with hereditary tumor predisposition syndromes, and thus diagnosis of either in childhood should initiate a thorough family history and referral to an expert in cancer genetics for counseling and germline testing.

ACTs are very rare and, in children, tend to present before age 10 years. They have a female predominance and are functional (hormone secreting) in >90% of cases, primarily producing androgens and/or glucocorticoids and causing clinically apparent **virilization** with or without **Cushing syndrome** (see Chapter 619). ACTs may also present as an abdominal mass or pain. In children, ACTs are most frequently associated with **Li-Fraumeni syndrome** (germline inactivating variants in the *TP53* tumor-suppressor gene) and **Beckwith-Wiedemann syndrome** (BWS), but they can also be seen in hemihyperplasia other than that seen as part of BWS, MEN1, McCune-Albright syndrome, FAP, and very rarely, congenital adrenal hyperplasia. Unusual causes of bilateral nodular adrenocortical disease, which also typically present with Cushing syndrome, include the Carney complex and macronodular adrenocortical hyperplasia.

PHEOs/PGLs are rare tumors that are more likely to be bilateral, malignant, and secondary to a heritable tumor syndrome when diagnosed in childhood compared with adulthood (see Chapter 621). **Von Hippel-Lindau disease** is the most common genetic association in the pediatric population, followed by the **familial PGL syndromes (1, 2, 3, 4)** caused by variants in the succinate dehydrogenase *(SDHx)* genes. MEN2 (types 2A and 2B) and neurofibromatosis type 1 *(NF1)* are also included in the differential diagnosis but are more often associated with a PHEO diagnosis during adulthood (Table 555.2). Overall, germline pathogenic variants in at least 16 different genes have been associated with predisposition to PHEO/PGL. PHEO/PGL is also associated with congenital cyanotic heart disorders (somatic gain-of-function variant in *EPAS1*). *Hypertension is usually sustained* in pediatric patients with PHEO/PGL, who may also lack the triad of intermittent headache, palpitations, and diaphoresis typically seen in adults. Nonetheless, PHEO/PGL accounts for <1% of pediatric hypertension. Additional manifestations may include chest pain, pallor, tremor, fever, cardiomyopathy, or exacerbations with exercise; flushing is not typical of PHEO/PGL. The differential diagnosis is noted in Table 555.3. The most appropriate screening test for PHEO/PGL is measurement of fractionated plasma and/or urine **metanephrine** levels. Initial imaging studies, when metanephrine levels are elevated, include CT or MRI. When indicated, to confirm abnormal biochemistry and/or cross-sectional imaging, ^{18}F-DOPA and ^{68}Ga-DOTATATE (DOTA-octreotate) PET/MRIs are the functional imaging modalities of choice given greater sensitivity and specificity than earlier radioisotopes (Fig. 555.2). ^{131}I-Metaiodobenzyguanidine (MIBG) imaging may also be considered in such circumstances.

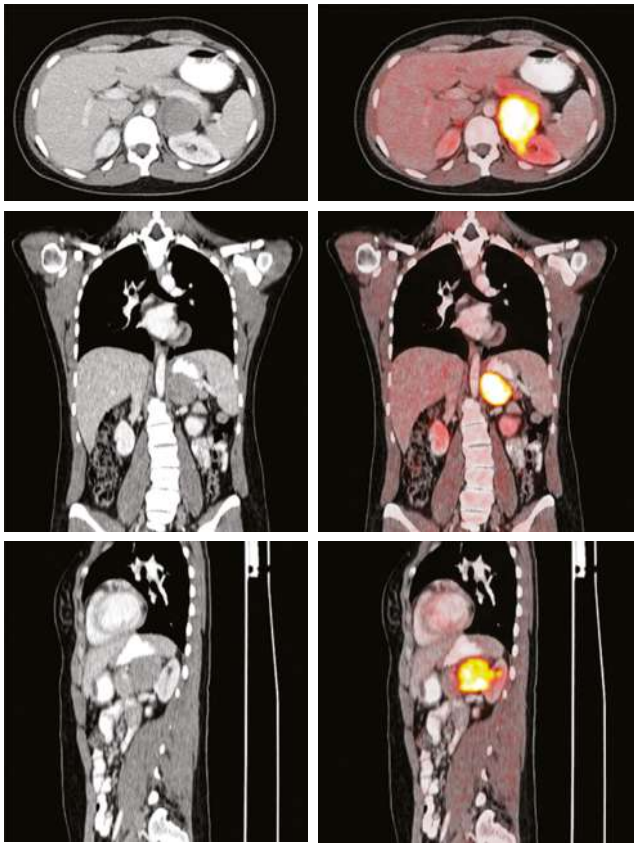

Fig. 555.2 Appearance of pheochromocytoma on functional imaging (^{18}F-l -dihydroxyphenylalanine [^{18}F-DOPA] PET/CT). Focal uptake is seen in the left suprarenal fossa. *(From Duh QY, Livhits M, Yeh MW. The adrenal glands. In: Mattox KL, Townsend CM, Beauchamp RD, Evers BM, eds. Sabiston Textbook of Surgery. 21st ed. Philadelphia: Elsevier; 2022. Fig. 40.18A.)*

Table 555.2 Germline Pathogenic Variants Associated with Pheochromocytoma and Paraganglioma

SYNDROME/NAME	GENE	TYPICAL TUMOR LOCATION AND OTHER ASSOCIATIONS
HYPOXIC PATHWAY: CLUSTER 1*		
SDHD (familial paraganglioma type 1)†	*SDHD*	Primarily skull base and neck; occasionally adrenal medulla, mediastinum, abdomen, pelvis; GIST; possible pituitary adenoma
SDHAF2 (familial paraganglioma type 2)†	*SDHAF2*	Primarily skull base and neck; occasionally abdomen and pelvis
SDHC (familial paraganglioma type 3)	*SDHC*	Primarily skull base and neck; occasionally abdomen, pelvis, or chest; GIST; possible pituitary adenoma
SDHB (familial paraganglioma type 4)	*SDHB*	Abdomen, pelvis, and mediastinum; rarely adrenal medulla, skull base, and neck; GIST; renal cell carcinoma; possible pituitary adenoma
SDHA	*SDHA*	Primarily skull base and neck; occasionally abdomen and pelvis; GIST; possible pituitary adenoma
VHL disease	*VHL*	Adrenal medulla, frequently bilateral; occasionally paraganglioma that may be localized from skull base to pelvis
Hereditary leiomyomatosis and renal cell carcinoma (Reed syndrome)—fumarate hydratase variant	*FH*	Multifocal and metastatic; associated with hereditary leiomyomatosis, uterine fibroids, and renal cell cancer
Hypoxia-inducible factor (HIF) 2α	*HIF2A*	Paraganglioma, polycythemia, and rarely somatostatinoma
Familial erythrocytosis associated with pathogenic variant in prolyl hydroxylase isoform 1 (PDH1)	*EGLN2*	Polycythemia associated with pheochromocytoma and paraganglioma
Familial erythrocytosis associated with pathogenic variant in prolyl hydroxylase isoform 2 (PDH2)	*EGLN1*	Polycythemia associated with pheochromocytoma and paraganglioma
KIF1B	*KIF1B*	Neuroblastoma
KINASE SIGNALING PATHWAY: CLUSTER 2‡		
MEN2A and MEN2B	*RET*	Adrenal medulla, frequently bilateral
Neurofibromatosis type 1 (NF1)	*NF1*	Adrenal or periadrenal
MAX†	*MAX*	Adrenal medulla
Familial pheochromocytoma	*TMEM127*	Adrenal medulla; possible renal cell carcinoma

*Cluster 1 tumors are mostly extraadrenal paragangliomas (except in VHL, where most tumors are localized to the adrenal) and nearly all have a noradrenergic biochemical phenotype.
†Associated with maternal imprinting.
‡Cluster 2 tumors are usually adrenal pheochromocytomas with an adrenergic biochemical phenotype.
GIST, Gastrointestinal stromal tumor; MEN, multiple endocrine neoplasia; SDH, succinate dehydrogenase; VHL, von Hippel-Lindau disease.
Modified from Melmed S, Auchus RJ, Goldfine AB, et al., eds. *Williams Textbook of Endocrinology*. 14th ed. Philadelphia: Elsevier; 2020: Table 16.4, p. 550.

Table 555.3 Differential Diagnosis of Pheochromocytoma-Type Spells

ENDOCRINE CAUSES
Carbohydrate intolerance
Hyperadrenergic spells

CARDIOVASCULAR CAUSES
Orthostatic hypotension
Paroxysmal cardiac arrhythmia
Pulmonary edema
Renovascular disease
Syncope (e.g., vasovagal reaction)
PSYCHOLOGIC CAUSES
Factitious (e.g., drugs, Valsalva maneuver)
Hyperventilation
Severe anxiety and panic disorders
Somatization disorder
PHARMACOLOGIC CAUSES
Chlorpropamide-alcohol flush
Combination of a monoamine oxidase inhibitor and a decongestant
Illegal drug ingestion (cocaine, phencyclidine, lysergic acid diethylamide)
Sympathomimetic drug ingestion
Vancomycin (red man syndrome)
Withdrawal of adrenergic inhibitor
NEUROLOGIC CAUSES
Autonomic neuropathy
Diencephalic epilepsy (autonomic seizures)
Migraine headache
Postural orthostatic tachycardia syndrome
Stroke
OTHER CAUSES
Carcinoid syndrome
Mast cell disease
Recurrent idiopathic anaphylaxis
Unexplained flushing spells

Modified from Melmed S, Auchus RJ, Goldfine AB, et al., eds. *Williams Textbook of Endocrinology*. 14th ed. Philadelphia: Elsevier; 2020: Table 16.3, p. 547.

The initial treatment of ACT and PHEO/PGL is *resection by a surgeon experienced in the management of these tumors.* Children with suspected or confirmed PHEO/PGL require preoperative medical management with α-adrenergic blockade (and sometimes β-blockade) to mitigate risk of hypertensive crisis.

Medical therapy for metastatic ACT includes mitotane and chemotherapy with cisplatin, etoposide, and doxorubicin. Endocrine therapy targeting hormonal overproduction may also be needed to palliate symptoms and improve quality of life. Metastatic PHEO/PGL has historically been poorly responsive to cytotoxic chemotherapy. Kinase inhibitor therapy and peptide-receptor radiotherapy (such as ^{177}Lu-DOTATATE) have demonstrated promise in some studies.

Long-term follow-up is warranted for both ACTs and PHEOs to monitor for recurrence, particularly in the context of hereditary tumor predisposition syndromes.

555.5 Desmoplastic Small Round Cell Tumor

Cynthia E. Herzog

Desmoplastic small round cell tumor **(DSRCT)** is a very rare and aggressive mesenchymal tumor that occurs predominantly in adolescent and young adult males. It is associated with a diagnostic chromosomal translocation between the Ewing tumor gene and the Wilms tumor gene, t(11;22) (p13;q12), creating a chimeric gene *(EWS-WT1)* that encodes a chimeric protein with oncogenic properties. Patients typically present at advanced stage with a bulky abdominal mass, multiple peritoneal and omental implants, and symptoms of abdominal sarcomatosis, including pain, ascites, intestinal obstruction, hydronephrosis, and weight loss. DSRCT mainly involves the abdominal cavity but can spread to the lymph nodes, liver, lungs, and bones, and in ~10% of cases, arise outside of the abdomen. There is no standard treatment approach. Aggressive treatment with combination chemotherapy, debulking surgery, and whole abdominopelvic irradiation results almost universally in a poor outcome. Median survival ranges between 17 and 25 months, and the 5-year overall survival remains <20%. Hyperthermic intraperitoneal chemotherapy may be of benefit but requires further study. Novel targeted agents and radioimmunotherapy with monoclonal antibodies targeting different surface antigens on tumor cells are being studied.

Chapter 556
Histiocytosis Syndromes of Childhood

Stephan Ladisch

INTRODUCTION

Childhood histiocytoses constitute a diverse group of disorders that are frequently severe in their clinical expression. These disorders are individually rare and are grouped together because they have in common a prominent proliferation or accumulation of cells of the monocyte-macrophage system of bone marrow (myeloid) origin. Although these disorders sometimes are difficult to distinguish clinically, accurate diagnosis is essential for facilitating progress in treatment. A current systematic classification of histiocytoses is based on histopathologic, clinical, and genetic findings (Tables 556.1-556.3) A thorough, comprehensive evaluation of a biopsy specimen obtained at diagnosis is critical. This evaluation includes studies such as immunostaining, molecular genetic analyses, and electron microscopy that may require special sample processing.

CLASSIFICATION AND PATHOLOGY

Three classes of childhood histiocytosis are defined, based on histopathologic findings. The first and best known is **Langerhans cell histiocytosis (LCH)**, previously called *histiocytosis X.* LCH includes the clinical entities of bone or skin limited disease (**eosinophilic granuloma**), **Hand-Schüller-Christian disease,** and **Letterer-Siwe disease.** The normal Langerhans cell is an antigen-presenting cell (APC) of the skin. The hallmark of LCH in all forms is the presence of a clonal proliferation of cells of the monocyte–dendritic cell lineage containing the characteristic electron microscopic findings of a Langerhans cell, the **Birbeck granule**. This tennis racket–shaped bilamellar granule, when seen in the cytoplasm of lesional cells in LCH, is diagnostic of the disease. The Birbeck granule expresses a newly characterized antigen, *langerin* (CD207), which itself is involved in antigen presentation to T lymphocytes. CD207 expression has been established to be uniformly present in LCH lesions and thus becomes an additional reliable diagnostic marker. However, it is now clear that the LCH cell is not actually a (differentiated) Langerhans cell but rather an immature cell of myeloid origin, possibly in an arrested state of development. The definitive diagnosis of LCH is established by demonstrating CD1a positivity of lesional cells, which can be done using fixed tissue (Fig. 556.1). Lesional cells must be distinguished from normal Langerhans cells of the skin, which are also CD1a positive but are only sparsely distributed and are not diagnostic of LCH. The peripheral lesions usually leading to the diagnosis of LCH (e.g., skin, lymph node, bone) contain various proportions of Birbeck granule–containing CD1a-positive cells, lymphocytes, granulocytes, monocytes, and eosinophils.

Clonality of individual lesions exists in some cases of LCH. Importantly, an activating *somatic* pathogenic variant of the *BRAF* gene *(V600E)* (part of the mitogen-activated protein kinase [MAPK] cell signaling pathway: Fig. 556.2) has been identified in many patients with LCH. Studies in patients negative for *BRAFV600E* have revealed pathogenic variants in other genes of the MAPK pathway, including *MAP2K1* and *ARAF.* With the majority of LCH patients having one or another of these activating variants in the MAPK pathway (see Fig. 556.2), it has been suggested that LCH is driven by a disorder in MAPK signaling affecting cell migration and resulting in an accumulation of LCH cells in the lesions.

In contrast to the prominence of an APC in LCH, the other common form of histiocytosis is characterized by accumulation of activated macrophages and lymphocytes and is known as **hemophagocytic lymphohistiocytosis (HLH)**. This diagnosis is the result of uncontrolled hemophagocytosis and uncontrolled activation (upregulation) of inflammatory cytokines driven by an abnormality of T cells. It has some similarities to the **macrophage activation syndrome**. Tissue infiltration by activated CD8 T lymphocytes, activated macrophages, and hypercytokinemia are classic features (Fig. 556.3). With the characteristic morphology of normal macrophages by light microscopy, these phagocytic cells (see Fig. 556.1) are CD163 positive but negative for the markers that are characteristic of LCH cells (Birbeck granules, CD1a, CD207).

The two major forms of HLH, primary and secondary, have indistinguishable pathologic findings but are important to differentiate because of implications for treatment and prognosis. **Primary HLH**, originally named *familial erythrophagocytic lymphohistiocytosis,* is now known as **familial hemophagocytic lymphohistiocytosis (FHLH)**. This disease is an autosomal recessive disorder and represents approximately 25% of patients with HLH (see Table 556.3).

L, Langerhans; R, Rosai-Dorfman-Destombes; M, Malignant, C, cutaneous; H, hemophagocytic; JXG, juvenile xanthogranuloma; MAPK: mitogen-activated kinase.
From Emile JF, Cohen-Aubart F, Collin M, et al. Histiocytosis. *Lancet*. 2021;398:157–168. Supplementary Appendix, Table 1.

Genes are known for four of five familial HLH syndromes and other hereditary causes of HLH; these pathogenic variants affect the ability of T lymphocytes and natural killer (NK) cells to synthesize and release perforin and granzymes, thus reducing cytotoxic granule formation (Fig. 556.4). **Secondary HLH** includes other forms of the syndrome triggered by a separate pathologic process, such as infection *(infection-associated hemophagocytic syndrome),* tumor *(malignancy-associated HLH),* or primary immunodeficiency diseases and metabolic disorders (Tables 556.4 and 556.5). Both primary and secondary HLH affect multiple organs and are characterized by massive infiltrates of hyperactivated lymphocytes and activated phagocytic macrophages in the involved organs, with the lymphocytes serving as the driver of the resulting disease process.

In primary HLH, genetic pathogenic variants in multiple different steps in granule formation and release by cytotoxic T cells have been identified (Fig. 556.5, *bottom*). Pathogenic variants in the *PRF1* perforin gene or the *MUNC13-4* gene are the most common causes of defective function of the cytotoxic lymphocytes whose activity is inhibited in primary HLH. In an analogous way, a trigger can result in secondary HLH (see Fig. 556.5, *top*). A myriad of both infectious and noninfectious processes can trigger secondary HLH (Fig. 556.6; see Table 556.4 and Fig. 556.11). Examples of noninfectious triggers include drugs (e.g., phenytoin, Lamictal, highly active antiretroviral therapy), hematopoietic stem cell transplantation, chemotherapy, autoimmune diseases, inflammatory bowel disease, cancer, and immunodeficiency states (e.g., DiGeorge syndrome, Bruton agammaglobulinemia, severe combined immunodeficiency syndrome, chronic granulomatous disease). A complicating factor in diagnosis is the realization that there are also both mixed genetic variants causing primary HLH and heterozygotic variants (therefore not strictly primary HLH) also causing disease, particularly triggered by infection.

In addition to these two most common forms of childhood histiocytosis (LCH and HLH), rarer diseases are included under this rubric (see Table 556.2). **Juvenile xanthogranuloma (JXG)** is characterized by vacuolated histiocytes with foamy cytoplasm in lesions that evolve into mixed granulomas also containing eosinophils, lymphocytes, and other cells. **Erdheim-Chester disease (ECD)** predominantly affects adults. Surface markers suggest a link among LCH, JXG, and ECD; all three are dendritic cell diseases, and represent a spectrum, or continuum, of differentiation stages of the abnormal dendritic cell precursors, frequently with *BRAFV600E* pathogenic variants in the affected cells. Another rare form of histiocytosis is **Rosai-Dorfman disease**, also known as **sinus histiocytosis** with massive lymphadenopathy. Rosai-Dorfman disease is characterized by packing of sinusoids of the lymph nodes with hemophagocytic histiocytes, although extranodal involvement may also be present. Last, there is a group of unequivocal **malignancies** of cells of monocyte–macrophage lineage. By this definition, acute monocytic leukemia and true malignant histiocytosis are included among the class III histiocytoses (see Chapter 544). True neoplasms of Langerhans cells have been reported but are extremely rare.

556.1 Langerhans Cell Histiocytosis

Stephan Ladisch

CLINICAL MANIFESTATIONS

LCH has an extremely variable presentation. The skeleton is involved in 80% of patients and may be the only affected site, especially in children >5 years old. **Bone lesions (eosinophilic granuloma)** may be single or multiple and are seen most often in the skull (Fig. 556.7). Other sites include the pelvis, femur, vertebra, maxilla, and mandible. Lesions may be asymptomatic or associated with pain and local swelling. Involvement of the spine may result in collapse of the vertebral body, which can be seen radiographically and may cause secondary compression of the spinal cord. In flat and long bones, osteolytic lesions with sharp borders occur, and no evidence exists of reactive new bone formation until the lesions begin to heal. Lesions that involve weight-bearing long bones may result in pathologic fractures. Chronically draining, infected ears are usually associated with destruction in the mastoid area. Bone destruction in the mandible and maxilla may result in teeth that appear to be free floating on radiographs. With response to therapy, healing of bone lesions is usually complete.

Approximately 50% of patients experience **skin involvement** (isolated or part of multisystem disease) at some time during the course of disease. This is a frequently difficult-to-treat scaly, papular, seborrheic dermatitis of the scalp, diaper, axillary, or posterior auricular regions (see Fig. 556.7; Figs. 556.8 and 556.9). The lesions may spread to involve the back, palms, and soles. The exanthem may be petechial or hemorrhagic, even in the absence of thrombocytopenia. Localized or disseminated **lymphadenopathy** is present in approximately 33% of patients. **Hepatosplenomegaly** occurs in approximately 20% of patients. Various degrees of hepatic malfunction may occur, including jaundice and ascites.

Gastrointestinal involvement, more common than previously appreciated**,** can present as vomiting, abdominal pain, bloody diarrhea, and/or failure to thrive.

Exophthalmos, when present, may be bilateral and is caused by retroorbital accumulation of granulomatous tissue. Gingival mucous membranes may be involved with infiltrative lesions that appear superficially like candidiasis. Otitis media is present in 30–40% of patients; deafness may follow

Table 556.2 Clinical Features, Investigations, and Treatment of Langerhans Cell Histiocytosis, Erdheim-Chester Disease, and Rosai-Dorfman-Destombes Disease

	MOST FREQUENT REVEALING CLINICAL FEATURES	INITIAL INVESTIGATIONS* WHEN DIAGNOSIS IS CONFIRMED BY BIOPSY	MOST FREQUENT FIRST-LINE SYSTEMIC THERAPIES FOR MULTIORGAN OR DISSEMINATED FORMS	MOST FREQUENT SYSTEMIC SECOND-LINE AND SALVAGE THERAPIES
Childhood Langerhans cell histiocytosis	Bone pain or fracture; vertebra plana†; skin papules; lymphadenomegaly; palpable tumor; diabetes insipidus†; exophthalmos†; deafness or chronic otorrhea; systemic symptoms with fever, hepatosplenomegaly, or hematologic cytopenia (risk organs); pneumothorax	For all patients: blood tests (full blood count, erythrocyte sedimentation rate or CRP, albumin, renal function tests, liver function tests, coagulation tests); chest and skeletal radiographs According to initial investigations: CT scan or MRI focused on involved area; brain MRI when diabetes insipidus or any sign of CNS involvement or visual or hearing dysfunction; chest high-resolution CT scan when signs of lung involvement	Vinblastine combined with corticosteroids	Should be decided according to initial extension and risk-organ involvement status, as assessed by a trained team With risk organ involvement: BRAF or MEK inhibitors‡ Without risk organ involvement: monotherapy or combined chemotherapies with cladribine, and, in less documented approaches, cytarabine or clofarabine
Adult Langerhans cell histiocytosis	Bone pain or fracture; skin papules; lymphadenopathy; palpable tumor; diabetes insipidus†; exophthalmos†; repeated dental loss; pneumothorax; dyspnea, dry cough	^{18}F-FDG-PET (full body); chest, abdomen, and pelvis CT scan; brain MRI; blood tests (full blood count, CRP, albumin, renal function tests, liver function tests)	Cytarabine, alone or combined with methotrexate; vinblastine combined with corticosteroids; cladribine	BRAF or MEK inhibitors
Erdheim-Chester disease	Lower limb pain; general symptoms (fatigue, weight loss, fever); xanthelasma; diabetes insipidus†; exophthalmos†; dyspnea, dry cough; signs of cardiac involvement (e.g., tamponade); signs of CNS involvement (degenerative or tumoral)	^{18}F-FDG-PET (full body); chest, abdomen, and pelvis CT scan; brain MRI; cardiac MRI; blood tests (full blood count, CRP, albumin, renal function tests, liver function tests)	Interferon alfa-2a or pegylated interferon alfa-2a; other potential options are anakinra, infliximab, or sirolimus plus corticosteroids; BRAF or MEK inhibitors for life-threatening cases (e.g., CNS or heart involvement)	BRAF or MEK inhibitors
Rosai-Dorfman-Destombes disease	Lymphadenopathy; skin nodules; nasal obstruction, epistaxis, nasal dorsum deformity; dyspnea, dry cough; signs of CNS or nerve root involvement; testicular enlargement	Children: chest x-ray with neck and abdominal ultrasound scans Adults: neck, chest, abdomen, and pelvis CT scan; ^{18}F-FDG-PET is recommended by some experts All patients: brain MRI when signs of orbital or CNS involvement; blood tests (full blood count, CRP, albumin, renal function tests, liver function tests)	Corticosteroids; sirolimus; methotrexate; azathioprine	Several drugs or combined chemotherapies or MEK inhibitors reported to be active in case reports or small case series

^{18}F-FDG-PET, ^{18}F-fluorodeoxyglucose PET; CNS, central nervous system..
*Aimed to determine the extent of the disease; thus each clinical feature drives specific investigation of the potentially involved organ(s), including for any signs of endocrine dysfunction or autoimmunity.
†Features that are suggestive of the disease.
‡BRAF inhibitors: vemurafenib, dabrafenib, encorafenib. MEK inhibitors: cobimetinib, trametinib, binimetinib, selumetinib.
From Emile JF, Cohen-Aubart F, Collin M, et al. Histiocytosis. *Lancet*. 2021;398:157–168. Fig. 1, p. 158.

destructive lesions of the middle ear. In 10–15% of patients, **pulmonary infiltrates** are found on radiography. The lesions may range from diffuse fibrosis and disseminated nodular infiltrates to diffuse cystic changes (Fig. 556.10). Rarely, pneumothorax is a complication. If the lungs are severely involved, tachypnea and progressive respiratory failure may result.

Pituitary dysfunction or hypothalamic involvement in patients often presents as diabetes insipidus and may also cause growth retardation. Patients suspected of having LCH should demonstrate the ability to concentrate their urine before going to the operating room for a biopsy. Rarely, panhypopituitarism may occur, as may primary hypothyroidism as a result of thyroid gland infiltration.

Patients with multisystem disease who are affected more severely are those who have systemic manifestations, including fever, weight loss, malaise, irritability, and failure to thrive. These systemic manifestations will distinguish patients at high risk of mortality (i.e., risk organ–positive, or RO+, patients) from patients at low risk of mortality (i.e., without systemic

Table 556.3 Hemophagocytic Lymphohistiocytosis

DISEASE	GENE	PROTEIN	PERCENTAGE OF FHLH	IMMUNE IMPAIRMENT	UNIQUE CLINICAL CHARACTERISTICS
FHLH-1	Unknown		Rare	Cytotoxicity	
FHLH-2	*PRF1*	Perforin	~20–37, 50delT mainly in African American/ African descent	Cytotoxicity; forms pores in APCs	
FHLH-3	*UNC13D*	Munc13–4	20–33	Cytotoxicity; vesicle priming	Increased incidence of CNS HLH
FHLH-4	*STX11*	Syntaxin	<5	Cytotoxicity; vesicle fusion	Mild recurrent HLH, colitis
FHLH-5	*STXBP2*	Syntaxin-binding protein 2	5–20	Cytotoxicity; vesicle fusion	Colitis, hypogammaglobulinemia

manifestations; risk organ–negative patients). The **risk organs** are liver, spleen, and the hematopoietic (bone marrow) system. The lung is not considered a risk organ. The distinction of risk-organ involvement is important for deciding the intensity of the treatment approach and has been addressed in standard treatment approaches for LCH, as delineated in the Histiocyte Society protocols. Bone marrow involvement may cause anemia and thrombocytopenia. Two uncommon but serious manifestations of LCH are hepatic involvement (leading to fibrosis and cirrhosis) and a peculiar central nervous system (CNS) involvement characterized by ataxia, dysarthria, and other neurologic symptoms. **Hepatic involvement** is associated with multisystem disease that is often already present at diagnosis. In contrast, neurodegenerative **CNS involvement**, which is progressive and

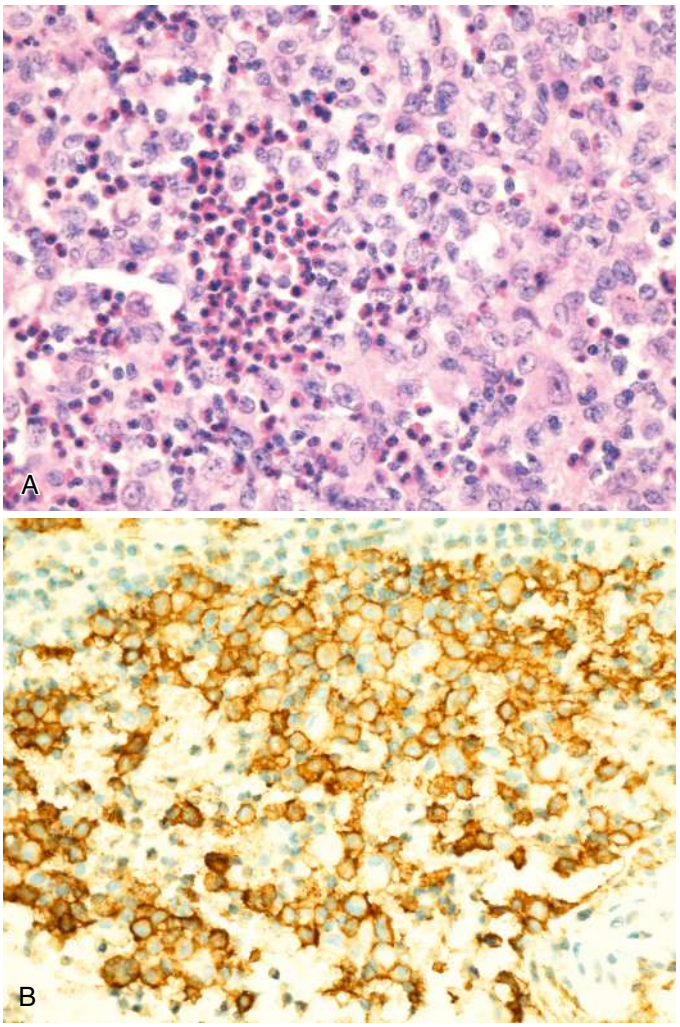

Fig. 556.1 A, Histopathology of Langerhans cell histiocytosis (LCH) shows eosinophilic granuloma of a lytic bone lesion of the femoral head. Multiple LCH cells with characteristic grooved nuclei, as well as numerous eosinophils, are visible in this mixed infiltrate. B, CD1a staining, characteristic and diagnostic of lesions with LCH cells.

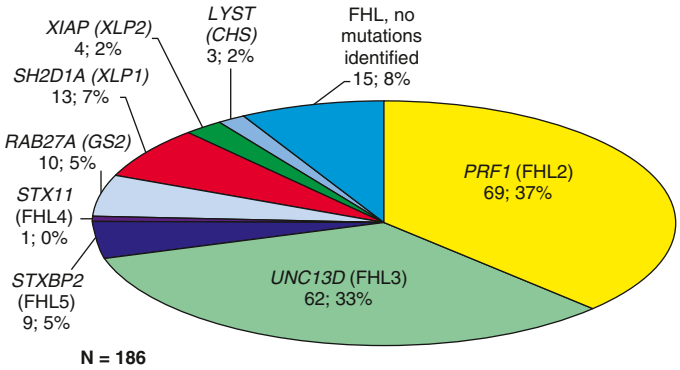

Fig. 556.4 Different genetic subtypes in 171 patients with familial hemophagocytic lymphohistiocytosis (FHL) or FHL-related disease. For each subtype, the name of the gene, the abbreviation of the disease subtype, the absolute number, and the percentage are shown. Furthermore, we include as FHL one subgroup of 15 patients with either familial recurrence or refractory/recurrent disease despite specific therapy and/or repeatedly documented severe functional defect in degranulation or cytotoxicity assays. *(From Cetica V, Sieni E, Pende D, et al. Genetic predisposition to hemophagocytic lymphohistiocytosis: Report on 500 patients from the Italian registry. J Allergy Clin Immunol. 2016;137:188–196. Fig. 2, p. 191.)*

histopathologically characterized by gliosis and has no definitive treatment, may be observed only many years after the initial diagnosis of LCH. These manifestations are not known to be associated with LCH cells, Birbeck granules, CD1a positivity, or any other indication of LCH cell infiltration, raising questions about their pathogenesis and the suggestion that they may be cytokine-mediated.

After tissue biopsy, which is diagnostic of LCH and is easiest to perform on skin or bone lesions, a comprehensive clinical and laboratory evaluation is essential and should be undertaken. This should include a series of studies in all patients: CBC, liver function tests, coagulation studies, skeletal survey, chest radiograph, and measurement of urine osmolality. In addition, detailed evaluation of any organ system shown to be involved by physical examination or by these studies should be performed to establish the extent of disease before initiation of treatment.

TREATMENT AND PROGNOSIS

The clinical course of **single-system disease** (usually bone, lymph node, or skin) generally is benign, with a high chance of spontaneous remission. Therefore treatment should be minimal and should be directed at arresting the progression of a bone lesion that could result in permanent damage before it resolves spontaneously. Curettage or, less often but especially

when a weight-bearing bone is involved, corticosteroid injection or low-dose local radiation therapy (5-6 Gy) may accomplish this goal.

In contrast, **multisystem disease** requires treatment with systemic multiagent chemotherapy. Several different regimens have been proposed, but central elements are the inclusion of vinblastine and corticosteroids, both of which have been found to be very effective in treating LCH. Etoposide has been excluded from the standard treatment of multisystem LCH, which is treated with multiple agents, designed to reduce mortality, reactivation of disease, and long-term consequences. The response rate to therapy is quite high, and mortality in severe LCH has been substantially reduced by multiagent chemotherapy, especially if the diagnosis is made accurately and expeditiously. The most recent treatment results associated with lengthened continuation therapy (HS LCH-III) show a greater than 85% survival rate in severe (RO+) multisystem disease and a reduced rate of reactivation.

Experimental therapies are suggested only for unresponsive disease (often in very young children with multisystem disease and organ dysfunction who have not responded to multiagent initial treatment) and reactivation of RO+ disease in risk organs but not in reactivation of mild disease (any risk organ–negative reactivations) (see Fig. 556.2). The approaches include immunosuppressive therapy with cyclosporine/antithymocyte globulin and possibly imatinib, 2-chlorodeoxyadenosine, and clofarabine. With the discovery of the *BRAFV600E* pathogenic variant causing hyperactivation of the MAPK pathway in LCH cells, pharmacologic inhibition of BRAF and pharmacologic inhibition of MEK are currently the subject of clinical trials as therapeutic approaches for resistant disease.

Late (fibrotic) complications, whether hepatic or pulmonary, are irreversible and require organ transplantation to be definitively treated. Current treatment approaches and experimental protocols for both LCH and HLH can be obtained at the Histiocyte Society website (http://www.histiocytesociety.org). An unresolved problem is treatment of the (usually late-onset) severe, progressive, and intractable LCH-associated **neurodegenerative** syndrome. This is also under investigation for response to experimental therapies, including the pharmacologic inhibitors of the MAPK pathway. Regarding current treatment recommendations for LCH as well as HLH, the continuing rapid advances in understanding of their pathogeneses is likely to result in further rapid development and validation of new therapeutic approaches.

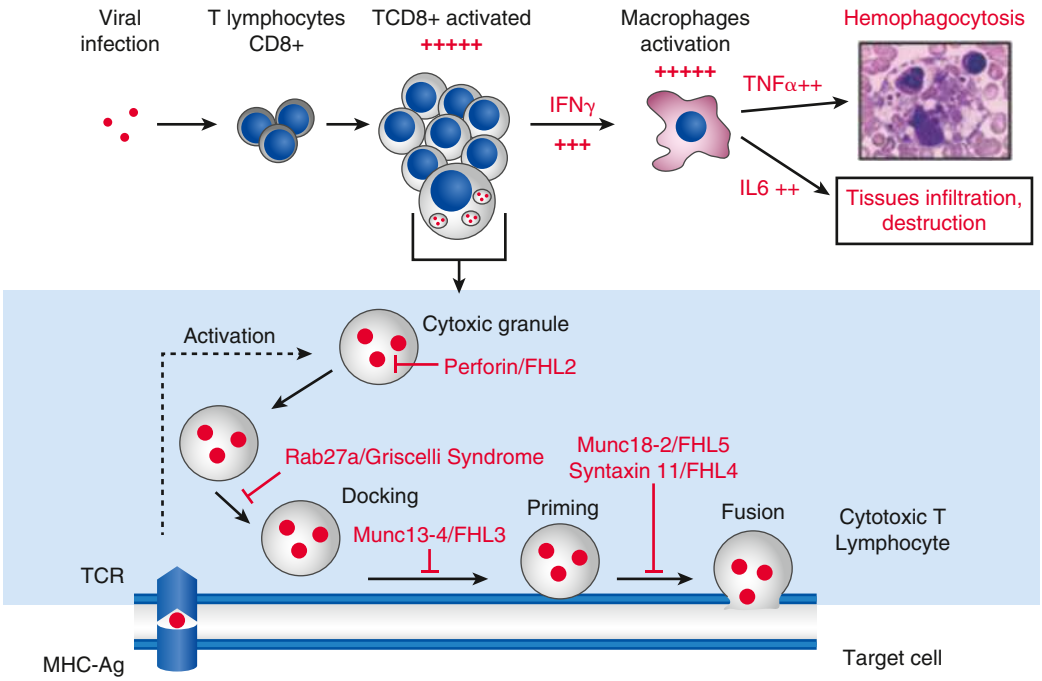

Fig. 556.5 Inborn errors in the cytotoxic activity of lymphocytes. **Top,** Immune mechanisms leading to the occurrence of a hemophagocytic syndrome. Following a viral infection, antigen-specific $CD8^+$ T lymphocytes undergo massive expansion and activation and secrete high levels of interferon (IFN)-γ. The overwhelming activated effector cells induce excessive macrophage activation and proinflammatory cytokine production, including tumor necrosis factor (TNF)-α and interleukin-6 (IL-6). Macrophages spontaneously phagocytose blood elements (platelets, red blood cells, and a polymorphonuclear cell shown here). Activated lymphocytes and macrophages infiltrate various organs, resulting in massive tissue necrosis and organ failure. **Bottom,** Genetic variants causing hemophagocytic lymphohistiocytic syndrome (HLH) affect a precise step of the cytotoxic machinery: granule content, docking, priming, or fusion. Only the defects causing Griscelli syndrome and familial hemophagocytic lymphohistiocytosis (FHL) are shown. MHC-Ag, Major histocompatibility complex antigen; TCR, T-cell receptor. *(From Pachlopnik Schmid J, Cote M, Menager MM, et al. Inherited defects in cytotoxic lymphocyte activity. Immunol Rev. 2010;235:10–23.)*

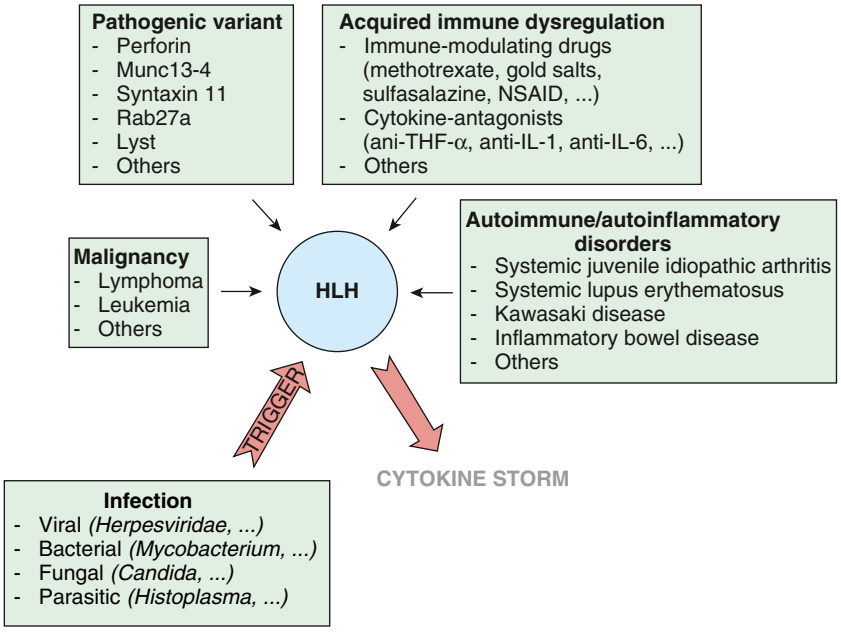

Fig. 556.6 Hemophagocytic lymphohistiocytosis (HLH) comprises a heterogeneous spectrum of disorders that all present with severe cytokine storm and life-threatening immunopathology. HLH can be caused by pathogenic variants in genes involved in granule-mediated cytotoxicity but can also be acquired on a multitude of underlying autoimmune/autoinflammatory diseases or malignancies, with possible facilitation by immunomodulating therapies. Clinical manifestations of HLH are generally precipitated by an infection. IL, Interleukin; NSAID, nonsteroidal antiinflammatory drugs. *(From Brisse E, Wouters CH, Matthys P. Hemophagocytic lymphohistiocytosis (HLH): a heterogeneous spectrum of cytokine-driven immune disorders. Cytokine Growth Factor Rev. 2015;26:263–280. Fig. 2, p. 267.)*

Langerhans cell histiocytosis presenting as a blueberry muffin rash. Lancet. 2017;390:155.)*

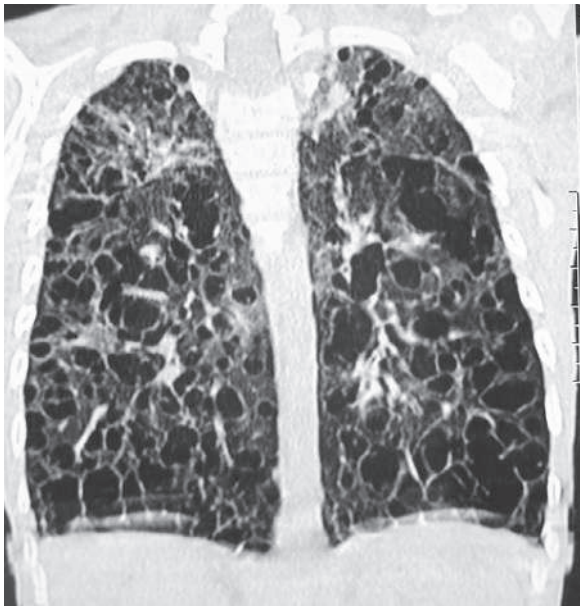

Fig. 556.10 High-resolution coronal CT image (lung window) reveals diffuse lung cysts with parenchymal destruction in bilateral lung fields. *(From Chauhan L, Aggarwal N. Honey-comb Langerhans cell histiocytosis. J Pediatr. 2016;168:248. Fig. 2.)*

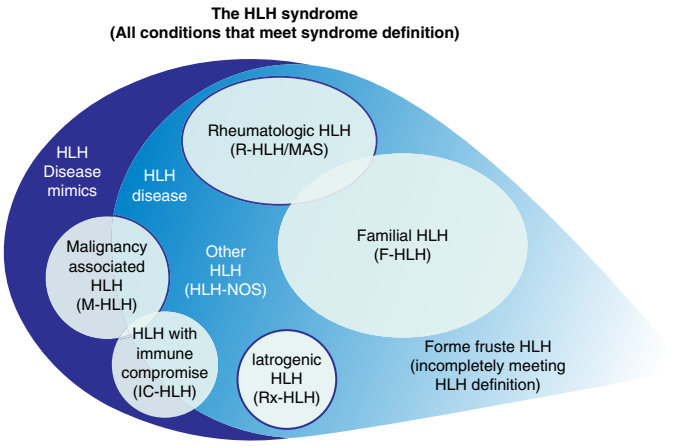

Fig. 556.11 Spectrum of the hemophagocytic lymphohistiocytosis (HLH) syndrome. The HLH syndrome includes all conditions meeting consensus diagnostic criteria. This syndrome includes conditions that would benefit from HLH-directed immunosuppressive therapies, which are termed "HLH disease," and those conditions that would not benefit from such therapy or require entirely different treatments, termed "HLH disease mimics." HLH disease includes recognizable subgroups: familial HLH with clear genetic etiology, HLH associated with malignancy, HLH associated with rheumatologic conditions (also called MAS), HLH observed after immune-activating therapies (iatrogenic HLH, also called cytokine release syndrome), HLH associated with immune compromise (either primary immune deficiency or treatment-related immune suppression), and HLH not associated with other specific conditions. Recognition of these subcategories is valuable as this may alter treatment. *(From Jordan MB, Allen CE, Greenberg J, et al. Challenges in the diagnosis of hemophagocytic lymphohistiocytosis: Recommendations from the North American Consortium (NACHO). Pediatr Blood Cancer. 2019;66:e27929.)*

556.2 Hemophagocytic Lymphohistiocytosis

Stephan Ladisch

See the previous section on "Classification and Pathology," Table 556.3, and Chapter 174.

CLINICAL MANIFESTATIONS

Primary FHLH and secondary HLH have a remarkably similar, clinically indistinguishable presentation (Fig. 556.11). It consists of a generalized disease process, most often with fever (90–100%), maculopapular and/or petechial rash (10–60%), weight loss, and irritability. The initial clinical presentation can vary but is usually severe. In the case of secondary HLH, onset may be camouflaged by a primary disease process. Acute presentations of HLH include a hyperferritinemic septic shock–like picture, acute respiratory distress, seizures, ataxia, focal lesions, or coma (because of CNS infiltration). Other features that are frequently present result from bone marrow involvement and pancytopenia or hepatic dysfunction.

Children with primary HLH are generally <1-2 years old, and children with secondary HLH typically present at an older age, but both forms may present at any age. **Physical examination** often reveals hepatosplenomegaly (70–100%), lymphadenopathy (20–50%), respiratory distress (40–90%), jaundice, and symptoms of CNS involvement (50%) that are not unlike those of aseptic meningitis, CNS vasculitis, or acute demyelinating encephalomyelitis. MRI may demonstrate systemic T2 weighted/fluid-attenuated inversion recovery (FLAIR) hyperintensities in gray and white matter and in supratentorial and infratentorial regions (Fig. 556.12). The cerebrospinal fluid (CSF) pleocytosis (50–90%) associated with CNS involvement in primary HLH is characterized by cells that are the same phagocytic macrophages found in the peripheral blood or bone marrow. HLH may initially or only manifest CNS symptoms. Isolated neuroinflammation may be present in the absence of cytopenias, splenomegaly, or other systemic features. Approximately 35% will eventually develop diagnostic features of HLH (Table 556.6). The interval from neurologic onset to eventual diagnosis often exceeds 2 years. In CNS isolated disease, the diagnosis of familial HLH is often made by whole exome sequencing for other diseases.

The **diagnosis** of HLH is arrived at in two stages. The first stage is based on a set of eight clinical and laboratory findings, with the presence of five of the eight being diagnostic of HLH. The eight findings, formulated by the Histiocyte Society, are fever, splenomegaly, cytopenia of two cell lines (in 90–100%), hypertriglyceridemia (80–100%) or hypofibrinogenemia (65–85%), hyperferritinemia (≥500 but often >10,000), extremely elevated soluble CD25 (interleukin-2 receptor), reduced or absent NK cell activity, and bone marrow, CSF, or lymph node evidence of hemophagocytosis (see Table 556.6). The second stage involves genetic analysis and is undertaken as quickly as possible but generally requires ~2 weeks to complete and should not interfere with initiation of treatment (Fig. 556.13). The genetic findings and family history will determine whether the diagnosis is (autosomal

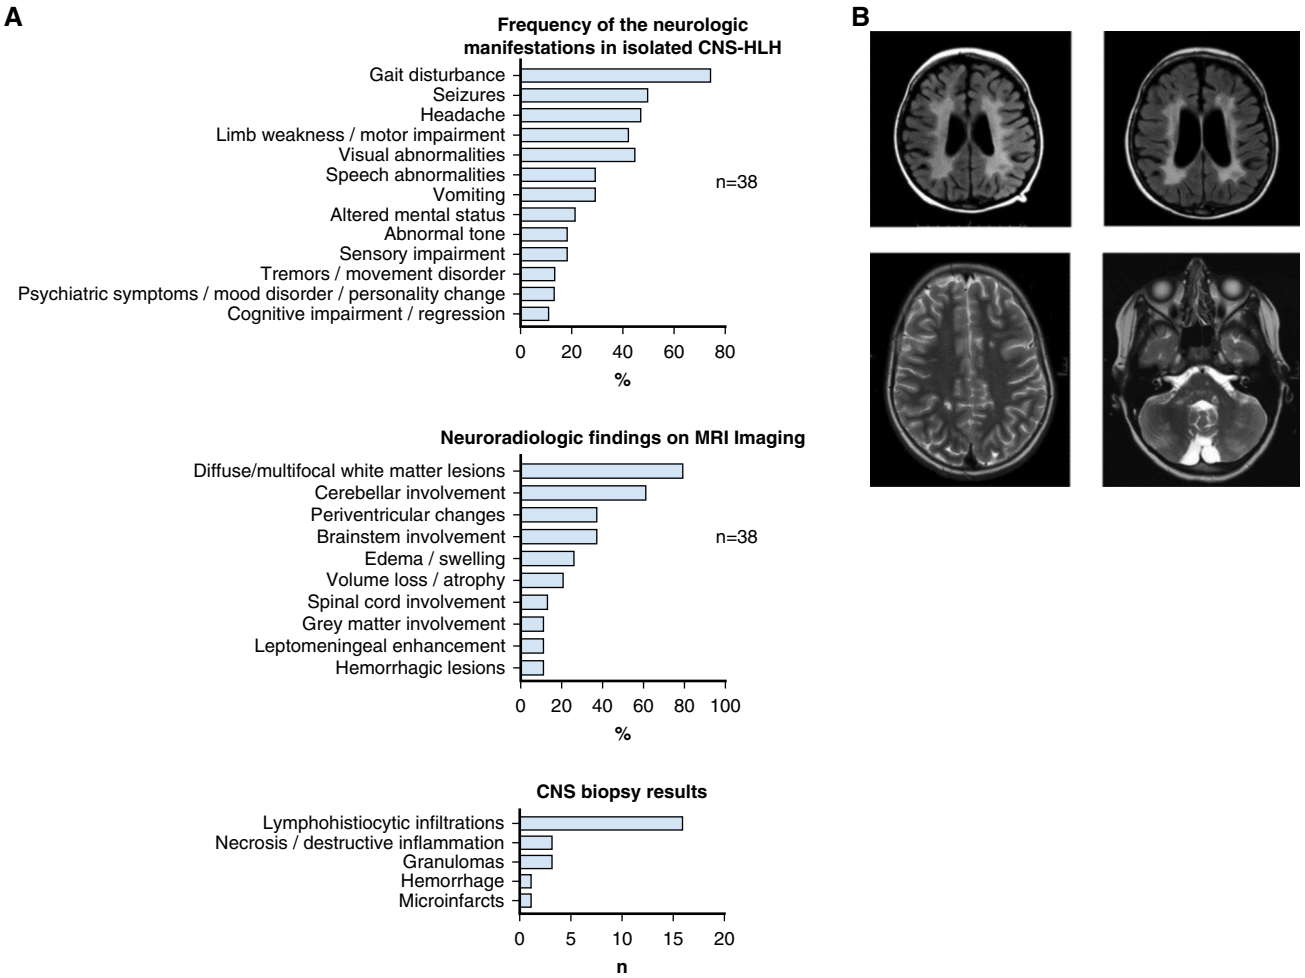

Fig. 556.12 A, Frequencies of neurologic manifestations, neuroradiologic findings, and histopathologic central nervous system (CNS) biopsy results in 38 patients with isolated CNS hemophagocytic lymphohistiocytosis (HLH). B, Examples of CNS MRI imaging in patients with isolated CNS-HLH. *Upper panels*, T2 images in one patient from 2016 *(left)* and 2017 *(right)* demonstrate cerebral atrophy with diffuse white matter involvement. Neuroradiologic findings on MRI show imaging abnormalities. *Lower panels*, T2 images from another patient reveal multiple nodular lesions in the pons, cerebellum, and white matter. *(From Blincoe A, Heeg M, Campbell PK, et al. Neuroinflammatory disease as an isolated manifestation of hemophagocytic lymphohistiocytosis. J Clin Immunol. 2020;40:901–916. Fig. 1.)*

recessive) primary HLH, secondary HLH, or a genetic hybrid form of HLH.

Hemophagocytosis is not specific for HLH and should be considered only in the context of the diagnostic criteria. No absolute clinical or laboratory distinction can be made between primary HLH and secondary HLH. In some subgroups of HLH, perforin assays may be normal. Similarly, some patients with primary FHLH have no known identifiable pathogenic variant, while new genetic variants associated with HLH continue to be discovered.

In the absence of either (1) a documented genetic defect coupled with defective NK cell cytotoxicity or (2) frank hemophagocytosis, care should be taken in making the diagnosis of secondary HLH, given the implication to use cytotoxic chemotherapy. The nonspecific criteria (indicative of inflammation) used to diagnose HLH can also be seen in diseases that are not always associated with hemophagocytosis (e.g., overwhelming acute viral infection with appropriate T-cell activation), in which the cytotoxic and immunosuppressive therapy used in treating HLH might be contraindicated.

Macrophage activation syndrome, particularly in the context of systemic-onset juvenile idiopathic arthritis (JIA) or infection, has many similarities to HLH (see Chapter 196). Indeed, whole exome sequencing of patients with systemic-onset JIA or those with fatal influenza has revealed a higher than expected incidence of HLH genes.

TREATMENT AND PROGNOSIS

Therapy for **primary HLH** (autosomal recessive genetic disease or familial occurrence) consists of a combination of etoposide, dexamethasone, cyclosporine, and intrathecal methotrexate. It should be stressed that pancytopenia and the presence of an infection are *not* contraindications to cytotoxic or immunosuppressive therapy (etoposide and steroid, cyclosporine or antithymocyte globulin for maintenance therapy). Paradoxically they ameliorate the HLH. Emapalumab, a monoclonal antibody against interferon-γ, is approved for recurrent, refractory, or progressive familial HLH or for patients who cannot tolerate chemotherapy. The goal for all therapies is to reach the point of initiating **stem cell transplantation,** to date the only known potentially curative treatment for primary HLH, effective in achieving cure in >60% of patients. Chemotherapy is inadequate for sustained cure of primary HLH, which is ultimately fatal without transplantation.

In **secondary HLH**, it is critical that the underlying disease (e.g., infection, malignancy) be identified and successfully treated. The diagnostic distinction between primary HLH and secondary HLH sometimes can be based on the acute onset of secondary HLH in the presence of an already documented infection or cancer, including leukemia, and certain autoimmune or immunodeficiency disorders. In this case, treatment of the underlying infection is coupled with supportive care. If the diagnosis is made in the setting of iatrogenic immunodeficiency, immunosuppressive

Table 556.6 Diagnostic Criteria for the HLH-2004 Trial and Their Relevance for Clinical Diagnosis

HLH2004 ENTRY CRITERIA	COMMENT
A. Molecular diagnosis consistent with HLH: Pathogenic variants of *PRF1, UNC13D, STXBP2,* Rab27a, *STX11, SH2D1A,* or *XIAP* or	In a patient with known variants, treatment before full development of HLH may be appropriate, but genetic studies usually just help to define HLH recurrence risk, not the presence of an active disease state.
B. Five of the eight criteria listed below are fulfilled	
1. Fever ≥38.3°C	Nearly universal in untreated HLH.
2. Splenomegaly	Although splenomegaly and hepatomegaly are very common in HLH, adenopathy is not.
3. Cytopenias (affecting at least two of three lineages in the peripheral blood): Hemoglobin <9 g/dL (in infants <4 wk: hemoglobin <10 g/dL), platelets <100 × 10^3/mL, neutrophils <1 × 10^3/mL	Cytopenias are ubiquitous in HLH. Lack of cytopenias should make one doubt a diagnosis of HLH, except in the special case of isolated, CNS-only disease.
4. Hypertriglyceridemia (>265 mg/dL) and/or hypofibrinogenemia (<150 mg/dL)	Low fibrinogen in the context of inflammation is paradoxical and one of the more distinctive features of HLH.
5. Hemophagocytosis in bone marrow or spleen or lymph nodes or liver	Not specific to HLH, or essential for the diagnosis, but helpful as a disease marker. Of note, it is often not evident early after disease onset.
6. Low or absent NK-cell activity	More modern and robust assays measuring perforin levels and its degranulation should replace this assay for reliable diagnosis of HLH. This assay is not specific for primary HLH.
7. Ferritin >500 ng/mL	Most patients have much higher levels than this threshold suggests.
8. Elevated soluble CD25 (soluble IL-2 receptor α)	As HLH is a T-cell driven disease, this assay is extremely informative for diagnosis and response to therapy.

HLH, Hemophagocytic lymphohistiocytosis; NK, natural killer; IL, interleukin; CNS, central nervous system.
From Jordan MB, Allen CE, Greenberg J, et al. Challenges in the diagnosis of hemophagocytic lymphohistiocytosis: Recommendations from the North American Consortium (NACHO). *Pediatr Blood Cancer.* 2019;66(11):e27929. Table 1.

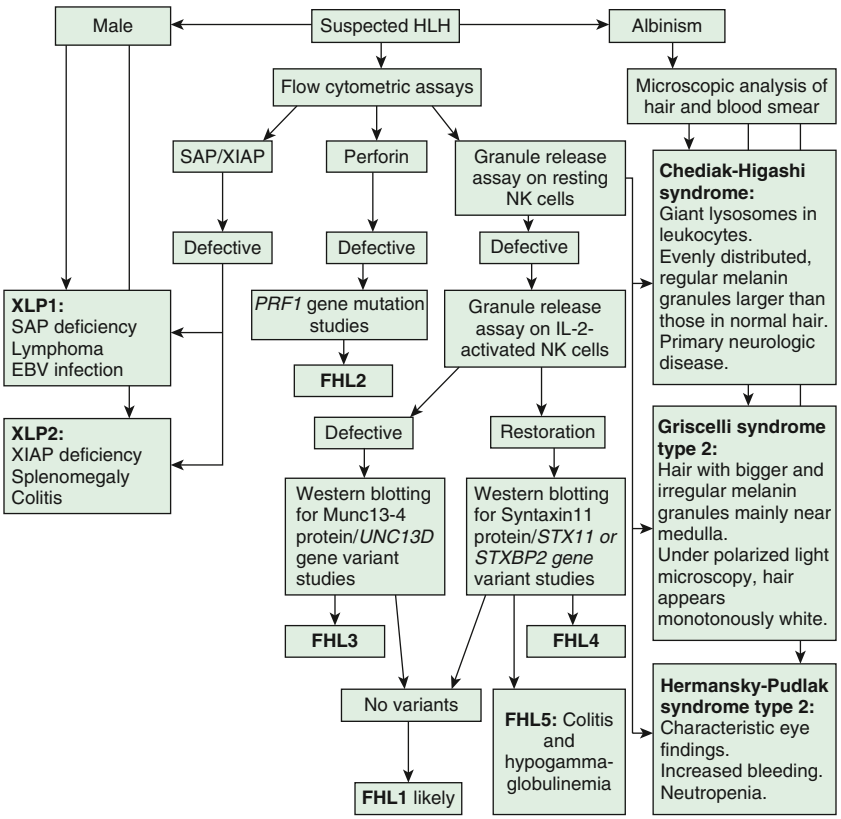

Fig. 556.13 Algorithm for identification of genetic causes of hemophagocytic lymphohistiocytosis (HLH). The HLH algorithm is based on flow cytometry assays: all the patients fitting into HLH criteria, irrespective of age and clinical presentations, should be screened for perforin expression and granule release assay. All male patients should be screened for signaling lymphocyte activation molecule–associated protein (SAP) and X-linked inhibitor of apoptosis protein (XIAP) expression. For patients clinically presenting with albinism, microscopic analysis of hair and blood smear is essential for differential diagnosis of Chédiak-Higashi syndrome, Griscelli syndrome, and Hermansky-Pudlak syndrome. Based on the defect in expression of a particular protein identified, molecular characterization for the respective gene should be performed for confirmation of diagnosis. EBV, Epstein-Barr virus; FHL, familial hemophagocytic lymphohistiocytosis; IL, interleukin; NK, natural killer. *(Adapted from Madkaikar M, Shabrish S, Desai M. Current updates on classification, diagnosis and treatment of hemophagocytic lymphohistiocytosis (HLH). Indian J Pediatr. 2016;83:434–443.)*

treatment should be withdrawn and supportive care instituted along with specific therapy for the underlying infection. In many patients the prognosis is excellent without additional specific treatment other than treating the triggering infection. However, when a treatable infection or other cause cannot be documented, and when the clinical presentation is severe, the prognosis for secondary HLH is as poor as for primary HLH. These patients should receive the identical initial 8-week chemotherapeutic approach, including etoposide, even in the face of cytopenias. In both primary and secondary HLH, the cytotoxic effect of etoposide on macrophages interrupts cytokine production and the consequent cytokine storm, the hemophagocytic process, and the accumulation of macrophages, all of which may contribute to the pathogenesis of **infection-associated hemophagocytic syndrome**. A broad spectrum of infectious agents, including viruses (e.g., cytomegalovirus, Epstein-Barr virus, human herpesvirus 6), fungi, protozoa, and bacteria, may trigger secondary HLH, often in the setting of immunodeficiency (see Table 556.3). A thorough evaluation for infection should be undertaken in immunodeficient patients with hemophagocytosis. The same syndrome may be identified in conjunction with a rheumatologic disorder (e.g., systemic lupus erythematosus, Kawasaki disease) or a neoplasm (e.g., leukemia). In these patients, effective treatment of the underlying disease (e.g., infection, cancer) is critical and may itself lead to ultimate resolution of the hemophagocytosis. In addition anakinra or ruxolitinib (JAK inhibitors) has been used in patients with secondary HLH.

556.3 Other Histiocytoses

Stephan Ladisch

Other rare histiocytoses that have been named for their clinical presentation include xanthogranuloma in JXG, ECD, and striking lymphadenopathy in Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy). JXG and ECD may require systemic treatment with cytotoxic chemotherapy or potentially MAPK pathway inhibitors, reflecting the presence of a *BRAF* pathogenic variant. Rosai-Dorfman disease usually is not treated, although the massive lymphadenopathy may require intervention because of its tendency to cause physical obstruction.

Rare histiocytic malignancies include acute monocytic leukemia, true malignant histiocytosis, and histiocytic sarcoma. Also included is the more recently identified histiocytic malignancy, ALK+ histiocytosis, which is a systemic histiocytic proliferation presenting as disseminated disease in infants. The cells bear histiocytic markers (CD68, CD163) but not those of LCH (CD1a, BRAF V600E). Whereas all these rare histiocytic malignancies are referred to as histiocytoses because of their monocyte-macrophage lineage, they are better considered under the rubric of true proliferative malignancies of the monocyte–macrophage lineage.

Section 1

Glomerular Disease

Chapter 557

Introduction to Glomerular Diseases

557.1 Anatomy of the Glomerulus

Edward J. Nehus

The kidneys lie in the retroperitoneal space slightly above the level of the umbilicus. They range in length and weight, respectively, from approximately 6 cm and 24 g in a full-term newborn to ≥12 cm and 150 g in an adult. The kidney (Fig. 557.1) has an outer layer, **the cortex,** which contains the glomeruli, proximal and distal convoluted tubules, and collecting ducts, and an inner layer, **the medulla,** which contains the straight portions of the tubules, the loops of Henle, the vasa recta, and the terminal collecting ducts (Fig. 557.2).

The blood supply to each kidney usually consists of a main renal artery that arises from the aorta, although multiple renal arteries can occur. The main artery divides into segmental branches within the medulla, becoming the interlobar arteries that pass through the medulla to the corticomedullary junction. At this point, the interlobar arteries branch to form the arcuate arteries, which run parallel to the surface of the kidney. Interlobular arteries originate from the arcuate arteries and give rise to the afferent arterioles of the glomeruli. Specialized muscle cells in the wall of the afferent arteriole and specialized distal tubular cells adjacent to the glomerulus (macula densa) form the juxtaglomerular apparatus that controls the secretion of renin. The afferent arteriole divides into the glomerular capillary network, which then recombines into the efferent arteriole (see Fig. 557.2). The juxtamedullary efferent arterioles are larger than those in the outer cortex and provide the blood supply, as the vasa recta, to the tubules and medulla.

Each kidney contains approximately one million **nephrons** (each consisting of a glomerulus and associated tubules). There is a large distribution of normal nephron numbers in humans, ranging from 200,000 to 1.8 million nephrons per kidney. This variation can have major pathophysiologic significance as a risk factor for the later development of hypertension and progressive renal dysfunction. In humans, the formation of nephrons is complete at 34-36 weeks of gestation, but functional maturation with tubular growth and elongation continues during the first decade of life. Because new nephrons cannot be formed after birth, any disease that results in progressive loss of nephrons can lead to renal insufficiency. A decreased number of nephrons secondary to low birthweight, prematurity, and/or unknown genetic or environmental factors has been implicated as a significant risk factor for the development of primary hypertension and progressive renal dysfunction in adulthood. A low nephron number presumably results in hyperfiltration and eventual sclerosis of *overworked* nephron units.

The glomerular network of specialized capillaries serves as the filtering mechanism of the kidney. The glomerular capillaries are lined by endothelial cells (Fig. 557.3) and have very thin cytoplasm that contains many holes (fenestrations). The **glomerular basement membrane** (GBM) forms a continuous layer between the endothelial and mesangial cells on one side and the epithelial cells on the other. The membrane has three layers: a central electron-dense lamina densa; the lamina rara interna, which lies between the lamina densa and the endothelial cells; and the lamina rara externa, which lies between the

The glomerular filtrate passes through the endothelial fenestrae, crosses the basement membrane, and passes through the filtration slits *(black arrow)* between the epithelial cell foot processes to reach the urinary space *(US)* (×60,000). *j*, Junction between two endothelial cells. *(From Farquhar MG, Kanwar YS. Functional organization of the glomerulus: state of the science in 1979. In: Cummings NB, Michael AF, Wilson CB, eds. Immune Mechanisms in Renal Disease. New York: Plenum; 1982.)*

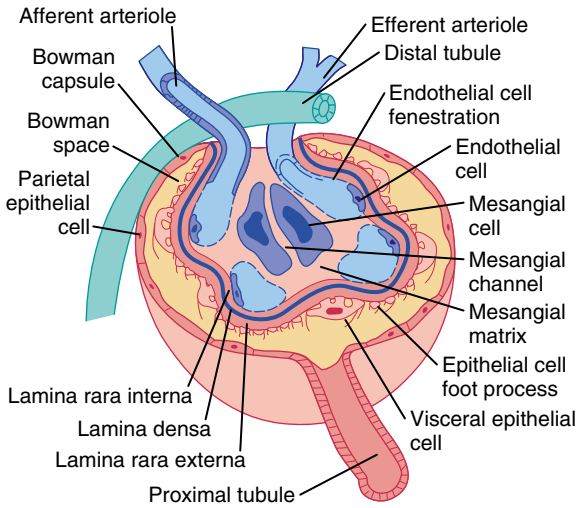

Fig. 557.4 Schematic depiction of the glomerulus and surrounding structures.

lamina densa and the epithelial cells. The visceral epithelial cells cover the capillary and project cytoplasmic foot processes, which attach to the lamina rara externa. Between the foot processes are spaces or filtration slits. The **mesangium** (mesangial cells and matrix) lies between the glomerular capillaries on the endothelial cell side of the GBM and forms the medial part of the capillary wall. The mesangium may serve as a supporting, stalk-like structure for the glomerular capillaries and probably has a role in the regulation of glomerular blood flow, filtration, and the removal of macromolecules (such as immune complexes) from the glomerulus. The Bowman's capsule, which surrounds the glomerulus, is composed of a basement membrane, which is continuous with the basement membranes of the glomerular capillaries and the proximal tubules, and the parietal epithelial cells, which are adjacent to the visceral epithelium (Fig. 557.4).

557.2 Glomerular Filtration

Edward J. Nehus

Kidney function is best measured as the **glomerular filtration rate (GFR)**. As the blood passes through the glomerular capillaries, the plasma is filtered through the glomerular capillary walls. Small plasma molecules filter freely (e.g., electrolytes, glucose, phosphate, urea, creatinine, peptides, low molecular weight proteins), whereas larger molecules are retained in the circulation (such as albumin and globulins). The filtrate is collected in Bowman's space and enters the tubules. There its composition is modified by tightly regulated secretion and absorption of solute and fluid by the multiple tubular segments of the nephron and the ductal system, until it exits the kidney, via the ureter, as urine.

Glomerular filtration is the net result of opposing forces applied across the capillary wall. The force for ultrafiltration (glomerular capillary hydrostatic pressure) is a result of systemic arterial pressure, modified by the tone of the afferent and efferent arterioles. The major force opposing ultrafiltration is glomerular capillary oncotic pressure, created by the gradient between the high concentration of plasma proteins within the capillary and the almost protein-free ultrafiltrate in Bowman's space. Filtration may be modified by the rate of glomerular plasma flow, the hydrostatic pressure within Bowman's space, and/or the permeability of the glomerular capillary wall.

Although glomerular filtration begins at approximately the sixth week of fetal life, kidney function is not necessary for normal intrauterine homeostasis because the placenta serves as the major fetal excretory organ. After birth, the GFR increases until renal growth ceases (by age ~18-20 years in most people). To compare GFRs of children and adults, the GFR is standardized to the body surface area (1.73 m^2) of an "ideal" 70-kg adult. Even after correction for surface area, the GFR of a child does not approximate adult values until the second to third year of life (Fig. 557.5). The GFR may be estimated by measurement of the serum creatinine level. Creatinine is derived from muscle metabolism. Its production is typically constant, and its excretion is primarily through glomerular filtration, although tubular secretion can become important as the serum creatinine rises in renal insufficiency. In contrast to the concentration of blood urea nitrogen, which is affected by the state of hydration and nitrogen balance, the serum creatinine level is primarily influenced by muscle mass and the level of glomerular function.

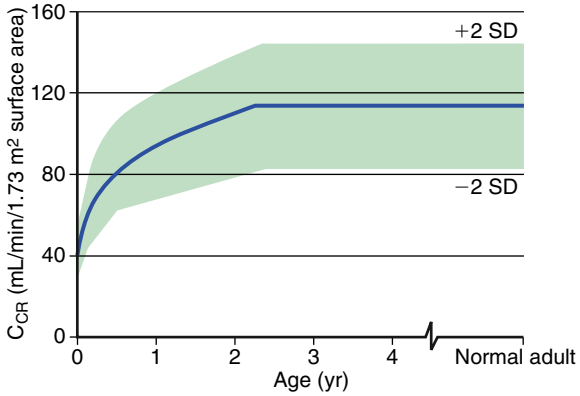

Fig. 557.5 Changes in the normal value of the glomerular filtration rate, as measured by the creatinine clearance *(Ccr)*, when standardized to mL/min/1.73 m^2 of body surface area. The *solid line* depicts the mean, and the *shaded area* includes 2 standard deviations (SDs). *(From McCrory W. Developmental Nephrology. Cambridge, MA: Harvard University Press; 1972.)*

The serum creatinine is of value only in estimating the GFR under steady-state conditions. A patient can have a normal serum creatinine level with decreased renal function very shortly after the onset of acute kidney injury. In this clinical setting, serum creatinine may take days to reach the steady state. Furthermore, kidney function may fall significantly before a noticeable rise in serum creatinine occurs.

The precise measurement of the GFR is accomplished by quantitating the clearance of a substance that is freely filtered across the capillary wall and is neither reabsorbed nor secreted by the tubules. The clearance (C_s) of such a substance is the volume of plasma that, when completely cleared of the contained substance, would yield an equal quantity of that substance excreted in the urine over a specified time. Renal clearance is calculated by the following formula:

$$C_s\left(\text{mL/min}\right) = U_s\left(\text{mg/mL}\right) \times \left(V\left(\text{mL/min}\right) / P_s\left(\text{mg/mL}\right)\right)$$

where C_s equals the clearance of substance s, U_s reflects the urinary concentration of s, V represents the urinary flow rate, and P_s equals the plasma concentration of s. To correct the clearance for individual body surface area, the formula is:

$$\text{Corrected clearance}\left(\text{mL/min/1.73 m}^2\right) = C_s\left(\text{mL/min}\right) \times \frac{1.73}{\text{Surface area}\left(\text{m}^2\right)}$$

The GFR is optimally measured by the clearance of inulin, a fructose polymer having a molecular weight of approximately 5.7 kDa. Because the inulin clearance technique is cumbersome, radioisotopes are commonly used to measure GFR in clinical practice. GFR can be accurately determined by a single intravenous injection of a radioisotope, most commonly ^{99m}TC-DTPA, followed by timed monitoring of serum samples.

Because true measurement of the GFR is expensive and time-consuming, the GFR is commonly estimated (eGFR) by the clearance of endogenous creatinine. Formulas that estimate creatinine clearance accurately in clinical settings have been useful tools in patient care. The "bedside" Schwartz formula is the most widely used pediatric formula and is based on the serum creatinine (S_{cr}), patient height, and an empirical constant:

$$\text{eGFR} = 0.413\,\text{height}\left(\text{cm}\right) / S_{cr}\left(\text{mg/dL}\right)$$

The accuracy of GFR-estimating equations can be further improved utilizing an additional endogenous marker, cystatin C, in addition to serum creatinine. Cystatin C is a 13.6-kDa protease inhibitor produced by nucleated cells that is freely filtered by the kidney. It continues to gain popularity as a clinical tool to provide an alternative to creatinine-based formulas because it has distinct advantages in estimating the GFR. Unlike creatinine, cystatin C is not secreted by the renal tubules under any conditions. Furthermore, it is less affected by sex, age, and muscle mass than serum creatinine. Several cystatin C-based formulas have been developed, including a multivariable eGFR equation that combines both cystatin C and creatinine in addition to height, BUN, and gender:

$$\text{eGFR} = 39.8 \times \left[\text{height}\left(\text{m}\right)/S_{cr}\left(\text{mg/dl}\right)\right]^{0.456} \times \left[1.8/\text{cystatin C}\left(\text{mg/L}\right)\right]^{0.418} \times \left[30/\text{BUN}\left(\text{mg/dl}\right)\right]^{0.079} \times \left[1.076\right]^{\text{male}} \times \left[\text{ht}\left(\text{m}\right)/1.4\right]^{0.179}$$

However, cystatin C assays are not available in many laboratories and lack standardization. Therefore the creatinine-based bedside Schwartz equation remains the most widely used assessment of kidney function in children.

557.3 Glomerular Diseases

Edward J. Nehus

PATHOGENESIS

Glomerular injury may be the result of a genetic, immunologic, perfusion, or coagulation disorder. Genetic disorders of the glomerulus may result from pathogenic variants in genes encoding proteins located within the glomerulus, interstitium, or tubular epithelium; pathogenic variants in regulatory genes controlling DNA transcription; abnormal posttranscriptional modification of RNA transcripts; or abnormal posttranslational modification of proteins. Immunologic injury to the glomerulus results in **glomerulonephritis,** which is a generic term for several diseases but more precisely is a histopathologic term defining inflammation of the glomerular capillaries. Evidence that glomerulonephritis is caused by immunologic injury includes morphologic and immunopathologic similarities to experimental immune-mediated glomerulonephritis, the demonstration of immune reactants (immunoglobulin, complement) in glomeruli, abnormalities in serum complement, and the finding of autoantibodies (anti-GBM) in some of these diseases (Fig. 557.6). There appear to be two major mechanisms of immunologic injury: glomerular deposition of circulating antigen-antibody immune complexes and direct interaction of antibody with specific glomerular antigens in situ. In the former, antibody is produced against and combines with a circulating antigen that is usually unrelated to the kidney (see Fig. 557.6). The immune complexes accumulate in GBMs and activate the complement system, leading to immune injury. Immunofluorescence microscopy often demonstrates granular or irregular deposits containing immunoglobulin and complement in the glomerular capillary wall. Electron microscopic studies may show these deposits in the GBM and in the mesangium. Examples of circulating immune complex–mediated glomerulonephritis include postinfectious glomerulonephritis, IgA nephropathy, membranoproliferative glomerulonephritis, and lupus nephritis. In situ immune complex formation occurs when an antibody reacts with antigen(s) of the GBM. Immunopathologic studies reveal linear deposition of immunoglobulin and complement along the GBM. This type of immune complex injury occurs in Goodpasture syndrome and membranous nephropathy.

The inflammatory reaction that follows immunologic injury results from activation of one or more mediator pathways. The most important of these is the complement system, which has two initiating sequences: the classic pathway, which is activated by antigen-antibody immune complexes, and the alternative or properdin pathway, which occurs by autoactivation of C3 by a process known as C3 tick over. These pathways converge at C3; from that point on, the same sequence leads to lysis of cell membranes (see Chapter 173). The major noxious products of complement activation are produced after activation of C3 and include anaphylatoxin (which stimulates contractile proteins within vascular walls and increases vascular permeability) and chemotactic factors (C5a) that recruit neutrophils and perhaps macrophages to the site of complement activation, leading to consequent damage to vascular cells and basement membranes.

PATHOLOGY

The glomerulus may be injured by several mechanisms, but it has only a limited number of histopathologic responses; different disease states can produce similar microscopic changes.

Proliferation of glomerular cells occurs in most forms of glomerulonephritis and may be generalized (involving all glomeruli) or focal (involving only some glomeruli and sparing others). Within a single glomerulus, proliferation may be diffuse (involving all parts of the glomerulus) or segmental (involving only one or more tufts, but not others). Proliferation commonly involves the endothelial and mesangial cells and is often associated with an increase in the mesangial matrix (see Fig. 557.6). Mesangial proliferation can result from deposition of

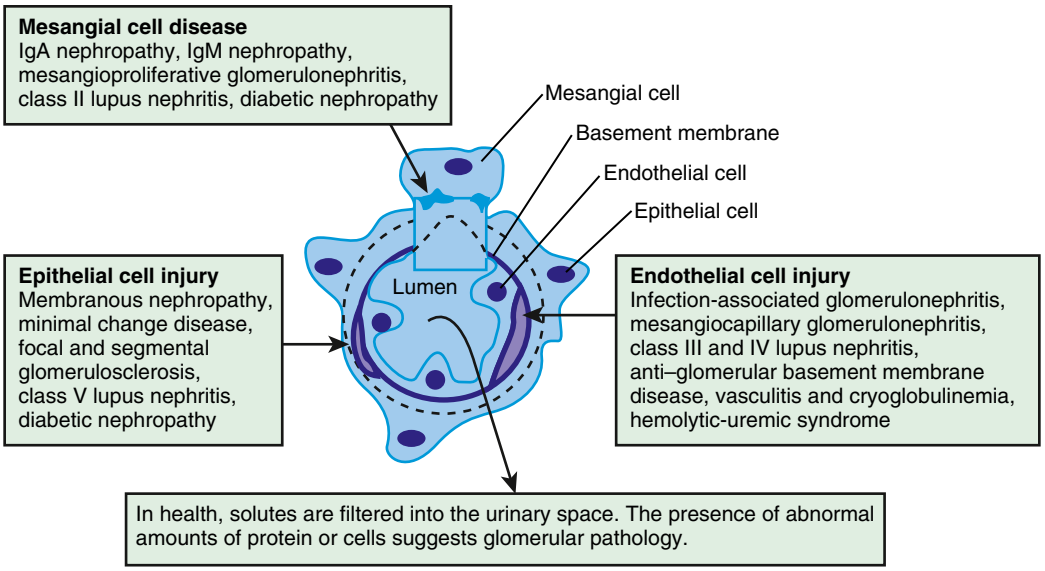

Fig. 557.6 Cellular location of injury during glomerulonephritis. Mesangial cells are directly exposed to the circulation. Deposition of immune complexes within these cells is typically seen in disorders such as immunoglobulin A *(IgA)* nephropathy; it results in proliferation and expansion of the cells, leading to hematuria, proteinuria, and renal impairment. Epithelial cells, in conjunction with basement membrane, allow filtration of plasma solutes but retard passage of cells and plasma proteins. Disease related to these cells is typified by the presence of subepithelial deposits and flattening of the foot processes that engage the basement membrane, resulting in disruption of the filtration barrier and proteinuria. Endothelial cell disease can result from deposition of immune complex (as occurs in mesangiocapillary glomerulonephritis), attachment of antibody to the basement membrane (Goodpasture disease), or trauma and activation of coagulation (hemolytic-uremic syndrome). Endothelial cell proliferation and necrosis are accompanied by leukocyte accumulation; rupture of the basement membrane, crescent formation, and disruption of glomerular architecture can develop. A nephritic or rapidly progressive presentation ensues. *(From Chadban SJ, Atkins RC. Glomerulonephritis. Lancet. 2005;365:1797–1806.)*

immune complex within the mesangium. The resultant increase in cell size and number, and production of mesangial matrix, can increase the glomerular size and narrow the lumens of glomerular capillaries, leading to renal insufficiency.

Crescent formation in Bowman's space (capsule) is a result of proliferation of parietal epithelial cells and is often associated with clinical signs of renal dysfunction. Crescents develop in several forms of glomerulonephritis (termed **rapidly progressive** or **crescentic;** see Chapter 559.7) and are a characteristic response to deposition of fibrin in Bowman's space. Newly formed crescents contain fibrin, the proliferating epithelial cells of Bowman's space, basement membrane–like material produced by these cells, and macrophages that might have a role in the genesis of glomerular injury. Over subsequent days to weeks, the crescent is invaded by connective tissue and becomes a fibroepithelial crescent. This process generally results in glomerular obsolescence and the clinical development of chronic renal failure. Crescent formation is often associated with glomerular cell death. The necrotic glomerulus has a characteristic eosinophilic appearance and usually contains nuclear remnants. Crescent formation is usually associated with generalized proliferation of the mesangial cells and with either immune complex or anti-GBM antibody deposition in the glomerular capillary wall.

Certain forms of acute glomerulonephritis show glomerular exudation of blood cells, including neutrophils, eosinophils, basophils, and mononuclear cells. The thickened appearance of GBM can result from a true increase in the width of the membrane (as seen in membranous glomerulopathy; see Chapter 559.5), from massive deposition of immune complexes that have staining characteristics similar to the membrane (as seen in systemic lupus erythematosus; see Chapter 560.2), or from the interposition of mesangial cells and matrix into the subendothelial space between the endothelial cells and the GBM. The last can give the basement membrane a split appearance, as seen in membranoproliferative glomerulonephritis (see Chapter 559.6) and other diseases.

Sclerosis refers to obliteration of capillary loops within the glomerulus caused by increased mesangial matrix. Glomerulosclerosis may be caused by a putative circulating factor, as occurs in primary focal segmental glomerulosclerosis (FSGS), or it may be secondary to a variety of conditions including pathogenic variants, obesity, infection, certain medications, or any condition that results in reduced renal mass.

Tubulointerstitial fibrosis is present in all patients who have glomerular disease and who develop progressive renal injury. This fibrosis is initiated by injury to either the glomeruli, which, if severe, may secondarily involve the tubules, or direct injury to the tubules themselves. Tubular injury recruits mononuclear cell infiltrate, which releases a variety of soluble factors that have fibrosis-promoting effects. Matrix proteins of the renal interstitium begin to accumulate, leading to eventual destruction of renal tubules and peritubular capillaries.

Section 2

Conditions Particularly Associated with Hematuria

Chapter 558

Clinical Evaluation of the Child with Hematuria

Francisco X. Flores

Hematuria, defined as the persistent presence of more than five red blood cells (RBCs)/high-power field (hpf) in uncentrifuged urine, occurs in 4–6% of urine samples from school-aged children. Quantitative studies demonstrate that normal children can excrete more than 500,000 RBCs per 12-hour period; this increases with fever and/or exercise. In the clinical setting, qualitative estimates are provided by a urinary dipstick that uses a very sensitive peroxidase chemical reaction between hemoglobin (or myoglobin) and a colorimetric chemical indicator impregnated on the dipstick. Chemstrip (Boehringer Mannheim), a common commercially available dipstick, is very sensitive and capable of detecting 3-5 RBCs/hpf of unspun urine. The presence of 10-50 RBCs/μL may suggest underlying pathology, but significant hematuria is generally considered as >50 RBCs/hpf. False-negative results can occur in the presence of formalin (used as a urine preservative) or high urinary concentrations of ascorbic acid (i.e., in patients with vitamin C intake >2,000 mg/day). False-positive results may be seen in a child with an alkaline urine (pH >8), or more commonly following contamination with oxidizing agents such as hydrogen peroxide used to clean the perineum before obtaining a specimen. Microscopic analysis of 10-15 mL of freshly voided and centrifuged urine is essential in confirming the presence of RBCs suggested by >10 RBCs/hpf, or a 1+ positive urinary dipstick reading.

Red urine *without* RBCs is seen in a number of conditions (Table 558.1). Clinically significant heme-positive urine without RBCs may be caused by the presence of either hemoglobin or myoglobin. **Hemoglobinuria** without hematuria can occur in the presence of acute or chronic hemolysis. **Myoglobinuria** without hematuria occurs in the presence of rhabdomyolysis resulting from skeletal muscle injury and is generally associated with a fivefold increase in the plasma concentration of creatine kinase. Clinically innocuous heme-negative urine can appear red, cola colored, or burgundy, due to ingestion of various drugs, foods (blackberries, beets), or dyes used in food and candy, whereas dark brown (or black) urine can result from various urinary metabolites.

Evaluation of the child with hematuria begins with a careful history, physical examination, and microscopic urinalysis. This information is used to determine the level of hematuria (upper vs lower urinary tract) and to determine the urgency of the evaluation based on symptomatology. Special consideration needs to be given to the family history, identification of anatomic abnormalities and malformation syndromes, presence of gross hematuria, and manifestations of hypertension, edema, or heart failure.

Table 558.2 lists causes of hematuria. Upper urinary tract sources of hematuria originate within the nephron (glomerulus, tubular system, or interstitium). Lower urinary tract sources of hematuria originate from the pelvicalyceal system, ureter, bladder, or urethra. Hematuria from within the glomerulus is often associated with brown, cola- or tea-colored, or burgundy urine, proteinuria >100 mg/dL via dipstick, urinary microscopic findings of RBC casts, and deformed urinary RBCs (particularly acanthocytes). Hematuria originating within the tubular system may be associated with the presence of leukocytes or renal tubular casts. Lower urinary tract sources of hematuria may be associated with gross hematuria that is bright red or pink, terminal hematuria (gross hematuria occurring at the end of the urine stream), blood clots, normal urinary RBC morphology, and minimal proteinuria on dipstick (<100 mg/dL).

Patients with hematuria can present with a number of symptoms suggesting specific disorders. Tea- or cola-colored urine, facial or body edema, hypertension, and oliguria are classic symptoms of **glomerulonephritis.** Diseases commonly manifesting as glomerulonephritis include postinfectious glomerulonephritis, immunoglobulin A (IgA) nephropathy, membranoproliferative glomerulonephritis (MPGN), IgA vasculitis nephritis (formerly Henoch-Schönlein purpura nephritis), systemic lupus erythematosus (SLE) nephritis, granulomatosis with polyangiitis (formerly Wegener granulomatosis), microscopic polyangiitis, Goodpasture syndrome, and hemolytic-uremic syndrome. A history of recent upper respiratory, skin, or gastrointestinal infection suggests postinfectious glomerulonephritis, hemolytic-uremic syndrome, or IgA vasculitis nephritis. Rash and joint complaints suggest IgA vasculitis or SLE nephritis.

Hematuria associated with glomerulonephritis is typically painless but can be associated with flank pain when acute or unusually severe. Frequency, dysuria, and unexplained fevers suggest a urinary tract infection, whereas renal colic suggests nephrolithiasis. A flank mass can suggest hydronephrosis, renal cystic diseases, renal vein thrombosis, or tumor. Hematuria associated with headache, mental status changes, visual changes (diplopia), epistaxis, or heart failure suggests associated severe hypertension. Patients with hematuria and a history of trauma require immediate evaluation (see Chapter 80). Child abuse must always be suspected in the child presenting with unexplained perineal bruising and hematuria.

A careful family history is critical in the initial assessment of the child with hematuria given the numerous genetic causes of renal disorders. Hereditary glomerular diseases include hereditary nephritis (isolated Alport syndrome or with leiomyomatosis or macrothrombocytopenia); thin glomerular basement membrane disease; SLE nephritis; hereditary angiopathy with nephropathy, aneurysms, and muscle cramps (HANAC); and IgA nephropathy (Berger disease). Other hematuric renal disorders with a hereditary component include both autosomal recessive and autosomal dominant polycystic kidney diseases, atypical hemolytic-uremic syndrome, urolithiasis, and sickle cell disease/trait.

Physical examination may also suggest possible causes of hematuria. The presence of hypertension, edema, or signs of heart failure suggests acute glomerulonephritis. Several malformation syndromes are associated with renal disease, including VATER (*v*ertebral body anomalies, *a*nal atresia, *t*racheo*e*sophageal fistula, and *r*enal dysplasia) syndrome. Abdominal masses may be caused by bladder distention in posterior urethral valves, hydronephrosis in ureteropelvic or ureterovesical junction obstruction, polycystic kidney disease, or Wilms tumor. Hematuria seen in patients with neurologic or cutaneous abnormalities may be the result of a number of syndromic renal disorders, including tuberous sclerosis, von Hippel-Lindau syndrome, and Zellweger (cerebrohepatorenal) syndrome. Anatomic abnormalities of the external genitalia may be associated with hematuria and/or renal disease.

Patients with gross hematuria present additional challenges because of the associated parental anxiety. The most common cause of gross hematuria is bacterial or viral urinary tract infection. **Urethrorrhagia,** which is urethral bleeding in the absence of urine, is associated with

dysuria and blood spots on underwear after voiding. This condition, which often occurs in prepubertal boys at intervals several months apart, has a benign self-limited course. Less than 10% of patients have evidence of glomerulonephritis. Recurrent episodes of gross hematuria suggest IgA nephropathy, Alport syndrome, or thin glomerular basement membrane disease. Dysuria and abdominal or flank pain are symptoms of idiopathic hypercalciuria, or urolithiasis. Table 558.3 lists common causes of gross hematuria; Figure 558.1 outlines a general approach to the laboratory and radiologic evaluation of the patient with glomerular or nonglomerular hematuria. Asymptomatic patients with isolated microscopic hematuria should not undergo extensive diagnostic evaluation, because such hematuria is often transient and benign.

The child with completely asymptomatic isolated microscopic hematuria that persists on at least three urinalyses observed over a minimum of a 2-week period poses a dilemma in regard to the degree of further diagnostic testing that should be performed. Significant disease of the urinary tract is uncommon with this clinical presentation. The initial evaluation of these children should include a urine culture followed by a spot urine for hypercalciuria with a calcium:creatinine ratio in culture-negative patients. In Black patients, a sickle cell screen should be included. If these studies are normal, urinalysis of all first-degree relatives is indicated. Renal and bladder ultrasonography should be considered to rule out structural lesions such as tumor, cystic disease, hydronephrosis, or urolithiasis. Ultrasonography of the urinary tract is most informative in patients presenting with gross hematuria, abdominal pain, flank pain, or trauma. If these initial studies are normal, assessment of serum creatinine and electrolytes is recommended.

The finding of certain hematologic abnormalities can narrow the differential diagnosis. **Anemia** in this setting may be caused by

hypervolemia with dilution associated with acute kidney injury; decreased RBC production in chronic kidney disease; hemolysis from hemolytic-uremic syndrome, a chronic hemolytic anemia, or SLE; blood loss from pulmonary hemorrhage, as seen in Goodpasture syndrome; or melena in patients with IgA vasculitis or hemolytic-uremic syndrome. Inspection of the peripheral blood smear might reveal a **microangiopathic** process consistent with the hemolytic-uremic syndrome. The presence of autoantibodies in SLE can result in a positive Coombs test, the presence of antinuclear antibody, leukopenia, and multisystem disease. **Thrombocytopenia** can result from decreased platelet production (malignancies) or increased platelet consumption (SLE, idiopathic thrombocytopenic purpura, hemolytic-uremic syndrome, renal vein thrombosis, or congenital hepatic fibrosis with portal hypertension secondary to autosomal recessive polycystic kidney disease). Although urinary RBC morphology may be normal with lower tract bleeding and dysmorphic from glomerular bleeding, it is not sensitive enough to unequivocally delineate the site of hematuria. A bleeding diathesis is an unusual cause of hematuria, and coagulation studies are not routinely obtained unless a personal or family history suggests a bleeding tendency.

A voiding cystourethrogram is only required in patients with a urinary tract infection, renal scarring, hydroureter, or pyelocaliectasis. Cystoscopy is an unnecessary and costly procedure in most pediatric patients with hematuria and carries the associated risks of anesthesia. This procedure should be reserved for evaluating the rare child with a bladder mass noted on ultrasound, urethral abnormalities caused by trauma, posterior urethral valves, or tumor. The finding of unilateral gross hematuria localized by cystoscopy is rare, but it can indicate a vascular malformation or another anatomic abnormality.

Children with persistent asymptomatic isolated hematuria and a completely normal evaluation should have their blood pressure and urine checked every 3 months until the hematuria resolves. Referral to a pediatric nephrologist should be considered for patients with persistent asymptomatic hematuria greater than 1 year in duration and is recommended for patients with nephritis (glomerulonephritis, tubulointerstitial nephritis), hypertension, renal dysfunction, urolithiasis or nephrocalcinosis, or a family history of renal disease such as polycystic kidney disease or hereditary nephritis. Renal biopsy is indicated for some children with persistent microscopic hematuria and for most children with recurrent gross hematuria associated with decreased renal function, proteinuria, or hypertension.

Chapter 559

Isolated Glomerular Diseases Associated with Recurrent Gross Hematuria

Francisco X. Flores

INTRODUCTION

Approximately 10% of children with gross hematuria have an acute or a chronic form of glomerulonephritis that may be associated with a systemic illness. The gross hematuria, which is usually characterized by brown or cola-colored urine, may be painless or associated with vague flank or abdominal pain. A presentation with gross hematuria is common within 1-2 days after the onset of an apparent viral upper respiratory tract infection in immunoglobulin (Ig) A nephropathy and typically resolves within 5 days. This relatively short period contrasts with a latency period of 7-21 days occurring between the onset of a streptococcal pharyngitis or impetiginous skin infection and the development of postinfectious acute glomerulonephritis. Gross hematuria in these circumstances can last as long as 4-6 weeks. Gross hematuria can also be seen in children with glomerular basement membrane (GBM) disorders such as hereditary nephritis (Alport syndrome [AS]) and thin GBM disease. These glomerular diseases can also manifest as microscopic hematuria and/or proteinuria without gross hematuria.

559.1 Immunoglobulin A Nephropathy (Berger Nephropathy)

Francisco X. Flores

IgA nephropathy is the most common chronic glomerular disease in children. It is characterized by a predominance of IgA within mesangial glomerular deposits in the absence of systemic disease. Its diagnosis requires a renal biopsy, which is performed when clinical features warrant confirmation of the diagnosis or characterization of the histologic severity, which might affect therapeutic decisions.

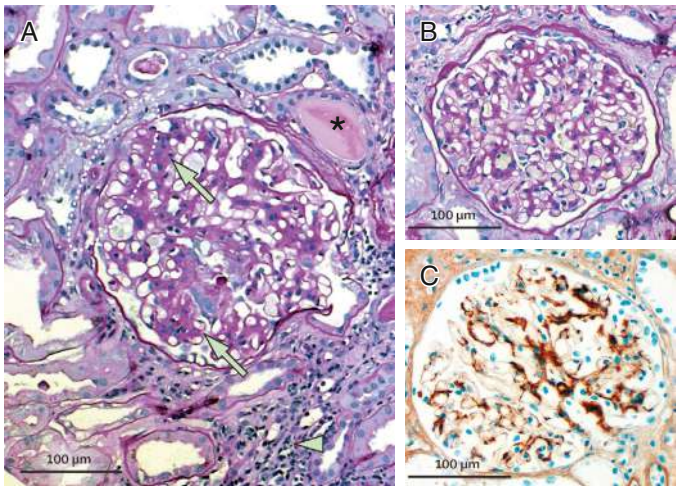

Fig. 559.1 IgA nephropathy. **A,** In IgA nephropathy, segmental areas *(arrows)* of mesangial hypercellularity and matrix expansion occur, characteristic of mesangioproliferative glomerulonephritis. Part of the glomerular tuft adheres to Bowman's capsule *(white dashed oval)*, constituting the starting point of a secondary focal segmental glomerulosclerosis lesion. Tubulointerstitial damage with leukocyte infiltrates, tubular atrophy and fibrosis *(arrowhead)*, and tubular protein casts *(asterisk)* is also present. Periodic acid–Schiff (PAS) stain. **B,** Other glomeruli in the same patient exhibit few pathologic abnormalities on light microscopy (PAS stain), but the characteristic mesangial granular IgA deposition (**C**) can be found in these glomeruli as well. *(From Floege J, Amann K. Primary glomerulonephritides. Lancet. 2016;387:2036–2046. Fig. 2.)*

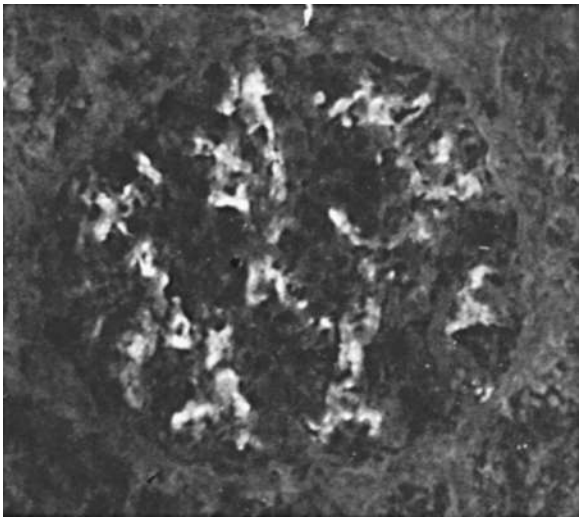

Fig. 559.2 Immunofluorescence microscopy of the biopsy specimen from a child with episodes of gross hematuria demonstrating mesangial deposition of IgA (×150).

PATHOLOGY AND PATHOLOGIC DIAGNOSIS

Focal and segmental mesangial proliferation and an increased mesangial matrix are seen in the glomerulus (Fig. 559.1). Renal histology demonstrates mesangial proliferation that may be associated with epithelial cell crescent formation and sclerosis. IgA deposits in the mesangium are often accompanied by C3 complement (Fig. 559.2).

IgA nephropathy is an immune complex disease initiated by excessive amounts of poorly galactosylated IgA_1 in the serum, causing the production of IgG and IgA autoantibodies. The abnormalities identified in the IgA system have also been observed in patients with IgA vasculitis (formerly known as Henoch-Schönlein purpura), and this finding lends support to the hypothesis that these two diseases are part of the same disease spectrum. Familial clustering of IgA nephropathy cases suggests the importance of genetic factors. Genome-wide linkage analysis suggests the linkage of IgA nephropathy to 6q22-23 in multiplex IgA nephropathy kindreds. Additional genomic studies demonstrate a high predisposition to IgA nephropathy in Southeast Asia.

CLINICAL AND LABORATORY MANIFESTATIONS

IgA nephropathy is seen more often in male than in female patients. Although there are rare cases of rapidly progressive forms of the disease, the clinical presentation of childhood IgA nephropathy is often benign compared with that of adults. IgA nephropathy is an uncommon cause of end-stage renal failure during childhood. A majority of children with IgA nephropathy in the United States and Europe present with gross hematuria, whereas microscopic hematuria and/or proteinuria is a more common presentation in Japan. Other presentations include acute nephritic syndrome, nephrotic syndrome, or a combined nephritic-nephrotic picture. Gross hematuria often occurs within 1-2 days of onset of an upper respiratory or gastrointestinal infection, in contrast with the longer latency period observed in acute postinfectious glomerulonephritis and may be associated with loin pain. Proteinuria is often <1,000 mg/24 hr in patients with asymptomatic microscopic hematuria. Mild to moderate hypertension is most often seen in patients with nephritic or nephrotic syndrome but is rarely severe enough to result in hypertensive emergencies. Normal serum levels of C3 in IgA nephropathy help to distinguish this disorder from postinfectious glomerulonephritis. Serum IgA levels have limited diagnostic value because they are elevated in only 50% of pediatric patients.

PROGNOSIS AND TREATMENT

Although IgA nephropathy does not lead to significant kidney damage in most children, progressive disease develops in 20–30% of adult patients 15-20 years after disease onset. Therefore most children with IgA nephropathy do not display progressive renal dysfunction until adulthood, prompting the need for careful long-term follow-up. Poor

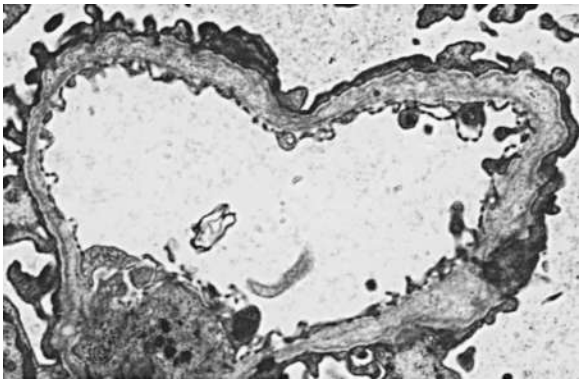

Fig. 559.3 Electron micrograph of a biopsy specimen from a child with Alport syndrome depicting thickening, thinning, splitting, and layering of the glomerular basement membrane (GBM; ×1,650). *(From Yum M, Bergstein JM. Basement membrane nephropathy. Hum Pathol. 1983;14:996–1003.)*

prognostic indicators at presentation or follow-up include persistent hypertension, diminished renal function, and significant, increasing, or persistent proteinuria. A more severe prognosis is correlated with histologic evidence of diffuse mesangial proliferation, extensive glomerular crescents, glomerulosclerosis, and diffuse tubulointerstitial changes, including inflammation and fibrosis.

The primary treatment of IgA nephropathy is appropriate blood pressure control and management of significant proteinuria. Angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists are effective in reducing proteinuria and slowing the rate of disease progression when used individually or in combination. Fish oil, which contains antiinflammatory omega-3 polyunsaturated fatty acids, may decrease the rate of disease progression in adults. If a renin-angiotensin system (RAS) blockade proves ineffective and significant proteinuria persists, then addition of immunosuppressive therapy with corticosteroids is recommended. Corticosteroids reduce proteinuria and improve renal function in those patients with a glomerular filtration rate >60 mL/min/m^2. It remains unclear if the effects of glucocorticoids deter progression to end-stage renal failure to a degree to offset their significant side effects. Additional immunosuppression with cyclophosphamide or azathioprine has not appeared to be effective. Tonsillectomy has been used as a treatment for IgA nephropathy in many countries, including Japan. Performing a tonsillectomy in the absence of significant tonsillitis in association with IgA nephropathy is currently not recommended. Targeted-release oral budesonide is approved by the FDA to reduce proteinuria in adult patients with IgA nephropathy. Patients with IgA nephropathy may undergo successful kidney transplantation. Although recurrent disease is frequent, allograft loss caused by IgA nephropathy occurs in only 15–30% of patients.

559.2 Alport Syndrome

Francisco X. Flores

Alport syndrome (AS), or hereditary nephritis, is a genetically heterogeneous disease caused by pathogenic variants in the genes coding for type IV collagen, a major component of basement membranes. These genetic alterations are associated with marked variability in the clinical presentation, natural history, and histologic abnormalities.

GENETICS

Approximately 70–80% of patients have X-linked inheritance caused by a mutation in the *COL4A5* gene encoding the α5 chain of type IV collagen. Patients with a subtype of X-linked AS and diffuse **leiomyomatosis** demonstrate a contiguous pathogenic variant within the *COL4A5* and *COL4A6* genes that encodes the α5 and α6 chains, respectively, of type IV collagen. Autosomal recessive forms of AS in approximately 5% of patients are caused by pathogenic variants in the *COL4A3* and *COL4A4* genes on chromosome 2 encoding the α3 and α4 chains, respectively, of type IV collagen. An autosomal dominant form of AS linked to the *COL4A3-COL4A4* gene locus occurs in 19–31% of cases.

Fechtner syndrome (AS with macrothrombocytopenia) and **Epstein syndrome** are autosomal dominant disorders due to pathogenic variants in *MYH9*. **Hereditary angiopathy with nephropathy, aneurysms, and muscle cramps (HANAC)** may initially resemble AS. HANAC is due to pathogenic variants in the *COL4A1* gene.

PATHOLOGY

Kidney biopsy specimens during the first decade of life will show only a few changes on light microscopy. Later, the glomeruli may develop mesangial proliferation and capillary wall thickening, leading to progressive glomerular sclerosis. Tubular atrophy, interstitial inflammation and fibrosis, and lipid-containing tubular or interstitial cells, called *foam cells,* develop as the disease progresses. Immunopathologic studies are usually nondiagnostic.

In most patients, electron microscopy reveals diffuse thickening, thinning, splitting, and layering of the glomerular and tubular basement membranes (Fig. 559.3). To confound the diagnosis, the ultrastructural analysis of the GBM in all genetic forms of AS may be completely normal, display nonspecific alterations, or demonstrate only uniform thinning.

CLINICAL MANIFESTATIONS

All patients with AS have *asymptomatic* microscopic hematuria, which may be *intermittent* in females and younger males. Single or recurrent episodes of gross hematuria commonly occurring 1-2 days after an upper respiratory infection are seen in approximately 50% of patients. Proteinuria is often seen in males but may be absent, mild, or intermittent in females. Progressive proteinuria, often exceeding 1 g/24 hours, is common by the second decade of life and can be severe enough to cause nephrotic syndrome.

Bilateral **sensorineural hearing loss,** which is never congenital, develops in 90% of hemizygous males with X-linked AS, 20% of heterozygous females with X-linked AS, and 67% of patients with autosomal recessive AS. This deficit begins in the high-frequency range but progresses to involve the hearing associated with normal speech, prompting the need for hearing aids. This progression of hearing loss seems to run parallel to the loss of renal function. **Ocular abnormalities**, which occur in 30–40% of patients with X-linked AS, include anterior lenticonus (extrusion of the central portion of the lens into the anterior chamber), macular flecks, and corneal erosions. **Leiomyomatosis** of the esophagus, tracheobronchial tree, and female genitals has been reported but is rare.

DIAGNOSIS

A combination of a thorough family history, a screening urinalysis of first-degree relatives, an audiogram, and an ophthalmologic examination are critical in making the diagnosis of AS. The presence of anterior lenticonus is pathognomonic. AS is highly likely in the patient who has hematuria and at least two of the following characteristic clinical features: macular flecks, recurrent corneal erosions, GBM thickening and thinning, or sensorineural deafness. The absence of epidermal basement membrane staining for the α5 chain of type IV collagen in male hemizygotes and discontinuous epidermal basement membrane staining in female heterozygotes on skin biopsy is pathognomonic for X-linked AS and can preclude a diagnostic renal biopsy. Genetic testing is clinically available for X-linked AS and *COL4A5* pathogenic variants. Prenatal diagnosis is available for families with members who have X-linked AS and who carry an identified pathogenic variant.

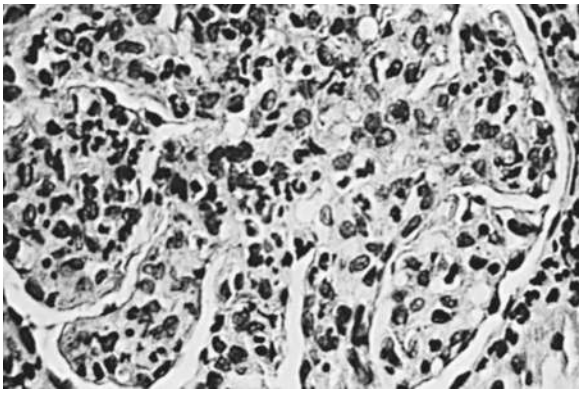

Fig. 559.4 Glomerulus from a patient with poststreptococcal glomerulonephritis appears enlarged and relatively bloodless and shows mesangial proliferation and exudation of neutrophils (×400).

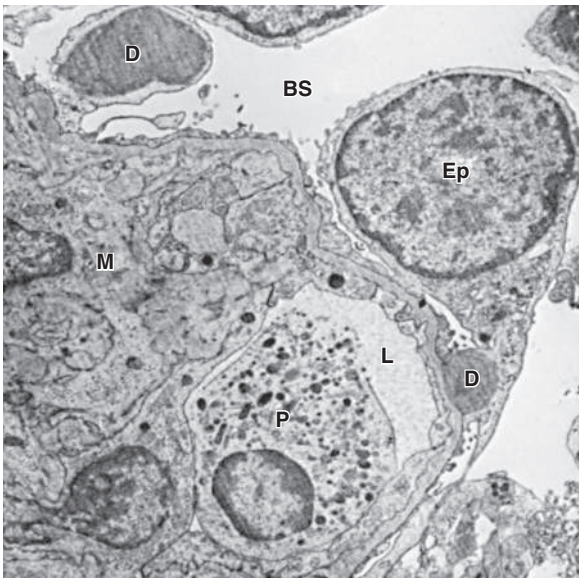

Fig. 559.5 Electron micrograph in poststreptococcal glomerulonephritis demonstrating electron-dense deposits *(D)* on the epithelial cell *(Ep)* side of the glomerular basement membrane. A polymorphonuclear leukocyte *(P)* is present within the lumen *(L)* of the capillary. BS, Bowman's space; M, mesangium.

PROGNOSIS AND TREATMENT

The risk of progressive renal dysfunction leading to end-stage kidney disease (ESKD) is highest among hemizygotes and autosomal recessive homozygotes. ESKD occurs before age 30 years in approximately 75% of hemizygotes with X-linked AS. The risk of ESKD in X-linked heterozygotes is 12% by age 40 years and 30% by age 60 years. Risk factors for progression are gross hematuria during childhood, nephrotic syndrome, and prominent GBM thickening. An intrafamilial variation in phenotypic expression results in significant differences in the age of ESKD among family members. No specific therapy is available to treat AS, although angiotensin-converting enzyme inhibitors (and possibly angiotensin II receptor inhibitors) can slow the rate of progression. Careful management of renal failure complications, such as hypertension, anemia, and electrolyte imbalance, is critical. Patients with ESKD are treated with dialysis and kidney transplantation (see Chapter 573). Approximately 5% of kidney transplantation recipients develop anti-GBM nephritis, which occurs primarily in males with X-linked AS who develop ESKD before age 30 years.

Pharmacologic treatment of proteinuria with angiotensin-converting enzyme inhibition or angiotensin II receptor blockade has proven effective in other glomerular diseases and has also shown promise in AS. Screening of heterozygote carriers for significant renal disease in later adulthood and possible treatment of significant proteinuria is also recommended.

559.3 Thin Basement Membrane Disease

Francisco X. Flores

Thin basement membrane disease (TBMD) is defined by the presence of persistent microscopic hematuria and isolated thinning of the GBM (and, occasionally, tubular basement membranes) on electron microscopy. Microscopic hematuria is often initially observed during childhood and may be intermittent. Episodic gross hematuria can also be present, particularly after a respiratory illness. Isolated hematuria in multiple family members without renal dysfunction is referred to as **benign familial hematuria.** Although most of these patients will not undergo renal biopsy, it is often presumed that the underlying pathology is TBMD. TBMD may be sporadic or transmitted as an autosomal dominant trait. Heterozygous pathogenic variants in the *COL4A3* and *COL4A4* genes, which encode the α3 and α4 chains of type IV collagen present in the GBM, result in TBMD. Rare cases of TBMD progress, and such patients develop significant proteinuria, hypertension, or renal insufficiency. Homozygous pathogenic variants in these same genes result in autosomal recessive AS. Therefore in these rare cases, the absence of a positive family history for renal insufficiency or deafness would not necessarily predict a benign outcome. Consequently, monitoring patients with benign familial hematuria for progressive proteinuria, hypertension, or renal dysfunction is important throughout childhood and young adulthood.

559.4 Acute Poststreptococcal Glomerulonephritis

Francisco X. Flores

Group A β-hemolytic streptococcal infections are common in children and can lead to the postinfectious complication of acute GN. Acute poststreptococcal glomerulonephritis (APSGN) is a classic example of the **acute nephritic syndrome** characterized by the sudden onset of gross hematuria, edema, hypertension, and renal dysfunction. It is one of the most common glomerular causes of gross hematuria in children and is a major cause of morbidity in group A β-hemolytic streptococcal infections.

ETIOLOGY AND EPIDEMIOLOGY

APSGN follows infection of the throat or skin by certain *nephritogenic* strains of group A β-hemolytic streptococci. Epidemics and clusters of household (camps, military) cases occur throughout the world, and 97% of cases occur in less-developed countries. The overall incidence has decreased in industrialized nations, presumably as a result of improved hygienic conditions and the near eradication of streptococcal pyoderma. Poststreptococcal GN commonly follows streptococcal pharyngitis during cold-weather months and streptococcal skin infections or pyoderma during warm-weather months. Although epidemics of nephritis have been described in association with throat (serotypes M1, M4, M25, and some strains of M12) and skin (serotype M49) infections, this disease is most commonly sporadic.

PATHOLOGY

Glomeruli appear enlarged and relatively bloodless and show a diffuse mesangial cell proliferation, with an increase in mesangial matrix (Fig. 559.4). Polymorphonuclear leukocyte infiltration is common in glomeruli during the early stage of the disease. Crescents and interstitial inflammation may be seen in severe cases, but these changes are not specific for poststreptococcal GN. Immunofluorescence microscopy reveals a pattern of "lumpy-bumpy" deposits of immunoglobulin and complement on the glomerular basement membrane and in the mesangium. On electron microscopy, electron-dense deposits, or "humps," are observed on the epithelial side of the glomerular basement membrane (Fig. 559.5).

PATHOGENESIS

Morphologic studies and a depression in the serum complement (C3) level provide strong evidence that ASPGN is mediated by immune complexes. Circulating immune complex formation with streptococcal antigens and subsequent glomerular deposition is thought less likely to be a pathogenic mechanism. Molecular mimicry, whereby circulating antibodies elicited by streptococcal antigens react with normal glomerular antigens, in situ immune complex formation of antistreptococcal

antibodies with glomerular deposited antigen, and complement activation by directly deposited streptococcal antigens, continues to be considered as a probable mechanism of immunologic injury.

Group A streptococci possesses M proteins, and nephritogenic strains are related to the M protein serotype. The search for the precise nephritogenic antigen(s) that cause disease suggests that streptococcal pyogenic exotoxin (SPE) B and nephritis-associated streptococcal plasmin receptor are promising candidates. Both have been identified in glomeruli of affected patients, and in one study, circulating antibodies to SPE B were found in all patients. Cross reactivity of SPE B and other M proteins with various components of the glomerular basement membrane also give evidence for molecular mimicry.

CLINICAL MANIFESTATIONS

Poststreptococcal GN is most common in children ages 5-12 years and uncommon before the age of 3 years. The typical patient develops an acute nephritic syndrome 1-2 weeks after an antecedent streptococcal pharyngitis or 3-6 weeks after a streptococcal pyoderma. The history of a specific infection may be absent because symptoms may have been mild or have resolved without patients receiving specific treatment or seeking the care of a medical provider.

The severity of kidney involvement varies from asymptomatic microscopic hematuria with normal renal function to gross hematuria with acute renal failure. Depending on the severity of renal involvement, patients can develop various degrees of edema, hypertension, and oliguria. Patients are at risk for developing encephalopathy and/or heart failure secondary to hypertension or hypervolemia. Hypertensive encephalopathy must be considered in patients with blurred vision, severe headaches, altered mental status, or new seizures. The effects of acute hypertension not only depend on the severity of hypertension but also the absolute change in comparison with the patient's baseline blood pressure and the rate at which it has risen. Respiratory distress, orthopnea, and cough may be symptoms of pulmonary edema and heart failure. Peripheral edema typically results from salt and water retention and is common; nephrotic syndrome develops in a minority (<5%) of childhood cases. Atypical presentations of APSGN include those with subclinical disease and those with severe symptoms but an absence of initial urinary abnormalities; in individuals who present with a purpuric rash, it is difficult to distinguish APSGN from IgA vasculitis without a renal biopsy.

The acute phase generally resolves within 6-8 weeks. Although urinary protein excretion and hypertension usually normalize by 4-6 weeks after onset, persistent microscopic hematuria can persist for 1-2 years after the initial presentation.

DIAGNOSIS

Urinalysis demonstrates red blood cells, often in association with red blood cell casts, proteinuria, and polymorphonuclear leukocytes. A mild normochromic anemia may be present from hemodilution and low-grade hemolysis. The serum C3 level is significantly reduced in >90% of patients in the acute phase and returns to normal 8-10 weeks

after the onset. Although serum CH_{50} is commonly depressed, *C4 is most often normal in APSGN,* or only mildly depressed.

Confirmation of the diagnosis requires clear evidence of a prior streptococcal infection. A positive throat culture report might support the diagnosis or might represent the carrier state. A rising antibody titer to streptococcal antigen(s) confirms a recent streptococcal infection. The antistreptolysin O titer is commonly elevated after a pharyngeal infection but rarely increases after streptococcal skin infections. The best single antibody titer to document cutaneous streptococcal infection is the antideoxyribonuclease B level. If available, a positive Streptozyme screen (which measures multiple antibodies to different streptococcal antigens) is a valuable diagnostic tool. Serologic evidence for streptococcal infections is more sensitive than the history of recent infections and far more sensitive than positive bacterial cultures obtained at the time of onset of acute nephritis.

MRI of the brain is indicated in patients with severe neurologic symptoms and can demonstrate **posterior reversible encephalopathy syndrome** in the parietooccipital areas on T2 weighted images. Chest x-ray is indicated in those with signs of heart failure or respiratory distress, or physical exam findings of a heart gallop, decreased breath sounds, rales, or hypoxemia.

The clinical diagnosis of poststreptococcal GN is quite likely in a child presenting with acute nephritic syndrome, evidence of recent streptococcal infection, and a low C3 level. However, it is important to consider other diagnoses such as systemic lupus erythematosus, endocarditis, membranoproliferative GN, and an acute exacerbation of chronic GN. Renal biopsy should be considered only in the presence of acute renal failure, nephrotic syndrome, absence of evidence of streptococcal infection, or normal complement levels. In addition, renal biopsy is considered when hematuria and proteinuria, diminished renal function, and/or a low C3 level persist more than 2 months after onset. Persistent hypocomplementemia can indicate a chronic form of postinfectious GN or another disease such as membranoproliferative GN.

The differential diagnosis of poststreptococcal GN includes many of the causes of hematuria listed in Table 559.1 and Table 558.2, and algorithms to help with the diagnosis are presented in Figs. 559.6 and 559.7. Acute postinfectious GN can also follow other infections with coagulase-positive and coagulase-negative staphylococci, *Streptococcus pneumoniae,* and gram-negative bacteria. The clinical course, histopathology, and laboratory features are similar to those described for APSGN. For some, the terms APSGN and acute postinfectious GN are used synonymously. Acute GN can occur after certain fungal, rickettsial, protozoan, parasitic, or viral diseases. Among the latter, influenza and parvovirus infections are particularly notable.

COMPLICATIONS

Acute complications result from hypertension and acute renal dysfunction. Hypertension is seen in 60% of patients and is associated with hypertensive encephalopathy in 10% of cases. Although the

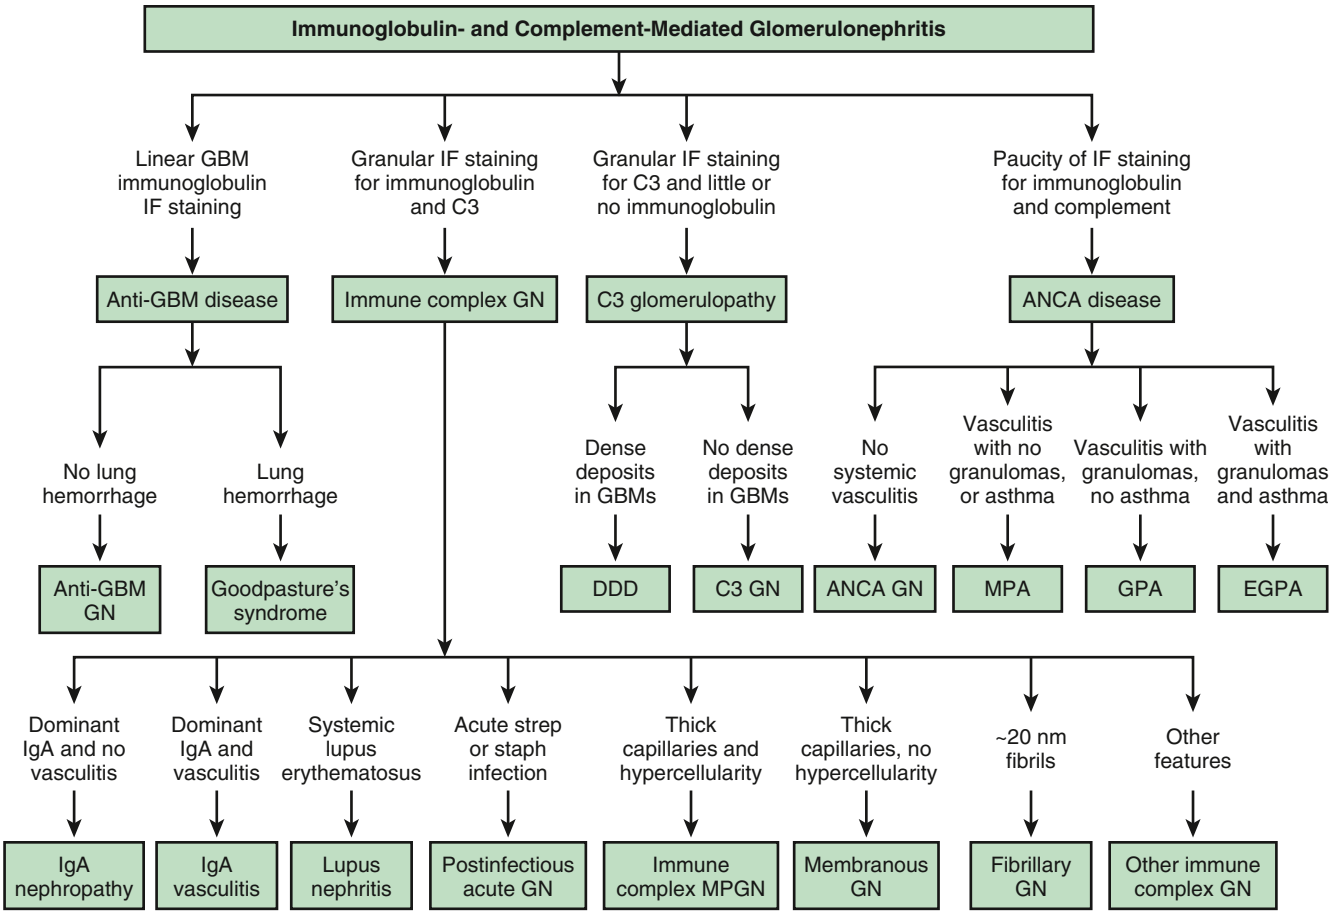

Fig. 559.7 Algorithm for diagnostic classification of glomerulonephritis *(GN)* that is known or suspected of being mediated by antibodies and complement. Note that the integration of light microscopy, immunofluorescence *(IF)* microscopy, electron microscopy, laboratory data, and clinical manifestations is required to precisely diagnose GN. ANCA, Anti–neutrophil cytoplasmic autoantibody; DDD, dense deposit disease; EGPA, eosinophilic granulomatosis with polyangiitis; GBM, glomerular basement membrane; GPA, granulomatosis with polyangiitis; IgA, immunoglobulin A; MPA, microscopic polyangiitis; MPGN, membranoproliferative glomerulonephritis. *(From Saha MK, Pendergraft WF III, Jennette JC, et al. Primary glomerular disease. In Yu AS, BChir GM, Chertow GM, et al., eds. Brenner & Rector's The Kidney, 11th ed. Philadelphia: Elsevier; 2020: Fig. 31-35.)*

neurologic sequelae are often reversible with appropriate management, severe prolonged hypertension can lead to intracranial bleeding. Other potential complications include heart failure, hyperkalemia, hyperphosphatemia, hypocalcemia, acidosis, seizures, and uremia. Acute renal failure can require treatment with dialysis.

PREVENTION

Early systemic antibiotic therapy for streptococcal throat and skin infections does not eliminate the risk of GN. Family members of patients with acute GN, especially young children, should be considered at risk and be cultured for group A β-hemolytic streptococci and treated if positive. Family pets, particularly dogs, have also been reported as carriers.

TREATMENT

Management is directed at treating the acute effects of renal dysfunction and hypertension (see Chapter 572.1). Although a 10-day course of systemic antibiotic therapy with penicillin is recommended to limit the spread of the nephritogenic organisms, antibiotic therapy does not affect the natural history of APSGN. This is unlike the GN seen in the context of ongoing or chronic infections, as noted in Chapter 560.1. Sodium and fluid restriction, diuretics, and pharmacotherapy with calcium channel antagonists, vasodilators, or angiotensin-converting enzyme inhibitors are standard therapies used to treat hypertension.

PROGNOSIS

Complete recovery occurs in >95% of children with APSGN. Recurrences are extremely rare. Mortality in the acute stage can be avoided by appropriate management of acute renal failure, cardiac failure, and hypertension. Infrequently, the acute phase is severe and leads to glomerulosclerosis and chronic renal disease in <2% of affected children.

559.5 Membranous Nephropathy

Francisco X. Flores

Membranous nephropathy (MN), among the most common causes of nephrotic syndrome in adults, is a rare cause of nephrotic syndrome in children. MN is classified as the primary, idiopathic form, where there is isolated renal disease, or secondary MN, where nephropathy is associated with other identifiable systemic diseases or medications. In children, *secondary* MN is far more common than primary, idiopathic MN. The most common etiologies of secondary

MN are systemic lupus erythematosus or chronic infections. Among the latter, chronic hepatitis B infection and congenital syphilis are the best characterized and recognized causes of MN. Other chronic infections have also been associated with MN, including malaria, which is likely the most common cause of nephrotic syndrome worldwide. Certain medications, such as penicillamine and gold, or chronic factor replacement in patients with hemophilia, can also cause MN. Rare causes associated with MN include tumors, such as neuroblastoma, or other idiopathic systemic diseases. Identification of secondary causes of MN is critical, because removal of the offending agent or treatment of the causative disease often leads to resolution of the associated nephropathy and improves patient outcome.

PATHOLOGY

Glomeruli have diffuse thickening of the glomerular basement membrane (GBM), without significant cell proliferative changes. Immunofluorescence and electron microscopy typically demonstrate granular deposits of IgG and C3 located on the epithelial side of the GBM. The GBM thickening presumably results from the production of membrane-like material in response to deposition of immune complexes (Fig. 559.8).

PATHOGENESIS

MN is believed to be caused by in situ immune complex formation. Therefore antigens from the infectious agents or medications associated with secondary MN directly contribute to the pathogenesis of the renal disease. The causative antigen in idiopathic MN is not established, but the podocyte phospholipase A2 receptor (PLA2R), present on normal podocytes, may be a target antigen in idiopathic MN. Antigen from this receptor is found in immune deposits extracted from glomeruli in patients with idiopathic MN. The majority of idiopathic MN patients have circulating antibody against this podocyte membrane antigen, as well as against several podocyte cytoplasmic antigens. Childhood MN may be associated with anticationic bovine serum albumin antibodies. In addition, neutral endopeptidase antigen may be the antigen in neonatal onset MN.

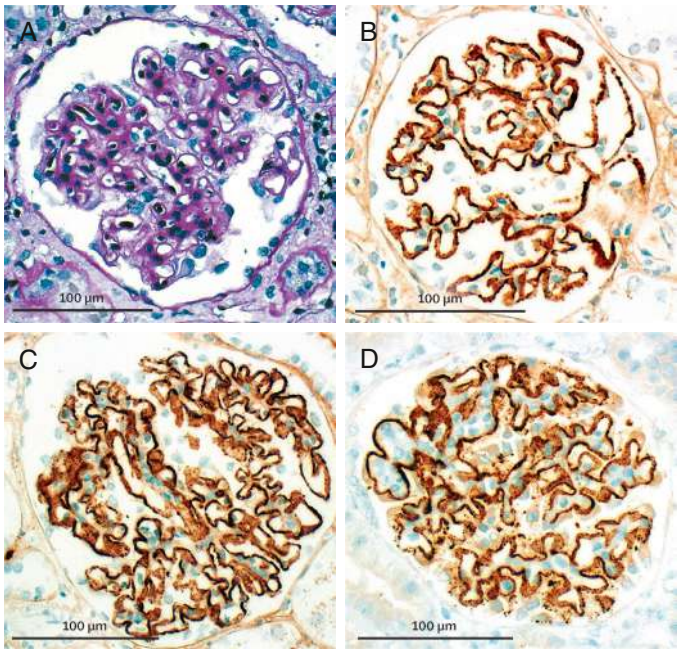

Fig. 559.8 Membranous glomerulonephritis. The periodic acid–Schiff (PAS) stain (A) shows slightly thickened glomerular basement membranes and prominent podocytes. On immunohistology, granular deposits of IgG (B) and C3c (C) can be found along the glomerular basement membrane, and pronounced de novo expression of phospholipase A2 receptor (PLA2R) (D) is present on the podocytes. *(From Floege J, Amann K. Primary glomerulonephritides. Lancet. 2016;387:2036–2046. Fig. 3.)*

CLINICAL MANIFESTATIONS

In children, MN is most common in the second decade of life, but it can occur at any age, including infancy. The disease usually manifests as nephrotic syndrome and accounts for 2–6% of all cases of childhood nephrotic syndrome. Most patients also have microscopic hematuria and only rarely present with gross hematuria. Approximately 20–30% of children have hypertension at presentation. A subset of patients with MN present with a major venous thrombosis, commonly **renal vein thrombosis**. This complication of nephrotic syndrome (see Chapter 567) is particularly common in patients with MN. Serum C3 and CH_{50} levels are normal, except in secondary forms such as in systemic lupus erythematosus, where levels may be depressed (see Fig. 559.6).

DIAGNOSIS

MN might be suspected on clinical grounds, particularly in the setting of known risk factors for secondary forms of the disease. In the past, the diagnosis could be established only by renal biopsy, but testing for PLA2R antibodies has allowed a noninvasive way to make the diagnosis, to differentiate primary vs secondary MN, and to guide treatment decisions. Common indications for renal biopsy leading to the diagnosis of MN include presentation with nephrotic syndrome in a child >10 years old or unexplained persistent hematuria with significant proteinuria.

PROGNOSIS AND TREATMENT

The clinical course of idiopathic membranous glomerulopathy is variable. Children presenting with asymptomatic, low-grade proteinuria can enter remission spontaneously. Retrospective reports of children 1-15 years after diagnosis treated with a variety of regimens indicate that 20% progress to chronic renal failure, 40% continue with active disease, and 40% achieve complete remission. Poor prognostic factors include male gender, high levels of proteinuria, reduced kidney function, and findings of glomerulosclerosis and tubular damage in the renal biopsy. Although no controlled trials have been performed in children, immunosuppressive therapy with an extended course of prednisone can be effective in promoting complete resolution of symptoms. The addition of chlorambucil or cyclophosphamide provides further benefit to those not responding to steroids alone. Rituximab has shown significant promise in adults and has been proposed by some as the first-line treatment but has yet to be studied in a randomized controlled trial in any age-group. For those unresponsive to immunosuppression, or with mild clinical features, proteinuria can be reduced with angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers.

559.6 Membranoproliferative Glomerulonephritis

Francisco X. Flores

Membranoproliferative glomerulonephritis (MPGN), also known as **mesangiocapillary glomerulonephritis**, most commonly occurs in older children or young adults. MPGN can be classified into *primary* (idiopathic) and *secondary* forms of glomerular disease. Secondary forms of MPGN are most commonly associated with subacute and chronic infection, including hepatitis B and C, syphilis, endocarditis, and infected shunts, especially ventriculoatrial

shunts (shunt nephritis) (Table 559.2). MPGN can also be one of the glomerular lesions seen in lupus nephritis (see Chapter 560.2).

PATHOLOGY

Primary MPGN is defined by the histologic pattern of glomeruli as seen by light, immunofluorescence, and electron microscopy. Two subtypes have been defined on histologic criteria and are associated with different clinical phenotypes. **Type I MPGN** is most common. Glomeruli have an accentuated lobular pattern from diffuse mesangial expansion, endocapillary proliferation, and an increase in mesangial cells and matrix. The glomerular capillary walls are thickened, often with splitting from interposition of the mesangium. Crescents, if present, indicate a poor prognosis. Immunofluorescence microscopy reveals C3 and lesser amounts of immunoglobulin in the mesangium and along the peripheral capillary walls in a lobular pattern. Electron microscopy confirms numerous deposits in the mesangial and subendothelial regions.

Far less common is **type II MPGN,** also called **dense deposit disease,** which has similar light microscopic findings as type I MPGN. Differentiation from type I disease is by immunofluorescence and electron microscopy. In type II disease, C3 immunofluorescence typically is prominent, without concomitant immunoglobulin. By electron microscopy, the lamina densa in the GBM undergoes a very dense transformation, without evident immune complex–type deposits.

C3 glomerulonephritis (C3GN) is a related but separate diagnostic category. By light and electron microscopy C3GN usually has features indistinguishable from classic MPGN. Immunofluorescence studies distinguish between the two, with C3GN having only C3 deposition and MPGN having both C3 and immunoglobulin fluorescence.

PATHOGENESIS

Although the histology of type I MPGN produced by primary and secondary forms is indistinguishable, it appears that type I disease occurs when circulating immune complexes become trapped in the glomerular subendothelial space, which then causes injury, resulting in the characteristic proliferative response and mesangial expansion. Further evidence confirming this pathway to glomerular injury is the finding of complement activation through the classic pathway in as many as 50% of affected patients.

Type II MPGN appears *not* to be mediated by immune complexes. The pathogenesis of the disease is not known, but the characteristic finding of severely depressed serum complement levels suggests that deranged complement regulation might play a major role in the disease. A typical finding is markedly depressed serum C3 complement levels, with normal levels of other complement components. In many patients with type II MPGN, **C3 nephritic factor** (ant–C3 convertase antibody) is present. This factor activates the alternative complement pathway. In unusual cases, patients with type II MPGN demonstrate an associated systemic disease called **partial lipodystrophy,** where there is diffuse loss of adipose tissue and decreased complement in the presence of C3 nephritic factor. The correlation between the presence of C3 nephritic factor, complement levels, and disease presence or severity is not strong, indicating that the complement abnormalities alone are not sufficient to cause the disease.

Type II MPGN (dense deposit disease) is considered part of the broader spectrum of C3GN. The latter, as defined previously pathologically, appears to be caused by primary dysregulation of the alternative or terminal cascade complement pathways.

CLINICAL MANIFESTATIONS

MPGN is most common in the second decade of life, equally affects males and females, and is more common in White individuals. Systemic features may provide clues to which type of MPGN may be present, but the two histologic types of idiopathic MPGN are indistinguishable in terms of their renal manifestations. Patients present in equal proportions with nephrotic syndrome, acute nephritic syndrome (hematuria, hypertension, and some level of renal dysfunction), or persistent asymptomatic microscopic hematuria and proteinuria. Serum C3 complement levels are low in the majority of cases (see Fig. 559.6).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes all forms of acute and chronic glomerulonephritis, including idiopathic and secondary forms, along with postinfectious glomerulonephritis. Postinfectious glomerulonephritis, far more common than MPGN, usually does not have nephrotic features but typically has hematuria, hypertension, renal dysfunction, and transiently low C3 complement, all features that may be seen with MPGN or C3GN. In contrast to MPGN and C3GN, where C3 levels usually remain persistently low, C3 returns to normal within 8-10 weeks after the onset of postinfectious glomerulonephritis (see Chapter 559.4). The diagnosis of MPGN is made by renal biopsy. Indications for biopsy include nephrotic syndrome in an older child, significant proteinuria with microscopic hematuria, and hypocomplementemia lasting >2 months in a child with acute nephritis. If C3 but no immunoglobulin deposition is found in glomeruli with MPGN, genetic testing and functional assays to define defects of complement cascade regulation should be pursued.

PROGNOSIS AND TREATMENT

It is important to determine whether MPGN is idiopathic or secondary to a systemic disease, particularly lupus or chronic infection, because treatment of the causative disease can result in resolution of the MPGN. Untreated, idiopathic MPGN, regardless of type, has a poor prognosis. By 10 years following onset, 50% of patients with MPGN have progressed to end-stage renal disease. By 20 years following onset, up to 90% have lost renal function. Those with nephrotic syndrome and hypertension at the time of presentation progress to renal failure more rapidly. No definitive therapy exists, but several reports, including a randomized controlled trial, indicate that extended courses of alternate-day prednisone (for years) provide benefit. Some patients treated with steroids enter a complete clinical remission of their disease, but many have ongoing disease activity. Nevertheless, an extended course of prednisone is associated with significant preservation of renal function when compared with patients receiving no such treatment.

The prognosis of C3GN, separate from dense deposit disease (considered a part of C3GN by some) and other forms of classically defined MPGN, is as yet hard to define because reports of the outcome of such patients previously had been grouped in studies of all forms of MPGN (types I and II, and even a poorly characterized type III form not considered earlier). The apparent pathophysiology of C3GN promises that treatments targeting the interruption of complement activation pathways, such as complement factor H replacement or shutting down the terminal complement cascade by blocking C5 activation with eculizumab (anti–C5 antibody), could be beneficial in preventing the progression of renal disease.

559.7 Rapidly Progressive (Crescentic) Glomerulonephritis

Francisco X. Flores

Rapidly progressive describes the clinical course of several forms of glomerulonephritis (GN) that have the unifying feature of a histopathologic finding of crescents in the majority of glomeruli (Fig. 559.9). The terms *rapidly progressive glomerulonephritis* (RPGN) and *crescentic glomerulonephritis* (CGN) are synonymous. The natural history of most forms of CGN is the rapid loss of the renal function.

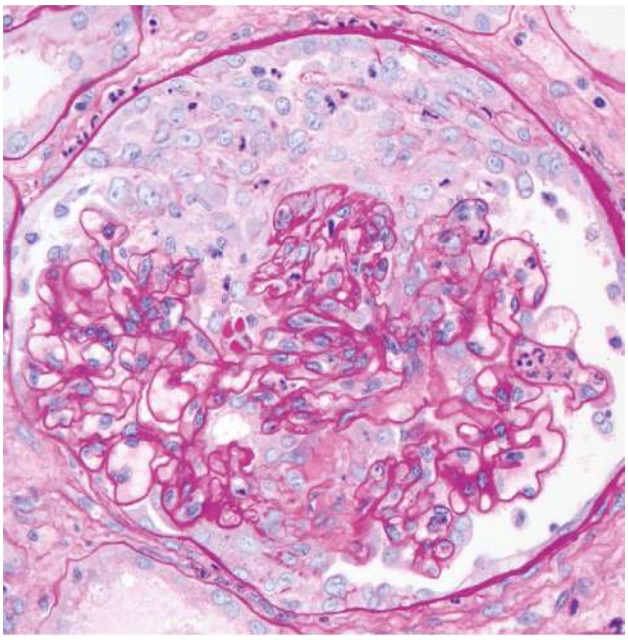

Fig. 559.9 Light micrograph showing a cellular crescent in Bowman's space. The underlying glomerular tuft is delineated by the glomerular basement membranes. (Periodic acid-Schiff stain, x500.) *(From Saha MK, Pendergraft WF, Jennette JC, Falk RJ. Primary glomerular dsease. In Yu AS, Chertow, G, et al, eds. Brenner and Rector's The Kidney, 11th edition. Philadelphia: Elsevier; 2020: Fig. 31.34.)*

CLASSIFICATION

CGN can be a severe manifestation of essentially every defined primary and secondary GN, but particular forms of GN are more likely to present as, or evolve into, RPGN (Table 559.3). If no underlying cause is identified by systemic features, serologic testing, or histologic examination, the disease is classified as idiopathic CGN. The incidence of specific etiologies of CGN in children varies widely; certain common themes are shared in all such reports. Patients with systemic vasculitis appear to be particularly prone to develop CGN. Patients with IgA vasculitis, antineutrophil cytoplasmic antibody (ANCA)-mediated GN (microscopic polyangiitis and granulomatosis with polyangiitis), and systemic lupus erythematosus account for the majority of patients with CGN. Postinfectious GN or endocarditis rarely progresses to CGN, but because it is the most common form of GN in childhood, it accounts for a significant percentage of patients with CGN in most reports. MPGN and idiopathic disease make up most of the remaining cases of CGN. IgA nephropathy, a common GN, only rarely is rapidly progressive. Goodpasture disease often has rapidly progressive GN as a component of the syndrome, but its rarity in childhood results in only a small percentage of children with CGN.

PATHOLOGY AND PATHOGENESIS

The hallmark of CGN is the histopathologic finding of epithelial crescents involving 50% or more glomeruli (see Fig. 559.9). Crescent formation, through proliferation of parietal epithelial cells in Bowman's space, may be the final pathway of any severe inflammatory glomerular injury. Podocytes and renal progenitor cells are involved in the pathogenesis of CGN. Fibrous crescents, in which proliferative cellular crescents are replaced by collagen, are a late finding. The immunofluorescence findings, as well as the pattern of any deposits by electron microscopy, can delineate the underlying glomerulopathy in CGN secondary to lupus, IgA vasculitis nephritis, MPGN, postinfectious GN, IgA nephropathy, or Goodpasture disease. Rare or absent findings by immunofluorescence and electron microscopy typify pauciimmune GN (granulomatosis with polyangiitis and microscopic polyangiitis) and idiopathic crescentic GN.

Table 559.3 Classification of Rapidly Progressive (Crescentic) Glomerulonephritis

PRIMARY
Anti–glomerular basement membrane antibody disease
Goodpasture syndrome (with pulmonary disease)
Immune complex mediated
Pauci-immune (usually antineutrophil cytoplasmic antibody positive)
SECONDARY
Membranoproliferative glomerulonephritis
Immunoglobulin A nephropathy, IgA vasculitis
Poststreptococcal glomerulonephritis
Systemic lupus erythematosus

CLINICAL MANIFESTATIONS

Most children present with acute nephritis (hematuria, various degrees of renal dysfunction, and hypertension) and usually have concomitant proteinuria, often with nephrotic syndrome. Occasional patients present late in the course of disease with oliguric renal failure. Extrarenal manifestations, such as pulmonary involvement, joint symptoms, or skin lesions, can help lead to the diagnosis of the underlying systemic disease causing the CGN.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of CGN is made by obtaining a kidney biopsy. Delineation of the underlying etiology is reached by a combination of additional biopsy findings (described earlier), extrarenal symptoms and signs, and serologic testing, including the evaluation of antinuclear and anti-DS DNA antibodies, serum complement levels, anti-GBM antibodies, and ANCA titers. If the patient has no extrarenal manifestations and a negative serologic evaluation, and if the biopsy has no immune or electron microscopy deposits, the diagnosis is idiopathic, rapidly progressive CGN.

PROGNOSIS AND TREATMENT

The natural course of CGN is far more severe in the setting of other etiologies, including the idiopathic category, and progression to end-stage kidney disease within weeks to months from the onset is common. Having a majority of fibrous crescents on a renal biopsy portends a poor prognosis, because the disease usually has progressed to irreversible damage. Although there are few controlled data, the consensus of most nephrologists is that the combination of high-dose corticosteroids and cyclophosphamide may be effective in preventing progressive renal failure in patients with systemic lupus erythematosus, IgA vasculitis nephritis, granulomatosis with polyangiitis, and IgA nephropathy if given early in the course when acute cellular crescents predominate. Although such therapy can also be effective in the other diseases causing RPGN, renal outcomes in those settings are less favorable. Progression to end-stage kidney disease often occurs despite aggressive immunosuppressive therapy. In combination with immunosuppression, plasmapheresis has been reported to benefit patients with Goodpasture disease. Plasmapheresis may also benefit patients with ANCA-associated CGN, in particular those with the most severe renal dysfunction and pulmonary hemorrhage at presentation. The possible benefits of plasmapheresis in other forms of RPGN are unclear.

Chapter 560

Multisystem Disease Associated with Hematuria

Prasad Devarajan

Gross or microscopic hematuria may be associated with several multisystem disorders, including chronic systemic infections, systemic lupus erythematosus (SLE), IgA vasculitis nephritis (formerly known as Henoch-Schönlein purpura nephritis), Goodpasture disease, hemolytic uremic syndrome (HUS), nephrotoxicity, and renal cortical necrosis. In most of these conditions, the presenting complaints pertain primarily to the underlying systemic illness, and hematuria often heralds or portends renal involvement (see Chapters 560.1-560.8).

560.1 Chronic Infections

Prasad Devarajan

Glomerulonephritis (GN) with hematuria is a recognized complication of various chronic infections. Examples include bacterial endocarditis caused by viridans group streptococci and other organisms, and ventriculoatrial shunts infected with *Staphylococcus epidermidis*. Other infections, observed less commonly in children than in adults, include those due to HIV, hepatitis B virus (HBV), or hepatitis C virus; syphilis; and renal candidiasis. Parasitic infections associated with glomerular disease include malaria, schistosomiasis, leishmaniasis, filariasis, hydatid disease, trypanosomiasis, and toxoplasmosis. In each condition, the infecting organism has a low virulence, and the host is chronically infected with a microbial antigen. In the presence of high levels of circulating antigen, the host's antibody response leads to the formation of **immune complexes** that are deposited in the kidneys and initiate glomerular inflammation. Foreign antigens can also stimulate an autoimmune response through the production of antibodies that cross react with such antigens incorrectly recognized as glomerular structural components.

The kidney histopathology in GN due to chronic infections can resemble poststreptococcal GN, membranous GN, or membranoproliferative GN. The clinical manifestations are generally those of an acute nephritic syndrome (active urinary sediment with hematuria, proteinuria, and granular and/or red blood cell (RBC) casts, edema, hypertension) or nephrotic syndrome (proteinuria, edema, hypoalbuminemia). *The serum C3 and CH_{50} complement levels are often decreased due to activation of the classic complement pathway.*

In **HIV-associated nephropathy,** direct viral infection of nephrons occurs because renal cells express a variety of lymphocyte chemokine receptors that are essential for and facilitate viral invasion. The kidney expression of HIV infection is quite variable and includes an immune complex injury and a direct cytopathic effect. The classic histopathologic lesion of HIV-associated nephropathy is *focal segmental glomerulosclerosis.* In the era of antiretroviral therapy, the decline in mortality from HIV disease has led to the increased recognition of renal disorders as an important long-term complication in children who survive perinatal HIV infection.

HBV infection is a global public health problem. It is estimated that there are more than 350 million HBV carriers in the world.

Prompt eradication of any infection before severe glomerular injury occurs usually results in resolution of the GN associated with chronic infections. Progression to end-stage kidney disease has been described but is uncommon. Spontaneous resolution of hepatitis B infection is common in children (30–50%) and results in remission of the glomerulopathy. Widespread use of hepatitis B vaccines has decreased the incidence of HBV-related renal diseases. Also, with the new availability of direct-acting antivirals for hepatitis C virus, a sustained virologic response, successful remission, and even regression of glomerular lesions can be achieved if treatment is initiated at an early stage. Similarly, in patients with HIV-associated nephropathy, several clinical studies have demonstrated the overall improvement in kidney function with early initiation of antiretroviral therapy. Particularly in children, modern antiretroviral therapy has improved the outcome and decreased the prevalence of childhood HIV-associated nephropathy.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

560.2 Glomerulonephritis Associated with Systemic Lupus Erythematosus

Prasad Devarajan

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease characterized by fever, weight loss, dermatitis, hematologic abnormalities, arthritis, and involvement of the heart, lungs, central nervous system (CNS), and kidneys (see Chapter 199). Although SLE is less frequent in children, kidney involvement (lupus nephritis) is more common and is more severe than that seen in adults. Lupus nephritis is the most important cause of morbidity and mortality in SLE.

PATHOGENESIS AND PATHOLOGY

The hallmark of SLE is the abnormal production of pathogenic autoantibodies to self-antigens such as DNA (anti–double stranded DNA antibody [anti-dsDNA]) and nuclear proteins (antinuclear antibodies [ANA]), driven by immune dysregulation and loss of self-tolerance. The antigen-antibody complexes accumulate in small vessels of many organs, where they incite a local inflammatory response by activating complement pathways and by binding to Fc receptors. Lupus nephritis is a result of the deposition of circulating immune complexes, as well as the direct binding of autoantibodies to glomerular components with resultant complement stimulation.

Kidney biopsy and evaluation of kidney histopathology remain the gold standard for establishing the diagnosis of SLE nephritis and determining specific therapeutic regimens. The World Health Organization (WHO) classification of lupus nephritis has been employed in clinical trials and is based on a combination of features, including light microscopy, immunofluorescence, and electron microscopy. In patients with **WHO class I nephritis** (minimal mesangial lupus nephritis), no histologic abnormalities are detected on light microscopy, but mesangial immune deposits are present on immunofluorescence or electron microscopy. In **WHO class II nephritis** (mesangial proliferative nephritis), light microscopy shows both mesangial hypercellularity and an increased matrix, along with mesangial deposits containing immunoglobulin and complement.

WHO class III nephritis and **WHO class IV nephritis** are interrelated lesions characterized by both mesangial and endocapillary lesions. Class III nephritis is defined by <50% glomeruli with involvement, and class IV has ≥50% glomerular involvement. Immune deposits are present in both the mesangium and subendothelial areas. A **subclassification** scheme helps grade the severity of the proliferative lesion based on whether the glomerular lesions are segmental (<50% glomerular tuft involved) or global (≥50% glomerular tuft involved). The WHO classification scheme also delineates whether there is a predominance of chronic disease versus active disease. Chronic injury results in glomerular sclerosis and is felt to be the consequence of significant proliferative disease seen in classes III and IV. Other signs of active disease include capillary walls that are thickened secondary to subendothelial deposits (creating the characteristic wire-loop lesion), necrosis, and crescent formation. WHO class IV nephritis is associated with poorer outcomes but can be successfully treated with aggressive immunosuppressive therapy.

WHO class V nephritis (membranous lupus nephritis) is less commonly seen as an isolated lesion and resembles idiopathic membranous nephropathy with subepithelial immune deposits. This lesion is often seen in combination with class III or IV proliferative nephritis, and if the membranous lesion is present in >50% glomeruli, both classes are noted in the designation. This classification scheme also identifies cases with combinations of mixed classes III, IV, and V lesions, directing appropriate treatment for such patients.

Another classification scheme proposed by both the International Society of Nephrology and the Renal Pathology Society differs mainly in its subclassification of class IV into diffuse global and diffuse segmental lesions (Table 560.1). Although this classification is widely preferred, it should be noted that most available results of clinical trials are based on the WHO classification.

Transformation of the histologic lesions of lupus nephritis from one class to another is common. This is more likely to occur among inadequately treated patients and usually results in progression to a more severe histologic lesion.

Immunofluorescence microscopy is an essential component of the pathologic evaluation. Lupus nephritis is characterized by the granular deposition of all immunoglobulin isotypes (IgG, IgM, and IgA—also referred to as "full house"), as well as complements (C3, C4, and C1q) in the glomerular mesangium and capillary walls. This pattern of extensive glomerular immune deposition is referred to as full-house immune staining and is diagnostic of lupus nephritis.

CLINICAL MANIFESTATIONS

Most children with SLE are adolescent females (female-to-male ratio of 5:1) and present with extrarenal manifestations. The relative risk of SLE is three- to sevenfold higher in Asian, Black, and Hispanic females compared with White females. Lupus nephritis in Black and Hispanic populations also typically displays an increased severity and worse prognosis. Lupus nephritis affects 80% of pediatric patients with SLE, and although it commonly presents within the first year of diagnosis, may occur at any time during the disease. The clinical findings in patients having milder forms of lupus nephritis (all class I and II, some class III) include hematuria, normal renal function, and proteinuria <1 g/24 hr. Some patients with class III and all patients with class IV nephritis have hematuria and proteinuria, active urinary sediment with cellular casts, hypertension, reduced kidney function, nephrotic syndrome, or acute kidney injury. The urinalysis may be normal on rare occasions in patients with proliferative lupus nephritis. Patients with class V nephritis commonly present with nephrotic syndrome.

Table 560.1 Classification of Lupus Nephritis

CLASS	CLINICAL FEATURES
I. Minimal mesangial LN	No renal findings
II. Mesangial proliferative LN	Mild clinical renal disease; minimally active urinary sediment; mild to moderate proteinuria (never nephrotic) but may have active serology
III. Focal proliferative LN (<50% glomeruli involved) A. Active A/C. Active and chronic C. Chronic	More active sediment changes; often active serology; increased proteinuria (>25% nephrotic); hypertension may be present; some evolve into class IV pattern; active lesions require treatment; chronic do not
IV. Diffuse proliferative LN (>50% glomeruli involved); all may be with segmental or global involvement (S or G) A. Active A/C. Active and chronic C. Chronic	Most severe renal involvement with active sediment, hypertension, heavy proteinuria (frequent nephrotic syndrome), often reduced glomerular filtration rate; serology very active; active lesions require treatment
V. Membranous LN glomerulonephritis	Significant proteinuria (often nephrotic) with less active lupus serology
VI. Advanced sclerosing LN	More than 90% glomerulosclerosis; no treatment prevents renal failure

LN, Lupus nephritis.
From Radhakrishnan J, Appel GB. Glomerular disorders and nephrotic syndromes. In: Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020: Table 113.7.

DIAGNOSIS

The diagnosis of SLE is confirmed by the detection of circulating ANA and by demonstrating antibodies that react with native anti-dsDNA. In most patients with active disease, C3 and C4 levels are depressed. In view of the lack of a clear correlation between the clinical manifestations and the severity of the kidney involvement, kidney biopsy should be performed in all patients with SLE who display even minor urinary abnormalities or other clinical evidence for renal disease. Histopathologic findings are used to determine the classification, severity, prognosis, and selection of specific immunosuppressive therapies.

TREATMENT

Current therapies are largely based on the histology, clinical severity, and lessons learned from clinical trials of adults with lupus nephritis. Immunosuppression remains the cornerstone of therapy. The goal of immunosuppressive therapy in lupus nephritis is to produce both a clinical remission, defined as normalization of renal function and proteinuria, and a serologic remission, defined as normalization of anti-DNA antibody, C3, and C4 levels. Therapy is initiated in all patients with prednisone at a dose of 1-2 mg/kg/day in divided doses, followed by a slow steroid taper over 4-6 months beginning 4-6 weeks after achieving a serologic remission.

For patients with more severe forms of nephritis (WHO classes III and IV), more aggressive immunosuppressive regimens are required because corticosteroid therapy alone is insufficient to induce a remission. In general, such regimens are separated into two phases, namely, induction and maintenance. The most commonly employed induction therapy has been six consecutive monthly intravenous infusions of cyclophosphamide at a dose of 500-1,000 mg/m^2. Pulse intravenous methylprednisolone (1,000 mg/m^2) is also used in addition to oral corticosteroids. Maintenance therapy previously consisted of additional cyclophosphamide infusions every 3 months for 18 months, which reduced the risk of progressive renal dysfunction. Serious side effects of cyclophosphamide have included infections, hair loss, hemorrhagic cystitis, and gonadal failure.

As an alternative induction therapy, in adult and pediatric clinical trials, mycophenolate mofetil was as efficacious as, or even superior to, cyclophosphamide, and is increasingly considered for use in children at a dosage of 600 mg/m^2 per dose twice daily. Maintenance therapy using mycophenolate mofetil or azathioprine is also as efficacious as intravenous cyclophosphamide and results in less serious side effects. Mycophenolate mofetil is particularly more efficacious than cyclophosphamide in Black patients. Major side effects of mycophenolate mofetil have included diarrhea, leukopenia, and teratogenicity. Azathioprine, at a single daily dose of 1.5-2.0 mg/kg, may be used as a steroid-sparing agent in patients with WHO class I or II lupus nephritis.

Rituximab, a chimeric monoclonal antibody specific for human CD20, is an alternative that has been shown to induce a remission in adults and children with proliferative lupus nephritis refractory to steroids and other immunosuppressants. Rituximab is used in cases where resistance to conventional treatment is demonstrated. Plasmapheresis is ineffective in lupus nephritis unless there is accompanying thrombotic thrombocytopenic purpura (TTP) or antineutrophilic cytoplasmic antibody (ANCA)-associated disease. Other therapies include belimumab, a fully humanized monoclonal antibody against a type II transmembrane protein that functions in the normal survival and differentiation of B cells; it has been approved by the FDA for use

in SLE. Its role in lupus nephritis, either in combination with current therapies or to replace them, requires further study.

The optimal treatment for class V lupus nephritis remains unclear. On the one hand, the low risk of progression to end-stage kidney disease when compared with proliferative forms of lupus nephritis has encouraged a less aggressive approach. On the other hand, patients with uncontrolled nephrotic syndrome due to class V lupus nephritis are at a high risk of morbidity and may require more aggressive immunosuppression.

Hydroxychloroquine is prescribed for most patients with SLE for extrarenal manifestations but is thought to have a beneficial effect in maintaining the remission in lupus nephritis. It is a rational choice given its low side effect profile. Use of antihypertensive drugs to aggressively treat hypertension, as well as the specific use of drugs that block the renin-angiotensin system (angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers) to reduce proteinuria, are also important adjuvant therapies that appear to decrease the long-term progression of renal disease.

PROGNOSIS

Overall, kidney survival (defined as chronic kidney disease without progression to end-stage kidney disease therapy) is seen in 80% of patients 10 years after the diagnosis of SLE nephritis. Patients with diffuse proliferative WHO class IV lupus nephritis, poor kidney function at presentation, or persistent nephrotic-range proteinuria exhibit the highest risk for progression to end-stage kidney disease. Concerns regarding the side effects of chronic immunosuppressive therapy and the risk of recurrent disease are lifelong. Close monitoring for the relapse of disease is critical to ensure maximally successful renal outcomes. Special care must be taken to minimize the risks of infection, osteoporosis, obesity, poor growth, hypertension, and diabetes mellitus associated with chronic corticosteroid therapy. Patients require counseling regarding the risk of malignancy or infertility, which may be increased in those receiving a cumulative dose of >20 g of cyclophosphamide or other immunosuppressant therapies.

560.3 IgA Vasculitis Nephritis

Prasad Devarajan

IgA vasculitis (formerly known as Henoch-Schönlein purpura) is an idiopathic systemic immune complex–mediated vasculitis associated with IgA deposition within small-vessel walls. It is the most common small-vessel vasculitis in children, with a peak incidence in early childhood (4-6 years of age). Ninety percent of cases occur in children, with about half the cases preceded by an upper respiratory infection. It is characterized by a purpuric rash and commonly accompanied by arthritis and abdominal pain (see Chapter 210.1). Approximately 50% of patients with IgA vasculitis develop kidney manifestations, which vary from asymptomatic microscopic hematuria to severe, progressive GN. IgA vasculitis nephritis shares a similar pathogenesis and nearly identical kidney histology with IgA nephropathy. Although the two are considered as distinct entities, many consider IgA vasculitis nephritis and IgA nephropathy as part of the same clinical spectrum and IgA nephropathy as one of the sequelae of IgA vasculitis nephritis.

PATHOGENESIS AND PATHOLOGY

The pathogenesis of IgA vasculitis nephritis appears to be mediated by the deposition of **polymeric IgA** in glomeruli. This is analogous to the same type of IgA deposits seen in systemic small vessels in IgA vasculitis, primarily those of the skin and intestine. Studies have identified defective glycosylation of the hinge region of IgA1 in patients with both IgA vasculitis nephritis and IgA nephropathy. Recognition of the exposed hinge region of IgA1 by naturally occurring autoantibodies leads to formation of immune complexes that are deposited in the glomerular mesangium. Any mucosal infection or food antigen may trigger the increased production of pathogenic IgA1. IgA immune complexes are deposited throughout the body and activate pathways leading to necrotizing vasculitis. A skin biopsy characteristically shows leukocytoclastic vasculitis with IgA, C3, and fibrin deposition. The glomerular findings can be indistinguishable from those of IgA nephropathy. Pathognomonic IgA deposits are detected by immunofluorescence as the dominant immunoglobulin in the glomerular mesangium. Histologically, a broad spectrum of glomerular lesions that can range from mild mesangial and endocapillary proliferation to necrotic and crescentic changes from extracapillary proliferation can be seen.

CLINICAL AND LABORATORY MANIFESTATIONS

The classic tetrad of IgA vasculitis nephritis includes a palpable purpura, arthritis or arthralgia, abdominal pain, and evidence for kidney disease. *These may develop over a period of days to weeks and may vary in their order of presentation.* Notably, not all of the tetrad are present in all patients. The nephritis associated with IgA vasculitis usually *follows* the onset of the rash, often presenting weeks or even months after the initial nonkidney manifestations have resolved. Nephritis can be manifest at the initial presentation but only rarely before onset of the rash. Some degree of kidney involvement occurs in approximately 50% of IgA vasculitis cases, more commonly in older children (age >8 years confers a threefold greater risk for kidney involvement). Most patients (80%) initially display only mild renal involvement, principally isolated microscopic hematuria without significant proteinuria. About 20% of patients can present with a more severe kidney involvement, including a combined acute nephritic and nephrotic picture (hematuria, hypertension, renal insufficiency, significant proteinuria, and nephrotic syndrome). Older children (and adults) have a greater risk for more severe involvement. Initial mild kidney involvement can also occasionally progress to more severe nephritis despite resolution of all other features of IgA vasculitis. The severity of the systemic manifestations is not correlated with the severity of the nephritis. *Most patients who develop nephritis have urinary abnormalities by 1 month, and nearly all have abnormalities by 3-6 months after the onset of IgA vasculitis.* Therefore a urinalysis (and blood pressure checks) should be performed weekly in patients with IgA vasculitis during the period of active clinical disease (usually during the first 4 weeks). Thereafter, a urinalysis (and blood pressure checks) should be performed once a month for up to 6 months. If all urinalyses and blood pressures are normal during this follow-up interval, nephritis is unlikely to develop. If proteinuria, kidney insufficiency, or hypertension develops along with hematuria, consultation with a pediatric nephrologist is indicated. Indications for a kidney biopsy in children with IgA vasculitis nephritis include significant proteinuria (urine protein >1 g/day or urine protein/creatinine ratio >1.0), significant hypertension, or elevated serum creatinine.

Mimics of IgA vasculitis include endocarditis (skin, renal) and granulomatosis with polyangiitis (skin, renal).

PROGNOSIS AND TREATMENT

The prognosis of IgA vasculitis nephritis for most patients is excellent. Spontaneous and complete resolution of the nephritis typically occurs in many patients with mild initial manifestations (isolated hematuria with insignificant proteinuria). However, such patients uncommonly can progress to severe kidney involvement, including development of chronic kidney disease. Patients with acute nephritic or nephrotic syndrome at presentation have a guarded kidney prognosis, particularly if they are found to have concomitant necrosis or substantial crescentic changes on kidney biopsy. Untreated, the risk of developing chronic kidney disease, including end-stage kidney disease, is 2–5% in all patients with IgA vasculitis, but almost 50% in those with the most severe early kidney clinical and histologic features.

No controlled studies have demonstrated any efficacy of short courses (weeks) of oral corticosteroids administered promptly after the onset of IgA vasculitis in either preventing the development of nephritis or decreasing the severity of subsequent kidney involvement. Tonsillectomy has been proposed as an intervention for IgA vasculitis nephritis, but it also does not appear to have any measurable effect on

the renal outcome. Mild IgA vasculitis nephritis does not require treatment because it usually resolves spontaneously.

The efficacy of treatment for moderate or severe IgA vasculitis nephritis, which is far more likely to progress to chronic kidney disease, is more difficult to assess. Several uncontrolled studies have reported a significant benefit from aggressive immunosuppression (high-dose and extended courses of corticosteroids with azathioprine, mycophenolate mofetil, or cyclophosphamide) in patients with poor prognostic features on kidney biopsy; such patients are at high risk of progressing to chronic kidney disease. Reports of the treatment of high-risk patients with either plasmapheresis or rituximab have also indicated a potential benefit. Balancing the absence of controlled data with the severe side effects of aggressive therapies in patients with poor renal prognostic factors is difficult. Aggressive therapy with careful monitoring may be reasonable in those with the most severe IgA vasculitis nephritis (>50% crescents on biopsy). One common approach in children with severe clinical kidney involvement (nephrotic range proteinuria, elevated serum creatinine, hypertension) is the use of oral prednisone (1 mg/kg/day for 3 months), along with angiotensin-converting enzyme inhibitors, followed by azathioprine or mycophenolate mofetil if severe clinical involvement persists. For children with severe histologic manifestations (>50% glomerular crescents), treatment with intravenous methylprednisolone pulses for 3 days, followed by a combination of oral prednisone (for 3 months) and azathioprine or mycophenolate mofetil (extended course) may be considered. For children with the most severe histology (>75% glomerular crescents) and progressive kidney disease, intravenous steroids plus plasmapheresis may be considered. If progression to end-stage kidney disease occurs, renal transplantation is the treatment of choice. Deposition of IgA in the transplanted kidney is common, but most cases are subclinical, and the overall graft survival is similar to that for other renal transplant recipients.

560.4 Goodpasture Disease

Prasad Devarajan

Goodpasture disease is an autoimmune disease characterized by pulmonary hemorrhage, **rapidly progressive glomerulonephritis**, and elevated **anti–glomerular basement membrane (anti-GBM) antibody** titers. The disease results from an attack on these organs by antibodies directed against certain epitopes of type IV collagen, located within the alveolar basement membrane in the lung and glomerular basement membrane (GBM) in the kidney. An acquired conformational change in the noncollagenous 1 domain of the alpha 3-chain of type IV collagen leads to the production of pathologic autoantibodies. The high affinity of these antibodies to the GBM results in the characteristic rapidly progressive kidney disease. Infusion of human anti-GBM antibodies into animals reproduces the rapidly aggressive glomerulonephritis, confirming the high pathogenicity of these antibodies.

PATHOLOGY

Kidney biopsy shows proliferative crescentic glomerulonephritis in most patients. Immunofluorescence microscopy demonstrates the pathognomonic continuous linear deposition of immunoglobulin G along the GBM (Fig. 560.1).

CLINICAL MANIFESTATIONS

Goodpasture disease is rare in childhood. Patients usually present with hemoptysis from pulmonary hemorrhage that can be life-threatening. Concomitant renal manifestations include acute glomerulonephritis with hematuria, nephritic urinary sediment with cellular casts, proteinuria, and hypertension, which usually follow a rapidly progressive course. Kidney failure commonly develops within days to weeks of the clinical presentation. Although fever may be present, other systemic complaints such as malaise or arthralgia are usually absent; their presence should raise suspicion for a systemic vasculitis. *Less commonly, patients can have anti-GBM nephritis manifesting as isolated, rapidly progressive glomerulonephritis without pulmonary hemorrhage.* In essentially all cases, anti-GBM antibody is present in the serum and/or the kidney, and the serum complement C3 level is normal. **Antineutrophilic cytoplasmic antibody (ANCA)** levels can be found to be elevated in 10–40% of patients, along with the anti-GBM antibody; such patients doubly positive for these autoantibodies have more severe disease at presentation. In general, anti-GBM antibody titers are correlated with the severity of the renal involvement. However, a kidney biopsy should be performed (unless contraindicated) because the accuracy of anti-GBM serology is variable, and renal biopsy provides additional histologic information that can guide therapy.

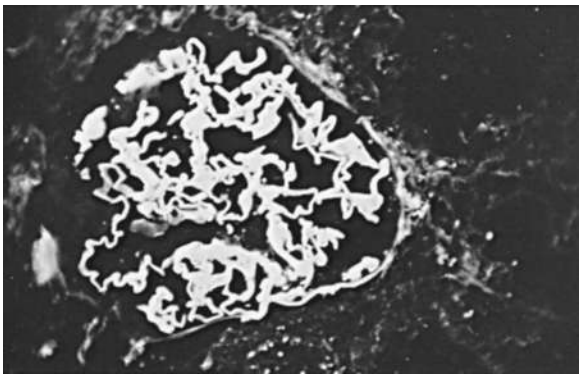

Fig. 560.1 Immunofluorescence micrograph demonstrating the continuous linear staining of immunoglobulin G along the glomerular basement membrane in Goodpasture disease (×250).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis is made by a combination of the clinical presentation of pulmonary hemorrhage with acute glomerulonephritis, the presence of serum antibodies directed against GBM (anti–type IV collagen in GBM), and characteristic renal biopsy findings. Other diseases that can cause a **pulmonary-renal syndrome** need to be considered and include SLE, IgA vasculitis, nephrotic syndrome–associated pulmonary embolism, and ANCA-associated vasculitis (such as granulomatosis with polyangiitis and microscopic polyangiitis). These diseases are ruled out by the absence of other characteristic clinical features, kidney biopsy findings, and negative serologic studies for antibodies against nuclear (ANA), DNA (anti-dsDNA), and neutrophil cytoplasmic components (ANCA antibody).

PROGNOSIS AND TREATMENT

Untreated, the prognosis of Goodpasture disease is poor. Treatment must be initiated emergently as soon as the diagnosis is suspected. The prompt institution of plasmapheresis, high-dose intravenous methylprednisolone, and cyclophosphamide often induces remission and improves survival times. Initial therapy with plasmapheresis removes circulating anti-GBM antibodies, and initial immunosuppression with steroids and cyclophosphamide inhibits ongoing antibody production. Rituximab may be used as a substitute in cases where cyclophosphamide toxicity is encountered. Initial treatment is guided by the clinical response and serial anti-GBM antibody titers. Retrospective cohort studies suggest that when this combination of treatments is started early, most patients will have a good kidney outcome. However, an initial presentation with oligoanuria, a high proportion of glomerular crescents, or kidney failure requiring dialysis predicts worse kidney and patient survival rates. After the induction of remission, maintenance therapy with lower doses of prednisone and azathioprine (or mycophenolate mofetil) is continued for 6-9 months. However, patients who survive the acute pulmonary hemorrhage and rapidly progressive glomerulonephritis can still progress to end-stage kidney disease despite ongoing immunosuppressive therapy. For patients who

progress, kidney transplantation is the treatment of choice. Relapse and recurrent disease after kidney transplantation are both uncommon.

560.5 Hemolytic-Uremic Syndrome

Prasad Devarajan

Hemolytic-uremic syndrome (HUS) is a common cause of community-acquired acute kidney injury in young children. It is the most common form of **thrombotic microangiopathy (TMA)** in children (Fig. 560.2). Like all TMAs, HUS is characterized by the triad of microangiopathic hemolytic anemia, thrombocytopenia, and kidney insufficiency. HUS has clinical features in common with thrombotic thrombocytopenic purpura (TTP) (see Chapter 533.5). The etiology and pathophysiology of the more common forms of HUS clearly delineate typical childhood HUS as separate from idiopathic TTP.

ETIOLOGY

The various etiologies of HUS and other related thrombotic microangiopathies allow classification into infection-induced, genetic, drug-induced, and HUS associated with systemic diseases characterized by microvascular injury (Table 560.2; see Fig. 560.2). The most common form of HUS is caused by **Shiga toxin–producing *Escherichia coli* (STEC)**, which causes prodromal acute enteritis and is commonly termed STEC-HUS or *diarrhea-associated HUS*. In the subcontinent of Asia and in southern Africa, the toxin of *Shigella dysenteriae* type 1 is causative, whereas in Western countries, verotoxin or STEC is the usual cause. STEC-HUS accounts for about 90% of all HUS cases in childhood.

Several serotypes of *E. coli* can produce the toxin. O157:H7 is most common in Europe and the Americas; other serotypes include O26, O111, O121, O145, O91, O103, O104, and O80. The reservoir of STEC is the intestinal tract of domestic animals, usually cows. Disease commonly is transmitted by undercooked meat or unpasteurized (raw) milk and apple cider. Local outbreaks have followed the ingestion of undercooked, contaminated hamburger or other foods cross-contaminated on unwashed cutting boards at fast food restaurants; contaminated municipal water supplies; petting farms; and swimming in contaminated ponds, lakes, or pools. With broad food distribution, wider epidemics have been traced to lettuce, raw spinach, and bean sprouts contaminated with STEC. Less often, STEC has been spread by person-to-person contact within families or childcare centers.

A rare but distinct entity of infection-triggered HUS is related to neuraminidase-producing *Streptococcus pneumoniae* (Sp-HUS). Sp-HUS, typically severe, develops during acute infection with this organism, typically manifesting as pneumonia with empyema. Compared with the prevaccine era, Sp-HUS incidence seems to be decreasing after the introduction of 7-serotype valent and 13-serotype valent pneumococcal vaccines. However, severe Sp-HUS cases continue to occur secondary to vaccine failure and emergence of nonvaccine/replacement serotypes. A TMA, similar to HUS or TTP, also can occur in patients with untreated HIV infection and influenza infection.

Genetic forms of HUS (atypical, nondiarrheal) compose the second major category of the disease (see Table 560.2 and Fig. 560.2). Inherited deficiencies of either von Willebrand factor–cleaving protease (ADAMTS13) or complement factor H, I, or B can cause HUS. A specific genetic defect has not been identified in approximately 50% of familial cases transmitted in classic Mendelian autosomal dominant or

Intestinal

recessive patterns. Some of these may be due to cobalamin C pathogenic variants. A major feature characteristic of genetic forms of HUS is the *absence* of a preceding diarrheal prodrome, although the presence of a diarrheal prodrome does not rule out atypical HUS. Genetic forms of HUS can be indolent and unremitting once they become manifest, or they can have a relapsing pattern precipitated by an infectious illness. The latter feature likely explains the association of many infectious agents with HUS, particularly in reports published before the recognition of the unique pathophysiology of STEC and neuraminidase-producing pneumococci in causing HUS.

HUS can be superimposed on any disease associated with microvascular injury, including malignant hypertension, SLE, and antiphospholipid syndrome. It can also occur after bone marrow or solid organ transplantation and may be triggered by the use of the calcineurin inhibitors cyclosporine and tacrolimus in that setting. Several other medications also can induce HUS (see Table 560.2 and Fig. 560.2).

PATHOLOGY

Kidney biopsies are only rarely performed in HUS because the diagnosis is usually established by clinical criteria, and the risks of biopsy are significant during the active phase of the disease. Early glomerular changes include thickening of the capillary walls caused by swelling of endothelial cells and accumulation of fibrillar material between endothelial cells and the underlying basement membrane, causing narrowing of the capillary lumens. Platelet-fibrin thrombi are often seen in glomerular capillaries. Thrombi are also seen in afferent arterioles and small arteries with fibrinoid necrosis of the arterial wall, leading to kidney cortical necrosis from vascular occlusion. Late findings include glomerular sclerosis and obsolescence secondary to either severe direct glomerular involvement or glomerular ischemia from arteriolar involvement.

PATHOGENESIS

Microvascular injury with endothelial cell damage is characteristic of all forms of TMA, including HUS. In the diarrhea-associated form of HUS, enteropathic organisms produce either Shiga toxin or the highly homologous Shiga-like verotoxin. These toxins are easily absorbed from the colonic mucosa into the systemic circulation, bind to endothelial cells in the glomerulus and elsewhere, and directly cause endothelial cell damage. Shiga toxin can also directly activate platelets to promote their aggregation. Mechanical injury to RBCs passing through the thrombotic microvasculature results in a severe nonimmune anemia with a negative direct Coombs test. In pneumococcal-associated HUS, neuraminidase cleaves sialic acid on membranes of endothelial cells, red cells, and platelets to expose the underlying cryptic Thomsen-Friedenreich (T) antigen. Endogenous IgM antibodies recognize and react with the T antigen to trigger hemolysis and anemia with a positive direct Coombs test.

The *familial* recessive and dominant forms of HUS, including the inherited deficiencies of ADAMTS13 and regulators of the complement cascade, probably predispose patients to developing HUS but do not cause the disease per se because these patients might not develop HUS until later childhood or even adulthood. In such cases, HUS is often triggered by an inciting event such as an infectious disease. The absence of ADAMTS13 impairs cleavage of von Willebrand factor multimers, which enhances platelet aggregation. Factor H plays a central role in complement regulation, primarily arresting the amplification and propagation of complement activation. It is possible that mild endothelial injury that would normally resolve instead evolves to an aggressive microangiopathy because of the inherited deficiencies of these factors.

In each form of HUS, capillary and arteriolar endothelial injury in the kidney leads to localized thrombosis, particularly in glomeruli, causing a direct decrease in glomerular filtration. Progressive platelet aggregation in the areas of microvascular injury results in consumptive thrombocytopenia. Microangiopathic hemolytic anemia results from mechanical damage to RBCs as they pass through the damaged and thrombotic microvasculature.

CLINICAL MANIFESTATIONS

Typical HUS (diarrhea form) is most common in preschool- and school-age children, but it can occur in adolescents and adults. In HUS caused by toxigenic *E. coli,* the onset of HUS occurs 5-7 days after the onset of gastroenteritis with fever, vomiting, abdominal pain, and diarrhea. The prodromal intestinal symptoms may be severe and require hospitalization, but they can also be relatively mild and considered trivial. Not all infected patients will develop HUS. The diarrhea is often bloody but not necessarily so. After the prodromal illness, the sudden onset of pallor, weakness, and lethargy heralds the onset of HUS, and it reflects the development of microangiopathic hemolytic anemia. Oliguria can be present in early stages but may be masked by ongoing diarrhea because the prodromal enteritis often overlaps the onset of HUS, particularly with ingestion of large doses of toxin. Thus patients with HUS can present with either significant dehydration or volume overload, depending on whether the enteritis or kidney insufficiency from HUS predominates and the amount of fluid that has been administered.

Patients with pneumococci-associated HUS usually are quite ill with pneumonia, empyema, and bacteremia when they develop HUS. The onset can be insidious in patients with the genetic forms of HUS, with HUS triggered by a variety of illnesses, including mild, nonspecific gastroenteritis or respiratory tract infections.

HUS can be relatively mild or can progress to a severe and fatal multisystem disease. Leukocytosis, severe prodromal enteritis, hyponatremia, and antibiotic use portend a severe course, but no presenting features reliably predict the severity of HUS in any given patient. Patients with HUS who appear mildly affected at presentation can rapidly develop severe, multisystem, life-threatening complications. Kidney insufficiency can be mild but also can rapidly evolve into severe oliguric or anuric kidney failure. The combination of rapidly developing kidney failure and severe hemolysis can result in life-threatening hyperkalemia. Severe acute kidney injury requiring dialysis develops in about 50% of patients with STEC-HUS. The duration of the dialysis requirement is usually about 2 weeks. Volume overload, hypertension, and severe anemia can all develop soon after the onset of HUS and together can precipitate heart failure. Direct **cardiac involvement** is rare, but pericarditis, myocardial dysfunction, or arrhythmias can occur without predisposing features of hypertension, volume overload, or electrolyte abnormalities.

The majority of patients with HUS have some **CNS involvement**. Most have mild manifestations, with significant irritability, lethargy, or nonspecific encephalopathic features. Severe CNS involvement occurs in ≤20% of cases. Seizures and significant encephalopathy are the most common manifestations in those with severe CNS involvement, resulting from focal ischemia secondary to microvascular CNS thrombosis. Small infarctions in the basal ganglion and cerebral cortex have also been reported, but large strokes and intracranial hemorrhage are rare. Hypertension may produce an encephalopathy and seizures. Intestinal complications can be protean and include severe inflammatory colitis, ischemic enteritis, bowel perforation, intussusception, and pancreatitis. Patients can develop petechiae, but significant or severe bleeding is rare despite very low platelet counts.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis is made by the combination of microangiopathic hemolytic anemia with schistocytes, thrombocytopenia, and some degree of kidney involvement. The anemia can be mild at presentation, but it rapidly progresses. Thrombocytopenia is an invariable finding in the acute phase, with platelet counts usually 20,000-100,000/mm^3. Partial thromboplastin and prothrombin times are usually normal. The Coombs test is negative, except in pneumococci-induced HUS, where the Coombs test is usually positive. Leukocytosis is often present and significant. Urinalysis typically shows microscopic hematuria and low-grade proteinuria. The kidney insufficiency can vary from mild elevations in serum BUN and creatinine to acute, anuric kidney failure.

The etiology of HUS is often clear with the presence of a diarrheal prodrome or pneumococcal infection. The presence or absence of toxigenic organisms on stool culture has little role in making the diagnosis of diarrhea-associated STEC-HUS. Only a minority (~10%) of patients infected with those organisms develops HUS, and the organisms that cause HUS may be rapidly cleared. Therefore the stool culture may be negative in patients who have diarrhea-associated HUS. If no history of diarrheal prodrome or pneumococcal infection is obtained, then evaluation for genetic forms of HUS should be considered because those patients are at risk for recurrence, have a severe prognosis, and can benefit from specific therapy. Other causes of acute kidney injury associated with a microangiopathic hemolytic anemia and thrombocytopenia should be considered and excluded, such as SLE, malignant hypertension, and bilateral renal vein thrombosis. A kidney biopsy is rarely indicated to diagnose HUS.

PROGNOSIS AND TREATMENT

With early recognition and intensive supportive care, the mortality rate for diarrhea-associated HUS is <5%. Up to half of patients may require dialysis support during the acute phase of the disease. Recovery of platelet counts usually occurs first, followed by kidney recovery about 5 days later, and finally by resolution of anemia. Most recover kidney function completely, but of surviving patients, 5% remain dependent on dialysis, and up to 30% are left with some degree of chronic kidney disease. The prognosis for HUS not associated with diarrhea is more severe. Pneumococci-associated HUS causes increased patient morbidity (>80% require dialysis), with the mortality rate reported as 20%. The familial, genetic forms of HUS can be insidiously progressive or relapsing diseases and have a poor prognosis. Identification of specific factor deficiencies in some of these genetic forms provides an opportunity for directed therapy to improve the outcome.

The primary approach that has substantially improved an acute outcome in HUS is early recognition of the disease, monitoring for potential complications, and meticulous supportive care. Supportive care includes careful management of fluid and electrolytes, including prompt correction of a volume deficit, control of hypertension, and early institution of dialysis if the patient becomes significantly oliguric or anuric, particularly with hyperkalemia. Early intravenous volume expansion before the onset of oliguria or anuria may be nephroprotective in diarrhea-associated HUS. Red cell transfusions are usually required because hemolysis can be brisk and recurrent until the active phase of the disease has resolved. In pneumococci-associated HUS, it is critical that any administered red cells be washed before transfusion to remove residual plasma, because endogenous IgM directed against the revealed T antigen can play a role in accelerating the pathogenesis of the disease. Platelets should generally not be administered, regardless of the platelet count, to patients with HUS because they are rapidly consumed by the active coagulation and theoretically can worsen the clinical course. Despite low platelet counts, serious bleeding is very rare in patients with HUS.

There is no evidence that any therapy directed at arresting the disease process of the most common, diarrhea-associated STEC-HUS provides benefit, and some can cause harm. Attempts have been made using anticoagulants, antiplatelet agents, fibrinolytic therapy, plasma therapy, immune globulin, and antibiotics. Anticoagulation, antiplatelet, and fibrinolytic therapies are specifically contraindicated because they increase the risk of serious hemorrhage. Antibiotic therapy to clear enteric toxigenic organisms (STEC) can result in increased toxin release, potentially exacerbating the disease; therefore it is not recommended. However, prompt treatment of causative pneumococcal infection is important. The European experience with *E. coli* O104:H4 in adults who were treated with azithromycin demonstrated more rapid elimination of the organism. Furthermore, in vitro evidence suggests that meropenem, rifaximin, and azithromycin downregulate the release and expression of Shiga toxin. Nonetheless, *in children with E. coli O157:H7–associated HUS, antibiotics are still considered contraindicated.*

Plasma infusion or plasmapheresis has been proposed for patients suffering severe manifestations of HUS with serious CNS involvement. There are no controlled data demonstrating the effectiveness of this approach, and it is specifically contraindicated in those with pneumococcal-associated HUS because it could exacerbate the disease. The use of plasma therapy in STEC-HUS was one of many treatment strategies during one of the largest reported outbreaks of STEC-HUS. This outbreak was caused by an uncommon serotype (O104:H4) that had unique virulence factors. Thought initially to cause more severe disease, it differed epidemiologically from other STEC-HUS serotypes by affecting primarily healthy adults, rather than the usual pattern of affecting children and the elderly. Treatment in this epidemic included plasma exchange in most of the adult patients, as well as the use of eculizumab.

Eculizumab is an anti-C5 antibody that inhibits complement activation, a pathway that contributes to active disease in some forms of atypical familial HUS; this pathway may also contribute to the process in STEC-HUS. Eculizumab is approved by the FDA for the treatment of *atypical HUS*. Because of the risk of meningococcal disease in patients with defects in terminal complement components, it is recommended to give the meningococcal vaccine before giving eculizumab (if the patient has not been primarily immunized). Although initial reports suggested that eculizumab provided benefit in patients with

diarrhea-associated HUS, subsequent systematic analysis showed no benefit from either plasma exchange or eculizumab.

Plasma therapy can be of substantial benefit to patients with identified deficits of ADAMTS13 or factor H. It may also be considered in patients with other genetic forms of HUS, such as the undefined familial (recessive or dominant) form or sporadic but recurrent HUS. In contrast to its use in STEC-HUS, eculizumab shows great promise in the treatment of atypical HUS, including HUS occurring following renal transplantation. Whether it should be combined with plasma therapy or used as a primary treatment of atypical HUS is still undetermined.

Most patients with diarrhea-associated HUS recover completely, with little risk of long-term sequelae. Patients with hypertension, any level of kidney insufficiency, or residual urinary abnormalities persisting a year after an episode of diarrhea-positive HUS (particularly significant proteinuria) require careful follow-up. Patients who have recovered completely with no residual urinary abnormalities after 1 year are less likely but may still manifest long-term sequelae. In a multicenter pooled analysis of 3,476 children with hemolytic uremic syndrome followed up for a mean of 4.4 years, the combined average death and end-stage kidney disease rate was 12%, and the combined average kidney sequelae rate (chronic kidney disease, proteinuria, hypertension) was 25%. Because of reports of late sequelae in such patients, annual examinations with a primary physician are still warranted.

560.6 Toxic Nephropathy

Prasad Devarajan

Aberrant renal function often results from purposeful or accidental exposure to any number of diagnostic, biologic, or therapeutic agents that are potential or actual nephrotoxins. Among diagnostic agents, **contrast-induced nephropathy** is a common and generally reversible form of **acute kidney injury** that results from administration of radiocontrast media in predisposed individuals. Iodinated radiocontrast agents are generally well tolerated by most patients without significant adverse consequences. In volume-depleted patients or patients with underlying chronic kidney disease, their use poses a risk for the development of acute kidney injury with significant attendant morbidity and mortality. Contrast agents can lead to renal vasoconstriction as well as direct tubule cell injury. Contrast-induced nephropathy usually manifests as an increase in serum creatinine 1-2 days following exposure; most patients are not oliguric. In most cases, the serum creatinine normalizes in the next 3-7 days, and treatment is supportive. The overall risk of radiocontrast agents to cause acute kidney injury remains controversial but appears to be low in children with normal kidney function and with the dominant current practice of using low osmolar contrast agents. Biologic nephrotoxins include venomous exposures from insects, reptiles, amphibians, and a wide variety of sea-dwelling animals. The most common forms of toxic nephropathy unfortunately relate to the exposure of children to pharmacologic agents, accounting for close to 20% of episodes of acute kidney injury occurring in children and adolescents. Age, underlying medical condition, genetics, exposure dose, and the concomitant use of other drugs all influence the likelihood of developing acute kidney injury. One common scenario is the use of nonsteroidal antiinflammatory agents (NSAIDs) in febrile children with concomitant dehydration. In this situation, NSAIDs can inhibit the production of intrarenal vasodilatory prostaglandins, thereby leading to decreased renal perfusion and acute kidney injury.

Table 560.3 summarizes the agents that commonly cause acute kidney injury and some of their clinical manifestations. A combination of multiple drugs amplifies the risk. Mechanisms of injury often help to explain the presentation; however, multiple toxic exposures in patients with complicated clinical histories often limit the ability to clearly establish clinical cause and effect. For example, diminished urine output may be the clinical hallmark of tubular obstruction caused by agents such as methotrexate or agents that cause acute tubular necrosis, such as amphotericin B or pentamidine. Alternatively, nephrogenic

- Sulfonamides
- Tacrolimus
- Tetrachloroethylene
- Trimethoprim-sulfamethoxazole

STEC, Shiga toxin–producing *Escherichia coli*.

diabetes insipidus may be the critical clinical manifestation of agents that cause interstitial nephritis, such as lithium or cisplatin. Acute kidney injury due to nephrotoxins is frequently polyuric. Nephrotoxicity is often reversible if the noxious agent is promptly removed.

Clinical use of potential nephrotoxins should be judicious. Necessity of exposure, dosing parameters, and the use of drug levels or pharmacogenomic data, when available, should always be considered. Caution is particularly mandated for patients with complex medical conditions that include preexisting renal disease, cardiac disease, diabetes, and/or complicated surgeries. Alternative approaches to imaging or the use of different pharmacologic options should be considered when possible. Imaging modalities such as ultrasonography, radionuclide scanning, or MRI may be preferable to contrast studies in some patients. Alternatively, a judicious volume expansion with or without the administration of *N*-acetylcysteine might offer renoprotection when radioiodinated contrast studies are critical, especially in children with chronic kidney disease or those who are already on other nephrotoxic agents. Pharmacologic agents with no known kidney effects can often be substituted for known nephrotoxins with equal clinical efficacy. In all cases, simultaneous use of known nephrotoxins should be avoided whenever possible. The use of nephrotoxic agents represents one of the few modifiable risk factors for acute kidney injury, and promising new biomarkers for the early detection and modification of nephrotoxic injuries are currently becoming available. Use of the electronic health record for systematic surveillance for nephrotoxic medication exposure and acute kidney injury can also lead to sustained reductions in avoidable kidney injury.

560.7 Cortical Necrosis

Prasad Devarajan

BACKGROUND

Renal cortical necrosis is a rare cause of severe acute kidney injury occurring secondary to extensive ischemic damage of the renal cortex. Ischemic necrosis is due to markedly decreased renal arterial perfusion as a result of vascular spasm, microvascular injury, or intravascular coagulation. Renal cortical necrosis is usually bilateral and extensive, although focal and patchy forms have also been described. The medulla, the juxtamedullary cortex, and a thin rim of subcapsular cortex are usually spared. It occurs most commonly in neonates and in adolescents of childbearing age.

ETIOLOGY

In newborns, cortical necrosis is most associated with hypoxic or ischemic insults caused by perinatal asphyxia, placental abruption, and twin–twin or fetal–maternal transfusion. Other causes include renal vascular thrombosis and severe congenital heart disease. After the neonatal period, cortical necrosis is most commonly seen in children with septic shock or severe hemolytic-uremic syndrome. In adolescents and women, cortical necrosis occurs in association with obstetric complications, including prolonged intrauterine fetal death, placental abruption, septic abortion, or amniotic fluid embolism.

Less common causes of cortical necrosis include malaria, extensive burns, snakebites, infectious endocarditis, and medications (e.g., nonsteroidal antiinflammatory agents). Acute renal cortical necrosis has also been reported to occur in SLE-associated antiphospholipid antibody syndrome.

PATHOGENESIS

The presumed initiating factor in many cases is intense vasospasm of the small vessels. When prolonged, this leads to necrosis and thrombosis of the distal arterioles and glomeruli, with ensuing cortical necrosis. In hemolytic-uremic syndrome and septic abortion, endotoxin-mediated endothelial damage contributes to worsening vascular thrombosis.

CLINICAL MANIFESTATIONS

Cortical necrosis clinically presents as severe acute kidney injury in patients with predisposing causes. Urine output is diminished and gross, and/or microscopic hematuria may be present. Hypertension is common, and thrombocytopenia may be present because of renal microvascular injury.

LABORATORY AND RADIOLOGIC FINDINGS

Laboratory results are consistent with acute kidney injury: an elevated BUN and creatinine, hyperkalemia, and metabolic acidosis. Anemia and thrombocytopenia are common. Urinalysis reveals hematuria with red cell or granular casts, and proteinuria.

Ultrasound examination with Doppler flow studies demonstrates decreased perfusion to both kidneys. Kidneys are enlarged in the initial stages, but cortical tissue becomes shrunken in the later stages. Thin cortical shells of calcification (tram lines) are a radiologic hallmark, but they develop only 4-5 weeks after the initial insult.

CT scanning with contrast is the most sensitive imaging modality in renal cortical necrosis. Diagnostic features include absent opacification of the renal cortex and enhancement of subcapsular and juxtamedullary regions and of the medulla with absent excretion of contrast medium.

A radionuclide renal scan shows decreased uptake with significantly delayed or absent function. Renal scanning is the imaging technique of choice if contrast-enhanced CT scanning is not available or is contraindicated.

TREATMENT

The cornerstones of therapy for renal cortical necrosis are to restore hemodynamic stability, institute early dialysis, and treat the underlying cause. Most cases of renal cortical necrosis require initial treatment in an intensive care setting. It is important to prevent or treat the underlying cause of acute cortical necrosis, when possible. Therapy involves medical management of acute renal failure, often with the initiation of dialysis as indicated. Management is otherwise supportive and involves volume repletion, correction of asphyxia, and treatment of sepsis.

PROGNOSIS

The most important prognostic factors include the extent of necrosis, duration of oligoanuria, and severity of the overall associated conditions. Untreated, renal cortical necrosis has a high mortality rate, exceeding 50%. Early initiation of dialysis significantly diminishes the mortality rate. Most patients require dialysis for variable but extended periods of time. Twenty to 40% of patients have partial recovery of renal function, the extent of which depends on the amount of preserved cortical tissue. All patients require long-term follow-up for chronic kidney disease.

560.8 Coagulopathies and Thrombocytopenia

Prasad Devarajan

Gross or microscopic hematuria may be associated with inherited or acquired disorders of coagulation (hemophilia, disseminated intravascular coagulation, thrombocytopenia). In these cases, however, hematuria is not usually the presenting complaint or a major factor affecting the clinical management or outcome (see Chapters 524-533).

Chapter 561

Tubulointerstitial Disease Associated with Hematuria

Prasad Devarajan

Gross or microscopic hematuria may be associated with several disorders of the renal tubules and the interstitium (pyelonephritis, tubulointerstitial nephritis, papillary necrosis, acute tubular necrosis). However, except for papillary necrosis, hematuria is not usually the presenting complaint or a major factor affecting the clinical management or outcome (see Chapters 561.2-561.4).

561.1 Pyelonephritis

See Chapter 575, Urinary Tract Infections.

561.2 Tubulointerstitial Nephritis

Prasad Devarajan

Tubulointerstitial nephritis (TIN, also called interstitial nephritis) is the term applied to conditions characterized by tubulointerstitial inflammation and damage with relative sparing of glomeruli and vessels. Both acute and chronic primary forms exist. **Acute TIN** is characterized by an acute extensive lymphocytic inflammatory response and a rapid decline in renal function. **Chronic TIN** usually displays a protracted onset and a chronic patchy lymphocytic infiltrate, interstitial fibrosis, and a slow deterioration in renal function. Secondary forms of interstitial nephritis can be associated with primary glomerular diseases, as well as systemic diseases affecting the kidney.

ACUTE TUBULOINTERSTITIAL NEPHRITIS

The hallmarks of acute TIN are an extensive lymphocytic infiltration of the tubulointerstitium, interstitial edema, and varying degrees of tubular necrosis and regeneration. Eosinophils may be present, particularly in drug-induced TIN; occasionally, interstitial granulomas with giant cells occur. Glomeruli are usually normal in primary TIN. The pathogenesis is not fully understood, but a T-cell–mediated immune mechanism has been postulated. *Drugs are the most common cause of acute TIN in children.* Many medications, especially antimicrobials, anticonvulsants, and analgesics, have been implicated as etiologic agents (Table 561.1). Nonsteroidal antiinflammatory drugs (NSAIDs), penicillins, and sulfonamides account for most cases. Drug-induced TIN is an idiosyncratic reaction that occurs in only a very small subset of patients who ingest the medication, typically with repeated exposure. Drugs of abuse (including synthetic cannabinoids, bath salts, ecstasy, anabolic steroids, inhaled solvents, heroin, and cocaine) are an increasingly common problem in certain populations. Other causes of acute TIN include infections, primary glomerular diseases, and systemic diseases such as systemic lupus erythematosus.

Clinical Manifestations

The classic presentation of acute TIN is fever, rash, and arthralgia in the setting of a rising serum creatinine. Acute TIN accounts for about 5% of pediatric acute kidney injury cases. Although the full clinical triad may be noted in drug-induced TIN, most patients with acute TIN do not demonstrate all the typical features. The rash can vary from maculopapular to urticarial and is often transient. Patients often have nonspecific constitutional symptoms of nausea, vomiting, fatigue, and weight loss. Flank pain may be present, presumably secondary to stretching of the renal capsule from acute inflammatory enlargement of the kidney. If acute TIN is caused by a systemic disease such as systemic lupus erythematosus, the clinical presentation will be consistent with specific signs and symptoms of the underlying disease. Unlike the typical presentation of oliguric **acute kidney injury (AKI)** seen with glomerular diseases, 30–40% of patients with acute TIN are nonoliguric, and hypertension is less common. Peripheral eosinophilia can occur, especially with drug-induced TIN. Microscopic hematuria is invariably present, but significant hematuria or proteinuria >1.5 g/day is uncommon. One exception is patients whose TIN is caused by NSAIDs, who can present with nephrotic syndrome. Urinalysis can reveal white blood cell, granular, or hyaline casts, but red blood cell casts (a characteristic of glomerular disease) are absent. The presence of urine eosinophils is neither sensitive nor specific, being detected in only 25% of cases. Because of pyuria, the initial diagnosis may be a urinary tract infection.

Diagnosis

The diagnosis is usually based on the clinical presentation and laboratory findings. A renal biopsy will establish the correct diagnosis in cases where the etiology or clinical course confounds the diagnosis. A careful history of the timing of disease onset in relation to drug exposure is essential in suspected drug-induced TIN. Because of the immune-mediated nature of TIN, signs or symptoms generally appear within 1-2 weeks following exposure. In children, antimicrobials are a common inciting agent. NSAIDs are an important cause of acute TIN in children, and volume depletion or underlying chronic kidney disease can increase the risk of occurrence. Urinalysis and serial measurements of serum creatinine and electrolytes should be monitored. Renal ultrasonography, though not diagnostic, can demonstrate enlarged, echogenic kidneys. Removal of a suspected offending agent followed by spontaneous improvement in kidney function is highly suggestive of the diagnosis, and additional testing is generally not performed in this setting. In more severe cases, in which the cause is unclear, or the patient's kidney function deteriorates rapidly, a renal biopsy is indicated.

Treatment and Prognosis

Treatment of acute TIN starts with eliminating the suspected causative drug or agent. Most patients with mild ATN recover kidney function when the inciting agent is discontinued. Other treatment includes supportive care directed at addressing complications of AKI, such as hyperkalemia or volume overload (see Chapter 572.1). Corticosteroid administration within 2 weeks of the discontinuation of certain offending agents (e.g., NSAIDs or antibiotics) can hasten the recovery and improve the long-term prognosis in drug-induced TIN. Current recommendations favor the use of oral prednisone in children whose kidney function fails to improve soon after stopping the suspected agent. IV methylprednisolone is used in severe cases. Mycophenolate mofetil has been found to be beneficial in steroid-unresponsive cases. Whether such therapies are indicated in other causes of TIN is not clear. For patients with prolonged kidney insufficiency, the prognosis remains guarded, and severe acute TIN from any cause can progress to chronic TIN.

CHRONIC TUBULOINTERSTITIAL NEPHRITIS

In children, chronic TIN most commonly occurs in the context of (1) an underlying congenital urologic kidney disease, such as obstructive uropathy or vesicoureteral reflux, or (2) an underlying metabolic disorder affecting the kidneys (see Table 561.1). Some commonly used drugs such as cyclosporine and tacrolimus also cause chronic TIN. Chronic TIN can occur as an idiopathic disease, although this is more common in adults.

The **juvenile nephronophthisis (JN)–medullary cystic kidney disease complex (MCKD)** is a group of inherited, genetically determined cystic renal diseases that share the common histologic finding of chronic TIN. At least 20 different genes are associated with JN, usually

Table 561.1 Etiology of Interstitial Nephritis

ACUTE INTERSTITIAL NEPHRITIS

Drugs

- **Antimicrobials**
  - Penicillin derivatives
  - Cephalosporins
  - Sulfonamides
  - Trimethoprim-sulfamethoxazole
  - Ciprofloxacin
  - Tetracyclines
  - Vancomycin
  - Erythromycin derivatives
  - Rifampin
  - Amphotericin B
  - Acyclovir
- **Anticonvulsants**
  - Carbamazepine
  - Phenobarbital
  - Phenytoin
  - Sodium valproate

Drugs of Abuse

- Synthetic cannabinoids
- Bath salts
- Ecstasy
- Anabolic steroids
- Inhaled solvents
- Heroin
- Cocaine

Other Drugs

- Allopurinol
- All-trans-retinoic acid
- 5-Aminosalicylic acid
- Cimetidine
- Cyclosporine
- Diuretics
- Escitalopram
- Interferon
- Mesalazine
- Quetiapine
- Olanzapine
- Nonsteroidal antiinflammatory drugs
- Protease inhibitors
- Proton pump inhibitors
- Aristolochic acid (traditional Chinese herb)

Infections

- Adenovirus
- Bacteria associated with acute pyelonephritis
- BK virus

- Eagle-Barrett syndrome
- Ureteropelvic junction obstruction
- Vesicoureteral reflux

Miscellaneous

- Balkan nephropathy
- Radiation
- Sarcoidosis
- Neoplasm

Idiopathic

inherited as an autosomal recessive disease (Table 561.2). These genes only define 30% of cases, and new genes are being identified at a rapid pace. Although uncommon in the United States, JN causes 10–20% of pediatric cases of end-stage kidney disease (ESKD) in Europe. Patients with JN typically present with polyuria, growth failure, unexplained anemia, and chronic kidney disease in late childhood or adolescence.

JN is a **ciliopathy** and is often associated with extrarenal features such as retinal degeneration, hepatobiliary disease, cerebellar vermis hypoplasia, laterality defects, intellectual disability, and shortening of bones (see Chapter 101.3). These features are represented in several syndromes, such as **Senior-Løken syndrome (retinitis pigmentosa), Joubert syndrome (cerebellar vermis hypoplasia;** 22 subtypes),

From Wolf MTF. Nephronophthisis and related syndromes. *Curr Opin Pediatr.* 2015;27:201–211. Table 1.

Bardet-Biedl syndrome (intellectual disability, obesity; 17 subtypes), **Jeune asphyxiating thoracic dystrophy** (shortening of the long bones, narrow rib cage; 11 subtypes), and many others. **MCKD** is an autosomal dominant disease that typically manifests in adulthood, characterized by tubulointerstitial sclerosis leading to ESKD. Because at least four different gene pathogenic variants may give rise to the condition, the name **autosomal dominant tubulointerstitial kidney disease (ADTKD)** has been proposed for this condition. The two best known forms of ADTKD include mucin-1 kidney disease 1 (MKD1) and mucin-2 kidney disease/uromodulin kidney disease (MKD2), based on the pathogenic variant identified. **TIN with uveitis (TINU syndrome)** is a rare autoimmune syndrome of chronic TIN with bilateral anterior uveitis and bone marrow granulomas that occurs primarily in adolescent girls. Clinical manifestations include photophobia, ocular pain and redness, and visual impairment. Chronic TIN is seen in all forms of progressive kidney disease, regardless of the underlying cause, and the severity of interstitial disease is the single most important factor predicting progression to ESKD.

Pathogenesis and Pathology

The pathophysiology of chronic TIN is undefined, but data suggest that, other than the abnormal cilia structure and function in JN and MCKD, in other cases it is immune mediated. Cells making up the interstitial infiltrate appear to be a combination of native interstitial cells, inflammatory cells recruited from the circulation, and resident tubular cells that undergo epithelial-mesenchymal transformation. Grossly, kidneys can appear pale and small for age. Microscopically, tubular atrophy and "dropout" with interstitial fibrosis and a patchy lymphocytic interstitial inflammation are seen. Patients with JN often have characteristic small cysts in the corticomedullary region. In primary chronic TIN, glomeruli are relatively spared until late in the disease course. Patients with chronic TIN secondary to a primary glomerular disease have histologic evidence of the primary disease. Chronic TIN due to cyclosporine or tacrolimus use is characterized by tubular atrophy, "stripe" interstitial fibrosis, and vascular sclerosis.

Clinical Manifestations

The clinical features of chronic TIN are often nonspecific and can reflect signs and symptoms of slowly progressive chronic kidney disease (see Chapter 572). Fatigue, growth failure, polyuria, polydipsia, and enuresis are often present. Anemia that is seemingly disproportionate to the degree of kidney insufficiency is common and is a particularly prominent feature in JN. Because tubular damage often leads to salt wasting by the kidney, significant hypertension is unusual. Fanconi syndrome, proximal renal tubular acidosis, distal renal tubular acidosis, and hyperkalemic distal renal tubular acidosis can occur.

Extrarenal manifestations of **nephronophthisis** include ophthalmic, neurologic, hepatic, and skeletal disorders (Table 561.3).

Table 561.3 Extrarenal Manifestations Associated with Nephronophthisis and Resulting Syndromes Associated with *NPHP* Pathogenic Variants

DISORDER	SYNDROME
OPHTHALMOLOGIC	
Retinitis pigmentosa	Senior-Løken syndrome (SLSN)
	Arima syndrome (cerebro-oculo-hepato-renal syndrome)

Diagnosis

The diagnosis is suggested by signs or symptoms of kidney tubular damage such as polyuria and an elevated serum creatinine value, coupled with a history suggestive of a chronic disease, such as long-standing enuresis or the presence of anemia resistant to iron therapy. Radiographic studies, in particular ultrasonography, can give additional evidence of chronicity, such as small, echogenic kidneys, corticomedullary microcysts suggesting JN, or findings of obstructive uropathy. A voiding cystourethrogram can demonstrate the presence of vesicoureteral reflux or bladder abnormalities. If JN is suspected, a specific genetic diagnosis is available. In instances in which the cause is unclear, a kidney biopsy may be performed. In cases of advanced disease, a kidney biopsy might not be diagnostic. Many ESKDs display a common histologic appearance of tubular fibrosis and inflammation.

Treatment and Prognosis

Therapy is directed at maintaining the fluid and electrolyte balance and avoiding further exposure to nephrotoxic agents. Patients with obstructive uropathies can require salt supplementation and treatment with potassium-binding resin. Prevention of infection by antibiotic prophylaxis can slow the progression of renal damage in appropriate patients. The prognosis in patients with chronic TIN depends in large part on the nature of the underlying disease. Patients with obstructive uropathy or vesicoureteral reflux can have a variable degree of kidney damage and thus a variable course. ESKD can develop over months to years. Patients with JN uniformly progress to ESKD by adolescence. Patients with metabolic disorders can benefit from treatment when available.

561.3 Papillary Necrosis

Prasad Devarajan

Renal papillary necrosis (RPN) is a descriptive term applied to conditions that result in necrosis of the kidney medullary pyramids and papillae. The hypoxic and hypertonic environment that normally prevails in the kidney medullary region renders it especially vulnerable to ischemic necrosis. Common precipitating factors in children include shock, hypovolemia, hypoxia, pyelonephritis, urinary tract obstruction, and sickle cell hemoglobinopathies, Analgesic abuse and diabetes mellitus are additional important causes in adults. RPN can result in secondary infection, deposition of stones, and sloughing of papillae with resultant urinary tract obstruction. Both an acute progressive clinical course and a more chronic protracted form have been described. Patients most commonly present with flank pain and hematuria. Radiologic studies are key to establishing the diagnosis. Management is directed toward treating the underlying cause, ameliorating kidney ischemia with hydration, and surgical relief of obstruction.

PATHOGENESIS AND PATHOLOGY

RPN may be focal (involving only the papillary tips) or diffuse (involving the whole papilla and the innermost areas of the medulla). RPN may affect a single papilla or multiple papillae. Histologically, the tissue typically reveals classic coagulative necrosis, surrounded by an inflammatory response.

Under normal conditions, the medullary region of the kidney subsists on a hypoxic precipice due to low blood flow and countercurrent exchange of oxygen, although paradoxically housing nephron segments with very high energy requirements. The blood flow decreases even further as one approaches the innermost regions of the medulla and becomes marginal toward the apex and tips of the papillae. The already compromised blood supply is further attenuated in several pathophysiologic states, including the hypoxia from shock and dehydration, the intraluminal stasis of sickle cell nephropathy, the inflammation of pyelonephritis, the increased pressure of urinary tract obstruction, the microvascular changes of diabetes, and the direct damage from analgesics (including NSAIDs). Approximately 15–30% of patients with sickle cell disease will encounter episodes of RPN during their lifetime.

CLINICAL MANIFESTATIONS

The classic presentation of acute RPN is flank pain and renal colic, gross hematuria with clots and tissue debris, and fever with chills. AKI, an increase in the serum creatinine, and oliguria are not common but may accompany the rapidly progressive form. Patients with the chronic indolent form may be asymptomatic and may first present with the passage of sloughed papillae in the urine.

DIAGNOSIS

The diagnosis of RPN is usually based on the history, clinical presentation, laboratory findings, and radiologic investigations. Contrast-enhanced CT scanning is the imaging modality of choice. In the acute phase, this method depicts several typical features, including clefts in the medulla, pelvic filling defects, nonenhanced lesions surrounded by rings of excreted material, medullary calcifications, and the presence of obstruction. If IV contrast is contraindicated, CT scanning without contrast or renal ultrasonography may be performed. These modalities are now replacing IV urography, which was the imaging method of choice in the past.

TREATMENT AND PROGNOSIS

Treatment of acute RPN starts with ameliorating the kidney ischemia with IV hydration. In addition, it is important to treat the underlying cause, including appropriate medical management of shock, sepsis, pyelonephritis, or sickle cell disease. Cessation of any analgesics (including NSAIDs) is critical. Patients with acute obstruction may require surgical intervention for relief.

561.4 Acute Tubular Necrosis

Prasad Devarajan

Acute tubular necrosis (ATN) is a descriptive term applied to conditions that result in necrosis of the renal tubular epithelial cells. The hypoxic environment that normally prevails in the kidney medullary region renders its nephron segments especially vulnerable to necrotic cell death. ATN frequently coexists with other forms of cell death, as well as cellular regeneration. Common precipitating factors in children include prolonged renal ischemia, sepsis, shock, hypovolemia, and nephrotoxic medications. ATN is the most common cause of *intrinsic* **acute kidney injury (AKI)** (see Chapter 572). ATN is clinically characterized by a rapid (within hours to days) decline in kidney function that leads to retention of waste products such as BUN and creatinine, fluid overload, and reduced urine output in many cases. Patients with hospital-acquired ATN frequently have no specific symptoms, and the diagnosis requires a high index of suspicion in predisposed individuals. Laboratory tests and radiologic studies are the key to establishing the diagnosis. Management is directed toward treating the underlying or precipitating cause, correction of imbalances in fluid, electrolyte, and acid-base status, avoidance of nephrotoxic medications, and treatment of complications.

PATHOGENESIS AND PATHOLOGY

The pathologic findings are highly variable, depending on the etiology and the region of the kidney affected. In children with predominantly ischemic ATN, necrosis is relatively inconspicuous, whereas it is more widespread in nephrotoxic ATN. Because the medullary region of the kidney (including the straight segment of the proximal tubule and the medullary thick ascending limb of the loop of Henle) normally subsists in a hypoxic environment due to low blood flow and countercurrent exchange of oxygen, these nephron segments are usually the most severely affected. Typical findings include patchy areas of tubule cell necrosis with resultant loss of tubule epithelial cells and exposure of denuded basement membrane. Other forms of cell death, including apoptosis, necroptosis, and ferroptosis, occur simultaneously. Surviving proximal tubule cells show diffuse effacement and loss of the brush border and apical blebs. The distal nephron segments exhibit tubular dilatation with intraluminal casts. There is concomitant evidence for cellular regeneration and repair among freshly damaged tubule epithelial cells. Injury is aggravated by several pathophysiologic states, including the ischemia from sepsis, shock, and dehydration and the direct damage from nephrotoxic medications.

The significant decline in kidney function is often out of proportion to the observed patchy histologic changes. In addition to tubule cell necrosis, several other factors contribute to the decline in the glomerular filtration rate (GFR). First, a single collecting tubule drains multiple nephrons, such that obstruction of even a small number of collecting tubules results in failure of filtration from several nephrons. Second, obstruction aggravates the backflow of filtered tubular fluid into the vascular space across the denuded epithelium. Third, loss of the proximal tubular reabsorptive capacity results in increased delivery of sodium chloride to the macula densa, with activation of the tubuloglomerular feedback mechanisms that worsens the afferent arteriolar constriction. Fourth, many additional factors contribute to the pathogenesis of ATN, including changes in the microvascular blood flow, endothelial damage, and the activation of inflammatory pathways.

The pathophysiology and clinical course of ATN may be divided into three sequential phases, namely, initiation, maintenance, and recovery. The *initiation* phase occurs during the initial exposure to ischemia or nephrotoxins. Tubule cell damage begins to evolve, and the sloughed tubular cell debris results in obstruction of the tubular lumen. The combination of hypoperfusion and obstruction to the tubular fluid flow results in a fall in the GFR and urine output and a rise in serum creatinine levels. During the *maintenance* phase of ATN, renal tubule injury is established at its highest severity, the GFR and urine output become stabilized at a very low level, and the BUN and serum creatinine peak. It should be noted that ATN due to nephrotoxic

medications is typically nonoliguric. This phase typically lasts for 1-2 weeks but may extend to several weeks. Complications (e.g., metabolic, fluid, and electrolyte imbalances) typically occur during this phase. The *recovery* phase, also called the diuretic phase, is characterized by regeneration of lost tubule epithelial cells, repair of sub-lethally injured cells, and removal of intratubular casts by reestablishment of tubular fluid flow. It is clinically heralded by polyuria and a slow recovery of the GFR. Diuresis occurs because the rapidly increasing GFR precedes the complete recovery of the tubule cell structure and function and can result in volume depletion if not recognized and treated promptly.

The most prevalent causes of ATN in neonates and older children are shown in Tables 561.4 and 561.5, respectively.

CLINICAL MANIFESTATIONS

ATN is largely asymptomatic, and the clinical diagnosis depends on having a high index of suspicion in children with etiologic risk factors. ATN most frequently manifests with a progressive accumulation of fluid, a serial elevation in the BUN and serum creatinine, and a reduction in urine output, in a predisposed patient who has been exposed to either ischemic or nephrotoxic injury. The evaluation requires a complete history directed toward the known causes of ATN, physical examination, laboratory testing, and renal imaging. A detailed history of all ingested drugs and medications is especially important. Although ATN is technically a histologic diagnosis, kidney biopsies are only rarely performed in children with this condition.

Signs of ATN on physical examination include edema, hypertension, and evidence of heart failure. Children with intravascular volume depletion exhibit tachycardia, hypotension, decreased skin turgor, and dry mucous membranes.

Table 561.4 Prevalent Causes of Acute Tubular Necrosis in Neonates

MECHANISM	CAUSES
Ischemia	Perinatal asphyxia, respiratory distress syndrome, hemorrhage, congenital heart disease, sepsis, shock
Exogenous toxins	Aminoglycosides, maternal ingestion of angiotensin-converting enzyme inhibitors or nonsteroidal antiinflammatory drugs
Endogenous toxins	Hemoglobin (hemolysis), myoglobin (seizures)
Primary kidney disease	Renal vein thrombosis, renal artery thrombosis, polycystic kidney disease

Table 561.5 Prevalent Causes of Acute Tubular Necrosis in Older Children

MECHANISM	CAUSES
Ischemia	Severe dehydration, hemorrhage, shock, sepsis, burns, major surgery, severe cardiac disease, prolonged cold ischemia time in kidney transplant
Exogenous toxins	Aminoglycosides, cisplatin, contrast agents, cyclosporine, tacrolimus, angiotensin-converting enzyme inhibitors, nonsteroidal antiinflammatory drugs
Endogenous toxins	Hemoglobin (hemolysis, extracorporeal circulation), myoglobin (crush injuries, seizures, influenza)
Primary kidney disease	Hemolytic uremic syndrome, crescentic glomerulonephritis

DIAGNOSIS

The diagnosis of ATN is aided by laboratory findings and radiologic investigations. A freshly voided urine is typically positive for blood and protein, and microscopy reveals red blood cells and broad, muddy-brown granular casts. Heme-positive urine in the absence of red blood cells in the sediment should raise the suspicion for hemolysis or rhabdomyolysis. In ATN, the impaired kidney reabsorptive and concentrating capacity typically results in a low urine specific gravity and a high urinary sodium and fractional excretion of sodium. The hallmark of ATN is a progressive increase in the serum creatinine and BUN. Urine biomarkers, such as neutrophil gelatinase associated lipocalm (NGAL) and cystatin C, usually increase before creatinine levels and are helpful in predicting acute tubular injury. A mild to moderate anemia is common due to dilution and decreased erythropoiesis. A high anion gap metabolic acidosis results from impaired renal excretion of acids and decreased tubular reabsorption of bicarbonate. Several electrolyte disturbances may be encountered, including hyponatremia (usually dilutional), hyperkalemia, hyperphosphatemia, hypocalcemia, and hypomagnesemia. If rhabdomyolysis is suspected, the diagnosis can be confirmed by the detection of urine myoglobin and elevated levels of serum creatine kinase. The diagnosis of nephrotoxicity may be aided by the determination of serum drug levels. Renal ultrasonography in ATN typically reveals enlarged echogenic kidneys. Prolonged severe ATN results in renal cortical necrosis and a reduction in kidney size.

TREATMENT AND PROGNOSIS

See Chapter 572.1

Treatment of ATN starts with ameliorating the kidney ischemia by restoring and maintaining the intravascular volume with IV hydration. In addition, it is important to treat the underlying cause, including with appropriate medical management of shock, sepsis, or cardiac disease. Cessation of any potential nephrotoxic agent (including NSAIDs) is critical. Dosages of all medications should be chosen based on the estimated GFR. Children with oliguria and volume overload may require fluid restriction and the judicious use of furosemide. Although furosemide can convert the clinical picture from an oliguric to a nonoliguric one (which can facilitate medical management), there is little evidence that it changes the clinical course of ATN. Children with established ATN may not respond to furosemide and are at higher risk for ototoxicity. Common indications for dialysis in ATN include fluid overload that is unresponsive to diuretics or is a hindrance to the provision of adequate nutrition, hyperkalemia unresponsive to medical management, symptomatic acid-base imbalances, and refractory hypertension.

In the absence of multiorgan failure, most children with ATN eventually regain renal function to a large extent. In the context of severe multiorgan dysfunction, renal recovery is limited, and morbidity and mortality rates remain high. Patients who recover from severe ATN remain at risk for subsequently developing chronic kidney disease.

Chapter 562

Vascular Diseases Associated with Hematuria

562.1 Vascular Abnormalities

Prasad Devarajan

Hemangiomas, hemangiolymphangiomas, angiomyomas, and arteriovenous malformations of the kidneys and lower urinary tract are rare causes of hematuria. They can present clinically with microscopic hematuria or gross hematuria with clots. When associated cutaneous vascular malformations are present, they can offer a clue to these underlying causes of hematuria. **Angiomyolipomas,** the most common benign solid tumors of the kidney, are composed of vascular, smooth muscle, and fatty tissue elements. They can rupture on occasion to cause severe hemorrhage. Angiomyolipomas are an important component of the **tuberous sclerosis complex** (see Chapter 636.2), which includes developmental delay, facial angiofibromas, and lung cysts. Renal colic can develop with any upper tract vascular abnormality that obstructs urinary drainage, induces an inflammatory response, or distends the renal capsule. The diagnosis may be confirmed by angiography or endoscopy.

Unilateral bleeding of varicose veins of the left ureter, resulting from compression of the left renal vein between the aorta and superior mesenteric artery (mesoaortic compression), is referred to as the **nutcracker syndrome.** Patients with this syndrome typically present with persistent microscopic hematuria (and, occasionally, recurrent gross hematuria) that may be accompanied by proteinuria, left lower abdominal pain, left flank pain, or orthostatic hypotension. The diagnosis requires a high degree of suspicion and is confirmed by Doppler ultrasonography, CT scanning, phlebography of the left renal vein, or MRI.

562.2 Renal Vein Thrombosis

Prasad Devarajan

EPIDEMIOLOGY

Renal vein thrombosis (RVT) occurs in two distinct clinical settings: (1) In newborns and infants, RVT is commonly associated with asphyxia, dehydration, shock, sepsis, congenital hypercoagulable states, central venous catheters, and maternal diabetes or preeclampsia. (2) In older children, RVT is seen in patients with nephrotic syndrome, cyanotic heart disease, inherited hypercoagulable states, sepsis, sickle cell nephropathy, Behcet syndrome, antiphospholipid syndrome following kidney transplantation, and following exposure to angiographic contrast agents.

PATHOGENESIS

RVT begins in the intrarenal venous circulation and can then extend to the main renal vein and even the inferior vena cava. Thrombus formation is mediated by endothelial cell injury resulting from hypoxia, endotoxin, or contrast media. Other contributing factors include hypercoagulability from either nephrotic syndrome or pathogenic variants in genes that encode clotting factors (e.g., deficiencies of protein C, protein S, antithrombin, and factor V Leiden); hypovolemia and decreased venous blood flow associated with septic shock, dehydration, or nephrotic syndrome; and intravascular sludging caused by polycythemia.

CLINICAL MANIFESTATIONS

The development of RVT is classically heralded by the sudden onset of gross hematuria and unilateral or bilateral flank masses. However, patients can also present with any combination of microscopic hematuria, flank pain, hypertension, or a microangiopathic hemolytic anemia with thrombocytopenia or oliguria. RVT is usually unilateral. Bilateral RVT results in acute kidney injury.

DIAGNOSIS

The diagnosis of RVT is suggested by the development of hematuria and flank masses in patients seen in the high-risk clinical settings or with the predisposing clinical features noted previously. Ultrasonography shows marked renal enlargement, and radionuclide studies reveal little or no renal function in the affected kidney(s). Doppler flow studies of the inferior vena cava and renal vein are essential to confirm the diagnosis. Contrast studies should be avoided to minimize the risk of further vascular damage.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of RVT includes other causes of hematuria that are associated with rapid development of microangiopathic hemolytic anemia or enlargement of the kidney(s). These include hemolytic uremic syndrome, hydronephrosis, polycystic kidney disease, Wilms tumor, and intrarenal abscess or hematoma. All patients with RVT should be evaluated for congenital and acquired hypercoagulable states.

TREATMENT

The primary treatment of RVT starts with aggressive supportive intensive care, including correction of fluid and electrolyte imbalance and treatment of renal insufficiency. Recommendations include additional initial treatment of bilateral RVT with tissue plasminogen activator and unfractionated heparin followed by continued anticoagulation with unfractionated or low molecular weight heparin. Treatment recommendations for unilateral RVT with inferior vena cava extension include either unfractionated or low molecular weight heparin. There is no consensus as to whether unilateral RVT without extension should be managed with heparin or with supportive therapy alone. Aggressive treatment with thrombolytic agents in all these clinical settings, as well as antithrombotic prevention of patients with documented thrombotic risk, remains controversial despite such recommendations given the significant risks of bleeding. Evidence-based data, particularly in children, do not exist despite such best practice recommendations. Children with severe hypertension secondary to RVT who are refractory to antihypertensive medications may require nephrectomy.

PROGNOSIS

Perinatal mortality rates from RVT have decreased significantly over the past 20 years. Partial or complete renal atrophy is a common sequela of RVT in the neonate, leading to an increased risk of chronic kidney disease, renal tubular dysfunction, and systemic hypertension. These complications are also seen in older children. However, recovery of kidney function is not uncommon in older children with RVT resulting from nephrotic syndrome or cyanotic heart disease with correction of the underlying etiology. Long-term follow-up of infants and children with RVT by pediatric nephrologists is recommended for the monitoring of kidney function and the early detection of hypertension and chronic kidney disease

562.3 Sickle Cell Nephropathy

Prasad Devarajan

Gross or microscopic hematuria may be seen in children with sickle cell disease or sickle trait. Hematuria tends to resolve spontaneously in most children. Clinically apparent kidney involvement occurs more commonly in patients with sickle cell disease than in those with sickle

cell trait with the exception of an association with **renal cell carcinoma**, which is more common in patients with sickle cell trait.

ETIOLOGY

The kidney manifestations of sickle cell nephropathy (SCN) are generally related to microthrombosis secondary to sickling in the relatively hypoxic, acidic, hypertonic kidney medulla, where vascular stasis is normally present. Analgesic use, volume depletion with consequent prerenal acute kidney injury, infection, and iron-related hepatic disease are independent contributing factors. Glomerular hyperfiltration, mediated by the intrarenal production of prostaglandins and synthesis of nitric oxide, is involved in the pathogenesis of proteinuria and kidney injury in SCN.

PATHOLOGY

Ischemia, papillary necrosis, and interstitial fibrosis are common pathologic findings in SCN. The specific sickle cell glomerular lesion consists of glomerular hypertrophy, with glomerulomegaly and distended capillaries. In addition, a variety of glomerular lesions are also found in SCN; most commonly these include focal segmental glomerulosclerosis, membranoproliferative glomerulonephritis, and thrombotic microangiopathy. The pathophysiology of these specific glomerulonephritic lesions in SCN is poorly understood.

CLINICAL MANIFESTATIONS

Clinical manifestations of SCN include polyuria caused by a urinary concentrating defect, renal tubular acidosis, and proteinuria associated with the glomerular lesions noted previously.

Approximately 20–30% of patients with sickle cell disease develop proteinuria. Nephrotic-range proteinuria with or without clinically apparent nephrotic syndrome occurs in up to 30% of patients with SCN, and when present, generally heralds progressive kidney disease.

TREATMENT

Tubular manifestations have no specific treatment other than those recommended generally for patients with sickle cell disease. However, angiotensin-converting enzyme inhibitors and/or angiotensin II receptor inhibitors can be used to reduce the urine protein excretion in patients with daily amounts exceeding 500 mg and may slow the progression of chronic kidney disease. Gross hematuria secondary to papillary necrosis may respond to treatment with ε-aminocaproic acid or desmopressin acetate. Hydroxyurea and newer treatments for sickle cell disease (see Chapter 511.1) have decreased the manifestations of SCN in proportion to the other complications of the primary hemoglobinopathy.

PROGNOSIS

SCN can eventually lead to hypertension, chronic kidney disease, and progressive kidney failure. Dialysis and eventual kidney transplantation are successful treatment modalities when kidney failure is irreversible.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

562.4 Idiopathic Hypercalciuria

Prasad Devarajan

Idiopathic hypercalciuria, which may be inherited as an autosomal dominant disorder, can clinically present as recurrent *gross* hematuria, persistent microscopic hematuria, dysuria, crystalluria, or abdominal pain with or without **kidney stone** formation. Hypercalciuria can also accompany conditions resulting in hypercalcemia, such as hyperparathyroidism (see Chapter 613), vitamin D intoxication, immobilization, and sarcoidosis (see Chapter 209). Hypercalciuria may be associated with Cushing syndrome (see Chapter 619), corticosteroid therapy, tubular dysfunction secondary to Fanconi syndrome as occurs with Wilson disease (see Chapter 405.2), oculocerebrorenal (Lowe) syndrome, William syndrome, distal renal tubular acidosis, or Bartter syndrome (see Chapter 571.1). Hypercalciuria may also be seen in patients with Dent disease, which is an X-linked form of nephrolithiasis associated with hypophosphatemic rickets. Although microcrystal formation with consequent tissue irritation is believed to mediate symptoms, the precise mechanism by which hypercalciuria causes hematuria or dysuria is unknown.

DIAGNOSIS

Hypercalciuria is diagnosed by a 24-hour urinary calcium excretion >4 mg/kg. A screening test for hypercalciuria may be performed on a random urine specimen by measuring the calcium and creatinine concentrations. A spot urine calcium:creatinine ratio (mg/dL:mg/dL) >0.2 suggests hypercalciuria in an older child. Normal ratios may be as high as 0.8 in infants <7 months of age.

TREATMENT

Left untreated, hypercalciuria leads to nephrolithiasis in approximately 15% of cases. Hypercalciuria has also been associated with an increased risk for development of low bone mineral density, as well as an increased incidence of urinary tract infections. Idiopathic hypercalciuria has been identified as a risk factor in 40% of children with kidney stones, and a low urinary citrate level has been associated as a risk factor in approximately 38% of this group. Oral thiazide diuretics can normalize urinary calcium excretion by stimulating calcium reabsorption in the proximal and distal tubules. Such therapy can lead to the resolution of gross hematuria or dysuria and can prevent nephrolithiasis. The precise indications for thiazide treatment (including its duration if initiated) remain controversial.

In patients with persistent gross hematuria or dysuria, therapy is initiated with hydrochlorothiazide at a dose of 1-2 mg/kg/24 hours as a single morning dose. The dose is titrated upward until the 24-hour urinary calcium excretion is <4 mg/kg and clinical manifestations resolve. After 1 year of treatment, hydrochlorothiazide is usually discontinued, but it may be resumed if gross hematuria, nephrolithiasis, or dysuria recurs. During hydrochlorothiazide therapy, the serum potassium level should be monitored periodically to avoid hypokalemia. Potassium citrate at a dose of 1 mEq/kg/24 hours may also be beneficial, particularly in patients with low urinary citrate excretion, a low urine pH, and symptomatic dysuria or crystalluria.

Sodium restriction is important because urinary calcium excretion parallels sodium excretion. Importantly, *dietary calcium restriction is not recommended* (except in children with a massive calcium intake >250% of the recommended dietary allowance by dietary history) because calcium is a critical requirement for growth, and no evidence supports a relationship between decreased calcium intake and decreased urinary calcium levels. This is particularly important given the association of hypercalciuria in some patients with reduced bone mineral density. A number of uncontrolled, small-scale studies support a role for bisphosphonate therapy, which leads to a reduction in urinary calcium excretion and improvement in bone mineral density. Controlled studies are necessary to establish a clear role for such therapy in children with hypercalciuria.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

562.5 Nephrocalcinosis

See Chapter 584.

Chapter 563

Anatomic Abnormalities Associated with Hematuria

563.1 Congenital Anomalies

Prasad Devarajan

Gross or microscopic hematuria may be associated with many different types of malformations of the urinary tract. The sudden onset of gross hematuria after minor trauma to the flank is often associated with ureteropelvic junction obstruction, cystic kidneys, or enlarged kidneys from any cause (see Chapter 577).

563.2 Autosomal Recessive Polycystic Kidney Disease

Prasad Devarajan

Autosomal recessive polycystic kidney disease (ARPKD) (also known as ARPKD-congenital hepatic fibrosis [CHF]) is an autosomal recessive disorder occurring with an incidence of 1:20,000 and a gene carrier rate in the general population of 1/70. The gene for ARPKD ***(PKHD1** [polycystic kidney and hepatic disease 1])* encodes **fibrocystin**, a large protein (>4,000 amino acids) with multiple isoforms.

PATHOLOGY

Both kidneys are markedly enlarged and grossly show innumerable small cysts throughout the cortex and medulla. Microscopic studies demonstrate dilated, ectatic collecting ducts radiating from the medulla to the cortex. The development of progressive interstitial fibrosis and tubular atrophy during the advanced stages of the disease eventually leads to end-stage kidney disease (ESKD). ARPKD causes dual-organ disease, hence, the term *ARPKD/CHF*. Liver involvement is characterized by a basic ductal plate abnormality that leads to bile duct proliferation and ectasia, as well as progressive hepatic fibrosis.

PATHOGENESIS

Fibrocystin may form a multimeric complex with proteins of other primary genetic cystic diseases. Altered intracellular signaling from these complexes, located at epithelial apical cell surfaces, intercellular junctions, and basolateral cell surfaces in association with the focal adhesion complex, is a critical feature of the disease pathophysiology.

Over 300 pathogenic variants in *PKHD1* (without identified specific hot spots) cause disease, and the same pathogenic variant can give variable degrees of disease severity in the same family. This clinical observation is consistent with preclinical data demonstrating many environmental and unknown genetic factors affecting disease expression. The false-negative rate for genetic diagnosis is approximately 10%. Limited available information suggests only a gross genotype–phenotype correlation: pathogenic variants that modify fibrocystin appear to cause less severe disease than those that truncate fibrocystin.

CLINICAL MANIFESTATIONS

The diagnosis of ARPKD is often made antenatally by the demonstration of oligohydramnios and bilateral enlarged kidneys on prenatal ultrasound. The typical infant presents with bilateral flank masses during the neonatal period or in early infancy. ARPKD may be associated with respiratory distress and spontaneous pneumothorax in the neonatal period. Perinatal demise (25–30%) appears to be associated with truncating pathogenic variants. Severe bilateral cases often result in the **oligohydramnios complex (Potter syndrome),** which is marked by low-set ears, micrognathia, flattened nose, limb-positioning defects, intrauterine growth restriction, and pulmonary hypoplasia (see Chapter 574). Respiratory distress may also be secondary to large kidneys that compromise the diaphragm function. Hypertension is usually noted within the first few weeks of life, is often severe, and requires aggressive multidrug therapy for control. Oliguria and acute kidney injury are uncommon, but transient hyponatremia may be seen, which often responds to diuresis. Kidney function is usually impaired but may be initially normal in 20–30% of patients. Approximately 50% of patients with a neonatal-perinatal presentation develop ESKD by age 10 years.

ARPKD is increasingly recognized in infants (and, rarely, in adolescents and young adults) with a mixed renal-hepatic clinical picture. Such children and young adults often present with predominantly hepatic manifestations in combination with variable degrees of kidney disease. **Hepatic fibrosis** manifests as portal hypertension, hepatosplenomegaly, gastroesophageal varices, episodes of ascending cholangitis, prominent cutaneous periumbilical veins, reversal of portal vein flow, and thrombocytopenia. CHF may manifest with cholangiodysplastic changes or a frank **Caroli type** with marked intrahepatic bile duct dilation, affecting the whole liver or just one segment; biliary tract disease increases the risk of ascending cholangitis. Kidney findings in patients with a hepatic presentation may range from asymptomatic abnormal renal ultrasonography to systemic hypertension and chronic kidney disease. In the newborn, clinical evidence of liver disease by radiologic or clinical laboratory assessment is present in approximately 50% of children and believed to be universal by microscopic evaluation. Natural history studies of ARPKD patients presenting as infants and young children have classified this group in terms of the severity of their dual-organ phenotype: 40% have the severe kidney/severe liver phenotype, and 20% each have the severe kidney/mild liver, severe liver/mild kidney, and mild kidney/mild liver phenotype.

DIAGNOSIS

The diagnosis of ARPKD is strongly suggested by bilateral palpable flank masses in an infant with pulmonary hypoplasia, oligohydramnios, hypertension, and the absence of renal cysts by sonography of the parents (Fig. 563.1). Markedly enlarged and uniformly hyperechogenic kidneys with poor corticomedullary differentiation are commonly seen on ultrasonography (Fig. 563.2). The diagnosis is supported by clinical and laboratory signs of hepatic fibrosis, pathologic findings of ductal plate abnormalities seen on liver biopsy, anatomic and pathologic proof of ARPKD in a sibling, or parental consanguinity. The diagnosis can be confirmed by genetic testing. The differential diagnosis includes other causes of bilateral renal enlargement and/or cysts, such as multicystic dysplasia, hydronephrosis, Wilms tumor, and bilateral renal vein thrombosis (Tables 563.1 and 563.2).

Nephronophthisis, an autosomal recessive disorder with kidney fibrosis, tubular atrophy, and cyst formation, is a common cause of ESKD in children and adolescents (see Tables 563.1 and 563.2) (see also Chapter 561). Associated external findings include retinal degeneration (Senior-Løken syndrome), cerebellar ataxia (Joubert syndrome), and hepatic fibrosis (Boichis disease). Symptoms include polyuria (salt wasting, poor concentrating ability), failure to thrive, and anemia. Hypertension and edema are seen later when ESKD develops. Prenatal diagnostic testing using genetic linkage analysis or direct pathogenic variant analysis is available in families with a previously affected child.

Preimplantation genetic diagnosis with in vitro fertilization is available for families with a child affected with ARPKD.

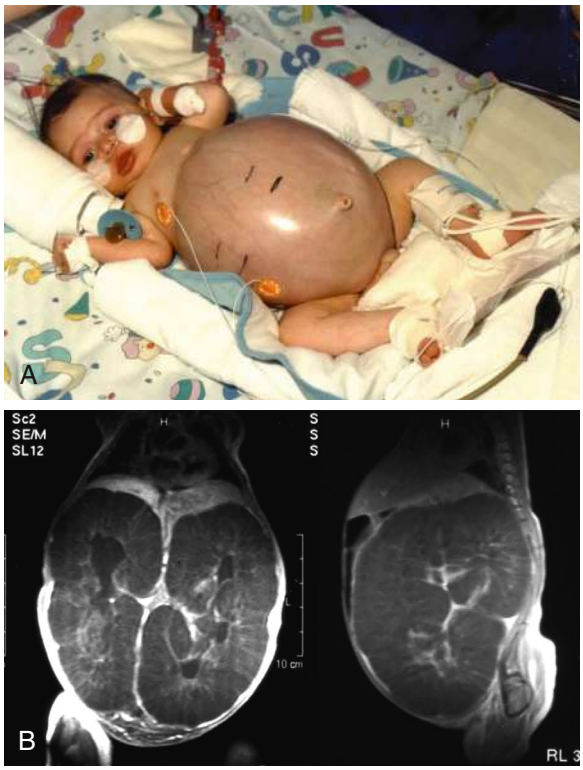

Fig. 563.1 A, Severe nephromegaly in a 3-mo-old infant with autosomal recessive polycystic kidney disease, with x-rays (B). *(From Bakkaloglu SA, Schaefer F. Disease of the kidney and urinary tract in children. In: Skorecki K, Chertow GM, Marsden PA, et al., eds. Brenner & Rector's The Kidney. 10th ed. Philadelphia: Elsevier; 2016: Fig. 74-6, p. 2320.)*

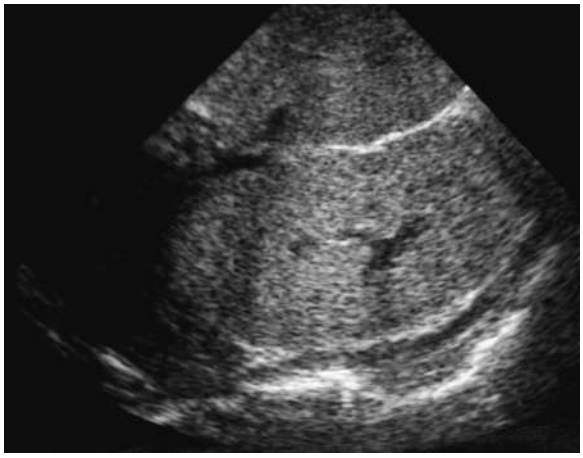

Fig. 563.2 Ultrasound examination of a neonate with autosomal recessive polycystic kidney disease demonstrating renal enlargement (9 cm) and increased diffuse echogenicity with complete loss of corticomedullary differentiation resulting from multiple small cystic interfaces.

TREATMENT

The treatment of ARPKD is supportive. Aggressive ventilatory support is often necessary in the neonatal period secondary to pulmonary hypoplasia, hypoventilation, and the respiratory illnesses of prematurity. Careful management of hypertension (angiotensin-converting enzyme inhibitors, and other antihypertensive medications as needed), fluid and electrolyte abnormalities, osteopenia, and clinical manifestations of kidney insufficiency are essential. Children with severe respiratory failure or feeding intolerance from enlarged kidneys can require unilateral or, more commonly, bilateral nephrectomies, prompting the need for renal replacement therapy. For many children approaching ESKD therapy, significant portal hypertension is present. This in combination with the dramatic improvement in liver transplantation survival has led to consideration of dual kidney and liver transplantation in a carefully selected group of patients. Dual transplantation thus avoids the later development of end-stage liver disease despite successful kidney transplantation.

PROGNOSIS

Mortality rates have improved dramatically, although approximately 30% of patients die in the neonatal period from complications of pulmonary hypoplasia. Neonatal respiratory support and renal replacement therapies have increased the 10-year survival of children surviving beyond the first year of life to >80%. The 15-year survival rate is currently estimated at 70–80%. Consideration of dual kidney and liver transplantation and the development of disease-specific therapies for pediatric clinical trials will further positively impact the natural history of ARPKD. An important resource for families of patients is the ARPKD/CHF Alliance (www.arpkdchf.org).

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

563.3 Autosomal Dominant Polycystic Kidney Disease

Prasad Devarajan

Autosomal dominant polycystic kidney disease (ADPKD), also known as adult-onset polycystic kidney disease, is the most common hereditary human kidney disease, with an incidence of 1/400 to 1/1,000. It is a systemic disorder with possible cyst formation in multiple organs (liver, pancreas, spleen, brain) and the possible development of saccular cerebral aneurysms.

PATHOLOGY

Both kidneys are enlarged and show large cortical and medullary cysts originating from all regions of the nephron.

PATHOGENESIS

Approximately 85% of patients with ADPKD have pathogenic variants that map to the *PKD1* gene on the short arm of chromosome 16, which encodes polycystin, a transmembrane glycoprotein. Another 10–15% of ADPKD pathogenic variants map to the *PKD2* gene on the long arm of chromosome 4, which encodes polycystin 2, a proposed nonselective cation channel. The majority of pathogenic variants appear to be unique to a given family. At present, a pathogenic variant can be found in 85% of patients with well-characterized disease.

Approximately 8–10% of patients will have de novo, disease-causing pathogenic variants. Pathogenic variants of *PKD1* are associated with more severe renal disease than pathogenic variants of *PKD2*. The pathophysiology of the disease appears to be related to the disruption of normal multimeric cystoprotein complexes, with consequent abnormal intracellular signaling resulting in abnormal proliferation, tubular secretion, and cyst formation. Abnormal growth factor expression, coupled with low intracellular calcium and elevated cyclic adenosine monophosphate, appear to be important features leading to formation of cysts and progressive enlargement. Pathogenic variants in *GANAB* have been reported in *PKD1*- and *PKD2*-negative patients.

CLINICAL PRESENTATION

The severity of renal disease and the clinical manifestations of ADPKD are highly variable. Symptomatic ADPKD most commonly occurs in the fourth or fifth decade of life. However, symptoms, including gross

Table 563.1 Differential Diagnosis in ARPKD and ADPKD Genotypes

	ASSOCIATED DISEASE	RENAL PHENOTYPE	EXTRARENAL PHENOTYPE
CLASSIC ARPKD			
	PKHD1, possibly *DZIP1L*	Bilateral nephromegaly, heterogenous parenchymal echogenicity with salt and pepper pattern Prenatal onset: bilateral nephromegaly, oligohydramnios, Potter-like syndrome	Progressive hepatic fibrosis, Caroli syndrome, portal hypertension
CLASSIC ADPKD			
PKD1	ADPKD-*PKD1* with truncating variant	Innumerable bilateral kidney cysts causing progressive kidney enlargement and reduction in eGFR; median age at ESKD about 55 years	Polycystic liver disease, mild to severe, SAH-CNS aneurysms*
PKD1	ADPKD-*PKD1* with nontruncating variant	Innumerable bilateral kidney cysts causing progressive kidney enlargement and reduction in eGFR; median age at ESKD about 67 years	Polycystic liver disease, mild to severe, SAH-CNS aneurysms*
PKD2	ADPKD-*PKD2*	Innumerable bilateral kidney cysts causing progressive kidney enlargement and reduction in eGFR; median age at ESKD about 79 years	Polycystic liver disease, mild to severe, SAH-CNS aneurysms*
ADPKD-LIKE PHENOTYPE			
GANAB	ADPKD-*GANAB*	Bilateral renal cysts, preserved kidney function	Polycystic liver disease, mild to severe
DNAJB11	ADPKD-*DNAJB11*	Normal or small-sized kidneys with multiple small renal cysts; possible evolution to ESKD after 60 years	Polycystic liver disease, absent to moderate
ADTKD-ASSOCIATED GENES			
HNF1B	ADTKD-*HNF1B*	Bilateral renal cysts in about 45% of affected individuals, occasionally mimics ADPKD imaging presentation; evolution to ESKD is highly variable, from childhood-onset ESKD to preserved kidney function throughout life	Diabetes, gout, hyperuricemia, hypomagnesaemia, elevated liver enzymes, bicornate uterus, solitary kidney
MUC1	ADTKD-*MUC1*	Normal or small-sized kidneys, few small renal cysts in half of patients; evolution to ESKD highly variable, age 20-70 years	Gout
SEC61A1	ADTKD-*SEC61A1*	Normal or small-sized kidneys, bilateral small renal cysts in about 50% of individuals	Congenital anemia, intrauterine growth retardation, neutropenia
UMOD	ADTKD-*UMOD*	Normal or small-sized kidneys, few small renal cysts in a third of patients, unilateral or bilateral; evolution to ESKD highly variable, age 20-70 years	Gout
ADPLD-ASSOCIATED GENES			
PRKCSH	ADPLD	Few renal cysts occasionally reported	Polycystic liver disease, mild to severe
SEC63	ADPLD	Few renal cysts occasionally reported	Polycystic liver disease, mild to severe
ALG8	ADPLD	Few renal cysts occasionally reported	Polycystic liver disease, mild to moderate
SEC61B	ADPLD	No renal cysts observed to date in the two families reported with a pathogenic variant in this gene	Polycystic liver disease, mild to moderate
LRP5	ADPLD	Few renal cysts occasionally reported	Polycystic liver disease, mild to moderate
RECESSIVE INHERITANCE			
PKHD1	ARPKD	Antenatally enlarged hyperechogenic kidneys; multiple bilateral millimeter-sized cysts; ESKD in the first decade of life in about 50% of individuals but milder renal presentation with diagnosis in adulthood possible	Congenital hepatic fibrosis, Caroli syndrome, small liver cysts in heterozygous patients
DZIP1L	ARPKD	Antenatal enlarged hyperechogenic kidneys; multiple bilateral millimeter-sized cysts; progression to ESKD variable (second and third decade of life)	No obvious extrarenal manifestations reported in the seven patients identified to date

Continued

Table 563.1 Differential Diagnosis in ARPKD and ADPKD Genotypes—cont'd

	ASSOCIATED DISEASE	RENAL PHENOTYPE	EXTRARENAL PHENOTYPE
PMM2	Hyperinsulinemic hypoglycemia with PKD	Antenatal enlarged hyperechogenic kidneys, enlarged kidneys with multiple cysts; progression to ESKD variable, from infancy to early adulthood	Hyperinsulinemic hypoglycemia; small liver cysts in some patients
SYNDROMIC FORMS OF PKD			
TSC1 or *TSC2*	Tuberous sclerosis	Multiple and bilateral angiomyolipomas and renal cysts; kidney function usually preserved; possible evolution to ESKD, either by destruction of the renal parenchyma by multiple angiomyolipomas or following nephrectomies for hemorrhagic angiomyolipomas; if there is contiguous gene deletion of *TSC2* and *PKD1*, severe PKD with evolution to ESKD occurs before age 30 years	CNS (cortical tubers, astrocytomas, epilepsy, and intellectual disabilities); skin lesions (facial angiofibromas and hypopigmented spots); pulmonary lymphangioleiomyomatosis; cardiac rhabdomyoma and retinal hamartoma; polycystic liver disease if contiguous deletion of both *PKD1* and *TSC2*
VHL	Von Hippel-Lindau disease	Bilateral renal cysts, renal cell carcinoma	Hemangioblastomas of the retina, spine, or brain; pheochromocytoma; neuroendocrine tumor of the pancreas
COL4A1	HANAC syndrome or *COL4A1*-related disease	Bilateral renal cysts occasionally reported; patients can develop renal insufficiency after about age 50-60 years	Microscopic hematuria, aneurysms, muscle cramps, elevated creatine phosphokinase, tortuosity of the retinal arteries
OFD1	Oro-facial-digital syndrome type 1	X-linked, embryonically lethal in males, PKD in females	Cleft palate, facial dysmorphy; syndactyly, clinodactyly, or polydactyly; intellectual disabilities; polycystic liver disease

*Intracranial aneurysms in 9–12% of patients with ADPKD.
ADPKD, Autosomal dominant PKD; ADPLD, autosomal dominant polycystic liver disease; ADTKD, autosomal dominant tubulointerstitial kidney disease; ARPKD, autosomal recessive polycystic kidney disease; CNS, central nervous system; eGFR, estimate glomerular filtration rate; ESKD, end-stage kidney disease; HANAC, hereditary angiopathy with nephropathy, aneurysms, and muscle cramps; PKD, polycystic kidney disease; SAH, subarachnoid hemorrhage.

Table 563.2 Autosomal Recessive Polycystic Kidney Disease and Hepatorenal Fibrocystic Disease Phenocopies

DISEASE	GENE(S)	RENAL DISEASE	HEPATIC DISEASE	SYSTEMIC FEATURES
ARPKD	*PKHD1*	Collecting duct dilation	CHF; Caroli disease	No
ADPKD	*PKD1; PKD2*	Cysts along entire nephron	Biliary cysts; CHF (rare)	Yes: adults
NPHP	*NPHP1-NPHP16*	Cysts at the corticomedullary junction	CHF	+/–
Joubert syndrome and related disorders	*JBTS1-JBTS20*	Cystic dysplasia; NPHP	CHF; Caroli disease	Yes
Bardet-Biedl syndrome	*BBS1-BBS18*	Cystic dysplasia; NPHP	CHF	Yes
Meckel-Gruber syndrome	*MKS1-MKS10*	Cystic dysplasia	CHF	Yes
Oral-facial-digital syndrome, type I	*OFD1*	Glomerular cysts	CHF (rare)	Yes
Glomerulocystic disease	*PKD1; HNF1B; UMOD*	Enlarged; normal or hypoplastic kidneys	CHF (with PKD1 pathogenic variants)	+/–
Jeune syndrome (asphyxiating thoracic dystrophy)	*IFT80 (ATD2) DYNC2H1 (ADT3) ADT1, ADT4, ADT5*	Cystic dysplasia	CHF; Caroli disease	Yes
Renal-hepatic-pancreatic dysplasia (Ivemark II)	*NPHP3, NEK8*	Cystic dysplasia	Intrahepatic biliary dysgenesis	Yes
Zellweger syndrome	*PEX1-3;5-6;10-11;13;14;16;19;26*	Renal cortical microcysts	Intrahepatic biliary dysgenesis	Yes

ADPKD, Autosomal dominant PKD; ARPKD, autosomal recessive polycystic kidney disease; CHF, congenital hepatic fibrosis; NPHP, nephronophthisis.
Modified from Guay-Woodford LM, Bissler JJ, Braun MC, et al. Consensus expert recommendations for the diagnosis and management of autosomal recessive polycystic kidney disease: report of an international conference. *J Pediatr*. 2014;165:611–617.

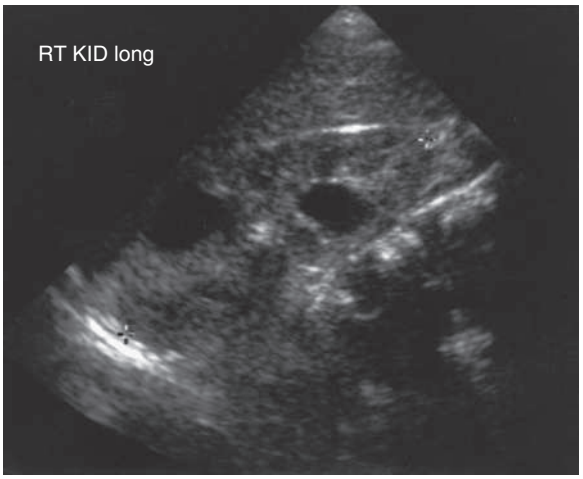

Fig. 563.3 Ultrasound examination of an 18-mo-old male with autosomal dominant polycystic kidney disease demonstrating renal enlargement (10 cm) and two large cysts.

or microscopic hematuria, bilateral flank pain, abdominal masses, hypertension, and urinary tract infection, may be seen in neonates, children, and adolescents. With the increased utilization of abdominal sonography in the pediatric population, as well as ADPKD families requesting possible screening in their asymptomatic, at-risk offspring, most children with ADPKD are diagnosed by abnormal renal sonography in the absence of symptoms. Renal ultrasonography usually demonstrates multiple bilateral macrocysts in enlarged kidneys (Fig. 563.3), although normal kidney size and unilateral disease may be seen in the early phase of the disease in children.

ADPKD is a multiorgan disorder affecting many tissue types. Cysts may be asymptomatic but present within the liver, pancreas, spleen, and ovaries and, when present, help confirm the diagnosis in childhood. **Intracranial aneurysms,** which appear to segregate within certain families, have an overall prevalence of 15% and are an important cause of mortality in adults but only occasionally occur in children. Mitral valve prolapse is seen in approximately 12% of children; aortic and coronary artery aneurysms and aortic valve insufficiency are noted in affected adults. Hernias, bronchiectasis, and intestinal diverticula can also occur in these children.

DIAGNOSIS

ADPKD is confirmed by the presence of enlarged kidneys with bilateral macrocysts in a patient with an affected first-degree relative. De novo pathogenic variants occur in 8–10% of patients with newly diagnosed disease. The diagnosis might be made in children before their affected parent, making parental renal sonography an important diagnostic test to be performed in families with no apparent family history. Among patients with genetically defined ADPKD, screening renal ultrasonography results may be normal in ≤20% by 20 years of age and <5% by 30 years of age.

Prenatal diagnosis is suggested from the presence of enlarged kidneys with or without cysts on ultrasonography in families with known ADPKD. Prenatal DNA testing is available in families with affected members whose disease is caused by identified pathogenic variants in the *PKD1* or *PKD2* genes.

The differential diagnosis includes renal cysts associated with glomerulocystic kidney disease, tuberous sclerosis, and von Hippel-Lindau disease, which may be inherited in an autosomal dominant pattern (see Table 563.1). The neonatal manifestations of ADPKD and ARPKD may rarely be indistinguishable.

TREATMENT AND PROGNOSIS

Treatment of ADPKD is primarily supportive. Control of blood pressure is critical because the rate of disease progression in ADPKD correlates with the presence of hypertension. Angiotensin-converting enzyme inhibitors and/or angiotensin II receptor antagonists are agents of choice. Obesity, dietary salt and protein excess, caffeine ingestion, smoking, multiple pregnancies, and male gender appear to accelerate the disease progression. Older patients with a family history of intracranial aneurysm rupture should be screened for cerebral aneurysms. Although the approach remains controversial, most nephrologists now recommend initial screening for cerebral aneurysms with an MR angiogram around 18 years of age in asymptomatic patients with a family history of ADPKD and associated aneurysms.

Although neonatal ADPKD may be fatal, long-term survival of the patient and the kidneys is possible for children surviving the neonatal period. ADPKD that occurs initially in older children has a favorable prognosis, with normal kidney function during childhood seen in >80% of children. Pain may be a manifestation of infection, hemorrhage, cyst rupture, stones, or tumors and should be managed appropriately with pain medications and specifically based on its etiology.

Although disease-specific therapy is not yet available, clinical trials are in progress based on promising preclinical laboratory investigations. These potential therapies include renin-angiotensin blockade, vasopressin V_2 receptor antagonism (tolvaptan), statins (to reduce pain), and somatostatin analogues. Tolvaptan has been effective in adults in slowing the progression of renal impairment. A valuable resource for patients and their families is the Polycystic Kidney Disease Foundation (www.pkdcure.org).

563.4 Trauma

Prasad Devarajan

Infants and children are more susceptible to kidney injury following blunt or penetrating injury to the back or abdomen because of their decreased muscle mass "protecting" the kidney. Gross or microscopic hematuria, flank pain, and abdominal rigidity can occur; associated injuries may be present (see Chapter 80). In the absence of hemodynamic instability, most kidney trauma can be managed nonoperatively. Urethral trauma can result from crush injury, often associated with a fractured pelvis or from direct injury. Such injury is suspected in the appropriate clinical setting when gross blood appears at the external urethral meatus. Rhabdomyolysis and consequent acute kidney injury is another complication of crush injury that can be ameliorated by vigorous fluid resuscitation. There may be a relationship between microscopic hematuria and recreational accidents in individuals >16 years of age, none of whom exhibited hypotension or required surgical intervention.

563.5 Renal Tumors

See Chapters 547 and 548.

Chapter 564

Lower Urinary Tract Causes of Hematuria

564.1 Infectious Causes of Cystitis and Urethritis

Prasad Devarajan

Gross or microscopic hematuria may be associated with bacterial, mycobacterial, or viral infections of the bladder (see Chapter 575).

564.2 Hemorrhagic Cystitis

Prasad Devarajan

Hemorrhagic cystitis is defined as the presence of sustained hematuria and lower urinary tract symptoms (e.g., dysuria, frequency, urgency) in the absence of other bleeding conditions such as vaginal bleeding, a generalized bleeding condition, or a bacterial urinary tract infection. Depending on the severity, patients can present with microscopic or gross hematuria, often with clots. In severe forms, bleeding can lead to a significant decrease in blood hemoglobin levels and symptoms of lower urinary tract obstruction.

Hemorrhagic cystitis can occur in response to chemical toxins (cyclophosphamide, penicillins, busulfan, thiotepa, dyes, insecticides), viruses (adenovirus types 11 and 21 [see Chapter 309] and influenza A [see Chapter 305]), radiation, and amyloidosis. The polyoma **BK virus** (see Chapter 321), present latently in immunocompetent hosts, is associated with the development of drug-induced cystitis in immunosuppressed patients. The pediatric bone marrow transplantation population is particularly susceptible to hemorrhagic cystitis.

For chemical irritation related to the use of cyclophosphamide, hydration, bladder washes, and the use of mesna disulfide, which inactivates urinary cyclophosphamide metabolites, helps to protect the bladder. Administration of oral cyclophosphamide in the morning followed by aggressive oral hydration throughout the remainder of the day is very effective in minimizing the risk of hemorrhagic cystitis. Treatment of hemorrhagic cystitis consists of a combination of intensive intravenous hydration, forced diuresis, analgesia, and spasmolytic drugs. Consultation with a urologist is recommended for more invasive measures if the cystitis does not respond to conservative measures. Gross hematuria associated with viral hemorrhagic cystitis usually resolves within 1 week.

564.3 Vigorous Exercise

Prasad Devarajan

Gross or microscopic hematuria can follow vigorous exercise. **Exercise-induced hematuria** is less common in females and can be associated with dysuria. Approximately 30–60% of runners completing marathons have dipstick-positive urine for blood. In limited follow-up, none appeared to have any significant kidney or urinary tract abnormalities. The color of the urine following vigorous exercise can vary from red to black. Blood clots may be rarely present in the urine. Findings on urine culture, intravenous pyelography, voiding cystourethrography, and cystoscopy are normal in most patients. This seems to be a benign condition, and the hematuria generally resolves within 48 hours after cessation of exercise. The absence of red blood cell casts or evidence of renal disease and the presence of dysuria and blood clots in some patients suggest that the source of bleeding lies in the lower urinary tract. **Rhabdomyolysis** with **myoglobinuria** or hemoglobinuria must be considered in the differential diagnosis when the condition is associated with symptoms in the appropriate clinical context. Hydronephrosis or other anatomic abnormalities must be considered in any child who presents with hematuria (particularly gross hematuria) after mild exercise or following mild trauma. Appropriate imaging studies are indicated in this setting.

Section 3

Conditions Particularly Associated With Proteinuria

Chapter 565

Clinical Evaluation of the Child with Proteinuria

Francisco X. Flores

NORMAL PHYSIOLOGY

The charge and size selective properties of the glomerular capillary wall prevent significant amounts of albumin, globulin, and other large plasma proteins from entering the urinary space (see Chapter 557). Smaller proteins (low molecular weight proteins) do cross the capillary wall but are reabsorbed by the proximal tubule. A very small amount of protein that normally appears in the urine is the result of normal tubular secretion. The normally excreted protein mostly consists of **Tamm-Horsfall protein (uromodulin)**, a protective glycoprotein secreted by the tubules that inactivates cytokines.

PATHOPHYSIOLOGY OF PROTEINURIA

Abnormal amounts of protein may appear in the urine from three possible mechanisms: *glomerular proteinuria,* which occurs as a result of disruption of the glomerular capillary wall; *tubular proteinuria,* a tubular injury or dysfunction that leads to ineffective reabsorption of mostly low molecular weight proteins; and *increased production of plasma proteins* (in multiple myeloma, rhabdomyolysis, or hemolysis), which may cause the production or release of very large amounts of protein that are filtered at the glomerulus and overwhelm the absorptive capacity of the proximal tubule.

MEASUREMENT OF URINE PROTEIN

Urine protein can be measured in random collected samples or in timed (e.g., 24-hour or overnight) samples. Tests to accurately quantify the urine protein concentration rely on precipitation with sulfosalicylic acid and measurement of turbidity (Table 565.1).

Table 565.1 Quantification of Proteinuria in Children

METHOD	INDICATIONS	NORMAL RANGE	COMMENTS
Dipstick testing	Routine screening for proteinuria performed in the office	Negative or trace in a concentrated urine specimen (specific gravity: ≥1.020) Test interpretation: 1+ ~30 mg/dL 2+ ~100 mg/dL 3+ ~300 mg/dL	False-positive test can occur if urine is very alkaline (pH >8.0) or very concentrated (specific gravity: >1.025), or when there is pus, vaginal secretions, or semen present
24-hr urine for protein and creatinine*excretion	Quantitation of proteinuria (as well as creatinine clearances)	<150 mg/m^2/24 hr	More accurate than spot urine analysis; inconvenient for patient; the creatinine content should be measured to determine whether the specimen is truly a 24-hr collection. The amount of creatinine in a 24-hr specimen can be estimated as follows: females, 15-20 mg/kg; males, 20-25 mg/kg
Spot urine for protein/creatinine ratio, preferably on first morning urine specimen	Semiquantitative assessment of proteinuria	<0.2 mg protein/mg creatinine in children older than 2 yr old <0.5 mg protein/mg creatinine in those 6-24 mo old	Simplest method to quantitate proteinuria; less accurate than measuring 24-hr proteinuria
Microalbuminuria	Assess risk of progressive glomerulopathy in patients with diabetes mellitus	<30 mg urine albumin per gram of creatinine on first morning urine	Therapy should be intensified in diabetics with microalbuminuria

*Note that in a 24-hr urine specimen, the creatinine content should be measured to determine whether the specimen is truly a 24-hr collection. The amount of creatinine in a 24-hr specimen can be estimated as follows: females, 15-20 mg/kg and males, 20-25 mg/kg.

Adapted from Hogg RJ, Portman RJ, Milliner D, et al. Evaluation and management of proteinuria and nephrotic syndrome in children: recommendations from a Pediatric Nephrology Panel Established at the National Kidney Foundation Conference on Proteinuria, Albuminuria, Risk Assessment, Detection, and Elimination (PARADE). *Pediatrics.* 2000;105(6):1242–1249.

Urine Dipstick Measurement of Protein

The total protein concentration in urine can be estimated with chemically impregnated plastic strips that contain a pH-sensitive colorimetric indicator that changes color when negatively charged proteins, such as albumin, bind to it. Dipsticks primarily detect albuminuria and are less sensitive for other forms of proteins (low molecular weight proteins, Bence-Jones protein, gamma globulins). Visual changes in the color of the dipstick are a semiquantitative measure of urinary protein concentration. The dipstick is reported as negative, trace (10-29 mg/dL), 1+ (30-100 mg/dL), 2+ (100-300 mg/dL), 3+ (300-1,000 mg/dL), and 4+ (>1,000 mg/dL). False-positive results can occur with a very high urine pH (>7.0), a highly concentrated urine specimen, contamination of the urine with blood, and the presence of pyuria or prolonged dipstick immersion. False-negative test results can occur in patients with a low urine pH (<4.5), dilute urine or a large volume of urine output, or in disease states in which the predominant urinary protein is not albumin.

Positive urine dipstick test for protein is considered to be present if there is more than a trace (10-29 mg/dL) in a urine sample in which the specific gravity is <1.010. If the specific gravity is >1.015, the dipstick must read ≥1+ (>30 mg/dL) to be considered clinically significant.

Because the dipstick reaction offers only a qualitative measurement of urinary protein excretion, children with persistent proteinuria should have proteinuria quantitated more precisely. **Timed (24-hour) urine collections** offer more precise information regarding urine protein excretion than a randomly performed dipstick test. Urinary protein excretion in the normal child is <100 mg/m^2/day or a total of 150 mg/day. In neonates, normal urinary protein excretion is higher, up to 300 mg/m^2, because of reduced reabsorption of filtered proteins. A reasonable upper limit of normal protein excretion in healthy children is 150 mg/24 hr. More specifically, normal protein excretion in children is defined as ≤4 mg/m^2/hr, abnormal proteinuria is defined as excretion of 4-40 mg/m^2/hr, and nephrotic-range proteinuria is defined as > 40 mg/m^2/hr.

Timed urine collections are cumbersome to obtain, and the sensitivity and specificity of the test can be influenced by fluid intake, the volume of urine output, and the importance of including a complete collection without missed voids.

Urine Protein-to-Creatinine Ratio Measurement

Urine protein-to-creatinine ratio measurement of an untimed (spot) urine specimen has largely replaced timed urine collection. In children, urine protein-to-creatinine ratios have been shown to be significantly correlated with measurements of 24-hour urine protein and are useful to screen for proteinuria and to longitudinally monitor urine protein levels.

This ratio is calculated by dividing the urine protein concentration (mg/dL) by the urine creatinine concentration (mg/dL) to provide a simple measure. It should be ideally performed on a first morning voided urine specimen to eliminate the possibility of orthostatic (postural) proteinuria (see Chapter 566.2). A ratio of <0.5 in children <2 years of age and <0.2 in children >2 years of age suggests normal urinary protein excretion. A ratio >2 suggests nephrotic-range proteinuria.

CLINICAL CONSIDERATIONS

The finding of proteinuria in children and adolescents in a single, non–first morning urine specimen is common, varying between 5% and 15%. The prevalence of persistent proteinuria on repeated testing is much less common. The challenge is to differentiate the child with proteinuria related to renal disease from the otherwise healthy child with transient or other benign forms of proteinuria. When proteinuria is detected, it is important to determine whether it is transient, orthostatic, or fixed in nature.

Microalbuminuria is defined as the presence of albumin in the urine above the normal level but below the detectable range of conventional urine dipstick methods. In adults, persistent microalbuminuria (defined as a urinary albumin excretion of 30-300 mg/g creatinine on at least two to three samples) is accepted as evidence of diabetic nephropathy and also a predictor of cardiovascular and renal disease. The mean level of urinary albumin excretion falls between 8 and 10 mg/g of creatinine in children >6 years of age. Similar to adults, microalbuminuria in children has been found to be associated with obesity and to predict, with reasonable specificity, the development of diabetic nephropathy in type 1 diabetes mellitus.

Chapter 566

Conditions Associated with Proteinuria

566.1 Transient Proteinuria

Francisco X. Flores

The majority of children found to have positive tests for protein on urinary dipsticks will have negative evaluations on repeated dipsticks and normal urinary protein if formally quantitated. Approximately 10% of children who undergo random urinalysis have proteinuria by a single dipstick measurement. Across the school-age spectrum, this finding occurs more commonly in adolescents than in younger children. In most cases, serial testing of the patient's urine demonstrates resolution of the abnormality. This phenomenon defines **transient proteinuria,** and its cause remains elusive. Defined contributing factors include a temperature >38.3°C (101°F), exercise, dehydration, cold exposure, heart failure, recent use of epinephrine, seizures, or stress. Transient proteinuria usually does not exceed 1-2+ on the dipstick. No evaluation or therapy is needed for children with this benign condition, and it resolves spontaneously or as the cause resolves. Persistence of proteinuria, even if low grade, is not consistent with the diagnosis and suggests the need for additional evaluation (Fig. 566.1).

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

566.2 Orthostatic (Postural) Proteinuria

Francisco X. Flores

Orthostatic proteinuria is the most common cause of *persistent* proteinuria in school-age children and adolescents, occurring in up to 60% of children with persistent proteinuria. Children with this condition are usually asymptomatic, and the condition is discovered by routine urinalysis. Patients with orthostatic proteinuria excrete normal or minimally increased amounts of protein in the supine position. In the upright position, urinary protein excretion may be increased 10-fold, up to 1,000 mg/24 hr (1 g/24 hr). *Hematuria, hypertension, hypoalbuminemia, edema, and renal dysfunction are absent.*
