Infectious Diseases

PART XV

Section 1

General Considerations

Chapter 214

Public Health Approach to Pandemics

Kevin P. O'Callaghan

INTRODUCTION

Public health as a field aims to promote healthy lifestyles and communities and to protect the public at large from health threats from known and emerging diseases, chronic noncommunicable diseases, and environmental risks and vulnerabilities. In this context, public health authorities have a core role in prevention, preparedness, and response to epidemic and pandemic infectious diseases. The field of public health has a long and storied history in investigating and ending outbreaks of infectious diseases, extending back to one of the founders of modern epidemiology, John Snow, and the Broad Street pump cholera outbreak. Modern epidemiology and public health practices have an integral role in the management of outbreaks, epidemics, and pandemics, using both traditional methodologies that look like the "shoe leather epidemiology" of John Snow's time, meshed with modern best practices that leverage genomic sequencing, data analytics, and medical innovations in therapeutics and vaccination.

DEFINITIONS

Infectious disease outbreak response hinges on an understanding of current and ongoing incidence and prevalence of the disease in the affected community. The transmission dynamics of a disease will look different in a population that is entirely **susceptible** (e.g., a novel or emerging disease) than in a population in which some members are **recovered/immune** (e.g., a disease has been present for some time).

Sporadic diseases occur infrequently and irregularly in a population. **Endemic** diseases are continually circulating, often at low levels, maintaining a constant presence among members of the community. **Epidemic** disease occurs when there is a substantial increase above the baseline amount of a disease. This may occur as an increase in a disease that is already endemic at low levels or by the introduction of a novel disease that has not been seen in the affected population. A **pandemic** refers to an epidemic that has spread over several countries and continents, affecting large numbers of people. This is frequently defined and declared by international public health authorities, for example, the World Health Organization.

Public Health Authorities and Partners

Although describing "public health" as a specialty may sound somewhat monolithic, the majority of public health work is done collaboratively across a variety of partners, including local, city, state, and national public health authorities, city and state governments, healthcare systems, individual clinical providers, and members of the affected communities. The most important aspect of public health work is often community involvement, whether as part of outbreak investigations, public-facing communications, or education around prevention and response measures.

At an international level, the World Health Organization operates as an international collaborative agency set up in 1948 under the auspices of the United Nations. One of its core responsibilities is to direct and coordinate the world's response to health emergencies, working with national governments, international organizations, researchers, and health systems. At a national level, responsibility for public health management typically devolves to national and federal government departments (e.g., the Department of Health and Human Services in the United States) and their constituent agencies, such as the Centers for Disease Control and Prevention (CDC). The CDC coordinates national surveillance systems for a variety of health conditions, including endemic and newly emergent diseases.

The bulk of regional and local public health surveillance, preparedness, and response work falls under the purview of city, county, and state public health departments. These agencies liaise closely with healthcare systems, specialty and primary care practices, and individual clinicians within their region to help facilitate their public health goals, as well as with nonmedical partners, including school districts, other government agencies, and community groups.

Aims of Public Health Response to Infectious Diseases

Broadly, the aims of a public health response are to prevent the emergence of novel diseases in human hosts, prevent the spread of new diseases or the increase in prevalence of a known endemic disease, and mitigate the health effects of any spread that may occur. Based on these goals, the arms of public health response for epidemic and pandemic infectious diseases fall into four groupings: mitigation/prevention, preparedness, response, and recovery. These areas stem from a common approach to emergency management in general but have specific meanings and impact in the context of pandemic response. Some active public health measures, such as education and public-facing communication, occur across all four arms.

Arms of Intervention

Mitigation/Prevention

A primary approach to pandemic management includes proactive activities to prevent new human infections with target diseases, both to prevent endemic diseases from becoming epidemic and to arrest emergence of novel diseases. Some recent epidemics and pandemics likely represent "spillover" events from animal populations, with these zoonoses then becoming prevalent in human populations through human-to-human transmission (e.g., Zika, SARS-CoV-2). There is a complex interplay between human and animal populations related to farming, deforestation, changes in land use, water management, and climate change that makes the emergence of new zoonotic diseases intermittently more likely and unfortunately somewhat unpredictable. Prevention of emergence of these diseases is best approached through a One Health approach, which is an international project using a "collaborative, multisectoral, and transdisciplinary approach" at local, national, and international levels to optimize health outcomes, recognizing the interconnectedness of people, animals, plants, and their environment. Individual approaches to prevent disease outbreaks of this type may require the involvement of agricultural regulators and inspectors, veterinarians, and environmental health specialists, among others.

A more concrete example of a salient mitigation effort involving human healthcare providers is antimicrobial stewardship. The emergence of multidrug-resistant (MDR) and extensively drug-resistant (XDR) organisms in response to the selection pressure of antimicrobial usage is a critical vulnerability in epidemic and pandemic preparedness. Stewardship efforts at a grassroots, individual patient level provide a necessary bulwark against the proliferation of further MDR and XDR strains of currently endemic diseases.

Preparedness

Separate from mitigation and prevention, a preparedness stance plans for the potentially inevitable outcome of the emergence of a novel epidemic or pandemic disease. Preparedness efforts can be targeted against specific disease threats (e.g., seasonal and pandemic influenza, which has predictable seasonality) or against previously unknown or less predictable threats (e.g., SARS-CoV-2, Ebola virus disease). Given the broad range of potential pathogens that may pose a threat over time, much preparedness planning takes place in an "all hazards" stance, where the preparation is necessarily agnostic as to the specific pathogen, with surveillance and resources that can be quickly pivoted to cover a broad variety of potential risks.

A core element of preparedness involves case-based surveillance or the active observation and documentation of incidence and prevalence of a specific disease or syndrome at local, regional, and national levels. Robust surveillance infrastructure requires both regulatory and material support, including both voluntary and mandatory reporting requirements, as well as a reporting infrastructure that includes clear and consistent case definitions that are reproducible across venues of care. In the United States, the National Notifiable Diseases Surveillance System (NNDSS) coordinates case definitions and reporting requirements for approximately 120 nationally notifiable diseases. A coherent and centralized reporting infrastructure such as that provided by NNDSS allows for a more global understanding of burden of disease and disease trends over time. However, case surveillance as described here remains dependent on close partnership with healthcare systems, clinical laboratories, and individual providers at a local level to ensure that these systems are both sensitive and specific. Case-based surveillance is also predicated on a good understanding of both the pathophysiology and available diagnostics for a specific disease. For newly emergent diseases, where a coherent case definition is less readily available, early warning systems seek to detect syndromic clusters that elude identification on routine diagnostics. Expansion of such programs in the wake of the 2019 SARS-CoV-2 pandemic have received governmental support and may use novel approaches such as wastewater screening and genomic sequencing within syndromic clusters.

In terms of tangible supplies that may be required for an acute response, personal protective equipment (PPE) and medical countermeasures (MCMs, e.g., vaccines, therapeutics) may be needed in high volume on short notice, at which point a "just in time" supply chain approach may prove lacking. Stockpiling of critical supply needs is a necessary part of pandemic preparedness, particularly with regard to high-risk, low-frequency, unpredictable events such as international travel of a patient with undiagnosed Ebola virus disease. For a longer-term outbreak or epidemic, such as that seen with the 2020 response to COVID-19, even the most aggressive stockpiling cannot support a protracted pandemic response, and close collaboration with manufacturers of durable medical supplies, therapeutics, and vaccines may be necessary to ensure sustained availability and a flexible supply chain.

Lastly, healthcare capacity is a separate but critically important resource with concrete limits (e.g., total bed spaces, provider person-days, and critical care and ventilator availability). In responding to the exponential growth of a rapidly reproducing pathogen, hospital capacity may be rapidly overwhelmed, as seen in some early surges of COVID-19 in 2020. Infrastructure planning for healthcare systems can help alleviate some of these pressures through rapidly accessible, flexible patient care space normally kept in reserve and through thoughtful capacity management, such as plans that allow for restriction of elective or nonemergent care for short periods. Ultimately, such efforts need to be matched with public-facing interventions described later, which can "flatten the curve" of epidemic transmission.

Response

Pandemic response begins with identification of the emergence of a specific risk (through surveillance systems described previously), followed by activation of applicable plans developed during the preparedness phase. Early pandemic response may be, by necessity, nonspecific to a known disease, particularly if the identification of risk is predicated on a syndromic cluster or a novel, not-yet-identified pathogen.

For novel pathogens, short-term goals will include rapid identification of the pathogen at a genus and species level, sequencing of its genome, development of accurate and readily available diagnostic tests, and development of targeted therapeutics and vaccines. As these individual targets may take weeks to months to come to fruition, early response will focus on mitigation of disease transmission through the application of standard public health measures, including social distancing, transmission-based precautions, isolation of cases, contact tracing, and quarantine of known contacts. All of these approaches occur simultaneously and require extensive public communication and education to ensure their effectiveness. **Social distancing** involves the temporary application of new social norms and social constructs designed to keep individuals, particularly those from separate households, physically distanced so that the likelihood of disease transmission between individuals is substantially reduced or eliminated. This may include infrastructural changes that promote contactless payment options at stores, physical barriers in offices and at public-facing service desks, and others. This distancing is assisted by application of **transmission-based precautions**, which are PPE recommendations based on the transmission modality of a specific pathogen. In non-healthcare settings, the most common application of PPE is facial masking designed to protect oral and nasal mucosa from diseases spread by droplets (e.g., influenza). **Isolation of cases** is a public health measure that strongly encourages or, depending on regulatory support, legally requires diagnosed cases of a specific disease to isolate for the duration of their period of infectivity, usually at home, in a healthcare setting, or at a designated isolation facility. After identification of a case, **contact tracing** should occur, during which identification of potential contacts of the known case (during the period of infectivity) is made. Completion of contact tracing involves notification of the affected contacts and a recommendation that they quarantine, typically for the duration of the upper bound of the incubation period for the disease. All of these responses require a large commitment in terms of time, personnel, and resources, and in a rapidly accelerating epidemic, these resources may ultimately be overwhelmed.

While these core public health responses are ongoing, rapid development of diagnostics, therapeutics, and vaccine candidates will continue. Of these, the earliest steps involve genomic sequencing and targeted diagnostics, the latter of which ultimately will greatly assist with consistent case definitions and subsequent contact tracing, isolation, and quarantine. The timeline for development of suitable vaccine candidates has greatly decreased in recent decades, with development of messenger RNA (mRNA) vaccine candidates during the COVID-19 pandemic being a hallmark example. Regulatory changes in timelines for vaccine assessment and approval for emergency use have assisted in these efforts, while not altering safety and efficacy oversight.

Recovery

Termination of pandemic response is rarely clear-cut, as elimination or eradication of specific pathogens from human population is rare. Most epidemic or pandemic responses end with a slow decrease in case counts and ultimate quiescence for a period (e.g., Ebola virus disease outbreaks) or the attainment of endemicity—the low-level constant circulation of a pathogen within remaining susceptible human hosts. Ultimately, transition from response to recovery is predicated on ongoing case counts, pressure on healthcare infrastructure, and an amalgamation of other metrics that may include test positivity, case severity, vaccine uptake, and hospitalization rates.

A core aspect of the recovery phase is an analysis of pandemic response measures as a whole, including their relative success, their tolerability, and their tangible and intangible costs. Future pandemic response, for the same and other pathogens, can be informed and improved by this analysis, typically developed in an after-action report or similar post hoc analytic framework.

Communication and Education

A core element of public health response to epidemic and pandemic disease, which spans across all four stances, is public communication and education. At each stage of pandemic preparedness and response, public engagement is key. This is particularly true in a response phase, where data become available rapidly and contradictory findings in early reports can cause confusion and mistrust. Clear, concise messaging

that focuses on core concepts of preparedness and response is key. A large portion of public health response may be spent in developing and promulgating this messaging, but it can be extremely worthwhile insofar as it can lead to dramatic increases in tolerability and uptake of other public health interventions, including social distancing, isolation and quarantine, and vaccines.

Viruses, bacteria, fungi, and other microbes are a fact of life on this earth and are an integral part of the biodiversity upon which we as humans depend. Although infectious diseases may also be a dependable fact of life, their broader societal impact can be shifted, reduced, and controlled in the ways described here. Pandemic preparedness and response can be difficult and time-consuming, but done well, with engaged partners at all levels, can be lifesaving on a societal level.

Section 2

Preventive Measures

Chapter 215

Immunization Practices

Alexandra Kilinsky, Henry H. Bernstein, and Walter A. Orenstein

Immunization is one of the most beneficial and cost-effective disease prevention measures available. As a result of effective and safe vaccines, smallpox has been eradicated, polio is close to worldwide eradication, and measles and rubella are no longer endemic in the United States. However, cases of vaccine-preventable diseases, including measles, mumps, and pertussis, continue to occur in the United States. Incidence of most vaccine-preventable diseases of childhood has been reduced by ≥99% from representative 20th-century annual morbidity, usually before development of the corresponding vaccines (Table 215.1), with most of the newer vaccines not achieving quite the same percentage decrease (Table 215.2). An analysis of effective prevention measures recommended for widespread use by the U.S. Preventive Services Task Force (USPSTF) reported that childhood immunization received a perfect score based on clinically preventable disease burden and cost-effectiveness.

Immunization is the process of inducing immunity against a specific disease. Immunity can be induced either passively or actively. **Passive immunity** is generated through administration of an antibody-containing preparation. **Active immunity** is achieved by administering a vaccine or toxoid to stimulate the immune system to produce a prolonged humoral and/or cellular immune response. As of 2023, infants, children, and adolescents in the United States are recommended to be routinely immunized against **19 pathogens**: *Corynebacterium diphtheriae, Clostridium tetani, Bordetella pertussis,* polio virus, *Haemophilus influenzae* type b **(Hib)**, hepatitis A, hepatitis B, measles virus, mumps virus, rubella virus, rotavirus, varicella-zoster virus, SARS-CoV-2, pneumococcus, meningococcus, influenza virus, human papillomavirus **(HPV)**, and respiratory syncytial virus **(RSV)**.

PASSIVE IMMUNITY

Rather than producing antibodies through the body's own immune system, passive immunity is achieved by administration of preformed antibodies. Protection is immediate, yet transient, lasting weeks to months. Products used include:

- Immunoglobulin administered intramuscularly **(IMIG)**, intravenously **(IVIG)**, or subcutaneously **(SCIG)**
- Specific or hyperimmune immunoglobulin preparations administered IM or IV

Section 2

Preventive Measures

Chapter 215

Immunization Practices

Alexandra Kilinsky, Henry H. Bernstein, and Walter A. Orenstein

Immunization is one of the most beneficial and cost-effective disease prevention measures available. As a result of effective and safe vaccines, smallpox has been eradicated, polio is close to worldwide eradication, and measles and rubella are no longer endemic in the United States. However, cases of vaccine-preventable diseases, including measles, mumps, and pertussis, continue to occur in the United States. Incidence of most vaccine-preventable diseases of childhood has been reduced by ≥99% from representative 20th-century annual morbidity, usually before development of the corresponding vaccines (Table 215.1), with most of the newer vaccines not achieving quite the same percentage decrease (Table 215.2). An analysis of effective prevention measures recommended for widespread use by the U.S. Preventive Services Task Force (USPSTF) reported that childhood immunization received a perfect score based on clinically preventable disease burden and cost-effectiveness.

Immunization is the process of inducing immunity against a specific disease. Immunity can be induced either passively or actively. **Passive immunity** is generated through administration of an antibody-containing preparation. **Active immunity** is achieved by administering a vaccine or toxoid to stimulate the immune system to produce a prolonged humoral and/or cellular immune response. As of 2023, infants, children, and adolescents in the United States are recommended to be routinely immunized against **19 pathogens**: *Corynebacterium diphtheriae, Clostridium tetani, Bordetella pertussis,* polio virus, *Haemophilus influenzae* type b **(Hib)**, hepatitis A, hepatitis B, measles virus, mumps virus, rubella virus, rotavirus, varicella-zoster virus, SARS-CoV-2, pneumococcus, meningococcus, influenza virus, human papillomavirus **(HPV)**, and respiratory syncytial virus **(RSV)**.

PASSIVE IMMUNITY

Rather than producing antibodies through the body's own immune system, passive immunity is achieved by administration of preformed antibodies. Protection is immediate, yet transient, lasting weeks to months. Products used include:

- Immunoglobulin administered intramuscularly **(IMIG)**, intravenously **(IVIG)**, or subcutaneously **(SCIG)**
- Specific or hyperimmune immunoglobulin preparations administered IM or IV

Table 215.1 Comparison of 20th-Century Annual Morbidity and Current Morbidity: Vaccine-Preventable Diseases

- Antibodies of animal origin
- Monoclonal antibodies

Passive immunity also can be induced naturally through transplacental transfer of maternal antibodies (IgG) during gestation. This transfer can provide protection during an infant's first few months of life; other antibodies (IgA) are transferred to the infant during breastfeeding. Protection for some diseases can persist for as long as 1 year after birth, depending on the quantity of antibody transferred and the time until levels fall below those considered protective.

The major indications for inducing passive immunity are immunodeficiencies in children with B-lymphocyte defects who have difficulty making antibodies (e.g., hypogammaglobulinemia, secondary immunodeficiencies), who have exposure to infectious diseases or to imminent risk of exposure when there is inadequate time for them to develop an active immune response to a vaccine (e.g., newborn exposed to maternal hepatitis B), and who have infectious diseases that require antibody administration as part of the specific therapy (Table 215.3).

Intramuscular Immunoglobulin

Immunoglobulin is a sterile antibody-containing solution, usually derived through cold ethanol fractionation of large pools of human plasma from adults. Antibody concentrations reflect the infectious disease exposure and immunization experience of plasma donors. IMIG contains 15–18% protein and is predominantly IgG. Intravenous use of human IMIG is contraindicated. Immunoglobulin is not known to transmit infectious agents, including viral hepatitis and HIV. The major indications for immunoglobulin are:

- Replacement therapy for children with antibody deficiency disorders
- Measles prophylaxis
- Hepatitis A prophylaxis

For **replacement therapy**, the usual dose of IMIG is 100 mg/kg (equivalent to 0.66 mL/kg) monthly. The usual interval between doses is 2-4 weeks depending on trough IgG serum concentrations and clinical response. In practice, IVIG has replaced IMIG for replacement therapy.

IMIG can be used to prevent or modify **measles** if administered to susceptible children within 6 days of exposure (usual dose: 0.5 mL/kg body weight; maximum dose: 15 mL). The recommended dose of IVIG is 400 mL/kg. Data suggest that measles vaccine, if given within 72 hours of measles exposure, will provide protection in some cases to infants ≥6 months of age. Measles vaccine and immunoglobulin should not be administered at the same time.

Two methods are available for **postexposure prophylaxis** against **hepatitis A** depending on the patient's age: Children 6-11 months old should receive a dose of hepatitis A vaccine before international travel. However, the dose of hepatitis A vaccine received before 12 months should not be counted in determining compliance with the recommended two-dose schedule. In those 12 months to 40 years of age, hepatitis A immunization is preferred over immunoglobulin for postexposure prophylaxis and for protection of people traveling to areas where hepatitis A is endemic. Persons age >40 years, persons with immunocompromising conditions, and persons with chronic liver disease planning on traveling to an area with high or intermediate hepatitis A virus (HAV) endemicity should receive a single dose of hepatitis A vaccine as soon as travel is considered. Persons traveling in <2 weeks should receive the initial dose of hepatitis A vaccine and simultaneously may be administered immunoglobulin in a different anatomic injection site (e.g., separate limbs). A second dose of hepatitis A vaccine is not required for postexposure prophylaxis; however, for long-term immunity, the vaccination series should be completed with a second dose at least 6 months after the first dose.

The most common adverse reactions to immunoglobulin are pain and discomfort at the injection site and, less commonly, flushing, headache, chills, and nausea. Serious adverse events are rare and include chest pain, dyspnea, anaphylaxis, and systemic collapse. Immunoglobulin should *not* be administered to people with selective IgA deficiency who can produce antibodies against the trace amounts of IgA in immunoglobulin preparations and can develop reactions after repeat doses. These reactions can include fever, chills, and a shocklike syndrome. Because these reactions are rare, testing for selective IgA deficiencies is not recommended.

Intravenous Immunoglobulin

IVIG is a highly purified preparation of immunoglobulin antibodies prepared from adult plasma donors using alcohol fractionation and is

Table 215.3 Immunoglobulin and Animal Antisera Preparations

PRODUCT	MAJOR INDICATIONS
Intramuscular immunoglobulin (IMIG)	Replacement therapy in antibody-deficiency disorders Hepatitis A prophylaxis Measles prophylaxis Rubella prophylaxis (pregnant women)
Intravenous immunoglobulin (IVIG)	Replacement therapy in antibody-deficiency disorders Kawasaki disease Pediatric HIV infection Hypogammaglobulinemia in chronic B-lymphocyte lymphocytic leukemia Varicella postexposure prophylaxis Guillain-Barré syndrome and chronic inflammatory demyelinating polyneuropathy and multifocal motor neuropathy Toxic shock syndrome Postexposure measles prophylaxis for immunocompromised contacts May be useful in a variety of other conditions
Subcutaneous immunoglobulin (SCIG)	Treatment of patients with primary immunodeficiencies
Hepatitis B immunoglobulin (IM)	Postexposure prophylaxis Prevention of perinatal infection in infants born to hepatitis B surface antigen–positive mothers
Rabies immunoglobulin (IM)	Postexposure prophylaxis
Tetanus immunoglobulin (IM)	Wound prophylaxis Treatment of tetanus
Varicella-zoster immunoglobulin (VariZIG, IM)	Postexposure prophylaxis of susceptible people at high risk for complications from varicella
Cytomegalovirus (IV)	Prophylaxis of disease in seronegative transplant recipients
Vaccinia immunoglobulin (IV)	Reserved for certain complications of smallpox immunization and has no role in treatment of smallpox
Human botulism (IV), BabyBIG	Treatment of infant botulism
Diphtheria antitoxin, equine	Treatment of diphtheria
Heptavalent botulinum antitoxin against all seven (A-G) botulinum toxin types (BAT)	Treatment of noninfant food and wound botulism
Palivizumab (monoclonal antibody), humanized mouse (IM)	Prophylaxis for infants against respiratory syncytial virus (see Chapter 307)
Nirsevimab (monoclonal antibody) produced in Chinese hamster ovary (CHO) cells by recombinant DNA technology. (IM)	Passive immunization to prevent RSV-associated lower respiratory tract infection among infants and younger children (see Chapter 307)
Crotalidae immune F(ab')2 (equine)	Effective for viper and pit viper bites, including rattlesnakes, copperheads, moccasins

Data from Passive Immunization. In Kimberlin DW, Barnett ED, Lynfield R, Sawyer MH, eds. Red Book: 2021–2024 Report of the Committee on Infectious Diseases, 32nd ed. Itasca, IL: American Academy of Pediatrics; 2021. (Recommendations for use of specific immunoglobulins are located in the sections for specific diseases in Section 3 of *Red Book*.)

modified to allow IV use. IVIG is more than 95% IgG and is tested to ensure minimum antibody titers to *C. diphtheriae,* hepatitis B virus, measles virus, and poliovirus. Antibody concentrations against other pathogens vary widely among products and even among lots from the same manufacturer. Liquid and lyophilized powder preparations are available. IVIG does not contain thimerosal.

Not all IVIG products are approved by the U.S. Food and Drug Administration (FDA) for all indications. The major recommended FDA-approved indications for IVIG are:

- Replacement therapy for primary immunodeficiency disorders
- Kawasaki disease to prevent coronary artery abnormalities and shorten the clinical course
- Replacement therapy for prevention of serious bacterial infections in children infected with HIV
- Prevention of serious bacterial infections in people with hypogammaglobulinemia in chronic B-lymphocyte leukemia
- Immune-mediated thrombocytopenia to increase platelet count

IVIG may be helpful for patients with severe toxic shock syndrome, Guillain-Barré syndrome, and anemia caused by parvovirus B19. IVIG is also used for many other conditions based on clinical experience, such as multisystem inflammatory syndrome in children (MIS-C) associated with COVID-19. IVIG may be used for varicella after exposure when varicella-zoster immunoglobulin is not available.

Reactions to IVIG may occur in up to 25% of patients. Some of these reactions appear to be related to the rate of infusion and can be mitigated by decreasing the rate. Such reactions include fever, headache, myalgia, chills, nausea, and vomiting. More serious reactions, including anaphylactoid events, thromboembolic disorders, aseptic meningitis, hemolytic anemia, and renal insufficiency, have rarely been reported. Renal failure occurs mainly in patients with preexisting renal dysfunction.

Specific or hyperimmune immunoglobulin preparations are derived from donors with high titers of antibodies to specific agents and are designed to provide protection against those agents (see Table 215.3).

Subcutaneous Immunoglobulin

(SCIG) is safe and effective in children and adults with primary immune deficiency disorders. Smaller doses administered weekly result in less fluctuation of serum IgG concentrations over time. Systemic reactions are less frequent than with IVIG, and the most common adverse effects of SCIG are injection site reactions. There are no data on administration of IMIG by the subcutaneous route.

Hyperimmune Animal Antisera Preparations

Animal antisera preparations are derived from horses. The immunoglobulin fraction is concentrated using ammonium sulfate, and some products are further treated with enzymes to decrease reactions to foreign proteins. The following two equine antisera preparations are available for humans (as of 2018):

- **Diphtheria antitoxin**, which can be obtained from the U.S. Centers for Disease Control and Prevention (CDC) (http://www.cdc.gov/diphtheria/dat.html) and is used to treat diphtheria.
- **Heptavalent botulinum antitoxin**, available from the CDC for use in adults with botulism. To request it, one can call the CDC's 24-hour line at 770-488-7100. This product contains antitoxin against all seven (A-G) botulinum toxin types.

Great care must be exercised before administering animal-derived antisera because of the potential for severe allergic reactions. Due caution includes testing for sensitivity before administration, desensitization if necessary, and treating potential reactions, including febrile events, serum sickness, and anaphylaxis. For infant botulism, IVIG (BabyBIG), a human-derived antitoxin, is licensed and should be used.

Monoclonal Antibodies

Monoclonal antibodies (mAbs) are antibody preparations produced against a single antigen. They are mass-produced from a hybridoma, a hybrid cell used as the basis for production of large amounts of antibodies. A hybridoma is created by fusing an antibody-producing B lymphocyte with a fast-growing immortal cell such as a cancer cell. There are two injectable monoclonal antibody products that help protect infants and young children from lower respiratory tract infection caused by RSV: nirsevimab and palivizumab. **Palivizumab** is used for prevention of severe disease from respiratory syncytial virus (RSV) among children ≤24 months old with bronchopulmonary dysplasia (BPD, a form of chronic lung disease), a history of premature birth, or congenital heart lesions or neuromuscular diseases. The American Academy of Pediatrics (AAP) has developed specific recommendations for the use of palivizumab. **Nirsevimab** is recommended for infants younger than 8 months of age who were born shortly before or are entering their first RSV season if the mother did not receive RSV vaccine (Abrysvo) during pregnancy, if the mother's RSV vaccination status is unknown, or the infant was born within 14 days of maternal RSV vaccination. Additionally, a dose of nirsevimab is recommended for some children 8 to 19 months of age who are at increased risk for severe RSV disease and entering their second RSV season. Given the atypical interseasonal change in RSV epidemiology in 2021-2023, the AAP strongly supports the use of palivizumab and nirsevimab in patients who would be candidates per the current eligibility recommendations. See https://publications.aap.org/redbook/resources/25379/ for details (see Chapter 307).

mAbs also are used to prevent transplant rejection and to treat some types of cancer, autoimmune diseases, and asthma. Use of mAbs against interleukin (IL)-2 and tumor necrosis factor (TNF)-α are being used as part of the therapeutic approach to patients with a variety of malignant and autoimmune diseases.

Serious adverse events associated with palivizumab are rare, primarily including cases of anaphylaxis and hypersensitivity reactions. Adverse reactions to nirsevimab are rare and mild to moderate in severity, including rash and injection site reactions. Adverse reactions to mAbs directed at modifying the immune response, such as antibodies against IL-2 or TNF-α, can be more serious and include cytokine release syndrome, fever, chills, tremors, chest pain, immunosuppression, and infection with various organisms, including mycobacteria.

ACTIVE IMMUNIZATION

Vaccines are defined as whole or parts of microorganisms administered to prevent an infectious disease. Vaccines can consist of whole inactivated microorganisms (e.g., polio, hepatitis A), parts of the organism (e.g., acellular pertussis, HPV, hepatitis B), polysaccharide capsules (e.g., pneumococcal and meningococcal polysaccharide vaccines), polysaccharide capsules conjugated to protein carriers (e.g., Hib, pneumococcal, and meningococcal conjugate vaccines), live-attenuated microorganisms (e.g., measles, mumps, rubella, varicella, rotavirus, and live-attenuated influenza vaccines), and toxoids (e.g., tetanus, diphtheria) (Table 215.4). In addition, vaccines against SARS-CoV-2 are messenger RNA (mRNA) vaccines, viral vector vaccines, or protein subunit vaccines. A **toxoid** is a bacterial toxin modified to be nontoxic but still capable of inducing an active immune response against the toxin.

Vaccines can contain a variety of other constituents besides the immunizing antigen. *Suspending* fluids may be sterile water or saline but can be a complex fluid containing small amounts of proteins or other constituents used to grow the immunobiologic culture. Preservatives, stabilizers, and antimicrobial agents are used to inhibit bacterial growth and prevent degradation of the antigen. Such components can include gelatin, 2-phenoxyethanol, and specific antimicrobial agents. Preservatives are added to multidose vials of vaccines, primarily to prevent bacterial contamination on repeated entry of the vial. In the past, many vaccines for children contained thimerosal, a preservative containing ethyl mercury. Removal of thimerosal as a preservative from vaccines for children began as a precautionary measure in 1999 in the absence of any data on harm from the preservative. This objective was accomplished by switching to single-dose packaging. Of the vaccines recommended for young children, only some preparations of influenza vaccine contain thimerosal as a preservative.*

Adjuvants are used in some vaccines to enhance the immune response. In the United States, the only adjuvants currently licensed by the FDA to be part of vaccines are **aluminum salts**: AsO_4, composed of 3-O-desacyl-4′-monophosphoryl 301 lipid A (MPL) adsorbed on to aluminum (as hydroxide salt) and MF59 and 1018 adjuvant. **AsO_4** is

*The thimerosal content in U.S.-licensed vaccines currently being manufactured is listed at http://www.fda.gov/BiologicsBloodVaccines/SafetyAvailability/VaccineSafety/ucm096228.htm#pres.

Table 215.4 Currently Available* Vaccines and Immunizing Agents in the United States by Type

PRODUCT	TYPE
Adenovirus	Live, oral vaccine indicated for active immunization for the prevention of febrile acute respiratory disease caused by adenovirus types 4 and 7 for use in military populations 17-50 yr of age
Anthrax vaccine adsorbed	Cell-free filtrate of components including protective antigen
Bacille Calmette-Guérin (BCG) vaccine	Live-attenuated mycobacterial strain used to prevent tuberculosis in very limited circumstances
Cholera vaccine	Oral vaccine containing live-attenuated *Vibrio cholerae* CVD 103-HgR strain for protection against serogroup O1 in adults age 18-64 traveling to cholera-affected areas
COVID-19 vaccines	Two messenger mRNA-based: Comirnaty (Pfizer-BioNTech) and Spikevax (Moderna). A single adjuvanted, protein subunit-based vaccine, is a Novavax product.
Dengue vaccine	Tetravalent live-attenuated dengue virus (DENV) manufactured by Sanofi Pasteur Use in children age 9-16 yr, with laboratory-confirmed previous dengue virus infection and living in an area where dengue is endemic
Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine	Toxoids of diphtheria and tetanus and purified and detoxified components from *Bordetella pertussis*
DTaP–hepatitis B–inactivated polio vaccine (DTaP-HepB-IPV)	DTaP with hepatitis B surface antigen (HBsAg) produced through recombinant techniques in yeast with inactivated whole polioviruses
DTaP with IPV and *Haemophilus influenzae* type b (Hib) (DTaP-IPV/Hib)	DTaP with inactivated whole polioviruses and Hib polysaccharide conjugated to tetanus toxoid
DTaP with inactivated polio vaccine, *Haemophilus influenzae* type b, and hepatitis B (DTaP-IPV-Hib-HepB)	DTaP with inactivated whole polioviruses, Hib conjugate, and hepatitis B vaccine
DTaP and inactivated polio vaccine (DTaP-IPV)	DTaP with inactivated whole polioviruses
Ebola	Live, recombinant viral vector vaccine: backbone: vesicular stomatitis virus (VSV), with gene encoding for envelope glycoprotein of *Zaire ebolavirus*. Approved for individuals 18 yr of age and older as a single-dose administration.
Hib conjugate vaccine (Hib)	Polysaccharide conjugated to either tetanus toxoid or meningococcal group B outer membrane protein
Hepatitis A vaccine (HepA)	Inactivated whole virus
Hepatitis A–hepatitis B vaccine (HepA-HepB)	Combined hepatitis A and B vaccine
Hepatitis B vaccine (HepB)	HBsAg produced through recombinant techniques in yeast
Human papillomavirus vaccine 9-valent (9vHPV)	The L1 capsid proteins of HPV types 6 and 11 to prevent genital warts and types 16 18, 31, 33, 45, 52, and 58 to prevent cervical cancer (9vHPV)
Influenza virus vaccine inactivated (IIV†)	Available as quadrivalent inactivated formulations that contain hemagglutinin-derived influenza A(H1N1)pdm09 and influenza A(H3N2) components, along with two influenza B viruses (one from each Victoria and Yamagata lineage) Flucelvax is a cell-based inactivated quadrivalent vaccine
Influenza virus vaccine live-attenuated, intranasal (LAIV4)	Live-attenuated, temperature-sensitive, cold-adapted quadrivalent intranasal vaccine containing the hemagglutinin and neuraminidase genes from the wild strains reassorted to have the six other genes from the cold-adapted parent; recommended for 2-49 yr of age
Recombinant influenza vaccine (RIV4)	A quadrivalent formulation of influenza vaccine approved for persons 18 yr old and older
Japanese encephalitis vaccine	Purified, inactivated whole virus
Measles, mumps, rubella (MMR) vaccine	Live-attenuated viruses
Measles, mumps, rubella, varicella (MMRV) vaccine	Live-attenuated viruses
Meningococcal conjugate vaccine against serogroups A, C, W135, and Y (MenACWY)	Polysaccharide from each serogroup conjugated to diphtheria toxoid CRM_{197} protein
Meningococcal polysaccharide vaccine against serogroups A, C, W135, and Y (MPSV4)	Polysaccharides from each of the serogroups conjugated to diphtheria toxoid protein. No longer available in the United States.
Meningococcal B (MenB)	Recombinant proteins from serogroup B developed in *Escherichia coli*
Mpox vaccine	Live replication-deficient modified vaccinia Ankara vaccine
Pneumococcal conjugate vaccine (15, 20 valent PCV15, PCV20)	Pneumococcal polysaccharides conjugated to diphtheria toxin CRM_{197}, containing 15 and 20 pneumococcal serotypes, respectively. These serotypes accounted for >80% of invasive disease in young children before vaccine licensure
Pneumococcal polysaccharide vaccine (23 valent) (PPSV23)	Pneumococcal polysaccharides of 23 serotypes responsible for 85–90% of bacteremic disease in the United States
Poliomyelitis (inactivated, enhanced potency) (IPV)	Inactivated whole virus highly purified from monkey kidney cells, trivalent types 1, 2, and 3
Rabies vaccines (human diploid and purified chicken fibroblasts)	Inactivated whole virus
Respiratory syncytial virus vaccines	RSVPreF3 (Arexvy) and RSVpreF (Abrysvo). Both vaccines are recombinant protein vaccines and are currently approved as a single dose in adults ages 60 and older. Arexvy is adjuvanted. For pregnant women during RSV season, one dose of Abrysvo is recommended
RSV immunization	Human immunoglobulin G1 kappa (IgG1κ) monoclonal antibody produced in Chinese hamster ovary (CHO) cells by recombinant DNA technology.

Table 215.4 Currently Available* Vaccines and Immunizing Agents in the United States by Type—cont'd

PRODUCT	TYPE
Rotavirus vaccines (RV5 and RV1)	Bovine rotavirus pentavalent vaccine (RV5), live reassortment attenuated virus, and human live-attenuated virus (RV1)
Smallpox vaccine	Vaccinia virus, an attenuated poxvirus that provides cross-protection against smallpox (variola)
Tetanus and diphtheria toxoids, adsorbed (Td, adult use)	Tetanus toxoid plus a reduced quantity of diphtheria toxoid compared with diphtheria toxoid used for children <7 yr of age
Tetanus and diphtheria toxoids adsorbed plus acellular pertussis (Tdap) vaccine	Tetanus toxoid plus a reduced quantity of diphtheria toxoid plus acellular pertussis vaccine to be used in adolescents and adults and in children 7-10 yr of age who have not been appropriately immunized with DTaP
Tickborne encephalitis vaccine	Whole tickborne-encephalitis virus (TBE) inactivated vaccine. Currently no ACIP/CDC recommendations available for this vaccine
Typhoid vaccine (polysaccharide)	Vi capsular polysaccharide of *Salmonella* Typhi Ty2 strain
Typhoid vaccine (oral)	Live-attenuated Ty21a strain of *S. typhi*
Varicella vaccine	Live-attenuated Oka/Merck strain
Yellow fever vaccine	Live-attenuated 17D-204 strain
Herpes zoster (shingles) vaccine	Zoster vaccine recombinant, adjuvanted (Shingrix) for use in adults ≥50 yr and in adults age 18 yr and older who are or will be at increased risk of herpes zoster because of immunodeficiency or immunosuppression caused by known disease or therapy

*As of November 2023.
†There are various types of inactivated flu vaccines—IIV4, ccIIV4, and aIIV4.
Data from U.S. Food and Drug Administration. Vaccines licensed for use in the United States. http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm093833.tm.

found in one type of HPV vaccine, no longer available in the United States but still used in Europe. **MF59** is an oil-in-water emulsion found in one type of influenza vaccine approved for people ≥65 years old; it is also being studied in children. 1018 is an immunostimulatory sequence adjuvant used in HepB-CpG, a hepatitis B vaccine approved for persons >18 years. HepB-CpG contains yeast-derived recombinant hepatitis B surface antigen (HBsAg) and is prepared by combining purified HBsAg with small synthetic immunostimulatory cytidine-phosphate-guanosine oligodeoxynucleotide motifs. The 1018 adjuvant binds to toll-like receptor 9 to simulate a directed immune response to HBsAg. Vaccines with adjuvants should be injected deeply into muscle masses to avoid local irritation, granuloma formation, and necrosis associated with SC or intracutaneous administration.

Vaccines can induce immunity by stimulating antibody formation, cellular immunity, or both. Protection induced by most vaccines is thought to be mediated primarily by B lymphocytes, which produce antibodies. Such antibodies can inactivate toxins, neutralize viruses, and prevent their attachment to cellular receptors, facilitate phagocytosis and killing of bacteria, interact with complement to lyse bacteria, and prevent adhesion to mucosal surfaces by interacting with the bacterial cell surface.

Most B-lymphocyte responses require the assistance of CD4 helper T lymphocytes. These T-lymphocyte–dependent responses tend to induce high levels of functional antibody with high avidity. The T-dependent responses mature over time from primarily an IgM response to a persistent, long-term IgG response and induce immunologic memory that leads to enhanced responses on boosting. **T-lymphocyte–dependent vaccines**, which include protein moieties, induce good immune responses even in young infants. In contrast, polysaccharide antigens induce B-lymphocyte responses in the absence of T-lymphocyte help. These **T-lymphocyte–independent vaccines** are associated with poor immune responses in children <2 years old and with short-term immunity and absence of an enhanced or booster response on repeat exposure to the antigen. With some polysaccharide vaccines, repeat doses actually are associated with reduced responses, as measured by antibody concentrations, compared with first doses (i.e., *hyporesponsive*). To overcome problems with plain polysaccharide vaccines, polysaccharides have been **conjugated**, or covalently linked, to protein carriers, converting the vaccine to a T-lymphocyte–dependent vaccine. In contrast to plain polysaccharide vaccines, conjugate vaccines induce higher-avidity antibody, immunologic memory leading to booster responses on repeat exposure to the antigen, long-term immunity, and community protection by decreasing carriage of the organism (Table 215.5). As of 2023 in the United States, licensed conjugate vaccines are available to prevent Hib, pneumococcal, and meningococcal diseases.

Table 215.5 Characteristics of Polysaccharide and Conjugate Vaccines

CHARACTERISTIC	CONJUGATE	POLYSACCHARIDE
T-lymphocyte–dependent immune response	Yes	No
Immune memory	Yes	No
Persistence of protection	Yes	No
Booster effect	Yes	No
Reduction of carriage	Yes	No
Community protection	Yes	No
Lack of hyporesponsiveness	Yes	No

Serum antibodies may be detected as soon as 7-10 days after initial injection of antigen. Early antibodies are usually of the IgM class that can fix complement. IgM antibodies tend to decline as IgG antibodies increase. The IgG antibodies tend to peak approximately 1 month after vaccination and with most vaccines persist for some time after a primary vaccine course. Secondary or booster responses occur more rapidly and result from rapid proliferation of memory B and T lymphocytes.

Assessment of the immune response to most vaccines is performed by measuring serum antibodies. Although detection of serum antibody at levels considered protective after vaccination can indicate immunity, loss of detectable antibody over time does not necessarily mean susceptibility to disease. Some vaccines induce immunologic memory, leading to a booster or anamnestic response on exposure to the microorganism, with resultant protection from disease. In some cases, cellular immune response is used to evaluate the status of the immune system. Certain vaccines (e.g., acellular pertussis) do not have an accepted serologic correlate of protection.

Live-attenuated vaccines routinely recommended for children and adolescents include measles, mumps, and rubella **(MMR)**; MMR and varicella **(MMRV)**; rotavirus; and varicella. In addition, a cold-adapted, live-attenuated quadrivalent influenza vaccine **(LAIV4)** is available for influenza.

Live-attenuated vaccines tend to induce long-term immune responses. They replicate, often similarly to natural infections, until an immune response inhibits reproduction. Most live vaccines are administered in one-dose or two-dose schedules. The purpose of

repeat doses, such as a second dose of the MMR or MMRV vaccine, is to induce an initial immune response in those who failed to respond to the first dose. Because influenza viruses tend to mutate to evade preexisting immunity to prior strains, at least one of the strains in influenza vaccines each year is often different than in the previous year. Thus influenza vaccines are recommended to be administered yearly.

The remaining vaccines in the recommended schedule for children and adolescents are inactivated vaccines. **Inactivated vaccines** tend to require multiple doses to induce an adequate immune response and are more likely than live-attenuated vaccines to need booster doses to maintain that immunity. However, some inactivated vaccines appear to induce long-term or perhaps lifelong immunity after a primary series, including hepatitis B vaccine and inactivated polio vaccine.

VACCINATION SYSTEM IN THE UNITED STATES

Vaccine Production

Vaccine production is primarily a responsibility of private industry. Many of the vaccines recommended routinely for children are produced by only one vaccine manufacturer. Vaccines with multiple manufacturers include Hib, hepatitis B, rotavirus, MCV4 (meningococcal conjugate vaccine against serogroups A, C, W135, and Y), COVID-19 vaccine, diphtheria and tetanus toxoids and acellular pertussis (DTaP), and tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccines for adolescents and adults. Inactivated polio vaccine (IPV) as an IPV-only vaccine has only one manufacturer, but IPV is also available in combination products (DTaP–hepatitis B–IPV, DTaP–IPV/Hib, and DTaP–IPV) from different manufacturers. Influenza vaccine for children 6-35 months of age is produced by fewer manufacturers. MMR, MMRV, varicella, pneumococcal conjugate vaccines, and tetanus and diphtheria (Td) vaccines also are produced by single manufacturers. The FDA has authorized for emergency use the Pfizer-BioNTech and Moderna COVID-19 vaccines for the prevention of COVID-19 disease in individuals 6 months of age and older. The FDA has also authorized the Novavax COVID-19 vaccine for individuals 12 years of age and older.

Vaccine Policy

Two major committees make vaccine policy recommendations for children: the Committee on Infectious Diseases (COID) of the AAP (the *Red Book* Committee) and the Advisory Committee on Immunization Practices (ACIP) of the CDC. Annually, the AAP, ACIP, American Academy of Family Physicians (AAFP), American College of Obstetricians and Gynecologists (ACOG), American College of Nurse-Midwives (www.midwife.org), American Academy of Physician Assistants (www.aapa.org), and National Association of Pediatric Nurse Practitioners (www.napnap.org) issue a harmonized childhood and adolescent immunization schedule. (http://www.cdc.gov/vaccines/schedules/index.html). The ACIP recommendations (http://www.cdc.gov/vaccines/acip/recs/index.html) are official only after adoption by the CDC director, which leads to publication in the *Morbidity and Mortality Weekly Report (MMWR Morb Mortal Wkly Rep)*. The AAP recommendations are published in *Pediatrics* and the *Red Book*, which includes its continuously updated online version (aapredbook.org).

Vaccine Financing

Approximately 50% of vaccines routinely administered to children and adolescents <19 years of age are purchased through a contract negotiated by the federal government with licensed vaccine manufacturers. Three major sources of funds are available to purchase vaccines through this contract. The greatest portion comes from the **Vaccines for Children (VFC)** program (http://www.cdc.gov/vaccines/programs/vfc/index.html), a federal entitlement program established in 1993. The VFC program covers children receiving Medicaid, children without insurance (uninsured), and Native Americans and Alaska Natives. In addition, underinsured children whose insurance does not cover immunization can be covered through VFC, but only if they go to a federally qualified health center (http://www.cms.gov/center/fqhc.asp). In contrast to other public funding sources that require approval of discretionary funding by legislative bodies, VFC funds are immediately available for new recommendations. These funds are only available if the ACIP votes the vaccine and the recommendation for its use into the VFC program, the federal government negotiates a contract, and the Office of Management and Budget (OMB) apportions funds. The VFC program can provide free vaccines to participating private providers for administration to children eligible for coverage under the program. The second major federal funding source is the Section 317 **Discretionary Federal Grant Program** to states and selected localities. These funds must be appropriated annually by Congress, and in contrast to VFC, they do not have eligibility requirements for use. The third major public source of funds is **state appropriations**.

The VFC program itself does not cover vaccine administration costs. Medicaid covers the administration fees for children enrolled in the program. Parents of other children eligible for VFC must pay administration fees out of pocket, although the law stipulates that no one eligible for the program can be denied vaccines because of inability to pay the administration fee. The Affordable Care Act (ACA) states that all vaccines recommended by ACIP and those included in the harmonized annual immunization schedules must be provided by qualified insurance programs with no copay and no deductible. For eligible children and adults, the COVID-19 vaccine is free of charge. (https://www.cdc.gov/vaccines/programs-/bridge/index.html).

Vaccine Safety Monitoring

Monitoring vaccine safety is the responsibility of the FDA, CDC, and vaccine manufacturers. A critical part of that monitoring depends on reports provided to the **Vaccine Adverse Event Reporting System (VAERS)**, the country's early warning system for vaccine safety comanaged by the CDC and the FDA. Adverse events after immunization can be reported by completing a VAERS form, which can be obtained from http://www.vaers.hhs.gov, or by calling 800-822-7967. VAERS can rapidly detect safety signals and rare adverse events but is not designed to assess causality. Individual VAERS case reports may be helpful in identifying potential vaccine safety concerns that can generate hypotheses about whether vaccines are causing certain clinical syndromes. In general, however, the reports are not helpful in evaluating the causal role of vaccines in the adverse event, because most clinical syndromes that follow vaccination are similar to syndromes that occur in the absence of vaccination, which constitute background rates. For causality assessment, epidemiologic studies are often necessary, comparing the incidence rate of the adverse event after vaccination with the rate in unvaccinated individuals. A statistically significant higher rate in vaccinated individuals would be consistent with causation. **V-safe** is a smartphone-based tool that uses text messaging and web surveys to provide personalized health check-ins for up to a year after someone receives a COVID-19 vaccine. Through v-safe, COVID-19 vaccine recipients are able to communicate with the CDC regarding possible side effects (https://www.cdc.gov/coronavirus/2019-ncov/vaccines/safety/pdfs/v-safe-information-sheet-508c.pdf).

The **Vaccine Safety Datalink** gathers data from nine participating integrated healthcare organizations on over 12 million people per year. It consists of inpatient and outpatient records of some of the largest managed-care organizations in the United States and facilitates causality evaluation. In addition, the **Clinical Immunization Safety Assessment (CISA)** network has been established to advise primary care physicians on evaluation and management of adverse events (http://www.cdc.gov/vaccinesafety/Activities/CISA.html). CISA facilitates the CDC's collaboration with a network of vaccine safety experts at seven leading academic medical centers and strengthens national capacity for vaccine safety monitoring and clinical research.

The Health and Medicine Division (HMD) of the National Academies of Sciences, Engineering and Medicine, previously the Institute of Medicine (IOM), has independently reviewed a variety of vaccine safety concerns and published reports summarizing its findings.* From 2001 through 2004, the IOM released eight reports, concluding that the body of epidemiologic evidence did not show an association between vaccines and autism. In 2012 the IOM (HMD) report *Adverse Effects of Vaccines: Evidence and Causality*** reviewed a list of reported adverse effects associated with eight vaccines to evaluate the scientific evidence, if any, of an event-vaccine relationship. The IOM committee had developed 158 causality conclusions and assigned each relationship between a vaccine and

* http://nationalacademies.org/hmd/Reports.aspx?filters=inmeta:activity=Immunization+Safety+Review.
** https://www.nap.edu/catalog/13164/adverse-effects-of-vaccines-evidence-and-causality

an adverse health problem to one of four causation categories. The committee concluded that available evidence convincingly supported a causal relationship between **anaphylaxis** and MMR, varicella-zoster, influenza, hepatitis B, meningococcal, and tetanus-containing vaccines. Additionally, the evidence *favored rejection* of five vaccine–adverse event relationships, including MMR vaccine and autism, inactivated influenza vaccines and asthma episodes and Bell palsy, and MMR and DTaP and type 1 diabetes mellitus. For the majority of cases (135 vaccine–adverse event pairs), the evidence was inadequate to accept or reject a causal relationship because of the rarity of the events. Overall, the committee concluded that few health problems are caused by or clearly associated with vaccines.

In 2013, the HMD released the report *Childhood Immunization Schedule and Safety: Stakeholder Concerns, Scientific Evidence, and Future Studies.*[†] The HMD uncovered no evidence of major safety concerns associated with adherence to the recommended childhood immunization schedule. The HMD specifically found no links between the immunization schedule and autoimmune diseases, asthma, hypersensitivity, seizures, child developmental disorders, learning or developmental disorders, or attention-deficit or disruptive disorders. Additionally, use of nonstandard schedules is harmful, because it increases the period of risk of acquiring vaccine-preventable diseases and increases the risk of incomplete immunization.[‡] In addition, the Agency for Healthcare Research and Quality (AHRQ) contracted with the Rand Corporation for an independent systematic review of the immunization schedule. That review concluded that although some vaccines are associated with serious adverse events, these events are extremely rare and must be weighed against the protective benefits that vaccines provide. The AAP has summarized the information on a variety of safety issues and different vaccines.[§]

The **National Vaccine Injury Compensation Program (VICP)** is designed to compensate people injured by vaccines in the childhood and adolescent immunization schedule. The program is funded through an excise tax of $0.75 on vaccines recommended by the CDC per disease prevented per dose (e.g., the quadrivalent influenza vaccine is taxed $0.75 because it prevents one disease; the MMR vaccine is taxed $2.25 because it prevents three diseases). As of 2023, this program covers all the routinely recommended vaccines that protect children against 16 diseases. The VICP was established to provide a no-fault system, with a table of related injuries and time frames. In April 2018 the table was modified to reflect changes in the 21st Century Cures Act, requiring that the VICP cover vaccines recommended for routine administration in pregnant women. All people alleging injury from covered vaccines must first file with the program. If the injury meets the requirements of the table, compensation is automatic. If not, the claimant has the responsibility to prove causality. If compensation is accepted, the claimant cannot sue the manufacturer or physician administering the vaccine. If the claimant rejects the judgment of the compensation system, the claimant can enter the tort system, which is uncommon. Information on the VICP is available at http://www.hrsa.gov/vaccinecompensation or by calling 800-338-2382. All vaccines included in the child and adolescent vaccine schedule are covered by VICP except dengue, PPSV23, and COVID-19 vaccines. COVID-19 vaccines that are authorized or approved by the FDA are covered by the Countermeasures Injury Compensation Program (CICP). For more information, see www.hrsa.gov/ vaccinecompensation or www.hrsa.gov/cicp. All physicians administering a vaccine covered by the program are required by law to give the approved **Vaccine Information Statement (VIS)** to the child's parent or guardian at each visit before administering vaccines. Information on the VIS can be obtained from http://www.cdc.gov/vaccines/hcp/vis/index.html. There is no VIS for COVID-19 vaccines authorized under an emergency use authorization (EUA). For each COVID-19 vaccine approved by the FDA, a Vaccine Information Fact Sheet for recipients and caregivers is available. The FDA also requires that recipients or their caregivers be provided with certain vaccine-specific information for any COVID vaccine authorized under an EUA to help make an informed decision about vaccination. This is accomplished by providing an EUA Fact Sheet for Recipients and Caregivers. The fact sheet is similar in purpose and content to VISs for licensed vaccines but differs in that the EUA fact sheet is specific to each authorized COVID-19 vaccine, is developed by the manufacturer of the vaccine, and is authorized by the FDA. EUA fact sheets are available at https://www.cdc.gov/vaccines/covid-19/eua/index.html.

Vaccine Delivery

To ensure potency, vaccines should be stored at recommended temperatures before and after reconstitution. A comprehensive resource for providers on vaccine storage and handling recommendations and best practice strategies is available (https://www.cdc.gov/vaccines/hcp/admin/storage/index.html). Expiration dates should be noted and expired vaccines discarded. Lyophilized vaccines often have long shelf lives. However, the shelf life of reconstituted vaccines generally is short, ranging from 30 minutes for varicella vaccine to 8 hours for MMR vaccine.

All vaccines have a preferred route of administration, which is specified in package inserts and in AAP and ACIP recommendations. Most inactivated vaccines, including DTaP, hepatitis A, hepatitis B, Hib, inactivated influenza vaccine (IIV), HPV, PCV, COVID-19 vaccines, MCV4, and Tdap, are administered IM. In contrast, the more commonly used live-attenuated vaccines (MMR, MMRV, and varicella) should be dispensed by the SC route. Rotavirus vaccine is administered orally. IPV and PPS23 (pneumococcal polysaccharide vaccine) can be given IM or SC. One influenza vaccine, LAIV4, when recommended, is administered intranasally. For IM injections, the anterolateral thigh muscle is the preferred site for infants and young children. The recommended needle length varies depending on age and size: ⅝ inch for newborn infants, 1 inch for infants 2-12 months old, and ⅝ to 1 inch for children 3-10 years of age. For adolescents and adults, the deltoid muscle of the arm is the preferred site for IM administration with needle lengths of 1-1¼ inches depending on patient size. Most IM injections can be made with 23- to 25-gauge needles. For SC injections, needle lengths generally range from ⅝ to ¾ inch with 23- to 25-gauge needles.

Additional aspects of immunization important for pediatricians and other healthcare providers are detailed on the websites listed in Table 215.6.

RECOMMENDED IMMUNIZATION SCHEDULE

All children in the United States should be immunized against 19 diseases (Fig. 215.1 and Table 215.7) (annually updated schedule available at http://www.cdc.gov/vaccines/schedules/index.html).

Hepatitis B vaccine (HepB) is recommended in a three-dose schedule starting at birth. The birth dose, as well as hepatitis B immunoglobulin, is critical for infants born to mothers who are HBsAg-positive or whose hepatitis B immune status is unknown. The recommendation is to administer the first hepatitis B vaccine to all newborns within 24 hours of birth, the second dose at 1-2 months, with a minimal interval between the first and second dose of 4 weeks, and the third dose from 6 to 18 months of age, ensuring that 8 weeks has passed between the second and third dose. If either the DTaP-HepB-IPV combination vaccine or the DTaP-IPV-Hib-HepB combination vaccine is used, a four-dose schedule is permissible, which includes the stand-alone hepatitis B vaccine at birth and the combination vaccine for the next three doses. There are multiple alternatives for catch-up vaccination with HepB vaccine depending on the child's age. See the immunization schedule notes for clarification.

The **DTaP** series consists of five doses administered at 2, 4, 6, and 15 through 18 months of age and 4 through 6 years of age. The fourth dose of DTaP may be administered as early as 12 months of age, provided at least 6 months have elapsed since the third dose. The fifth (booster) dose of DTaP vaccine is not necessary if the fourth dose was administered at 4 years or older. One dose of an adult preparation of Tdap is recommended for all adolescents 11 through 12 years of age, even if a dose of Tdap or DTaP was administered inadvertently or as part of the catch-up series at 7-9 years of age. If Tdap is administered at 10 years of age, an additional booster at 11-12 years of age is not recommended. Adolescents 13 through 18 years who missed the 11 through 12 year Tdap booster dose should receive a single dose of Tdap if they have completed the diphtheria, tetanus, and pertussis (DTP)/DTaP series. Tdap may be given at any interval after the last Td. Table 215.8 lists preparations in which DTaP is

Recommended Child and Adolescent Immunization Schedule for Ages 18 Years or Younger, United States, 2024

These recommendations must be read with the notes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars. To determine minimum intervals between doses, see the catch-up schedule (Table 215.7).

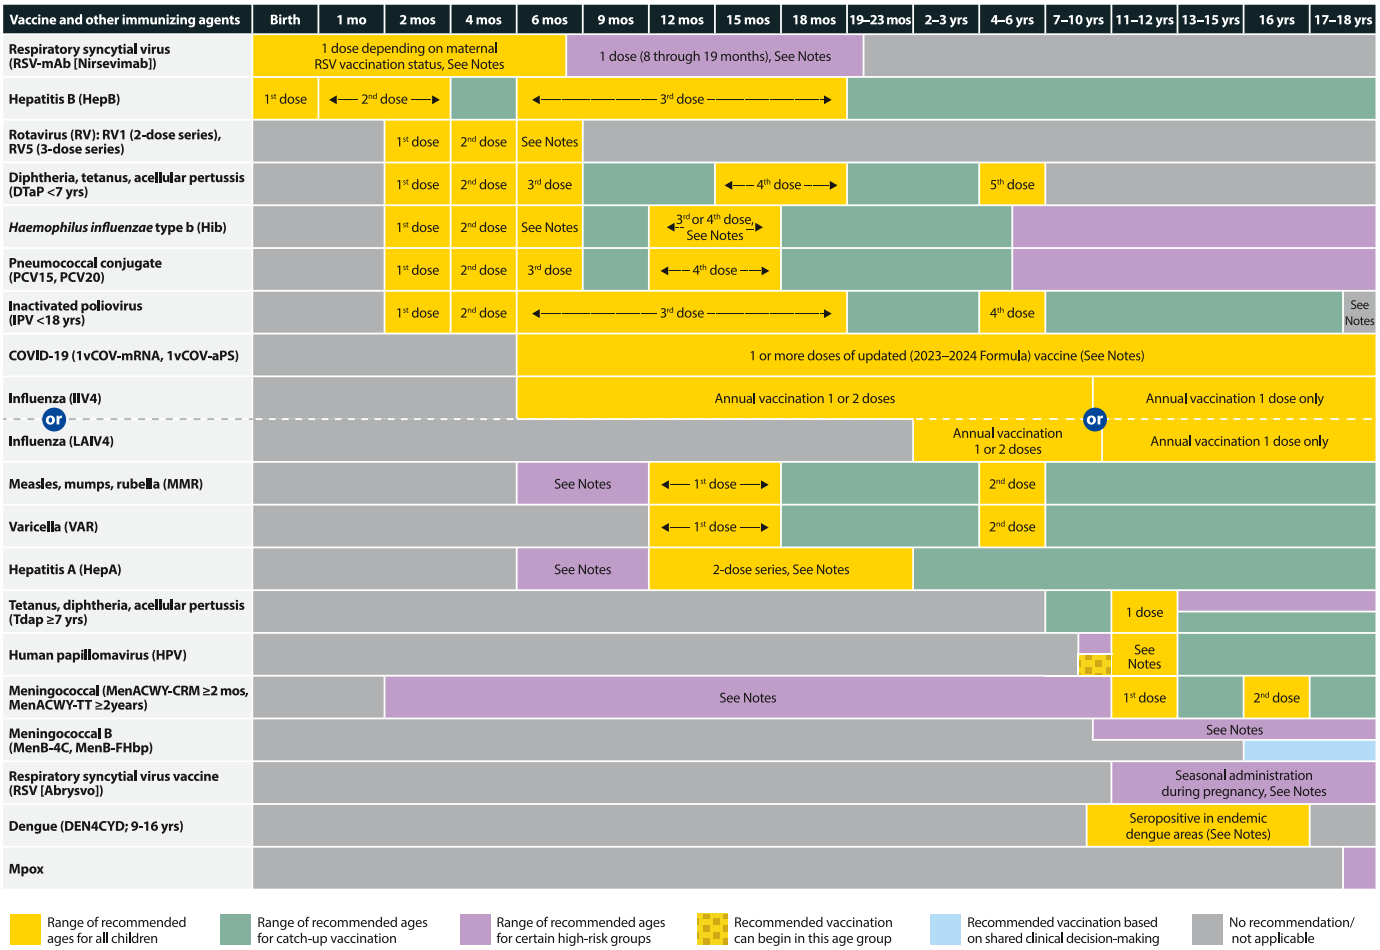

Fig. 215.1 Recommended immunization schedule for children and adolescents age 18 yr or younger—United States, 2024, including an appendix detailing contraindications and precautions for commonly used vaccines. *These recommendations must be read with the notes that follow.* For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the *green bars.* A new addendum section has been added to list any ACIP recommendations that occur by majority vote and are approved by CDC Director after the 2024 immunization schedules are approved and published. To determine minimum intervals between doses, see the Catch-Up Schedule (see Table 215.7). *(Courtesy U.S. Centers for Disease Control and Prevention, Atlanta, 2023. https://www.cdc.gov/vaccines/schedules/downloads/child/0-18yrs-child-combined-schedule.pdf; Appendix is adapted from the Advisory Committee on Immunization Practices [ACIP] General Best Practice Guidelines for Immunization: Contraindication and Precautions, Table 4-1, available at www.cdc.gov/vaccines/hcp/acip-recs/general-recs/contraindications.html and from the ACIP's Recommendations for the Prevention and Control of 2023-24 seasonal influenza with vaccines available at www.cdc.gov/mmwr/volumes/71/rr/rr7101a1.htm.)*

Notes

For vaccination recommendations for persons ages 19 years or older, see the Recommended Adult Immunization Schedule, 2024.

Additional information

- For calculating intervals between doses, 4 weeks = 28 days. Intervals of ≥4 months are determined by calendar months.
- Within a number range (e.g., 12–18), a dash (–) should be read as "through."
- Vaccine doses administered ≤4 days before the minimum age or interval are considered valid. Doses of any vaccine administered ≥5 days earlier than the minimum age or minimum interval should not be counted as valid and should be repeated as age appropriate. **The repeat dose should be spaced after the invalid dose by the recommended minimum interval.** For further details, see Table 3-2, Recommended and minimum ages and intervals between vaccine doses, in *General Best Practice Guidelines for Immunization* at www.cdc.gov/vaccines/hcp/acip-recs/general-recs/timing.html.
- Information on travel vaccination requirements and recommendations is available at www.cdc.gov/travel/.
- For vaccination of persons with immunodeficiencies, see Table 8-1, Vaccination of persons with primary and secondary immunodeficiencies, in *General Best Practice Guidelines for Immunization* at www.cdc.gov/vaccines/hcp/acip-recs/general-recs/immunocompetence.html, and Immunization in Special Clinical Circumstances (In: Kimberlin DW, Barnett ED, Lynfield Ruth, Sawyer MH, eds. *Red Book: 2021–2024 Report of the Committee on Infectious Diseases*. 32nd ed. Itasca, IL: American Academy of Pediatrics; 2021:72–86).
- For information about vaccination in the setting of a vaccine-preventable disease outbreak, contact your state or local health department.
- The National Vaccine Injury Compensation Program (VICP) is a no-fault alternative to the traditional legal system for resolving vaccine injury claims. All vaccines included in the child and adolescent vaccine schedule are covered by VICP except dengue, PPSV23, RSV, Mpox and COVID-19 vaccines. Mpox and COVID-19 vaccines are covered by the Countermeasures Injury Compensation Program (CICP). For more information, see www.hrsa.gov/vaccinecompensation or www.hrsa.gov/cicp.

COVID-19 vaccination (minimum age: 6 months [Moderna and Pfizer-BioNTech COVID-19 vaccines], 12 years [Novavax COVID-19 Vaccine])

Routine vaccination

Age 6 months–4 years

- **Unvaccinated:**
  - 2-dose series of updated (2023–2024 Formula) Moderna at 0, 4-8 weeks
  - 3-dose series of updated (2023–2024 Formula) Pfizer-BioNTech at 0, 3-8, 11-16 weeks
- **Previously vaccinated* with 1 dose of any Moderna:** 1 dose of updated (2023–2024 Formula) Moderna 4-8 weeks after the most recent dose.
- **Previously vaccinated* with 2 or more doses of any Moderna:** 1 dose of updated (2023–2024 Formula) Moderna at least 8 weeks after the most recent dose.
- **Previously vaccinated* with 1 dose of any Pfizer-BioNTech:** 2-dose series of updated (2023–2024 Formula) Pfizer-BioNTech at 0, 8 weeks (minimum interval between previous Pfizer-BioNTech and dose 1: 3-8 weeks).
- **Previously vaccinated* with 2 or more doses of any Pfizer-BioNTech:** 1 dose of updated (2023–2024 Formula) Pfizer-BioNTech at least 8 weeks after the most recent dose.

Age 5–11 years

- **Unvaccinated:** 1 dose of updated (2023–2024 Formula) Moderna or Pfizer-BioNTech vaccine.
- **Previously vaccinated* with 1 or more doses of Moderna or Pfizer-BioNTech:** 1 dose of updated (2023–2024 Formula) Moderna or Pfizer-BioNTech at least 8 weeks after the most recent dose.

Age 12–18 years

- **Unvaccinated:**
  - 1 dose of updated (2023–2024 Formula) Moderna or Pfizer-BioNTech vaccine
  - 2-dose series of updated (2023–2024 Formula) Novavax at 0, 3-8 weeks
- **Previously vaccinated* with any COVID-19 vaccine(s):** 1 dose of any updated (2023–2024 Formula) COVID-19 vaccine at least 8 weeks after the most recent dose.

Special situations

Persons who are moderately or severely immunocompromised**

Age 6 months–4 years

- **Unvaccinated:**
  - 3-dose series of updated (2023–2024 Formula) Moderna at 0, 4, 8 weeks
  - 3-dose series of updated (2023–2024 Formula) Pfizer-BioNTech at 0, 3, 11 weeks.
- **Previously vaccinated* with 1 dose of any Moderna:** 2-dose series of updated (2023–2024 Formula) Moderna at 0, 4 weeks (minimum interval between previous Moderna and dose 1: 4 weeks).
- **Previously vaccinated* with 2 doses of any Moderna:** 1 dose of updated (2023–2024 Formula) Moderna at least 4 weeks after the most recent dose.
- **Previously vaccinated* with 3 or more doses of any Moderna:** 1 dose of updated (2023–2024 Formula) Moderna at least 8 weeks after the most recent dose.
- **Previously vaccinated* with 1 dose of any Pfizer-BioNTech:** 2-dose series of updated (2023–2024 Formula) Pfizer-BioNTech at 0, 8 weeks (minimum interval between previous Pfizer-BioNTech and dose 1: 3 weeks).
- **Previously vaccinated* with 2 or more doses of any Pfizer-BioNTech:** 1 dose of updated (2023–2024 Formula) Pfizer-BioNTech at least 8 weeks after the most recent dose.

Age 5–11 years

- **Unvaccinated:**
  - 3-dose series of updated (2023–2024 Formula) Moderna at 0, 4, 8 weeks
  - 3-dose series updated (2023–2024 Formula) Pfizer-BioNTech at 0, 3, 7 weeks.
- **Previously vaccinated* with 1 dose of any Moderna:** 2-dose series of updated (2023–2024 Formula) Moderna at 0, 4 weeks (minimum interval between previous Moderna and dose 1: 4 weeks).
- **Previously vaccinated* with 2 doses of any Moderna:** 1 dose of updated (2023–2024 Formula) Moderna at least 4 weeks after the most recent dose.
- **Previously vaccinated* with 1 dose of any Pfizer-BioNTech:** 2-dose series of updated (2023–2024 Formula) Pfizer-BioNTech at 0, 4 weeks (minimum interval between previous Pfizer-BioNTech and dose 1: 3 weeks)
- **Previously vaccinated* with 2 doses of any Pfizer-BioNTech:** 1 dose of 2023–2024 Pfizer-BioNTech at least 4 weeks after the most recent dose.
  - **Prospectively:** Dose 4 may be administered as early as age 12 months if at least 6 months have elapsed since dose 3.
  - **Retrospectively:** A 4th dose that was inadvertently administered as early as age 12 months may be counted if at least 4 months have elapsed since dose 3.

Catch-up vaccination

- Dose 5 is not necessary if dose 4 was administered at age 4 years or older and at least 6 months after dose 3.
- For other catch-up guidance, see Table 2.

Special situations

- **Wound management** in children less than age 7 years with history of 3 or more doses of tetanus-toxoid-containing vaccine: For all wounds except clean and minor wounds, administer DTaP if more than 5 years since last dose of tetanus-toxoid-containing vaccine. For detailed information, see www.cdc.gov/mmwr/volumes/67/rr/rr6702a1.htm.

Haemophilus influenzae type b vaccination (minimum age: 6 weeks)

Routine vaccination

- **ActHIB®, Hiberix®, Pentacel®, or Vaxelis®:** 4-dose series (3-dose primary series at age 2, 4, and 6 months, followed by a booster dose* at age 12–15 months)
  - *Vaxelis® is not recommended for use as a booster dose. A different Hib-containing vaccine should be used for the booster dose.
- **PedvaxHIB®:** 3-dose series (2-dose primary series at age 2 and 4 months, followed by a booster dose at age 12–15 months)

Catch-up vaccination

- **Dose 1 at age 7–11 months:** Administer dose 2 at least 4 weeks later and dose 3 (final dose) at age12–15 months or 8 weeks after dose 2 (whichever is later).
- **Dose 1 at age 12–14 months:** Administer dose 2 (final dose) at least 8 weeks after dose 1.
- **Dose 1 before age 12 months and dose 2 before age 15 months:** Administer dose 3 (final dose) at least 8 weeks after dose 2.
- **2 doses of PedvaxHIB® before age 12 months:** Administer dose 3 (final dose) at age12–59 months and at least 8 weeks after dose 2.
- **1 dose administered at age 15 months or older:** No further doses needed
- **Unvaccinated at age 15–59 months:** Administer 1 dose.

- **Previously vaccinated* with 3 or more doses of any Moderna or Pfizer-BioNTech:** 1 dose of updated (2023–2024 Formula) Moderna or Pfizer-BioNTech at least 8 weeks after the most recent dose.

Age 12–18 years

- **Unvaccinated:**
  - 3-dose series of updated (2023–2024 Formula) Moderna at 0, 4, 8 weeks
  - 3-dose series of updated (2023–2024 Formula) Pfizer-BioNTech at 0, 3, 7 weeks
  - 2-dose series of updated (2023–2024 Formula) Novavax at 0, 3 weeks
- **Previously vaccinated* with 1 dose of any Moderna:** 2-dose series of updated (2023–2024 Formula) Moderna at 0, 4 weeks (minimum interval between previous Moderna dose and dose 1: 4 weeks).
- **Previously vaccinated* with 2 doses of any Moderna:** 1 dose of updated (2023–2024 Formula) Moderna at least 4 weeks after the most recent dose.
- **Previously vaccinated* with 1 dose of any Pfizer-BioNTech:** 2-dose series of updated (2023–2024 Formula) Pfizer-BioNTech at 0, 4 weeks (minimum interval between previous Pfizer-BioNTech dose and dose 1: 3 weeks).
- **Previously vaccinated* with 2 doses of any Pfizer-BioNTech:** 1 dose of updated (2023–2024 Formula) Pfizer-BioNTech at least 4 weeks after the most recent dose.
- **Previously vaccinated* with 3 or more doses of any Moderna or Pfizer-BioNTech:** 1 dose of any updated (2023–2024 Formula) COVID-19 vaccine at least 8 weeks after the most recent dose.
- **Previously vaccinated* with 1 or more doses of Janssen or Novavax or with or without dose(s) of any Original monovalent or bivalent COVID-19 vaccine:** 1 dose of any updated (2023–2024 Formula) COVID-19 vaccine at least 8 weeks after the most recent dose.

There is no preferential recommendation for the use of one COVID-19 vaccine over another when more than one recommended age-appropriate vaccine is available.

Administer an age-appropriate COVID-19 vaccine product for each dose. For information about transition from age 4 years to age 5 years or age 11 years to age 12 years during COVID-19 vaccination series, see Tables 1 and 2 at www.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us.html#covid-vaccines.

Current COVID-19 schedule and dosage formulation available at www.cdc.gov/covidschedule. For more information on Emergency Use Authorization (EUA) indications for COVID-19 vaccines, see www.fda.gov/emergency-preparedness-and-response/coronavirus-disease-2019-covid-19/covid-19-vaccines

***Note:** Previously vaccinated is defined as having received any Original monovalent or bivalent COVID-19 vaccine (Janssen, Moderna, Novavax, Pfizer-BioNTech) prior to the updated 2023–2024 formulation.

****Note:** Persons who are moderately or severely immunocompromised have the option to receive one additional dose of updated (2023–2024 Formula) COVID-19 vaccine at least 2 months following the last recommended updated (2023–2024 Formula) COVID-19 vaccine dose. Further additional updated (2023–2024 Formula) COVID-19 vaccine dose(s) may be administered, informed by the clinical judgement of a healthcare provider and personal preference and circumstances. Any further additional doses should be administered at least 2 months after the last updated (2023–2024 Formula) COVID-19 vaccine dose. Moderately or severely immunocompromised children 6 months–4 years of age should receive homologous updated (2023–2024 Formula) mRNA vaccine dose(s) if they receive additional doses.

Dengue vaccination (minimum age: 9 years)

Routine vaccination

- Age 9–16 years living in areas with endemic dengue **AND** have laboratory confirmation of previous dengue infection
  - 3-dose series administered at 0, 6, and 12 months
- Endemic areas include Puerto Rico, American Samoa, US Virgin Islands, Federated States of Micronesia, Republic of Marshall Islands, and the Republic of Palau. For updated guidance on dengue endemic areas and pre-vaccination laboratory testing see www.cdc.gov/mmwr/volumes/70/rr/rr7006a1.htm?s_cid=rr7006a1_w and www.cdc.gov/dengue/vaccine/hcp/index.html
- Dengue vaccine should not be administered to children traveling to or visiting endemic dengue areas.

Diphtheria, tetanus, and pertussis (DTaP) vaccination (minimum age: 6 weeks [4 years for Kinrix® or Quadracel®])

Routine vaccination

- 5-dose series (3-dose primary series at age 2, 4, and 6 months, followed by a booster doses at ages 15–18 months and 4–6 years

Fig. 215.1, cont'd

- **Previously unvaccinated children age 60 months or older who are not considered high risk:** Do not require catch-up vaccination

For other catch-up guidance, see Table 2. Vaxelis® can be used for catch-up vaccination in children less than age 5 years. Follow the catch-up schedule even if Vaxelis® is used for one or more doses. For detailed information on use of Vaxelis® see www.cdc.gov/mmwr/volumes/69/wr/mm6905a5.htm.

Special situations

- **Chemotherapy or radiation treatment:**
  Age 12–59 months
  - Unvaccinated or only 1 dose before age 12 months: 2 doses, 8 weeks apart
  - 2 or more doses before age 12 months: 1 dose at least 8 weeks after previous dose

  Doses administered within 14 days of starting therapy or during therapy should be repeated at least 3 months after therapy completion.
- **Hematopoietic stem cell transplant (HSCT):**
  - 3-dose series 4 weeks apart starting 6 to 12 months after successful transplant, regardless of Hib vaccination history
- **Anatomic or functional asplenia (including sickle cell disease):**
  Age 12–59 months
  - Unvaccinated or only 1 dose before age 12 months: 2 doses, 8 weeks apart
  - 2 or more doses before age 12 months: 1 dose at least 8 weeks after previous dose

  Unvaccinated* persons age 5 years or older
  - 1 dose
- **Elective splenectomy:**
  Unvaccinated* persons age 15 months or older
  - 1 dose (preferably at least 14 days before procedure)
- **HIV infection:**
  Age 12–59 months
  - Unvaccinated or only 1 dose before age 12 months: 2 doses, 8 weeks apart
  - 2 or more doses before age 12 months: 1 dose at least 8 weeks after previous dose

  Unvaccinated* persons age 5–18 years
  - 1 dose
- **Immunoglobulin deficiency, early component complement deficiency:**
  Age 12–59 months
  - Unvaccinated or only 1 dose before age 12 months: 2 doses, 8 weeks apart

Special situations

- Revaccination is not generally recommended for persons with a normal immune status who were vaccinated as infants, children, adolescents, or adults.
- **Post-vaccination serology testing and revaccination** (if anti-HBs <10mIU/mL) is recommended for certain populations, including:
  - Infants born to HBsAg-positive mothers
  - Persons who are predialysis or on maintenance dialysis
  - Other immunocompromised persons
  - For detailed revaccination recommendations, see www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/hepb.html.

Note: Heplisav-B and PreHevbrio are not recommended in pregnancy due to lack of safety data in pregnant persons

Human papillomavirus vaccination
(minimum age: 9 years)

Routine and catch-up vaccination

- HPV vaccination routinely recommended at **age 11–12 years (can start at age 9 years)** and catch-up HPV vaccination recommended for all persons through age 18 years if not adequately vaccinated
- 2- or 3-dose series depending on age at initial vaccination:
  - **Age 9–14 years at initial vaccination**: 2-dose series at 0, 6–12 months (minimum interval: 5 months; repeat dose if administered too soon)
  - **Age 15 years or older at initial vaccination**: 3-dose series at 0, 1–2 months, 6 months (minimum intervals: dose 1 to dose 2: 4 weeks / dose 2 to dose 3: 12 weeks / dose 1 to dose 3: 5 months; repeat dose if administered too soon)
- No additional dose recommended when any HPV vaccine series **of any valency** has been completed using recommended dosing intervals.

Special situations

- **Immunocompromising conditions, including HIV infection:** 3-dose series, even for those who initiate vaccination at age 9 through 14 years.
- **History of sexual abuse or assault:** Start at age 9 years
- **Pregnancy:** Pregnancy testing not needed before vaccination; HPV vaccination not recommended until after pregnancy; no intervention needed if vaccinated while pregnant
  - 2 or more doses before age 12 months: 1 dose at least 8 weeks after previous dose

Unvaccinated* = Less than routine series (through age 14 months) **OR no doses (age 15 months or older)

Hepatitis A vaccination
(minimum age: 12 months for routine vaccination)

Routine vaccination

- 2-dose series (minimum interval: 6 months) at age 12–23 months

Catch-up vaccination

- Unvaccinated persons through age 18 years should complete a 2-dose series (minimum interval: 6 months).
- Persons who previously received 1 dose at age 12 months or older should receive dose 2 at least 6 months after dose 1.
- Adolescents age 18 years or older may receive the combined HepA and HepB vaccine, **Twinrix®**, as a 3-dose series (0, 1, and 6 months) or 4-dose series (3 doses at 0, 7, and 21–30 days, followed by a booster dose at 12 months).

International travel

- Persons traveling to or working in countries with high or intermediate endemic hepatitis A (www.cdc.gov/travel/):
  - **Infants age 6–11 months**: 1 dose before departure; revaccinate with 2 doses (separated by at least 6 months) between age 12–23 months.
  - **Unvaccinated age 12 months or older**: Administer dose 1 as soon as travel is considered.

Hepatitis B vaccination
(minimum age: birth)

Routine vaccination

- 3-dose series at age 0, 1–2, 6–18 months **(use monovalent HepB vaccine for doses administered before age 6 weeks)**
  - Birth weight ≥2,000 grams: 1 dose within 24 hours of birth if medically stable
  - Birth weight <2,000 grams: 1 dose at chronological age 1 month or hospital discharge (whichever is earlier and even if weight is still <2,000 grams).
- Infants who did not receive a birth dose should begin the series as soon as possible (see Table 2 for minimum intervals).
- Administration of 4 doses is permitted when a combination vaccine containing HepB is used after the birth dose.
- **Minimum intervals (see Table 2):** when 4 doses are administered, substitute "dose 4" for "dose 3" in these calculations
- **Final (3rd or 4th) dose:** age 6–18 months **(minimum age 24 weeks)**
- **Mother is HBsAg-positive**
  - **Birth dose (monovalent HepB vaccine only):** administer **HepB vaccine** and **hepatitis B immune globulin (HBIG)** (in separate limbs) within 12 hours of birth, regardless of birth weight.
  - **Birth weight <2000 grams:** administer 3 additional doses of HepB vaccine beginning at age 1 month (total of 4 doses)
  - **Final (3rd or 4th) dose:** administer at age 6 months **(minimum age 24 weeks)**
  - Test for HBsAg and anti-HBs at age 9–12 months. If HepB series is delayed, test 1–2 months after final dose. Do not test before age 9 months.
- **Mother is HBsAg-unknown**

  If other evidence suggestive of maternal hepatitis B infection exists (e.g., presence of HBV DNA, HBeAg-positive, or mother known to have chronic hepatitis B infection), manage infant as if mother is HBsAg-positive
  - **Birth dose (monovalent HepB vaccine only):**
    - Birth weight ≥2,000 grams: administer **HepB vaccine** within 12 hours of birth. Determine mother's HBsAg status as soon as possible. If mother is determined to be HBsAg-positive, administer **HBIG** as soon as possible (in separate limb), but no later than 7 days of age.
    - Birth weight <2,000 grams: administer **HepB vaccine** and **HBIG** (in separate limbs) within 12 hours of birth. Administer 3 additional doses of **HepB vaccine** beginning at age 1 month (total of 4 doses)
  - **Final (3rd or 4th) dose:** administer at age 6 months **(minimum age 24 weeks)**
  - If mother is determined to be HBsAg-positive or if status remains unknown, test for HBsAg and anti-HBs at age 9–12 months. If HepB series is delayed, test 1–2 months after final dose. Do not test before age 9 months.

Catch-up vaccination

- Unvaccinated persons should complete a 3-dose series at 0, 1–2, 6 months. See Table 2 for minimum intervals
- Adolescents age 11–15 years may use an alternative 2-dose schedule with at least 4 months between doses (adult formulation **Recombivax HB®** only).
- Adolescents age 18 years may receive:
  - **Heplisav-B®:** 2-dose series at least 4 weeks apart
  - **PreHevbrio®:** 3-dose series at 0, 1, and 6 months
  - Combined HepA and HepB vaccine, **Twinrix®:** 3-dose series (0, 1, and 6 months) or 4-dose series (3 doses at 0, 7, and 21–30 days, followed by a booster dose at 12 months).

Influenza vaccination
(minimum age: 6 months [IIV], 2 years [LAIV4], 18 years [recombinant influenza vaccine, RIV4])

Routine vaccination

- Use any influenza vaccine appropriate for age and health status annually:
  - **Age 6 months–8 years** who have received **fewer** than 2 influenza vaccine doses before July 1, 2023, or whose influenza vaccination history is unknown: 2 doses, separated by at least 4 weeks. Administer dose 2 even if the child turns 9 years between receipt of dose 1 and dose 2.
  - **Age 6 months–8 years** who have received **at least** 2 influenza vaccine doses before July 1, 2023: 1 dose
  - **Age 9 years or older:** 1 dose
- For the 2023-2024 season, see www.cdc.gov/mmwr/volumes/72/rr/rr7202a1.htm.
- For the 2024–25 season, see the 2024–25 ACIP influenza vaccine recommendations.

Special situations

- **Close contacts (e.g., household contacts) of severely immunosuppressed persons who require a protected environment:** should not receive LAIV4. If LAIV4 is given, they should avoid contact with for such immunosuppressed persons for 7 days after vaccination.

Note: Persons with an egg allergy can receive any influenza vaccine (egg-based and non-egg-based) appropriate for age and health status.

Measles, mumps, and rubella vaccination
(minimum age: 12 months for routine vaccination)

Routine vaccination

- 2-dose series at age 12–15 months, age 4–6 years
- MMR or MMRV* may be administered

Note: For dose 1 in children age 12–47 months, it is recommended to administer MMR and varicella vaccines separately. MMRV* may be used if parents or caregivers express a preference.

Catch-up vaccination

- Unvaccinated children and adolescents: 2-dose series at least 4 weeks apart*
- The maximum age for use of MMRV* is 12 years.

Special situations

- **International travel**
  - **Infants age 6–11 months:** 1 dose before departure; revaccinate with 2-dose series at age 12–15 months (12 months for children in high-risk areas) and dose 2 as early as 4 weeks later.*
  - **Unvaccinated children age 12 months or older:** 2-dose series at least 4 weeks apart before departure*
- In mumps outbreak settings, for information about additional doses of MMR (including 3rd dose of MMR), see www.cdc.gov/mmwr/volumes/67/wr/mm6701a7.htm

***Note:** If MMRV is used, the minimum interval between MMRV doses is 3 months

Meningococcal serogroup A,C,W,Y vaccination
(minimum age: 2 months [MenACWY-CRM, Menveo], 2 years [MenACWY-TT, MenQuadfi]), 10 years [MenACWY-TT/MenB-FHbp, Penbraya])

Routine vaccination

- 2-dose series at age 11–12 years; 16 years

Catch-up vaccination

- Age 13–15 years: 1 dose now and booster at age 16–18 years (minimum interval: 8 weeks)
- Age 16–18 years: 1 dose

Special situations

Anatomic or functional asplenia (including sickle cell disease), HIV infection, persistent complement component deficiency, complement inhibitor (e.g., eculizumab, ravulizumab) use:

- **Menveo®***
  - Dose 1 at age 2 months: 4-dose series (additional 3 doses at age 4, 6, and 12 months)
  - Dose 1 at age 3–6 months: 3- or 4-dose series (dose 2 [and dose 3 if applicable] at least 8 weeks after previous dose until a dose is received at age 7 months or older, followed by an additional dose at least 12 weeks later and after age 12 months)
  - Dose 1 at age 7–23 months: 2-dose series (dose 2 at least 12 weeks after dose 1 and after age 12 months)
  - Dose 1 at age 24 months or older: 2-dose series at least 8 weeks apart
- **MenQuadfi®**
  - Dose 1 at age 24 months or older: 2-dose series at least 8 weeks apart

Fig. 215.1, cont'd

Travel to countries with hyperendemic or epidemic meningococcal disease, including countries in the African meningitis belt or during the Hajj (www.cdc.gov/travel/):

- Children less than age 24 months:
  - **Menveo®* (age 2–23 months)**
    - Dose 1 at age 2 months: 4-dose series (additional 3 doses at age 4, 6, and 12 months)
    - Dose 1 at age 3–6 months: 3- or 4-dose series (dose 2 [and dose 3 if applicable] at least 8 weeks after previous dose until a dose is received at age 7 months or older, followed by an additional dose at least 12 weeks later and after age 12 months)
    - Dose 1 at age 7–23 months: 2-dose series (dose 2 at least 12 weeks after dose 1 and after age 12 months)
- Children age 2 years or older: 1 dose Menveo®* or MenQuadfi®

First-year college students who live in residential housing (if not previously vaccinated at age 16 years or older) or military recruits:

- 1 dose **Menveo®*** or **MenQuadfi®**

Adolescent vaccination of children who received MenACWY prior to age 10 years:

- **Children for whom boosters are recommended** because of an ongoing increased risk of meningococcal disease (e.g., those with complement component deficiency, HIV, or asplenia): Follow the booster schedule for persons at increased risk.
- **Children for whom boosters are not recommended** (e.g., a healthy child who received a single dose for travel to a country where meningococcal disease is endemic): Administer MenACWY according to the recommended adolescent schedule with dose 1 at age 11–12 years and dose 2 at age 16 years.

**Menveo has two formulations: lyophilized and liquid. The liquid formulation should not be used before age 10 years. See www.cdc.gov/vaccines/vpd/mening/downloads/menveo-single-vial-presentation.pdf.*

Note: For MenACWY **booster dose recommendations** for groups listed under "Special situations" and in an outbreak setting and additional meningococcal vaccination information, see www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm.

Children age 10 years or older may receive a single dose of Penbraya™ as an alternative to separate administration of MenACWY and MenB when both vaccines would be given on the same clinic day (see "Meningococcal serogroup B vaccination" section below for more information).

Meningococcal serogroup B vaccination
(minimum age: 10 years [MenB-4C, Bexsero®; MenB-FHbp, Trumenba®; MenACWY-TT/MenB-FHbp, Penbraya™])

Shared clinical decision-making

- **Adolescents not at increased risk** age 16–23 years (preferred age 16–18 years) based on shared clinical decision-making:
  - **Bexsero®:** 2-dose series at least 1 month apart
  - **Trumenba®:** 2-dose series at least 6 months apart (if dose 2 is administered earlier than 6 months, administer a 3rd dose at least 4 months after dose 2)

For additional information on shared clinical decision-making for MenB, see www.cdc.gov/vaccines/hcp/admin/downloads/isd-job-aid-scdm-mening-b-shared-clinical-decision-making.pdf

Special situations

Anatomic or functional asplenia (including sickle cell disease), persistent complement component deficiency, complement inhibitor (e.g., eculizumab, ravulizumab) use:

- **Bexsero®:** 2-dose series at least 1 month apart
- **Trumenba®:** 3-dose series at 0, 1–2, 6 months (if dose 2 was administered at least 6 months after dose 1, dose 3 not needed; if dose 3 is administered earlier than 4 months after dose 2, a 4th dose should be administered at least 4 months after dose 3)

Note: Bexsero® and **Trumenba®** are not interchangeable; the same product should be used for all doses in a series.

For MenB **booster dose recommendations** for groups listed under "Special situations" and in an outbreak setting and additional meningococcal vaccination information, see www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm.

Children age 10 years or older may receive a dose of Penbraya™ as an alternative to separate administration of MenACWY and MenB when both vaccines would be given on the same clinic day. For age-eligible children not at increased risk, if Penbraya™ is used for dose 1 MenB, MenB-FHbp (Trumenba) should be administered for dose 2 MenB. For age-eligible children at increased risk of meningococcal disease, Penbraya™ may be used for additional MenACWY and MenB doses (including booster doses) if both would be given on the same clinic day **and** at least 6 months have elapsed since most recent Penbraya™ dose.

Mpox vaccination
(minimum age: 18 years [Jynneos®])

Special situations

- **Age 18 years and at risk for Mpox infection:** 2-dose series, 28 days apart.

  Risk factors for Mpox infection include:
  - Persons who are gay, bisexual, and other MSM, transgender or nonbinary people who in the past 6 months have had:
    - A new diagnosis of at least 1 sexually transmitted disease
    - More than 1 sex partner
    - Sex at a commercial sex venue
    - Sex in association with a large public event in a geographic area where Mpox transmission is occurring
  - Persons who are sexual partners of the persons described above
  - Persons who anticipate experiencing any of the situations described above
- **Pregnancy:** There is currently no ACIP recommendation for Jynneos use in pregnancy due to lack of safety data in pregnant persons. Pregnant persons with any risk factor described above may receive Jynneos.

For detailed information, see: www.cdc.gov/vaccines/acip/meetings/downloads/slides-2023-10-25-26/04-MPOX-Rao-508.pdf

Pneumococcal vaccination
(minimum age: 6 weeks [PCV15], [PCV 20]; 2 years [PPSV23])

Routine vaccination with PCV

- 4-dose series at 2, 4, 6, 12–15 months

Catch-up vaccination with PCV

- Healthy children ages 2–4 years with any incomplete* PCV series: 1 dose PCV
- For other catch-up guidance, see Table 2.

Note: For children **without** risk conditions, PCV20 is not indicated if they have received 4 doses of PCV13 or PCV15 or another age appropriate complete PCV series.

Special situations

Children and adolescents with cerebrospinal fluid leak; chronic heart disease; chronic kidney disease (excluding maintenance dialysis and nephrotic syndrome); chronic liver disease; chronic lung disease (including moderate persistent or severe persistent asthma); cochlear implant; or diabetes mellitus:

Age 2–5 years

- Any incomplete* PCV series with:
  - 3 PCV doses: 1 dose PCV (at least 8 weeks after the most recent PCV dose)
  - Less than 3 PCV doses: 2 doses PCV (at least 8 weeks after the most recent dose and administered at least 8 weeks apart)
- Completed recommended PCV series but have not received PPSV23
  - Previously received at least 1 dose of PCV20: no further PCV or PPSV23 doses needed
  - Not previously received PCV20: administer 1 dose PCV20 OR 1 dose PPSV23 administer at least 8 weeks after the most recent PCV dose.

Age 6–18 years

- Not previously received any dose of PCV13, PCV15, or PCV20: administer 1 dose of PCV15 or PCV20. If PCV15 is used and no previous receipt of PPSV23, administer 1 dose of PPSV23 at least 8 weeks after the PCV15 dose.**
- Received PCV before age 6 years but have not received PPSV23
  - Previously received at least 1 dose of PCV20: no further PCV or PPSV23 doses needed
  - Not previously received PCV20: 1 dose PCV20 OR 1 dose PPSV23 administer at least 8 weeks after the most recent PCV dose.
- Received PCV13 only at or after age 6 years: administer 1 dose PCV20 OR 1 dose PPSV23 at least 8 weeks after the most recent PCV13 dose.
- Received 1 dose PCV13 and 1 dose PPSV23 at or after age 6 years: no further doses of any PCV or PPSV23 indicated.

Children and adolescents on maintenance dialysis, or with immunocompromising conditions such as nephrotic syndrome; congenital or acquired asplenia or splenic dysfunction; congenital or acquired immunodeficiencies; diseases and conditions treated with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, Hodgkin disease, and solid organ transplant; HIV infection; or sickle cell disease or other hemoglobinopathies:

Age 2–5 years

- Any incomplete* PCV series:
  - 3 PCV doses: 1 dose PCV (at least 8 weeks after the most recent PCV dose)
  - Less than 3 PCV doses: 2 doses PCV (at least 8 weeks after the most recent dose and administered at least 8 weeks apart)
- Completed recommended PCV series but have not received PPSV23
  - Previously received at least 1 dose of PCV20: no further PCV or PPSV23 doses needed
  - Not previously received PCV20: administer 1 dose PCV20 OR 1 dose PPSV23 at least 8 weeks after the most recent PCV dose. If PPSV23 is used, administer 1 dose of PCV20 or dose 2 PPSV23 at least 5 years after dose 1 PPSV23.

Age 6–18 years

- Not previously received any dose of PCV13, PCV15, or PCV20: administer 1 dose of PCV15 or 1 dose of PCV20. If PCV15 is used and no previous receipt of PPSV23, administer 1 dose of PPSV23 at least 8 weeks after the PCV15 dose.**
- Received PCV before age 6 years but have not received PPSV23
  - Previously received at least 1 dose of PCV20: no additional dose of PCV or PPSV23
  - Not previously received PCV20: administer 1 dose PCV20 OR 1 dose PPSV23 at least 8 weeks after the most recent PCV dose. If PPSV23 is used, administer either PCV20 or dose 2 PPSV23 at least 5 years after dose 1 PPSV23.
- Received PCV13 only at or after age 6 years: administer 1 dose PCV20 OR 1 dose PPSV23 at least 8 weeks after the most recent PCV13 dose. If PPSV23 is used, administer 1 dose of PCV20 or dose 2 PPSV23 at least 5 years after dose 1 PPSV23.
- Received 1 dose PCV13 and 1 dose PPSV23 at or after age 6 years: administer 1 dose PCV20 OR 1 dose PPSV23 at least 8 weeks after the most recent PCV13 dose and at least 5 years after dose 1 PPSV23.

**Incomplete series* = Not having received all doses in either the recommended series or an age-appropriate catch-up series. See Table 2 in ACIP pneumococcal recommendations at stacks.cdc.gov/view/cdc/133252

***When both PCV15 and PPSV23 are indicated, administer all doses of PCV15 first. PCV15 and PPSV23 should not be administered during the same visit.*

For guidance on determining which pneumococcal vaccines a patient needs and when, please refer to the mobile app, which can be downloaded here: www.cdc.gov/vaccines/vpd/pneumo/hcp/pneumoapp.html

Poliovirus vaccination
(minimum age: 6 weeks)

Routine vaccination

- 4-dose series at ages 2, 4, 6–18 months, 4–6 years; administer the final dose on or after age 4 years and at least 6 months after the previous dose.
- 4 or more doses of IPV can be administered before age 4 years when a combination vaccine containing IPV is used. However, a dose is still recommended on or after age 4 years and at least 6 months after the previous dose.

Catch-up vaccination

- In the first 6 months of life, use minimum ages and intervals only for travel to a polio-endemic region or during an outbreak.
- **Adolescents age 18 years known or suspected to be unvaccinated or incompletely vaccinated:** administer remaining doses (1, 2, or 3 IPV doses) to complete a 3-dose primary series.* Unless there are specific reasons to believe they were not vaccinated, most persons aged 18 years or older born and raised in the United States can assume they were vaccinated against polio as children.

Series containing oral poliovirus vaccine (OPV), either mixed OPV-IPV or OPV-only series:

- Total number of doses needed to complete the series is the same as that recommended for the U.S. IPV schedule. See www.cdc.gov/mmwr/volumes/66/wr/mm6601a6.htm?s_%20cid=mm6601a6_w.
- Only trivalent OPV (tOPV) counts toward the U.S. vaccination requirements.
  - Doses of OPV administered before April 1, 2016, should be counted (unless specifically noted as administered during a campaign).
  - Doses of OPV administered on or after April 1, 2016, should not be counted.
  - For guidance to assess doses documented as "OPV," see www.cdc.gov/mmwr/volumes/66/wr/mm6606a7.htm?s_cid=mm6606a7_w.
- For other catch-up guidance, see Table 2.

Fig. 215.1, cont'd

Special situations

- **Adolescents aged 18 years at increased risk of exposure to poliovirus and completed primary series*:** may administer one lifetime IPV booster

***Note:** Complete primary series consist of at least 3 doses of IPV or trivalent oral poliovirus vaccine (tOPV) in any combination.

For detailed information, see: www.cdc.gov/vaccines/vpd/polio/hcp/recommendations.html

Respiratory syncytial virus immunization (minimum age: birth [Nirsevimab, RSV-mAb (Beyfortus™)]

Routine immunization

- **Infants born October – March in most of the continental United States***
  - Mother did not receive RSV vaccine OR mother's RSV vaccination status is unknown: administer 1 dose nirsevimab within 1 week of birth in hospital or outpatient setting
  - Mother received RSV vaccine **less than 14 days** prior to delivery: administer 1 dose nirsevimab within 1 week of birth in hospital or outpatient setting
  - Mother received RSV vaccine **at least 14 days** prior to delivery: nirsevimab not needed but can be considered in rare circumstances at the discretion of healthcare providers (see special populations and situations at www.cdc.gov/vaccines/vpd/rsv/hcp/child-faqs.html)
- **Infants born April–September in most of the continental United States***
  - Mother did not receive RSV vaccine OR mother's RSV vaccination status is unknown: administer 1 dose nirsevimab shortly before start of RSV season*
  - Mother received RSV vaccine **less than 14 days** prior to delivery: administer 1 dose nirsevimab shortly before start of RSV season*
  - Mother received RSV vaccine **at least 14 days** prior to delivery: nirsevimab not needed but can be considered in rare circumstances at the discretion of healthcare providers(see special populations and situations at www.cdc.gov/vaccines/vpd/rsv/hcp/child-faqs.html)

Infants with prolonged birth hospitalization** (e.g., for prematurity) discharged October through March should be immunized shortly before or promptly after discharge.

Special situations

- **Ages 8–19 months with chronic lung disease of prematurity requiring medical support (e.g., chronic corticosteroid therapy, diuretic therapy, or supplemental oxygen) any time during the 6-month period before the start of the second RSV season; severe immunocompromise; cystic fibrosis with either weight for length <10th percentile or manifestation of severe lung disease (e.g., previous hospitalization for pulmonary exacerbation in the first year of life or abnormalities on chest imaging that persist when stable)**:**
  - 1 dose nirsevimab shortly before start of second RSV season*
- **Ages 8–19 months who are American Indian or Alaska Native:**
  - 1 dose nirsevimab shortly before start of second RSV season*
- **Age-eligible and undergoing cardiac surgery with cardiopulmonary bypass**:** 1 additional dose of nirsevimab after surgery. For additional details see special populations and situations at www.cdc.gov/vaccines/vpd/rsv/hcp/child-faqs.html

***Note:** While the timing of the onset and duration of RSV season may vary, nirsevimab may be administered October through March in most of the continental United States. Providers in jurisdictions with RSV seasonality that differs from most of the continental United States (e.g., Alaska, jurisdiction with tropical climate) should follow guidance from public health authorities (e.g., CDC, health departments) or regional medical centers on timing of administration based on local RSV seasonality. Although optimal timing of administration is just before the start of the RSV season, nirsevimab may also be administered during the RSV season to infants and children who are age-eligible.

****Note:** Nirsevimab can be administered to children who are eligible to receive palivizumab. Children who have received nirsevimab should not receive palivizumab for the same RSV season.

For further guidance, see www.cdc.gov/mmwr/volumes/72/wr/mm7234a4.htm and www.cdc.gov/vaccines/vpd/rsv/hcp/child-faqs.html

Respiratory syncytial virus vaccination (RSV [Abrysvo™])

Routine vaccination

- **Pregnant at 32 weeks 0 days through 36 weeks and 6 days gestation from September through January in most of the continental United States*:** 1 dose RSV vaccine (Abrysvo™). Administer RSV vaccine regardless of previous RSV infection.
  - Either maternal RSV vaccination or infant immunization with nirsevimab (RSV monoclonal antibody) is recommended to prevent respiratory syncytial virus lower respiratory tract infection in infants.
- **All other pregnant persons:** RSV vaccine not recommended.

There is currently no ACIP recommendation for RSV vaccination in subsequent pregnancies. No data are available to inform whether additional doses are needed in later pregnancies.

***Note:** Providers in jurisdictions with RSV seasonality that differs from most of the continental United States (e.g., Alaska, jurisdiction with tropical climate) should follow guidance from public health authorities (e.g., CDC, health departments) or regional medical centers on timing of administration based on local RSV seasonality.

Rotavirus vaccination (minimum age: 6 weeks)

Routine vaccination

- **Rotarix®:** 2-dose series at age 2 and 4 months
- **RotaTeq®:** 3-dose series at age 2, 4, and 6 months
- If any dose in the series is either **RotaTeq®** or unknown, default to 3-dose series.

Catch-up vaccination

- Do not start the series on or after age 15 weeks, 0 days.
- The maximum age for the final dose is 8 months, 0 days.
- For other catch-up guidance, see Table 2.

Tetanus, diphtheria, and pertussis (Tdap) vaccination (minimum age: 11 years for routine vaccination, 7 years for catch-up vaccination)

Routine vaccination

- **Age 11–12 years:** 1 dose Tdap (adolescent booster)
- **Pregnancy:** 1 dose Tdap during each pregnancy, preferably in early part of gestational weeks 27–36.

Note: Tdap may be administered regardless of the interval since the last tetanus- and diphtheria-toxoid-containing vaccine.

Catch-up vaccination

- **Age 13–18 years who have not received Tdap:** 1 dose Tdap (adolescent booster)
- **Age 7–18 years not fully vaccinated* with DTaP:** 1 dose Tdap as part of the catch-up series (preferably the first dose); if additional doses are needed, use Td or Tdap.
- **Tdap administered at age 7–10 years:**
  - **Age 7–9 years** who receive Tdap should receive the adolescent Tdap booster dose at age 11–12 years.
  - **Age 10 years** who receive Tdap do not need the adolescent Tdap booster dose at age 11–12 years.
- **DTaP inadvertently administered on or after age 7 years**:
  - **Age 7–9 years**: DTaP may count as part of catch-up series. Administer adolescent Tdap booster dose at age 11–12 years.
  - **Age 10–18 years**: Count dose of DTaP as the adolescent Tdap booster dose.
- For other catch-up guidance, see Table 2.

Special situations

- **Wound management** in persons age 7 years or older with history of 3 or more doses of tetanus-toxoid-containing vaccine: For clean and minor wounds, administer Tdap or Td if more than 10 years since last dose of tetanus-toxoid-containing vaccine; for all other wounds, administer Tdap or Td if more than 5 years since last dose of tetanus-toxoid-containing vaccine. Tdap is preferred for persons age 11 years or older who have not previously received Tdap or whose Tdap history is unknown. If a tetanus-toxoid-containing vaccine is indicated for a pregnant adolescent, use Tdap.
- For detailed information, see www.cdc.gov/mmwr/volumes/69/wr/mm6903a5.htm.

**Fully vaccinated* = 5 valid doses of DTaP OR 4 valid doses of DTaP if dose 4 was administered at age 4 years or older*

Varicella vaccination (minimum age: 12 months)

Routine vaccination

- 2-dose series at age 12–15 months, 4–6 years
- VAR or MMRV may be administered*
- Dose 2 may be administered as early as 3 months after dose 1 (a dose inadvertently administered after at least 4 weeks may be counted as valid)

***Note**: For dose 1 in children age 12–47 months, it is recommended to administer MMR and varicella vaccines separately. MMRV may be used if parents or caregivers express a preference.

Catch-up vaccination

- Ensure persons age 7–18 years without evidence of immunity (see *MMWR* at www.cdc.gov/mmwr/pdf/rr/rr5604.pdf) have a 2-dose series:
  - **Age 7–12 years**: Routine interval: 3 months (a dose inadvertently administered after at least 4 weeks may be counted as valid)
  - **Age 13 years and older**: Routine interval: 4–8 weeks (minimum interval: 4 weeks)
  - The maximum age for use of *MMRV* is 12 years.

Fig. 215.1, cont'd

Appendix Recommended Child and Adolescent Immunization Schedule for Ages 18 Years or Younger, United States, 2024

Guide to Contraindications and Precautions to Commonly Used Vaccines

Vaccines and other Immunizing Agents	Contraindicated or Not Recommended[1]	Precautions[2]
COVID-19 mRNA vaccines [Pfizer-BioNTech, Moderna]	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a component of an mRNA COVID-19 vaccine[4]	• Diagnosed non-severe allergy (e.g., urticaria beyond the injection site) to a component of an mRNA COVID-19 vaccine[4]; or non-severe, immediate (onset less than 4 hours) allergic reaction after administration of a previous dose of an mRNA COVID-19 vaccine • Myocarditis or pericarditis within 3 weeks after a dose of any COVID-19 vaccine • Multisystem inflammatory syndrome in children (MIS-C) or multisystem inflammatory syndrome in adults (MIS-A) • Moderate or severe acute illness, with or without fever
COVID-19 protein subunit vaccine [Novavax]	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a component of a Novavax COVID-19 vaccine[4]	• Diagnosed non-severe allergy (e.g., urticaria beyond the injection site) to a component of Novavax COVID-19 vaccine[4]; or non-severe, immediate (onset less than 4 hours) allergic reaction after administration of a previous dose of a Novavax COVID-19 vaccine • Myocarditis or pericarditis within 3 weeks after a dose of any COVID-19 vaccine • Multisystem inflammatory syndrome in children (MIS-C) or multisystem inflammatory syndrome in adults (MIS-A) • Moderate or severe acute illness, with or without fever
Influenza, egg-based, inactivated injectable (IIV4)	• Severe allergic reaction (e.g., anaphylaxis) after previous dose of any influenza vaccine (i.e., any egg-based IIV, ccIIV, RIV, or LAIV of any valency) • Severe allergic reaction (e.g., anaphylaxis) to any vaccine component[3] (excluding egg)	• Guillain-Barré syndrome (GBS) within 6 weeks after a previous dose of any type of influenza vaccine • Moderate or severe acute illness with or without fever
Influenza, cell culture-based inactivated injectable (ccIIV4) [Flucelvax Quadrivalent]	• Severe allergic reaction (e.g., anaphylaxis) to any ccIIV of any valency, or to any component[3] of ccIIV4	• Guillain-Barré syndrome (GBS) within 6 weeks after a previous dose of any type of influenza vaccine • Persons with a history of severe allergic reaction (e.g., anaphylaxis) after a previous dose of any egg-based IIV, RIV, or LAIV of any valency. If using ccIV4, administer in medical setting under supervision of health care provider who can recognize and manage severe allergic reactions. May consult an allergist. • Moderate or severe acute illness with or without fever
Influenza, recombinant injectable (RIV4) [Flublok Quadrivalent]	• Severe allergic reaction (e.g., anaphylaxis) to any RIV of any valency, or to any component[3] of RIV4	• Guillain-Barré syndrome (GBS) within 6 weeks after a previous dose of any type of influenza vaccine • Persons with a history of severe allergic reaction (e.g., anaphylaxis) after a previous dose of any egg-based IIV, ccIIV, or LAIV of any valency. If using RIV4, administer in medical setting under supervision of health care provider who can recognize and manage severe allergic reactions. May consult an allergist. • Moderate or severe acute illness with or without fever
Influenza, live attenuated (LAIV4) [Flumist Quadrivalent]	• Severe allergic reaction (e.g., anaphylaxis) after previous dose of any influenza vaccine (i.e., any egg-based IIV, ccIIV, RIV, or LAIV of any valency) • Severe allergic reaction (e.g., anaphylaxis) to any vaccine component[3] (excluding egg) • Children age 2–4 years with a history of asthma or wheezing • Anatomic or functional asplenia • Immunocompromised due to any cause including, but not limited to, medications and HIV infection • Close contacts or caregivers of severely immunosuppressed persons who require a protected environment • Pregnancy • Cochlear implant • Active communication between the cerebrospinal fluid (CSF) and the oropharynx, nasopharynx, nose, ear or any other cranial CSF leak • Children and adolescents receiving aspirin or salicylate-containing medications • Received influenza antiviral medications oseltamivir or zanamivir within the previous 48 hours, peramivir within the previous 5 days, or baloxavir within the previous 17 days	• Guillain-Barré syndrome (GBS) within 6 weeks after a previous dose of any type of influenza vaccine • Asthma in persons age 5 years old or older • Persons with underlying medical conditions other than those listed under contraindications that might predispose to complications after wild-type influenza virus infection, e.g., chronic pulmonary, cardiovascular (except isolated hypertension), renal, hepatic, neurologic, hematologic, or metabolic disorders (including diabetes mellitus) • Moderate or severe acute illness with or without fever

1. When a contraindication is present, a vaccine should **NOT** be administered. Kroger A, Bahta L, Hunter P. ACIP General Best Practice Guidelines for Immunization.
2. When a precaution is present, vaccination should generally be deferred but might be indicated if the benefit of protection from the vaccine outweighs the risk for an adverse reaction. Kroger A, Bahta L, Hunter P. ACIP General Best Practice Guidelines for Immunization.
3. Vaccination providers should check FDA-approved prescribing information for the most complete and updated information, including contraindications, warnings, and precautions. See Package inserts for U.S.-licensed vaccines.
4. See package inserts and FDA EUA fact sheets for a full list of vaccine ingredients. mRNA COVID-19 vaccines contain polyethylene glycol (PEG).

Vaccines and other Immunizing Agents	Contraindicated or Not Recommended[1]	Precautions[2]
Dengue (DEN4CYD)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] • Severe immunodeficiency (e.g., hematologic and solid tumors, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy or patients with HIV infection who are severely immunocompromised) • Lack of laboratory confirmation of a previous Dengue infection	• Pregnancy • HIV infection without evidence of severe immunosuppression • Moderate or severe acute illness with or without fever
Diphtheria, tetanus, pertussis (DTaP)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] • For DTaP only: Encephalopathy (e.g., coma, decreased level of consciousness, prolonged seizures) not attributable to another identifiable cause within 7 days of administration of previous dose of DTP or DTaP	• Guillain-Barré syndrome (GBS) within 6 weeks after previous dose of tetanus-toxoid–containing vaccine • History of Arthus-type hypersensitivity reactions after a previous dose of diphtheria-toxoid–containing or tetanus-toxoid–containing vaccine; defer vaccination until at least 10 years have elapsed since the last tetanus-toxoid-containing vaccine • For DTaP only: Progressive neurologic disorder, including infantile spasms, uncontrolled epilepsy, progressive encephalopathy; defer DTaP until neurologic status clarified and stabilized • Moderate or severe acute illness with or without fever
Haemophilus influenzae type b (Hib)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] • Less than age 6 weeks	• Moderate or severe acute illness with or without fever
Hepatitis A (HepA)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] including neomycin	• Moderate or severe acute illness with or without fever
Hepatitis B (HepB)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] including yeast • *Pregnancy: Heplisav-B and PreHevbrio are not recommended due to lack of safety data in pregnant persons. Use other hepatitis B vaccines if HepB is indicated*[4].	• Moderate or severe acute illness with or without fever
Hepatitis A-Hepatitis B vaccine (HepA-HepB) [Twinrix]	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] including neomycin and yeast	• Moderate or severe acute illness with or without fever
Human papillomavirus (HPV)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] • *Pregnancy: HPV vaccination not recommended.*	• Moderate or severe acute illness with or without fever
Measles, mumps, rubella (MMR) Measles, mumps, rubella, and varicella (MMRV)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] • Severe immunodeficiency (e.g., hematologic and solid tumors, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy or patients with HIV infection who are severely immunocompromised) • Pregnancy • Family history of altered immunocompetence, unless verified clinically or by laboratory testing as immunocompetent	• Recent (≤11 months) receipt of antibody-containing blood product (specific interval depends on product) • History of thrombocytopenia or thrombocytopenic purpura • Need for tuberculin skin testing or interferon-gamma release assay (IGRA) testing • Moderate or severe acute illness with or without fever • For MMRV only: Personal or family (i.e., sibling or parent) history of seizures of any etiology
Meningococcal ACWY (MenACWY) MenACWY-CRM [Menveo] MenACWY-TT [MenQuadfi]	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] • For Men ACWY-CRM only: severe allergic reaction to any diphtheria toxoid—or CRM197—containing vaccine • For MenACWY-TT only: severe allergic reaction to a tetanus toxoid-containing vaccine	• For MenACWY-CRM only: Preterm birth if less than age 9 months • Moderate or severe acute illness with or without fever
Meningococcal B (MenB) MenB-4C [Bexsero] MenB-FHbp [Trumenba]	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3]	• Pregnancy • For MenB-4C only: Latex sensitivity • Moderate or severe acute illness with or without fever
Meningococcal ABCWY (MenACWY-TT/MenB-FHbp) [Penbraya]	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] • Severe allergic reaction to a tetanus toxoid-containing vaccine	• Moderate or severe acute illness, with or without fever
Mpox [Jynneos]	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3]	• Moderate or severe acute illness, with or without fever
Pneumococcal conjugate (PCV)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] • Severe allergic reaction (e.g., anaphylaxis) to any diphtheria-toxoid-containing vaccine or its component[3]	• Moderate or severe acute illness with or without fever
Pneumococcal polysaccharide (PPSV23)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3]	• Moderate or severe acute illness with or without fever
Poliovirus vaccine, inactivated (IPV)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3]	• Pregnancy • Moderate or severe acute illness with or without fever
RSV monoclonal antibody (RSV-mAb)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[5]	• Moderate or severe acute illness with or without fever
Respiratory syncytial virus vaccine (RSV)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3]	• Moderate or severe acute illness with or without fever
Rotavirus (RV) RV1 [Rotarix] RV5 [RotaTeq]	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] • Severe combined immunodeficiency (SCID) • History of intussusception	• Altered immunocompetence other than SCID • Chronic gastrointestinal disease • RV1 only: Spina bifida or bladder exstrophy • Moderate or severe acute illness with or without fever
Tetanus, diphtheria, and acellular pertussis (Tdap) Tetanus, diphtheria (Td)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] • For Tdap only: Encephalopathy (e.g., coma, decreased level of consciousness, prolonged seizures) not attributable to another identifiable cause within 7 days of administration of previous dose of DTP, DTaP, or Tdap	• Guillain-Barré syndrome (GBS) within 6 weeks after a previous dose of tetanus-toxoid–containing vaccine • History of Arthus-type hypersensitivity reactions after a previous dose of diphtheria-toxoid–containing or tetanus-toxoid–containing vaccine; defer vaccination until at least 10 years have elapsed since the last tetanus-toxoid–containing vaccine • For Tdap only: Progressive or unstable neurological disorder, uncontrolled seizures, or progressive encephalopathy until a treatment regimen has been established and the condition has stabilized • Moderate or severe acute illness with or without fever
Varicella (VAR)	• Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component[3] • Severe immunodeficiency (e.g., hematologic and solid tumors, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy or patients with HIV infection who are severely immunocompromised) • Pregnancy • Family history of altered immunocompetence, unless verified clinically or by laboratory testing as immunocompetent	• Recent (≤11 months) receipt of antibody-containing blood product (specific interval depends on product) • Receipt of specific antiviral drugs (acyclovir, famciclovir, or valacyclovir) 24 hours before vaccination (avoid use of these antiviral drugs for 14 days after vaccination) • Use of aspirin or aspirin-containing products • Moderate or severe acute illness with or without fever • If using MMRV, see MMR/MMRV for additional precautions

1. When a contraindication is present, a vaccine should NOT be administered. Kroger A, Bahta L, Hunter P. ACIP General Best Practice Guidelines for Immunization. www.cdc.gov/vaccines/hcp/acip-recs/general-recs/contraindications.html
2. When a precaution is present, vaccination should generally be deferred but might be indicated if the benefit of protection from the vaccine outweighs the risk for an adverse reaction. Kroger A, Bahta L, Hunter P. ACIP General Best Practice Guidelines for Immunization. www.cdc.gov/vaccines/hcp/acip-recs/general-recs/contraindications.html
3. Vaccination providers should check FDA-approved prescribing information for the most complete and updated information, including contraindications, warnings, and precautions. Package inserts for U.S.-licensed vaccines are available at www.fda.gov/vaccines-blood-biologics/approved-products/vaccines-licensed-use-united-states.
4. For information on the pregnancy exposure registries for persons who were inadvertently vaccinated with Heplisav-B or PreHevbrio while pregnant, please visit heplisavbpregnancyregistry.com or www.prehevbrio.com/#safety.
5. Full prescribing information for BEYFORTUS (nirsevimab-alip) www.accessdata.fda.gov/drugsatfda_docs/label/2023/761328s000lbl.pdf

Table 215.7 Recommended Catch-Up Immunization Schedule for Children and Adolescents Who Start Late or Who Are More than 1 Month Behind United States, 2024.*

VACCINE	MINIMUM AGE FOR DOSE 1	MINIMUM INTERVAL BETWEEN DOSES			
		DOSE 1 TO DOSE 2	DOSE 2 TO DOSE 3	DOSE 3 TO DOSE 4	DOSE 4 TO DOSE 5
CHILDREN AGE 4 MONTHS THROUGH 6 YEARS					
Hepatitis B	Birth	**4 weeks**	**8 weeks *and* at least 16 weeks after first dose** minimum age for the final dose is 24 weeks		
Rotavirus	6 weeks Maximum age for first dose is 14 weeks, 6 days.	**4 weeks**	**4 weeks** maximum age for final dose is 8 months, 0 days		
Diphtheria, tetanus, and acellular pertussis	6 weeks	**4 weeks**	**4 weeks**	**6 months**	**6 months** A fifth dose is not necessary if the fourth dose was administered at age 4 years or older ***and*** at least 6 months after dose 3
Haemophilus influenzae type b	6 weeks	**No further doses needed** if first dose was administered at age 15 months or older. **4 weeks** if first dose was administered before the 1st birthday. **8 weeks (as final dose)** if first dose was administered at age 12 through 14 months.	**No further doses needed** if previous dose was administered at age 15 months or older **4 weeks** if current age is younger than 12 months ***and*** first dose was administered at younger than age 7 months ***and*** at least 1 previous dose was PRP-T (ActHib®, Pentacel®, Hiberix®), Vaxelis® or unknown **8 weeks *and* age 12 through 59 months (as final dose)** if current age is younger than 12 months ***and*** first dose was administered at age 7 through 11 months; **OR** if current age is 12 through 59 months ***and*** first dose was administered before the 1st birthday ***and*** second dose was administered at younger than 15 months; **OR** if both doses were PedvaxHIB® and were administered before the 1st birthday	**8 weeks (as final dose)** This dose only necessary for children age 12 through 59 months who received 3 doses before the 1st birthday.	
Pneumococcal conjugate	6 weeks	**No further doses needed** for healthy children if first dose was administered at age 24 months or older **4 weeks** if first dose was administered before the 1st birthday **8 weeks (as final dose for healthy children)** if first dose was administered at the 1st birthday or after	**No further doses needed** for healthy children if previous dose was administered at age 24 months or older **4 weeks** if current age is younger than 12 months ***and*** previous dose was administered at <7 months old **8 weeks (as final dose for healthy children)** if previous dose was administered between 7–11 months (wait until at least 12 months old); **OR** if current age is 12 months or older ***and*** at least 1 dose was administered before age 12 months	**8 weeks (as final dose)** This dose is only necessary for children age 12 through 59 months regardless of risk, or age 60 through 71 months with any risk, who received 3 doses before age 12 months.	
Inactivated poliovirus	6 weeks	**4 weeks**	**4 weeks** if current age is <4 years**6 months (as final dose)** if current age is 4 years or older	**6 months (minimum age 4 years for final dose)**

Table 215.7 Recommended Catch-Up Immunization Schedule for Children and Adolescents Who Start Late or Who Are More than 1 Month Behind United States, 2024.*—cont'd

VACCINE	MINIMUM AGE FOR DOSE 1	MINIMUM INTERVAL BETWEEN DOSES			
		DOSE 1 TO DOSE 2	DOSE 2 TO DOSE 3	DOSE 3 TO DOSE 4	DOSE 4 TO DOSE 5
CHILDREN AGE 4 MONTHS THROUGH 6 YEARS					
Measles, mumps, rubella	12 months	**4 weeks**			
Varicella	12 months	**3 months**			
Hepatitis A	12 months	**6 months**			
Meningococcal ACWY	2 months MenACWY-CRM 2 years MenACWY-TT	**8 weeks**	See Notes	See Notes	
CHILDREN AND ADOLESCENTS AGE 7 THROUGH 18 YEARS					
Meningococcal ACWY	Not applicable (N/A)	**8 weeks**			
Tetanus, diphtheria; tetanus, diphtheria, and acellular pertussis	7 years	**4 weeks**	**4 weeks** if first dose of DTaP/DT was administered before the 1st birthday**6 months (as final dose)** if first dose of DTaP/DT or Tdap/Td was administered at or after the 1st birthday	**6 months** if first dose of DTaP/DT was administered before the 1st birthday	
Human papillomavirus	9 years	**Routine dosing intervals are recommended.**			
Hepatitis A	N/A	**6 months**			
Hepatitis B	N/A	**4 weeks**	**8 weeks *and* at least 16 weeks after first dose**		
Inactivated poliovirus	N/A	**4 weeks**	**6 months** A fourth dose is not necessary if the third dose was administered at age 4 years or older ***and*** at least 6 months after the previous dose.	A fourth dose of IPV is indicated if all previous doses were administered at <4 years **OR** if the third dose was administered <6 months after the second dose.	
Measles, mumps, rubella	N/A	**4 weeks**			
Varicella	N/A	**3 months** if younger than age 13 years. **4 weeks** if age 13 years or older			
Dengue	9 years	**6 months**	6 months		

*Always use this table in conjunction with Figure 215.1 and the notes that follow it.
This table provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age.
For vaccination recommendations for persons ages 19 yr or older, see the Recommended Adult Immunization Schedule, 2024 https://www.cdc.gov/vaccines/schedules/hcp/imz/adult.html.
Courtesy U.S. Centers for Disease Control and Prevention, Atlanta, Georgia. 2024. https://www.cdc.gov/vaccines/schedules/hcp/imz/catchup.html#table-catchup.

Downloaded for mohamed ahmed (dr.mms2020@gmail.com) at University of Southern California from ClinicalKey.com by Elsevier on April 21, 2024. For personal use only. No other uses without permission. Copyright ©2024. Elsevier Inc. All rights reserved.

combined with other vaccines. Either Td vaccine or Tdap can be used for the decennial Td booster, for tetanus prophylaxis in wound management, or for additional required doses in the catch-up immunization schedule if a person has received at least one Tdap dose. One dose of Tdap vaccine is recommended for pregnant adolescents with each pregnancy, preferably between 27 and 36 weeks of gestation, regardless of the time since the last Tdap or Td. Current available data suggest that vaccinating earlier in the 27- through 36-week period will maximize passive antibody transfer to the infant. This recommendation was made in response to data predicting lack of infant protection when maternal Tdap had been received before pregnancy.

There are three licensed preparations of single-antigen **Hib** vaccines. The two monovalent vaccines conjugated to tetanus toxoid (PRP-T) are each given in a four-dose series at 2, 4, 6, and 12 through 15 months of age. The third Hib vaccine is conjugated to meningococcal outer membrane protein (PRP-OMP) and is recommended in a three-dose series at 2, 4, and 12 through 15 months of age. There also are several vaccines in which Hib is a component, in addition to single-antigen Hib conjugate vaccines (see Tables 215.8 and 215.9).

Influenza vaccine is recommended for all children beginning at 6 months of age, with a minimum age of 6 months for IIVs and 24 months for LAIV4. Various influenza vaccine preparations are FDA-licensed for different age-groups.* Children 6 months through 8 years of age being vaccinated for the first time should receive two doses at least 4 weeks apart. If such children only received a single dose of IIV before July 1 of the current season, they need two doses. Children who have received two doses in a prior season only need one dose annually thereafter. For additional guidelines, follow dosing instructions in the influenza policy statements, which are updated annually by both the CDC (https://www.cdc.gov/flu/professionals/acip/index.htm) and AAP (aapredbook.org). Influenza vaccine usually is given in October or November, although there are benefits even when administered as late as February or March because influenza seasons most frequently peak in February. People ≥9 years old should receive one dose of influenza vaccine annually. LAIV4 is recommended for the 2023-2024 season. Because of limited use of LAIV4, there have been no effectiveness estimates in the United States. Data from other countries have demonstrated similar protection from LAIV4 to that of standard-dose, egg-based IIV in children. Although there are no reports of additional safety risks for LAIV4 in children with immunodeficiencies, anatomic or functional asplenia, cochlear implants, or active cerebrospinal fluid leaks, it is not recommended in these populations because the vaccine is a live attenuated product (see Table 215.7). For more information see https://pediatrics.aappublications.org/content/146/4/e2020024588

IPV should be administered at 2, 4, and 6 through 18 months of age with a booster dose at 4 through 6 years. The final dose in the series should be administered on or after 4 years of age and at least 6 months after the previous dose. Four or more doses of IPV can be administered before age 4 years when a combination vaccine containing IPV is used. The final dose in the IPV series should still be administered at 4 years or older regardless of the number of previous doses, and the minimal interval from dose 3 to dose 4 is 6 months. For series that contain oral polio vaccine (OPV), the total number of doses needed to complete the series is the same as that recommended for the U.S. IPV schedule. Only documentation specifying receipt of trivalent OPV constitutes proof of vaccination according to the U.S. polio vaccination recommendations. This is important because since April 2016, trivalent OPV (tOPV) is no longer available with the type 2 serotype removed. Thus children vaccinated since that time only received the type 1 and 3 components and are not immune to type 2. In contrast, IPV contains all three polio serotypes. Only IPV is available in the United States. One lifetime IPV booster should be considered for adolescents 18 years old who are at increased risk of exposure to poliovirus and completed IPV primary series. For catch-up vaccine recommendations, see the recommended childhood immunization schedule at http://www.cdc.gov/vaccines/schedules/hcp/imz/catchup.html (see Table 215.7).

MMR should be administered at 12 through 15 months of age followed by a second dose at 4 through 6 years. Before all international travel, infants 6 through 11 months of age should receive one dose of MMR vaccine. These children should be revaccinated with the routinely recommended two doses of MMR vaccine beginning at 12 months of age. For children 12 months or older, administer two doses before international travel; the second dose should be administered at least 4 weeks after the first dose.

Two doses of **varicella** vaccine should be given, the first at 12 through 15 months of age and the second at 4 through 6 years. The second dose may be administered before 4 years of age provided at least 3 months have elapsed since the first dose. MMR and MMRV preparations are available. Ensure persons age 7-18 years without evidence of immunity have a two-dose series. The **quadrivalent MMRV** vaccine is preferred in place of separate MMR and varicella vaccines at the 4- to 6-year-old visit. For dose 1 in children age 12-47 months, it is recommended to administer MMR and varicella vaccines separately because of the slight increase in febrile seizures associated with the combined MMRV vaccine compared with simultaneous administration of the separate products. MMRV may be used if parents or caregivers express a preference.

Protection against pneumococcal disease can be provided by either conjugated or polysaccharide vaccines. Conjugated vaccines offer several benefits over polysaccharide vaccines (see Table 215.5). A four-dose series of either PCV15 or 20 is recommended at 2, 4, 6, and 12 to 15 months of age. In the latest immunization schedule, PCV15 and 20 are referenced. Use of either pneumococcal conjugate vaccines is recommended for all children age 2–23 months according to currently recommended PCV dosing and schedules. References to the previously available thirteen-valent (PCV13) have been removed. For children without high risk conditions, PCV20 is not indicated if they have received four doses of PCV13 or PCV15 or another age-appopriate complete PCV series. For guidance on determining which pneumococcal vaccines a patient needs and when, a mobile app has been created. (www.cdc.gov/vaccines/vpd/pneumo/hcp/pneumoapp.html. PPSV23 is recommended for select children with conditions that place them at risk for pneumococcal disease. When both PCV and PPSV23 are indicated, administer PCV first. PCV and PPSV23 should be administered during the same visit.

A two-dose series of MCV4 includes a recommended dose for *all* adolescents at 11 through 12 years of age followed by a second dose at 16 years. If the first dose is administered at 13 through 15 years of age, a booster dose should be administered at 16-18 years. No booster dose is needed if the first dose is administered at 16 years. In addition, MCV4 should be administered to people 2 months through 55 years of age with underlying conditions that place them at high risk of meningococcal disease. There are two licensed quadrivalent meningococcal vaccines and one pentavalent vaccine that additionally provides coverage against serogroup B disease. Each vaccine has a different minimum age for beginning vaccination with that product. In addition to the quadrivalent meningoccal vaccine, two other vaccines provide coverage against serogroup B meningoccal disease. Two to three doses of the meningococcal B (MenB) vaccines are recommended for persons >10 years old at increased risk of meningococcal disease. Further, consideration should be given to adolsecents not at increased risk (16-23 years, preferred age 16-18 years) based on shared clinical decision making, which involves patients and families coming together to discuss the potential benefits of vaccination (https://www.cdc.gov/vaccines/hcp/admin/downloads/isd-job-aid-scdm-mening-b-shared-clinical-decision-making.pdf).

Children 10 years of age or older may receive a single dose of the quadrivalent vaccine as an alternative to separate administration of MenACWY and MenB when both vaccines would be given on the same clinic day. The two licensed MenB vaccine products are not interchangeable. MCV4 vaccines may be administered simultaneously with MenB vaccines if indicated, but at a different anatomic site if feasible.

Hepatitis A vaccine, licensed for administration to children ≥12 months old, is recommended for universal administration to all children at 12 through 23 months of age and for certain high-risk groups. The two doses in the series should be separated by at least 6 months.

* See http://www.cdc.gov/flu/protect/vaccine/vaccines.htm and http://aapredbook.aappublications.org/site/news/vaccstatus.xhtml#flu.

Table 215.8 Combination Vaccines Licensed and Available in the United States

VACCINE PRODUCT (MANUFACTURER)*	TRADE NAME (YR LICENSED)	COMPONENTS	RECOMMENDED AGES	
			PRIMARY SERIES	BOOSTER DOSE
DTaP-IPV/Hib (Sanofi Pasteur)	Pentacel (2008)	DTaP-IPV + PRP-T	2, 4, and 6 mo	15-18 mo
DTaP-HepB-IPV (GlaxoSmithKline)	Pediarix (2002)	DTaP + HepB + IPV	2, 4, and 6 mo	
DTap-HepB-IPV-Hib (MSP Vaccine Company)	Vaxelis (2020)	DTaP + HepB+ IPV + Hib	2, 4, and 6 mo	
DTaP-IPV	Kinrix (2008), Quadracel (2015)	DTaP + IPV		Kinrix: For use as the fifth dose of DTaP and the fourth dose of IPV in children age 4-6 yr Quadracel: For use as the fifth dose in the DTaP series and as the fourth or fifth dose in the IPV series in children 4-6 yr of age
HepA-HepB (GlaxoSmithKline)	Twinrix (2001)	HepA + HepB	>18 yr of age; 0, 1, and 6 mo schedule	
MMRV (Merck & Co)	ProQuad (2005)	MMR + varicella	†	4-6 yr

*Dash (-) indicates that products are supplied in their final form by the manufacturer and do not require mixing or reconstitution by user; slash (/) indicates that products are mixed or reconstituted by user.
†Although ProQuad is available for the first dose (at 12-15 mo of age), the CDC recommends that MMR vaccine and varicella vaccine be administered separately for the first dose in this age-group unless the parent or caregiver expresses a preference for MMRV vaccine.
DTaP, Diphtheria and tetanus toxoids and acellular pertussis vaccine; HepA, hepatitis A vaccine; HepB, hepatitis B vaccine; IPV/Hib, trivalent inactivated polio vaccine and *Haemophilus influenzae* type b vaccine; MMRV, measles-mumps-rubella and varicella vaccine, PRP-T, H. influenzae type b capsular polysaccharide (polyribosyl-ribitol279 phosphate [PRP]) covalently bound to tetanus toxoid (PRP-T).
Adapted from Cohn AC, MacNeil JR, Clark TA, et al. Prevention and control of meningococcal disease: recommendations of the Advisory Committee on Immunization Practices. *MMWR*. 2013;62(2):1–28.

Table 215.9 Vaccines Recommended for Children and Adolescents with Underlying Conditions or at High Risk

VACCINES	SPECIAL SITUATIONS
Pneumococcal conjugate (and PPSV23 in certain conditions)	Cerebrospinal fluid leak Chronic heart disease Chronic kidney disease (excluding maintenance dialysis and nephrotic syndrome, which are included in immunocompromising conditions) Chronic liver disease Chronic lung disease (including moderate persistent or severe persistent asthma) Cochlear implant Diabetes mellitus Immunocompromising conditions (on maintenance dialysis or with nephrotic syndrome; congenital or acquired asplenia or splenic dysfunction; congenital or acquired immunodeficiencies; diseases and conditions treated with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, Hodgkin disease, and solid organ transplant; HIV infection; and sickle cell disease and other hemoglobinopathies)
MCV4	Anatomic or functional asplenia (including sickle cell disease) Persistent complement component deficiency Complement inhibitor use Residents of or travelers to countries in African meningitis belt or pilgrims on the Hajj During outbreaks caused by a vaccine serogroup First-year college students who live in residential housing (if not previously vaccinated at age 16 yr or older) or military recruits HIV infection
MenB	Anatomic or functional asplenia (including sickle cell disease) Children with persistent complement component deficiency Complement inhibitor use During outbreaks caused by a vaccine serogroup
Hib	In addition to routine Hib vaccine recommendations. Persons at increased risk for Hib disease, including chemotherapy recipients and those with anatomic or functional asplenia (including sickle cell disease), HIV infection, immunoglobulin deficiency, or early component complement deficiency Recipients of hematopoietic stem cell transplant (HSCT) Elective splenectomy
Hep B	In addition to routine Hep B vaccine recommendations; infants born to HBsAg-positive mothers or mothers whose HBsAg status is unknown (administer vaccine within 12 hr of birth)
HPV	In addition to routine HPV vaccine recommendations; immunocompromising conditions, including HIV infection History of sexual abuse or assault
Tetanus	Wound management recommendations exist based on age, number of prior doses of tetanus-toxoid-containing vaccine, and type of wound.

From Centers for Disease Control and Prevention. Child and adolescent schedule. https://www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html

Persons who previously received one dose at age 12 months or older should receive dose 2 at least 6 months after dose 1. Unvaccinated persons through age 18 years should complete a two-dose series with a minimum interval of 6 months. Adolescents age 18 years or older may receive the combined HepA and HepB vaccine. Immunity against hepatitis A infection is particularly important in people with chronic liver disease and clotting factor disorders, in men who have sex with men, in those who use injection or noninjection drugs, in people who are homeless, exposed to hepatitis A virus at work or travel, and those in close contact with international adoptees. Before all international travel, infants 6 through 11 months of age should receive one dose of hepatitis A vaccine. These children should be revaccinated with the routinely recommended two doses of hepatitis A vaccine beginning at 12 months of age. For unvaccinated children 12 months or older, administer dose 1 as soon as travel is considered. Preferably two doses should be administered before international travel to countries with high or intermediate endemic hepatitis A; the second dose should be administered at least 6 months after the first dose.

The **9vHPV** vaccine is recommended at age 11 or 12 years, although some advocate for routinely administering it as early as 9 years of age. Catch-up HPV vaccination is recommended for all persons through age 18 years if not adequately vaccinated. For those who initiate the series before their 15th birthday, the recommended schedule is two doses of 9vHPV vaccine. The minimum interval is 5 months between the first and second dose. If the second dose is given at a shorter interval, a third dose should be administered a minimum of 12 weeks after the second dose and a minimum of 5 months after the first dose. For those initiating the series on or after their 15th birthday, the recommended schedule is three doses of 9vHPV vaccine. The minimum intervals are 4 weeks between the first and second dose, 12 weeks between the second and third dose, and 5 months between the first and third dose. For children with a history of sexual abuse or assault, the ACIP recommends routine HPV vaccination beginning at age 9 years. In males and females with primary or secondary immunocompromising conditions such as B-lymphocyte deficiencies, T-lymphocyte complete or partial defects, HIV, malignancy, transplantation, autoimmune disease, or immunosuppressive therapy, the ACIP recommends vaccination with three doses of 9vHPV (0, 1-2, and 6 months) because immune response to vaccination might be attenuated. 9vHPV may be used to continue or complete a vaccination series in patients who started with 4vHPV or 2vHPV, though no additional doses are recommended after completing the series with recommended dosing intervals using any HPV vaccine. If the vaccination schedule is interrupted, the series does not need to be restarted. HPV vaccination is not recommended until after pregnancy, but no intervention is needed if vaccinated while pregnant. Pregnancy testing is not needed before vaccination.

Two **rotavirus** vaccines are available: RotaTeq (RV5) and Rotarix (RV1). With both vaccines, the first dose can be administered as early as 6 weeks of age. Do not start the series on or after age 15 weeks, 0 days. The RV5 vaccine is administered in three doses at least 4 weeks apart. The RV1 vaccine is administered in two doses at least 4 weeks apart. If any dose in the series is either RotaTeq or unknown, default to a three-dose series. The maximum age for the final dose is 8 months, 0 days as stated in the immunization schedule.

A dengue vaccine (Dengvaxia) was approved by the FDA in May 2019 for use in children age 9-16 years living in dengue-endemic territories **AND** having laboratory confirmation of *previous* dengue infection. It is a three-dose series administered at 0, 6, and 12 months. Endemic areas include Puerto Rico, American Samoa, U.S. Virgin Islands, Federated States of Micronesia, Republic of Marshall Islands, and the Republic of Palau. For updated guidance on dengue-endemic areas and pre-vaccination laboratory testing see https://apps.who.int/mediacentre/factsheets/fs117/en/index.html. Dengvaxia is not approved for use in U.S. travelers who are visiting but not living in an area where dengue is endemic. See https://www.aappublications.org/news/2020/05/01/mmwr050120 for more information.

For those that are 18 years of age or older and at risk for Mpox infection, 2 doses of the Mpox vaccine are recommended. See https://www.cdc.gov/poxvirus/mpox/interim-considerations/jynneos-vaccine.html#:~:text=JYNNEOS%20is%20approved%20for%20the,22)%3A734%2D742) for more information.

To prevent RSV in infants, one dose of nirsevimab is recommended for infants younger than 8 months of age who were born shortly before or are entering their first RSV season (typically fall through spring) if: (1) the mother did not receive RSV vaccine during pregnancy, (2) the mother's RSV vaccination status is unknown, or (3) the infant was born within 14 days of maternal RSV vaccination. Additionally, a dose of nirsevimab is recommended for some children 8 to 19 months of age who are at increased risk for severe RSV disease and entering their second RSV season (https://www.cdc.gov/mmwr/volumes/72/wr/mm7234a4.htm#suggestedcitation).

The present schedule, excluding influenza vaccine, can require as many as 41 doses. Of the doses, more than half are recommended before 2 years of age. Influenza vaccination, starting at age 6 months, can add an additional 20 injections through 18 years. To reduce the injection burdens, several combination vaccines are available (see Table 215.8).

The recommended childhood and adolescent immunization schedule establishes a routine adolescent visit at 11 through 12 years of age. MCV4, a Tdap booster, and 9vHPV vaccine should be administered during this visit in addition to the COVID-19 vaccine if the child is 12 years of age or older. Influenza vaccine should be administered annually. In addition, the 11- to 12-year-old visit is an opportune time to review all the immunizations the adolescent has received previously, to provide any doses that were missed, and to review other age-appropriate preventive services. The 11- to 12-year visit establishes an important platform for incorporating other vaccines. Information on the current status of new vaccine licensure and recommendations for use is available.*

For children who are at least 1 month behind in their immunizations, catch-up immunization schedules are available for children 4 months through 18 years of age (http://www.cdc.gov/vaccines/schedules/hcp/imz/catchup.html) (see Table 215.7). Interactive immunization schedules are available for children from birth through 18 years of age at https://www2a.cdc.gov/vaccines/childquiz/. Only written/electronic, dated, authentic records should be accepted as evidence of immunization. In general, when in doubt, a person with unknown or uncertain immunization status should be considered "disease susceptible," and recommended immunizations should be initiated without delay on a schedule commensurate with the person's current age. No evidence suggests that administration of vaccines to already-immune recipients is harmful. A new addendum section has been added to list any ACIP recommendations that occur by majority vote and are approved by CDC Director after the 2024 immunization schedules are approved and published.

VACCINES RECOMMENDED IN SPECIAL SITUATIONS

Eight vaccines—PCV, PPSV23, MCV4, MenB, Flu, Hib, HepA, and HepB—are recommended for children and adolescents at increased risk for complications from vaccine-preventable diseases or children who have an increased risk for exposure to these diseases who are outside the age-groups for which these vaccines are normally recommended (PPSV23 and MenB are not routinely recommended for any age-group of children and are only used for children with high-risk conditions; Fig. 215.2 and Table 215.9). Specific recommendations for use of these vaccines in children with underlying conditions can be found in the recommended immunization schedule.

PCV15 or **PCV20** is recommended for children 24-71 months of age with specialized risk conditions that place them at high risk for pneumococcal disease. This recommendation includes children with sickle cell disease and other hemoglobinopathies, including hemoglobin SS, hemoglobin S-C, or hemoglobin S–β-thalassemia,

* http://aapredbook.aappublications.org/site/news/vaccstatus.xhtml and http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/UCM093833

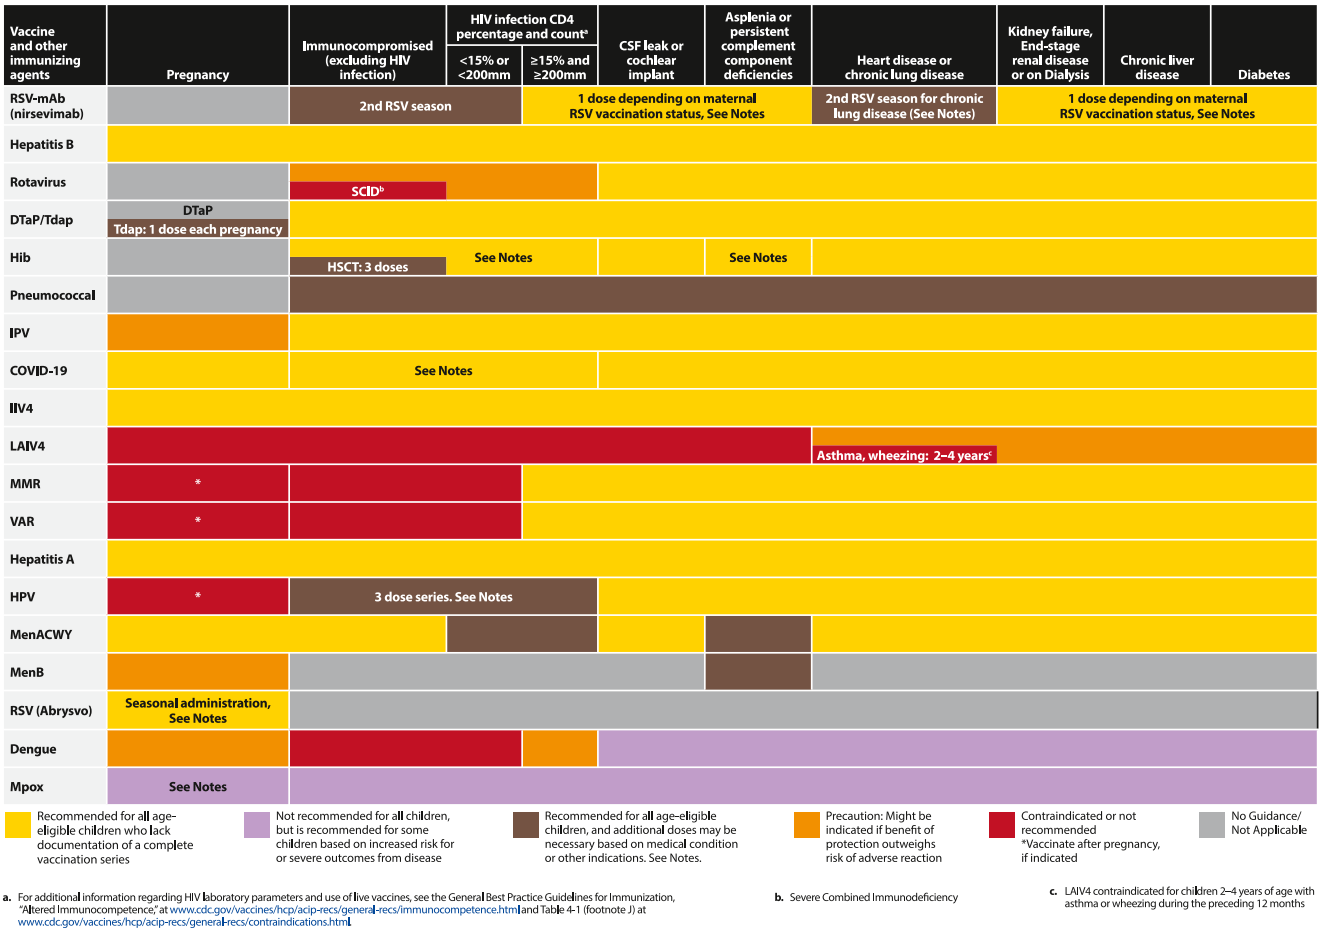

Fig. 215.2 Recommended child and adolescent immunization schedule by medical indication—United States, 2024. *Always use this figure in conjunction with Figure 215.1 and the notes that follow it. (Courtesy U.S. Centers for Disease Control and Prevention, Atlanta, Georgia. 2024. https://www.cdc.gov/vaccines/schedules/downloads/child/0-18yrs-child-combined-schedule.pdf.)*

or children who are functionally or anatomically asplenic; children with HIV infection; and children who have chronic disease (see Table 215.9 and Fig. 215.2). (For further recommendations on pneumococcal vaccine recommendations, see https://www.cdc.gov/vaccines/vpd/pneumo/hcp/who-when-to-vaccinate.html.)

Children at high risk for pneumococcal disease also should receive **PPSV23** to provide immunity to serotypes not contained in the 13- or 15-valent conjugate vaccine. PPSV23 should be administered on or after the second birthday and should follow completion of the PCV series by at least 8 weeks. Two doses of PPSV23 are recommended, with an interval of 5 years between doses. Immunization of children >5 years old with high-risk conditions can be performed with PCV15 or PCV20 and/or PPSV23, depending on the condition and vaccination history. When both PCV and PPSV23 are indicated, PCV should be administered first.

MCV4 is recommended for HIV-infected persons ≥2 months old, children with anatomic or functional asplenia (including sickle cell disease), children with persistent complement component deficiency (includes persons with inherited or chronic deficiencies in C3, C5-9, properdin, factor D, or factor H), or children taking a complement inhibitor (e.g., eculizumab or ravulizumab).

Meningococcal B (**MenB**) vaccine is recommended for persons ≥10 years old at increased risk of meningococcal disease. This includes people with complement deficiencies or anatomic or functional asplenia, people at increased risk because of serogroup B meningococcal disease outbreaks, and microbiologists who routinely are exposed to isolates of *Neisseria meningitidis*. Young adults age 16-23 (preferred range: 16-18 years) who are not at increased risk for meningococcal disease may be vaccinated with either of the two MenB vaccines, which are not interchangeable, to provide short-term protection against most strains of serogroup B meningococcal disease.

Hib vaccine and **HepA** vaccine are recommended for children with certain high-risk conditions. **HepB** is recommended for infants born to HBsAg-positive mothers or mothers whose HBsAg status is unknown (administer the vaccine within 12 hours of birth) (see Table 215.9).

In addition to vaccines in the recommended childhood and adolescent schedule, a variety of vaccines are available for children who will be **traveling** to areas of the world where certain infectious diseases are common (Table 215.10). Vaccines for travelers include typhoid fever, hepatitis A, hepatitis B, Japanese encephalitis, MCV4, cholera, rabies, and yellow fever, depending on the location and circumstances of travel. **Measles** is endemic in many parts of the world. Children 6-11 months old should receive a dose of MMR and hepatitis A vaccines before international travel outside of the United States. However, doses of MMR and hepatitis A vaccines received before 12 months should not be counted in determining compliance with the recommended two-dose MMR schedule. For unvaccinated children ≥12 months old, administer two doses before international travel following the recommended schedule. (Additional information on vaccines for international travel can be found at http://wwwnc.cdc.gov/travel/.)

Vaccine recommendations for children with **immunocompromising conditions**, either primary (inherited) or secondary (acquired), vary according to the underlying condition, the degree of immune deficit, the risk for exposure to disease, and the vaccine (Table 215.11 and see Fig. 215.2). Immunization of children who are

Table 215.10 Recommended Immunizations for International Travel*

IMMUNIZATIONS	LENGTH OF STAY	
	Brief, <1 mo	Long-Term / Residential, >1 mo
Review and complete age-appropriate childhood and adolescent schedule (see text for details) • DTaP, poliovirus, pneumococcal, and *Haemophilus influenzae* type b (Hib) vaccines may be given at 4-wk intervals if necessary to complete recommended schedule before departure. • Influenza • MMR: two additional doses given if <12 mo old at first dose • Meningococcal disease (MenACWY)† • Rotavirus • Varicella • Human papillomavirus (HPV) • Hepatitis A: two additional doses given if <12 mo old at 1st dose‡,§ • Hepatitis B§ • Tdap	+	+
Yellow fever#	+	+
Typhoid fever¶	+	+
Rabies**	±	±
Japanese encephalitis‡	±	+
Cholera‡‡	±	±

*See disease-specific chapters in the Centers for Disease Control and Prevention's *Yellow Book* for details. For further sources of information, see text.
†Recommended for regions of Africa with endemic infection and during local epidemics and required for travel to Saudi Arabia for the Hajj.
‡For infants age 6-11 mo, first dose is recommended before departure for all international travel. For unvaccinated children 12 mo and older, this vaccine is indicated for travelers to areas with intermediate or high endemic rates of hepatitis A virus infection.
§If there is insufficient time to complete 6-mo primary series, accelerated series can be given.
#For regions with endemic infection, see Health Information for International Travel (http://www.cdc.gov/travel). Because of the risk of serious adverse events after yellow fever vaccination, clinicians should only vaccinate people who (1) are at risk of exposure to yellow fever virus (YFV) or (2) require proof of vaccination to enter a country.
¶Indicated for travelers who will consume food and liquids in areas of poor sanitation.
**Indicated for people with high risk for animal exposure (especially to dogs) and for travelers to countries with endemic infection.
‡For regions with endemic infection (see Health Information for International Travel). For high-risk activities in areas experiencing outbreaks, vaccine is recommended, even for brief travel.
‡‡Cholera vaccine (CVD 103-HgR, Vaxchora) is recommended for adult (18-64 yr old) travelers to an area of active toxigenic *V. cholerae* O1 transmission.
+, Recommended; ±, consider; DTaP, diphtheria and tetanus toxoids and acellular pertussis.
Data from Centers for Disease Control and Prevention. Travelers' health. https://wwwnc.cdc.gov/travel.

Table 215.11 Vaccination of Persons with Primary and Secondary Immune Deficiencies

	PRIMARY			
CATEGORY	SPECIFIC IMMUNODEFICIENCY	CONTRAINDICATED VACCINES*	RISK-SPECIFIC RECOMMENDED VACCINES*	EFFECTIVENESS AND COMMENTS
B lymphocyte (humoral)	Severe antibody deficiencies (e.g., X-linked agammaglobulinemia and common variable immunodeficiency)	OPV[a] Smallpox[b] LAIV4 BCG Ty21a Yellow fever virus (YFV) and live-bacteria vaccines[c] No data for rotavirus vaccines	Annual IIV is the only vaccine given to patients receiving IG therapy; routine inactivated vaccines can be given if not receiving IVIG. Pneumococcal Hib (children 12-59 mo of age)	The effectiveness of any vaccine will be uncertain if it depends only on the humoral response (e.g., PPSV23). IG therapy interferes with the immune response to live vaccines MMR and VAR.
	Less severe antibody deficiencies (e.g., selective IgA deficiency and IgG subclass deficiency)	OPV[a] BCG YFV vaccine Other live vaccines[d] appear to be safe.	Vaccines should be given as on the annual immunization schedule for immunocompetent people.[e] PPSV23 should be given beginning at 2 yr of age.[f] Pneumococcal Hib (children 12-59 mo of age)	All vaccines are probably effective. Immune response may be attenuated.
T lymphocyte (cell-mediated and humoral)	Complete defects (e.g., SCID, complete DiGeorge syndrome)	All live vaccines[c,d,g]	Pneumococcal Hib (children 12-59 mo of age) and annual IIV	All inactivated vaccines are probably ineffective.
	Partial defects (e.g., most patients with DiGeorge syndrome, hyper-IgM syndrome, Wiskott-Aldrich syndrome, ataxia-telangiectasia)	All live vaccines[c,d,g]	Routine inactivated vaccines should be given.[e] PPSV23 should be given beginning at 2 yr of age.[f] Pneumococcal Hib (children 12-59 mo of age)	Effectiveness of any vaccine depends on degree of immune suppression.
	Interferon (IFN)-γ–interleukin (IL)-12 axis deficiencies	All live vaccines for IL-12/IL-12R deficiencies, IFN-γ, IFN-α, or STAT1 deficiencies	None	None

Table 215.11 Vaccination of Persons with Primary and Secondary Immune Deficiencies—cont'd

PRIMARY

CATEGORY	SPECIFIC IMMUNODEFICIENCY	CONTRAINDICATED VACCINES*	RISK-SPECIFIC RECOMMENDED VACCINES*	EFFECTIVENESS AND COMMENTS
Complement	Persistent complement, properdin, MBL, or factor B deficiency; secondary deficiency because taking eculizumab (Solaris)	None	PPSV23 should be given beginning at 2yr of age.[f] MCV series beginning in infancy.[h] MenB series beginning at 10 yr of age and Hib vaccine (children 12-59 mo of age)	All routine vaccines are probably effective.
Phagocytic function	Chronic granulomatous disease	Live-bacteria vaccines[c]	None	All inactivated vaccines are safe and probably effective. Live-virus vaccines are probably safe and effective.
	Phagocytic deficiencies that are undefined or accompanied by defect in T-cell and NK-cell dysfunction (e.g., Chédiak-Higashi syndrome, leukocyte adhesion defects, myeloperoxidase deficiency)	MMR, MMRV, OPV,[a] smallpox, LAIV4, Ty21a, YF, all bacteria vaccines	PPSV23 should be given beginning at 2yr of age.[f] MCV series beginning in infancy.[h]	All inactivated vaccines are safe and probably effective.

SECONDARY

SPECIFIC IMMUNODEFICIENCY	CONTRAINDICATED VACCINES*	RISK-SPECIFIC RECOMMENDED VACCINES*	EFFECTIVENESS AND COMMENTS
HIV/AIDS	OPV[a] Smallpox BCG Combined MMRV LAIV4 Withhold MMR, varicella, and zoster in severely immunocompromised persons. YF vaccine may have a contraindication or precaution depending on the indicators of immune function.[j]	PPSV23 should be given beginning at 2yr of age.[f] MCV series beginning in infancy.[h] HepB vaccine Consider Hib (if not administered in infancy).[l]	Rotavirus vaccine is recommended on standard schedule. MMR and VAR are recommended for HIV-infected children who are asymptomatic or only low-level immunocompromised.[k] All inactivated vaccines may be effective.
Generalized malignant neoplasm, transplantation, autoimmune disease, immunosuppressive or radiation therapy	Live-virus and live-bacteria vaccines, depending on immune status.[c,d,m]	PPSV23 should be given beginning at 2yr of age.[f] Annual IIV (unless receiving intensive chemotherapy or anti–B-cell antibodies). Hib vaccine may be indicated.[n]	Effectiveness of any vaccine depends on degree of immune suppression; inactivated standard vaccines are indicated if not highly immunosuppressed, but doses should be repeated after chemotherapy ends.
Asplenia (functional, congenital anatomic, surgical)	LAIV4	PPSV23 should be given beginning at 2yr of age.[f] MCV series beginning in infancy.[h] MenB series beginning at 10 yr of age. Hib (if not administered in infancy)[o]	All routine vaccines are probably effective.
Chronic renal disease	None	PPSV23 should be given beginning at 2yr of age.[f] HepB is indicated if not previously immunized.	All routine vaccines are probably effective.
CNS anatomic barrier defect (cochlear implant, congenital dysplasia of the inner ear, persistent CSF communication with naso-/oropharynx)	None	PPSV23 should be given beginning at 2yr of age.[f]	All standard vaccines are indicated.

*Other vaccines that are universally or routinely recommended should be given if not contraindicated.
[a]OPV is no longer available in the United States.
[b]This table refers to contraindications for nonemergency vaccination (i.e., ACIP recommendations).
[c]Live-bacteria vaccines: BCG and oral Ty21a *Salmonella* Typhi vaccine.
[d]Live-virus vaccines: MMR, MMRV, VAR, OPV, LAIV, YF, zoster, rotavirus, and vaccinia (smallpox). Smallpox vaccine is not recommended for children or the general public.
[e]Children who are delayed or underimmunized should be immunized with routinely recommended vaccines, according to age and catch-up schedule.
[f]PPSV23 is begun at 2 yr or older. If PCV13 is required, PCV13 doses should be administered first, followed by PPSV23 at least 8 wk later; a second dose of PPSV23 is given 5 yr after the first.
[g]Regarding T-lymphocyte immunodeficiency as a contraindication for rotavirus vaccine, data exist only for SCID.

Table 215.11 Vaccination of Persons with Primary and Secondary Immune Deficiencies—cont'd

[h]Age and schedule of doses depend on the product; repeated doses are required.
[i] Pneumococcal vaccine is not indicated for children with chronic granulomatous disease beyond age-based universal recommendations for PCV13. Children with chronic granulomatous disease are not at increased risk for pneumococcal disease.
[j]YF vaccine is contraindicated in HIV-infected children <6 yr old who are highly immunosuppressed. There is a precaution for the use of YF vaccine in asymptomatic HIV-infected children <6 yr with total lymphocyte percentage of 15–24%, and >6 yr old with $CD4^+$ T-lymphocyte counts of 200-499 cells/mm^3. Data from Centers for Disease Control and Prevention. Yellow fever vaccine: recommendations of the Advisory Committee on Immunization Practices, *MMWR Recomm Rep*. 2010;59(RR-07); 1–27.
[k]HIV-infected children should receive immunoglobulin after exposure to measles and may receive varicella vaccine if $CD4^+$ T-lymphocyte percentage is ≥15% for those <6 yr old or $CD4^+$ T-lymphocyte count ≥200 cells/mm^3 for those ≥6 yr old. People with perinatal HIV infection who were vaccinated with measles-, rubella-, or mumps-containing vaccine before the establishment of combination antiretroviral therapy (cART) should be considered unvaccinated and should receive two appropriately spaced doses of MMR vaccine once effective cART has been established (at least 6 mo with $CD4^+$ T lymphocytes ≥15% for children <6 yr old, or $CD4^+$ T-lymphocyte count ≥200 cells/mm^3 for children ≥6 yr old).
[l]For patients 5-18 yr old who have not received a Hib primary series and a booster dose or at least one Hib dose after age 14 mo.
[m]Withholding inactivated vaccines also is recommended with some forms of immunosuppressive therapy, such as anti-CD20 antibodies, induction or consolidation chemotherapy, or patients with major antibody deficiencies receiving immunoglobulins. Inactivated influenza vaccine is an exception, but consideration should be given to repeating doses of any inactivated vaccine administered during these therapies.
[n]For persons <60 mo old undergoing chemotherapy or radiation therapy who have not received a Hib primary series plus a booster dose or at least one Hib dose after age 14 mo.
[o]For persons >59 mo old who are asplenic and persons ≥15 mo who are undergoing elective splenectomy and who have not received a Hib primary series and a booster dose or at least one Hib dose after age 14 mo.
BCG, Bacille Calmette-Guérin vaccine; CNS, central nervous system; Hib, *Haemophilus influenzae* type b vaccine; HIV/AIDS, human immunodeficiency virus/acquired immunodeficiency syndrome; IG, immunoglobulin; IIV, inactivated influenza vaccine; LAIV4, live-attenuated influenza vaccine; MMR, measles, mumps, rubella vaccine; MMRV, measles-mumps-rubella-varicella; MCV, quadrivalent meningococcal polysaccharide vaccine; MenB, serogroup B meningococcal vaccine; OPV, oral poliovirus vaccine (live); PPSV23, pneumococcal polysaccharide vaccine; SCID, severe combined immunodeficiency disease; VAR, varicella; YF, yellow fever.
Adapted from Immunization in Special Circumstances. In: Kimberlin DW, Barnett ED, Lynfield R, Sawyer MH, eds. *Red Book: 2021–2024 Report of the Committee on Infectious Diseases*, 32nd ed. Itasca, IL: American Academy of Pediatrics; 2021.

immunocompromised poses the following potential concerns: the incidence or severity of some vaccine-preventable diseases is higher, and therefore certain vaccines are recommended specifically for certain conditions; vaccines may be less effective during the period of altered immunocompetence and may need to be repeated when immune competence is restored; and because of altered immunocompetence, some children and adolescents may be at increased risk for an adverse event after receipt of a live-virus vaccine. Live-attenuated vaccines generally are contraindicated in immunocompromised persons. The exceptions include **MMR**, which may be given to a child with HIV infection provided the child is asymptomatic or symptomatic without evidence of severe immunosuppression, and **varicella** vaccine, which may be given to HIV-infected children if the $CD4^+$ lymphocyte count is at least 15% and the total $CD4^+$ cell count is >200/mm^3. MMRV is not recommended in these situations.

Altered immunocompetence is considered a precaution for rotavirus; however, the vaccine is contraindicated in children with severe combined immunodeficiency disease. Inactivated vaccines may be administered to immunocompromised children, although their effectiveness might not be optimal depending on the immune deficit. Children with complement deficiency disorders may receive all vaccines, including live-attenuated vaccines. In contrast, children with phagocytic disorders may receive both inactivated and live-attenuated viral vaccines but not live-attenuated bacterial vaccines.*

Corticosteroids can suppress the immune system. Children receiving corticosteroids (≥2 mg/kg/day or ≥20 mg/day of prednisone or equivalent) for ≥14 days should not receive live vaccines until therapy has been discontinued for at least 1 month. Children on the same dose levels but for <2 weeks may receive live-virus vaccines as soon as therapy is discontinued, although some experts recommend waiting 2 weeks after therapy has been discontinued. Children receiving lower doses of corticosteroids may be vaccinated while receiving therapy.

Children and adolescents with malignancy and those who have undergone solid organ or hematopoietic stem cell transplantation and immunosuppressive or radiation therapy should not receive live-virus and live-bacteria vaccines depending on their immune status. Children who have undergone chemotherapy for leukemia may need to be reimmunized with age-appropriate single doses of previously administered vaccines. Preterm infants generally can be vaccinated at the same chronological age as full-term infants according to the recommended childhood immunization schedule. An exception is the birth dose of HepB. When mother is HBsAg-negative, infants weighing ≥2 kg and who are medically stable should receive a birth dose within the first 24 hours of life. However, HepB should be deferred in infants weighing <2 kg at birth until chronological age 1 months or hospital discharge (whichever is earlier and even if weight is still <2 kg). All preterm, low-birthweight infants born to HBsAg-positive mothers should receive hepatitis B immunoglobulin (HBIG) and HepB vaccine (at separate anatomic sites) within 12 hours of birth. However, such infants should receive an additional three doses of vaccine starting at 30 days of age (see Fig. 215.1). Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody at 9-12 months, or 1-2 months after completion of the HepB series if the series was delayed. If the test is negative for antibody against the surface antigen (anti-HBs), an additional dose of HepB is recommended with testing 1-2 months after the dose. If the child is still antibody negative, an additional two doses of vaccine should be administered.

If the mother's HBsAg status is unknown within 12 hours of birth, administer HepB vaccine regardless of birthweight. For infants weighing <2,000 g, administer HBIG in addition to HepB within 12 hours of birth. Determine the mother's HBsAg status as soon as possible and, if the mother is HBsAg-positive, also administer HBIG to infants weighing ≥2,000 g as soon as possible, but no later than 7 days of age.

Varicella-zoster immunoglobulin **(VariZIG)** is recommended for patients without evidence of immunity to varicella who are at high risk for severe varicella and complications, who have been exposed to varicella or herpes zoster, and for whom varicella vaccine is contraindicated. This includes immunocompromised patients without evidence of immunity, newborn infants whose mothers have signs and symptoms of varicella around the time of delivery (i.e., 5 days before to 2 days after), hospitalized premature infants born at ≥28 weeks of gestation whose mothers do not have evidence of immunity to varicella, hospitalized premature infants born at <28 weeks of gestation or who weigh ≤1,000 g at birth (regardless of their mother's evidence of immunity to varicella), and pregnant women without evidence of immunity.

The ACIP recommends the use of COVID-19 vaccines within the scope of the EUA or fully approved by the FDA based on a Biologics License Application for the particular vaccine. Interim ACIP recommendations for the use of COVID-19 vaccines can be found at https://www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/covid-19.html. COVID-19 vaccine and other routine vaccines may be administered on the same day. For more information about COVID-19 vaccines authorized for use in the United States, see https://www.cdc.gov/vaccines/covid-19/info-by-product/index.html. Rare serious adverse events have been reported after COVID-19 vaccination, including myocarditis in children older than 5 years of age. The ACIP continues to conclude that the benefits outweigh the risks for rare serious adverse events after COVID-19 vaccination.

*https://www.cdc.gov/vaccines/pubs/pinkbook/downloads/appendices/a/immuno-table.pdf

Some children have situations that are not addressed directly in current immunization schedules. Physicians can use general rules to guide immunization decisions in some of these instances. General Best Practice Guidelines for Immunization (including contraindications and precautions) can be found at https://www.cdc.gov/vaccines/hcp/acip-recs/general-recs/index.html. In general, vaccines may be given simultaneously on the same day, whether inactivated or live. Different inactivated vaccines can be administered at any interval between doses. However, because of theoretical concerns about viral interference, different live-attenuated vaccines (MMR, varicella), if not administered on the same day, should be given at least 1 month apart. An inactivated and a live vaccine may be spaced at any interval from each other.

Immunoglobulin does not interfere with inactivated vaccines. However, immunoglobulin can interfere with the immune response to measles vaccine and, by inference, to varicella vaccine. In general, immunoglobulin, if needed, should be administered at least 2 weeks after the measles vaccine. Depending on the dose of immunoglobulin received, MMR should be deferred for as long as 3-11 months. Immunoglobulin is not expected to interfere with the immune response to LAIV4 or rotavirus vaccines.

Certain adult (including pregnancy) immunizations are recommended to decrease the risk of infection in their children; these include influenza virus and pertussis (Tdap).

PRECAUTIONS AND CONTRAINDICATIONS

Observation of valid precautions and contraindications is critical to ensure that vaccines are used in the safest manner possible and to obtain optimal immunogenicity. When a child presents for immunization with a clinical condition considered a **precaution**, the physician must weigh benefits and risks to that individual child. If benefits are judged to outweigh risks, the vaccine or vaccines in question may be administered. A **contraindication** means the vaccine should not be administered under any circumstances.

A general contraindication for all vaccines is **anaphylactic reaction** to a prior dose. Anaphylactic hypersensitivity to vaccine constituents is also a contraindication. However, if a vaccine is essential, there are desensitizing protocols for some vaccines. The major constituents of concern are *egg proteins* for vaccines grown in eggs; *gelatin,* a stabilizer in many vaccines; and antimicrobial agents. The recommendations for persons with egg allergy were modified as follows: A previous severe allergic reaction to influenza vaccine is a contraindication to future receipt of any influenza vaccine. Persons with a history of egg allergy who have experienced only hives after exposure to egg should receive any flu vaccine appropriate for age and health status. Persons who had symptoms other than hives (e.g., angioedema, respiratory distress, need for emergency medical services or epinephrine) should receive any influenza vaccine appropriate for age and health status annually. If using an influenza vaccine other than Flublok or Flucelvax, administer in a medical setting under supervision of a healthcare provider who is able to recognize and manage severe allergic conditions. LAIV4 should not be used for persons with a history of severe allergic reaction to any component of the vaccine (excluding egg) or to a previous dose of any influenza vaccine. The measles and mumps components of MMR are grown in chick embryo fibroblast tissue culture. However, the amount of egg protein in MMR is so small that there are no special procedures for administering the vaccine to someone with a history of anaphylaxis after egg ingestion.

Vaccines should usually be deferred in children with moderate to severe acute illnesses, regardless of the presence of fever, until the child recovers. *However, children with mild illnesses may be vaccinated.* Studies of undervaccinated children have documented opportunities that were missed because mild illness was used as an invalid contraindication.

Complete tables of contraindications and precautions by vaccine can be found at https://www.cdc.gov/vaccines/hcp/acip-recs/general-recs/contraindications.html and as an appendix to the 2024 immunization schedule (https://www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html#appendix).

MEDICAL EXEMPTIONS

All 50 states, the District of Columbia, and Puerto Rico have regulations requiring verification of immunization for childcare and school attendance. This provides direct protection to the immunized population and indirect protection to those unable to be immunized. It also functions to improve timely immunization of children. Regulations also allow for medical exemption from immunization requirements in all 50 states, and the majority of states also have varied regulations that allow for nonmedical exemptions. Rare, medically recognized contraindications are important to observe. Nonmedical exemptions to immunization requirements include exemptions because of religious or philosophical beliefs. Persons with exemptions are at greater risk of vaccine-preventable diseases than the general population. When children with exemptions cluster, as can happen with nonmedical exemptions, the community may be at risk for outbreaks, leading to exposure of children who cannot be protected by vaccination to vaccine-preventable diseases, such as children too young for vaccination and those with medical contraindications. (For more information, see http://pediatrics.aappublications.org/content/early/2016/08/25/peds.2016-2145.)

IMPROVING IMMUNIZATION COVERAGE

Standards for child and adolescent immunization practices have been developed to support achievement of high levels of immunization coverage while providing vaccines in a safe and effective manner and educating parents about risks and benefits of vaccines (Table 215.12).

Pediatric vaccine uptake has decreased since the start of the COVID-19 pandemic resulting in decreased vaccination coverage. This identified decline may indicate that U.S. children and their communities face increased risks for outbreaks of vaccine-preventable diseases (Fig. 215.3).

Despite benefits that vaccines have to offer, many children are underimmunized as a result of not receiving recommended vaccines or not receiving them at the recommended ages. Much of the underimmunization problem can be solved through physician actions. Most children have a regular source of healthcare. However, missed opportunities to provide immunizations at healthcare visits include but are not limited to failure to provide all recommended vaccines that could be administered at a single visit during that visit, failure to provide immunizations to children outside of well child care encounters when contraindications are not present, and referral of children to public health clinics because of inability to pay for vaccines. Simultaneous administration of multiple vaccines is generally safe and effective. When the benefits of simultaneous vaccination are explained, many parents prefer such immunization to making an extra visit. Providing all needed vaccines simultaneously should be the standard of practice.

Only valid contraindications and precautions to vaccine administration should be observed. Ideally, immunizations should be provided during well child visits; however, if no contraindications exist, it is important to administer vaccines at other visits, particularly if the child is behind in the schedule. There is no good evidence that providing immunizations outside of well child care ultimately decreases the number of well child visits.

Financial barriers to immunization should be minimized. Participation in the **VFC** program allows physicians to receive vaccines at no cost for their eligible patients, which helps such patients get immunized in their medical home.

Several interventions have been shown to help physicians increase immunization coverage in their practices. Reminder systems for children before an appointment or recall systems for children who fail to keep appointments have repeatedly been demonstrated to improve coverage. Assessment and feedback are also important interventions. Many physicians overestimate the immunization coverage among patients they serve and thus are not motivated to make any changes in their practices to improve performance. Assessing the immunization coverage of patients served by an individual physician with feedback of results can be a major motivator for improvement. Often, public health departments can be contacted to provide the assessments and feedback. Alternatively, physicians can perform self-assessment. Review of approximately 60 consecutive charts of 2-year-old children may provide

Table 215.12 Standards for Child and Adolescent Immunization Practices

AVAILABILITY OF VACCINES
Vaccination services are readily available.
Vaccinations are coordinated with other healthcare services and provided in a medical home when possible.
Barriers to vaccination are identified and minimized.
Patient costs are minimized.
ASSESSMENT OF VACCINATION STATUS
Healthcare professionals review the vaccination and health status of patients at every encounter to determine which vaccines are indicated.
Healthcare professionals assess for and follow only medically accepted contraindications.
EFFECTIVE COMMUNICATION ABOUT VACCINE BENEFITS AND RISKS
Parents or guardians and patients are educated about the benefits and risks of vaccination in a culturally appropriate manner and in easy-to-understand language.*
Healthcare professionals offer strong and consistent recommendations for all universally recommended vaccines according to the current immunization schedule. They use presumptive language (e.g., these vaccines are routine) and deliver this recommendation in the same manner for all vaccines.
Healthcare professionals answer parents' or guardians' and patients' questions thoroughly and emphasize an unwavering commitment to the recommendation. If parents or guardians and patients are hesitant or refuse, healthcare professionals persevere and offer the vaccine again at the next most appropriate time.
PROPER STORAGE AND ADMINISTRATION OF VACCINES AND DOCUMENTATION OF VACCINATIONS
Healthcare professionals follow appropriate procedures for vaccine storage and handling.
Up-to-date, written vaccination protocols are accessible at all locations where vaccines are administered.
Persons who administer vaccines and staff who manage or support vaccine administration are knowledgeable and receive ongoing education.
Healthcare professionals simultaneously administer as many indicated vaccine doses as possible.
Vaccination records for patients are accurate, complete, and easily accessible.
Healthcare professionals report adverse events after vaccination promptly and accurately to the Vaccine Adverse Event Reporting System (VAERS) and are aware of a separate program, the National Vaccine Injury Compensation Program (VICP).
Healthcare professionals and personnel review the immunization timeline with parents or guardians and patients and schedule follow-up immunization visits before the family leaves the care setting.
All personnel who have contact with patients are appropriately vaccinated and communicate consistent messages about vaccines.
IMPLEMENTATION OF STRATEGIES TO IMPROVE VACCINATION COVERAGE
Systems are used to remind parents or guardians, patients, and healthcare professionals when vaccinations are due and to recall those who are overdue.
Office- or clinic-based patient record reviews and vaccination coverage assessments are performed annually.
Healthcare professionals practice community-based approaches.
Healthcare professionals understand cultural needs and disparities of different populations and use the most effective strategies for these populations.
Most healthcare visits (including acute care or sick visits) are viewed as opportunities to review immunization records, provide vaccines that are due, and catch up on missed vaccinations.

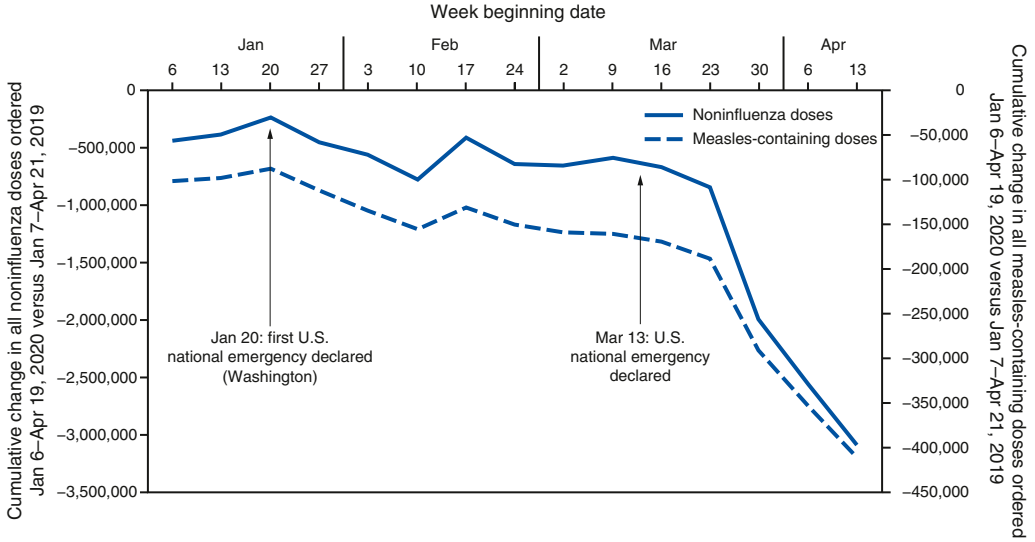

Fig. 215.3 Weekly changes in Vaccines for Children Program (VFC) provider orders* and Vaccine Safety Datalink (VSD) doses administered† for routine pediatric vaccines — United States, January 6–April 19, 2020. *VFC data represent the difference in cumulative doses of VFC-funded non-influenza and measles-containing vaccines ordered by healthcare providers at weekly intervals between Jan. 7–Apr. 21, 2019, and Jan. 6–Apr. 19, 2020; †VSD data depict weekly measles-containing vaccine doses administered by age-group (age ≤24 mo and >24 mo to 18 yr). *(From Santoli JM, Lindley MC, DeSilva MB, et al. Effects of the COVID-19 pandemic on routine pediatric vaccine ordering and administration – United States, 2020. MMWR Morb Mortal Wkly Rep. 2020;69:591–593.)*

a reasonable estimate of practice coverage. Another approach is to have a staff member review the chart of every patient coming in for a visit and placing immunization needs reminders on the chart for the physician. Electronic medical records can be designed to accomplish this goal.

VACCINE HESITANCY

The World Health Organization (WHO) characterized *vaccine hesitancy* as a delay in acceptance or refusal of vaccines despite availability of vaccination services. The COVID-19 pandemic has also changed the way outpatient care is being delivered across the United States. Because of COVID-19, providers face the additional challenges of maintaining and strengthening routine vaccinations. As communities are reopening, it is vitally important for providers to work with parents to ensure their children stay up to date on routine, universally recommended vaccines. The pandemic is a reminder of the threat of infectious diseases. Providers are well positioned to counsel parents about the value of vaccination. Uptake is highest when parents are aware that their child is due for specific vaccines and when they feel safe about their children receiving those vaccines. Factors implicated in vaccine hesitancy include complacency, convenience, and confidence. The percentage of children having a parent reporting they were "hesitant about childhood shots" was 25.8% in 2018 and 19.5% in 2019 (https://pediatrics.aappublications.org/content/146/6/e2020007609). Concerns about vaccine safety and questions about the necessity of vaccines are often cited as reasons for refusal. Vaccine-hesitant individuals are a heterogeneous group, and their individual concerns should be respected and addressed. Multiple studies have shown that the most important factor in persuading parents to accept vaccines remains the *one-on-one contact* with an informed, caring, and concerned pediatrician. Parents should be reassured that vaccines are tested thoroughly before licensure, that ongoing mechanisms of monitoring safety exist after licensure, and that the current vaccine schedule is the only recommended schedule. It is important to stress that serious disease can occur if a child and family are not immunized, because unvaccinated children put medically exempt children who live in that same area at risk, as well as some children who have been vaccinated (although most vaccines are highly effective, no vaccine is 100% effective). Parental education can be provided through reputable sources for vaccine information (see Table 215.8). (For more information, see http://pediatrics.aappublications.org/content/early/2016/08/25/peds.2016-2146.) Provider resources for vaccine conversations with parents are available at https://www.cdc.gov/vaccines/hcp/conversations/index.html.

Physician concerns about liability should be addressed by appropriate documentation of discussions in the chart. The Committee on Bioethics of the AAP has published guidelines for dealing with parents' refusal of immunization. Physicians also might want to consider having parents sign a **refusal waiver**. A sample refusal-to-vaccinate waiver can be found at http://www2.aap.org/immunization/pediatricians/pdf/refusaltovaccinate.pdf.

215.1 International Immunization Practices

W. William Schluter, Kari Johansen, and Tracey Goodman

Given that the epidemiology of infectious diseases varies across countries and continents, it is necessary for vaccination programs to be adapted accordingly. The WHO's Strategic Advisory Group of Experts (SAGE) on immunization evaluates the scientific evidence available for the various vaccines and products and develops advice on global policies and strategies ranging from vaccine type, recommendations for vaccine delivery, links with other health interventions, and suggested vaccine research. Its remit includes all vaccine-preventable infectious diseases for all age-groups. The WHO SAGE recommendations are summarized in the WHO Vaccine Position papers that are updated regularly. The latest information for recommended routine immunizations for children up to 18 years of age, including recommended ages for the initiation of the primary series and dose intervals, as well as recommendations for subsequent booster doses are listed in Table 215.13.

The WHO policy recommendations are adapted by the Regional and National Immunization Technical Advisory Groups making recommendations to respective country governments. As a consequence, the immunization schedules and the types of vaccines, including the specific vaccine products used, vary substantially. Country-specific immunization schedules have been compiled and are available online (https://immunizationdata.who.int/listing.html?topic=vaccine-schedule). Availability and cost play a major role in the choice of vaccine products and schedules in many countries.

According to the WHO recommended schedule, all children should be protected against 12 vaccine-preventable infectious pathogens: *Bordetella pertussis*, *Clostridium tetani*, *Corynebacterium diphtheriae, Haemophilus influenzae* type b, hepatitis B virus, human papillomavirus (HPV), measles virus, *Mycobacterium tuberculosis*, poliovirus, rotavirus, rubella virus, and *Streptococcus pneumoniae* (see Table 215.13).

BIRTH DOSE VACCINES

At birth, hepatitis B vaccine is recommended for all children within 24 hours of birth to prevent perinatal transmission. Additionally, Bacille Calmette-Guérin (BCG) vaccine is recommended at birth in countries or settings with a high incidence of tuberculosis (TB) and/or high leprosy burden, and the first dose of bivalent oral polio vaccine containing poliovirus type 1 and 3 (bOPV) is recommended to be given at birth in polio-endemic countries and in countries at high risk for importation and subsequent spread of poliovirus.

Primary Infant Series

Infant immunization visits are recommended to begin from the age of 6-8 weeks, with an interval of 4-8 weeks between doses to complete the primary series for protection against hepatitis B, polio, diphtheria, pertussis, tetanus, rotavirus, and invasive bacterial infections caused by *H. influenzae* type b and *S. pneumoniae*. To reduce the number of injections, some of these vaccines are provided in combination vaccines. Rotavirus vaccines are provided orally and can be administered concomitantly with the injectable vaccines and OPV. It should be noted that for all countries using OPV, two doses of injectable IPV are recommended from 14 weeks of age with an interval of at least 4 months between doses.

Two doses of measles vaccines are recommended, with the first dose given at 9-12 months of age and the second dose in the second year of life. Only one dose of rubella given at 9 months of age is sufficient to provide >95% protection. However, when using a rubella-containing vaccine that is combined with measles, it is often easier to provide a second dose using the same MR or MMR vaccine product for both doses, dependent on availability. HPV vaccine is recommended for girls from 9-14 years of age.

Booster Doses

In addition to the three doses provided in infancy, three booster doses of combination diphtheria toxoid– and tetanus toxoid–containing vaccine should be provided during childhood and adolescence, at 12-23 months (using DTP-containing vaccine), 4-7 years (with DT or Td), and 9-15 years of age (with Td). Ideally, there should be at least 4 years between booster doses. Depending on disease epidemiology, booster doses may also be recommended for Hib and pneumococcal conjugate vaccines. For countries where DTP/DT/Td booster doses are not provided, maternal vaccination with tetanus-containing vaccine (TT or Td) is provided to protect against neonatal and maternal tetanus.

Vaccination Against Outbreak-Prone Diseases for Endemic Areas

Cholera, Japanese encephalitis, meningococcal conjugate, typhoid, and yellow fever vaccines may be recommended for infants, children, and adolescents living in endemic areas, as shown in Table 215.14.

Table 215.13 Summary of Recommended Routine Immunization for *All* Children Up to 18 Years Based on WHO Vaccine Position Papers (updated as of September 2020)

For the most recent version of the respective position papers, the summary tables and further details per vaccine, consult the reference provided here*:

VACCINE		AGE OF FIRST DOSE	NUMBER OF DOSES IN PRIMARY SERIES	INTERVAL BETWEEN DOSES			BOOSTER DOSE(S) AFTER PRIMARY SERIES	CONSIDERATIONS TO BE MADE
				FIRST TO SECOND	SECOND TO THIRD	THIRD TO FOURTH		
BCG		As soon as possible after birth	1	NA	NA	NA	NA	• Universal vs selective vaccination of high-risk groups • Co-administration with hepatitis B and OPV • Birth dose and HIV • Vaccination of older age-groups
Hepatitis B	Option 1	As soon as possible after birth (<24 hr)	3	4 wk (min) with DTPCV1	4 wk (min) with DTPCV2	NA	NA	• Premature and low birthweight infants • Co-administration with other vaccines • High-risk infants
	Option 2	As soon as possible after birth (<24 hr)	4	4 wk (min) with DTPCV1	4 wk (min) with DTPCV2	4 wk with DTPCV3	NA	
Rotavirus		6 wk (min)	2 or 3 (dependent on product used)	4 wk (min) with DTPCV2	For the three-dose schedule: 4 wk with DTPCV3	NA	NA	• Not recommended if child >24 mo old
DTP-containing vaccine (DTPCV)		6 wk (min)	3	4 wk (min) to 8 wk	4 wk (min) to 8 wk	NA	3 boosters with DTPCV at 12-23 mo, 4-7 yr (Td/DT), and 9-15 yr (Td)	• Co-administration with other vaccines/combination vaccines • Maternal immunization if needed
Hemophilus influenzae type b	Option 1	6 wk (min) to 59 mo (max)	3	4 wk (min) with DTPCV2	4 wk (min) with DTPCV3	NA	At least 6 mo after last dose	• Single dose if >12 mo of age • Not recommended for children >5 yr • Co-administration with other vaccines/combination vaccines
	Option 2	6 wk (min) to 59 mo (max)	2-3	8 wk (min) if only 2 doses 4 wk (min) if 3 doses	4 wk (min) if 3 doses	NA	At least 6 mo (min) after last dose	
Pneumococcal conjugate	Option 1 3p + 0	6 wk (min)	3	4 wk (min)	4 wk	NA		• Schedule options • HIV+ • Preterm neonate booster
	Option 2 2p + 1	6 wk (min)	2	8 wk (min)		NA	9-18 mo	
Poliovirus	Option 1 bOPV + IPV	bOPV 6 wk IPV 14 wk	5 (3 bOPV + 2 IPV)	bOPV 4 wk (min) with DTPCV2 IPV 4 mo (min)	bOPV 4 wk (min) with DTPCV3			• bOPV birth dose • Fractional dose • Transmission and importation criteria
	Option 2 IPV/bOPV sequential	8 wk (IPV first)	1-2 IPV 2 bOPV	4-8 wk	4-8 wk	4-8 wk		
	Option 3 IPV-only	8 wk	3	4-8 wk	4-8 wk		Under evaluation	• IPV booster needed for early schedule (i.e., first dose given <8 wk)

Vaccine Supply and Production

Since 2000, the Global Alliance for Vaccines and Immunizations (GAVI, now known as *GAVI, The Vaccine Alliance*) has helped expand access to vaccines for infants, children, and adolescents in low-income countries by cost-sharing vaccine introduction and through market-sharing activities to expand vaccine production to drive down vaccine costs. There are other initiatives by the WHO and United Nations Children's Fund (UNICEF) that support pooled vaccine procurement to help expand access to vaccines in low- and middle-income countries. In many low- and middle-income countries, the private vaccine market is increasing. For relevant international vaccine websites and resources, see Table 215.15.

Vaccines are currently produced in many countries around the world, with India hosting the largest vaccine producers that serve many low- and middle-income countries. The number of countries with vaccine production capacity are expected to increase in the coming years as a result of the COVID-19 pandemic. Occasionally counterfeit vaccines have been identified, and therefore vigilant surveillance is needed to ensure safe and effective products reach the end consumer.

Vaccine Hesitancy and Demand

In addition to access, population willingness to accept vaccination is an important consideration influencing control of vaccine-preventable diseases. In 2019, the WHO declared vaccine hesitancy, which is the reluctance or refusal to accept vaccinations despite availability, as one of the top 10 threats to global health. Vaccination coverage for recommended vaccines varies between countries, and it is estimated that in 2022, 20.5 million children worldwide at the age of 1 year were considered unvaccinated or undervaccinated using DTP3 coverage data collected by UNICEF/WHO. Significant attempts to reach the unvaccinated and undervaccinated are underway, irrespective of the reasons.

Eradication and Elimination

After the success of the global eradication of smallpox, global eradication or regional disease elimination goals have been adopted for polio, measles, and rubella. In 1988 the World Health Assembly endorsed the goal of eradicating polio from the world by the end of 2000. Although that goal has not yet been reached, endemic wild poliovirus (WPV) transmission in 2023 is limited to two countries worldwide (Afghanistan and Pakistan). The principal eradication strategy has been the use of OPV both for routine immunization and mass supplemental immunization campaigns in endemic or high-risk areas, targeting all children <5 years of age for immunization, regardless of prior immunization status. In areas with low polio population immunity, the OPV virus can mutate over time to develop neurovirulence, similar to WPV. These mutated vaccine viruses are known as *vaccine-derived poliovirus* (VDPV). Since 2018, more paralytic cases have been caused by VDPVs than WPV. Once interruption of WPV transmission is achieved, the goal is to stop the use of OPV.

All six WHO regions have resolved to achieve measles elimination, and five (all but the Eastern Mediterranean region) have rubella elimination goals. In 2015, the Region of the Americas was the first region to achieve rubella elimination and has maintained that status since that time. Regional measles elimination in the Americas was verified in 2016 but was lost in 2018 when measles virus was reintroduced

and continued circulating for more than 12 months in Venezuela and Brazil. Though no other WHO region has achieved certification of regional measles or rubella elimination, national-level certification of elimination is continuing in all regions, with the European Region nearing regional elimination for both measles and rubella.

Goals to eliminate epidemics or to eliminate diseases as a public health problem have been adopted for other vaccine-preventable diseases that are not eradicable such as bacterial meningitis (*S. pneumoniae*, *N. meningitidis*), cervical cancer (HPV), cholera, hepatitis B, rabies, and tetanus (maternal and neonatal tetanus).

Vaccine Schedules in High-Income Countries

Immunization schedules in high-income countries are more variable than in low- and low-middle-income countries. In general, in high-income countries where disease incidence may be lower, doses of many vaccines are recommended to be given later than with the WHO recommended schedule. The infant primary series doses are usually given at 2, 3, and 4 months or at 2, 4, and 6 months (as in the United States) instead of starting early at 6 weeks of age. The first dose of measles-containing vaccines are often not administered until 12 months of age or later, with the second dose provided before school entry. Most middle- and high-income countries have moved to sequential IPV/OPV schedules or an IPV-only program with five or six recommended doses using combination vaccines.

Immunization recommendations for Canada are developed by the Canadian National Advisory Committee on Immunization (NACI) but vary by province. The Canadian schedule is similar to the U.S. immunization schedule, with a few exceptions. A birth dose of hepatitis B vaccine is not specifically recommended as it is in the United States, although some Canadian provinces do provide a birth dose. Conjugate meningococcal C vaccine is recommended in a one- or two-dose series, depending on the age at the time of administration (one dose if ≥12 months). In contrast to the United States, hepatitis A vaccine is not recommended in Canada as a routine pediatric immunization.

In Europe, there is significant variation in vaccines used and the immunization schedules recommended. The number of infectious diseases for which vaccines are offered vary between 12 and 17. As an example, an extensive immunization schedule is offered in the United Kingdom as recommended by the UK Joint Committee on Vaccine and Immunisation (JCVI). In 2023, it includes visits at 2, 3, and 4 months of age, when a combination DTaP-Hib-IPV-HepB vaccine is administered. Infants at high risk of developing hepatitis B infection from infected mothers are given doses of hepatitis B vaccine at birth, 4 weeks, and 1 year of age. MMR is recommended in a two-dose schedule at 12 and 40 months of age. During the second MMR visit, a booster of dTaP-IPV is provided. A Td/IPV booster is recommended at age 14 years. PCV13 is recommended at 3 and 12 months of age. Conjugate meningococcal C vaccine (MenC) is given in combination with a booster dose of Hib at 12 months, whereas MenB is offered at 2, 4, and 12 months of age, and conjugated MenACWY-135 is offered to adolescents at 14 years, with catch-up available up to 25 years of age. HPV vaccine is recommended for females and males at 12-13 years of age, with catch-up vaccination available up to 25 years of age. Rotavirus vaccination is offered at 2 and 3 months of age. Live attenuated influenza vaccine is provided to children 2-10 years of age. BCG is offered at birth in areas of the country with a TB incidence >40/100,000 or in families with a parent or grandparent born in a high-incidence country. As of June 2021, the UK schedule does not include the varicella and hepatitis A vaccines for universal childhood immunization.

Varicella vaccination has been initiated in 12 of the European Union countries, whereas hepatitis A vaccine is only offered routinely in a handful of these countries. However, hepatitis A is often provided to European children ahead of traveling to other regions of the world.

The 2020 Japanese immunization schedule differs from the U.S. schedule, in that a birth dose of hepatitis B vaccine is recommended only for infants born to mothers who test positive for HbsAg. The Japanese do not use MMR, instead recommending MR with mumps vaccine available on a voluntary basis. The recommendation for routine HPV vaccination was suspended in 2013 because of concerns about adverse events but was included for adolescent females in the 2020 schedule.

VACCINATION OF CHILDREN STARTING IMMUNIZATION OUTSIDE THE UNITED STATES

Some children come to the United States having started or completed international immunization schedules with vaccines produced outside the United States. In general, doses administered in other countries should be considered valid if administered at the same ages as recommended in the United States. For missing doses, age-inappropriate doses, lost immunization records, or other concerns, pediatricians have two options: administer or repeat missing or inappropriate doses, or perform serologic tests and, if they are negative, administer vaccines.

The childhood immunization schedule for China is unique because it recommends a sequential series for polio with IPV at 2 and 3 months of age, followed by OPV at 3 and 4 months of age. The infant primary series with diphtheria-tetanus-pertussis–containing vaccines is recommended at 3, 4, and 5 months of age. Similarly, China's schedule recommends one dose of MR vaccine at 8 months of age followed by one dose of MMR at 18 months.

India's childhood immunization schedule follows the WHO recommendations but includes two fractional doses (one fifth) of a full dose of IPV administered intradermally at 6 and 14 weeks.

Mexico recommends a schedule for pediatric immunization that is largely similar to the schedule in the United States. Some differences include that Mexico recommends the use of BCG and recommends HPV for females, but not males.

Vaccination Against Outbreak-Prone Diseases

Outbreaks spanning large geographical areas have affected several countries or continents caused by Ebola virus, influenza virus, circulating VDPV, and coronaviruses, including SARS-CoV-2 virus, have highlighted the need for preparedness to develop and assess in formal clinical trials and, if successful, rapidly produce vaccines to be used in outbreak response measures. For the Ebola virus outbreaks first identified in 2014 in West Africa and later in Democratic Republic of Congo, two new vaccines based on the recombinant vector-technology platform were developed, tested, and then used successfully in ring-vaccination outbreak vaccination campaigns.

The 2009 influenza A H1N1 pandemic triggered production of pandemic influenza vaccines (following the strain selection by WHO) by seasonal influenza vaccine producers worldwide, and adjuvants were used by several producers with the aim to be dose-sparing.

The eradication goal for polio and the chosen global strategy using a combination of OPV and IPV and the associated rare adverse event vaccine-induced paralytic polio have triggered development of a new oral poliovirus (nOPV) vaccine. This virus is more genetically stable and maintains an attenuation phenotype that will support the Global Polio Eradication Initiative during the final push to eliminate poliovirus globally, with the most immediate need in ongoing outbreak settings to control and eliminate circulating VDPVs.

The COVID-19 outbreak that started in late 2019 triggered unprecedented vaccine development, with clinical trials being conducted during the ongoing outbreak. Favorable short-term efficacy and safety data have resulted in the emergency use listing of eleven COVID-19 vaccines that were recommended by the WHO. The WHO vaccination recommendations had not been vaccine-product specific until the COVID-19 vaccines were made available. Since January 2021, each of the COVID-19 vaccine products has been recommended individually, because they are based on different technology production platforms and have been assessed in clinical trials including different age-groups and using different endpoints. Vaccination of children and adolescents 6 months of age and older is authorized for two mRNA vaccines. In June 2021, China was the first country globally that approved inactivated COVID-19 vaccines for children age 3-17 years. COVID-19 vaccines are made available globally either through direct contracts between vaccine producers and each country or through the COVAX facility, a global risk-sharing mechanism for pooled procurement and equitable distribution of COVID-19 vaccines.

Chapter 216

Infection Prevention and Control

Kevin P. O'Callaghan and Julia S. Sammons

Infection prevention and control (IPC) programs are a critical and core component of ensuring patient and employee safety in pediatric healthcare systems. The scope of IPC programs is often large and requires a coordinated, well-resourced, multidisciplinary approach. At their heart, IPC programs are designed to prevent the **acquisition** and **transmission** of potentially pathogenic organisms within a healthcare setting. A robust regulatory and policy focus on the prevention of healthcare-associated infections (HAIs) is critical given their frequency. Data from the Centers for Disease Control and Prevention (CDC) National Healthcare Safety Network (NHSN) provides evidence that on any given day approximately 1 in 31 hospitalized patients experiences at least one HAI. Federal and state-level infrastructures that support HAI improvement efforts include the CDC NHSN, which operates a national surveillance system for HAIs, and the Joint Commission's 2022 National Patient Safety Goals. With improved surveillance and detection and focused improvement efforts, preventable events of harm (including HAIs) are now linked by many payors to reduced levels of reimbursement to offset costs associated with these events.

As our understanding of HAIs has developed over time with better surveillance metrics, reporting has expanded beyond the walls of hospitals to include HAIs occurring throughout healthcare systems. This scope includes infections in ambulatory surgical and medical settings, nursing homes, long-term acute care facilities, and even in patients' homes, especially with regard to medical device–associated infections. We have also expanded our understanding of epidemiologic risk factors, environmental pressures, and specific at-risk patient populations. Through a variety of avenues, IPC programs seek to eliminate transmission events and keep patients and employees safe.

TRANSMISSION IN THE HEALTHCARE SETTING

Fundamentally, transmission in the healthcare setting is multifaceted and multimodal. Patients, their family and caregivers, healthcare personnel, and others interact in a complex environment that is fraught with opportunity for transmission events to occur. Modern understanding of human microbiota informs us that all humans carry a plethora of microorganisms that could potentially be pathogenic in the right circumstances and in the right host. These colonizing microbiotas can be transmitted from one person to another in the healthcare setting through contaminated hands or medical equipment. The majority of infections that arise in healthcare settings occur from endogenous flora representing colonizing organisms. New HAIs require the presence of a number of independent but linked concepts, including a susceptible host, an infectious agent, a portal of entry, and modes of transmission.

Modes of transmission are a critical element of HAI prevention work and include **contact**, **droplet**, and **airborne**. Contact transmission occurs by direct contact with the patient or indirect contact with environmental surfaces or patient care items in the patient's environment that are contaminated with the offending microorganism (e.g., rotavirus). Droplet transmission occurs through large respiratory droplets, which are generated by coughing, sneezing, or talking and typically travel approximately 3 feet from an infectious person (e.g., influenza). These droplets are heavy and do not remain suspended in air for long periods. Airborne transmission occurs through small particles, which can remain suspended in air and can be widely dispersed by air currents (e.g., measles, tuberculosis). Although many infections can occur through transmission directly from an infectious host to a susceptible host, infections can also occur through contact with contaminated environments, whether through contaminated surfaces, fomites, or previously occupied air spaces.

PREVENTION STRATEGIES

Hand Hygiene

One of the most fundamental elements of infection prevention is hand hygiene; thus one of the most critical elements of an IPC program is hand hygiene education and auditing. Ignaz Semmelweis first postulated the effects of hand hygiene in 1847 when he noted epidemiologic differences in maternal mortality rates secondary to puerperal fever between physician- and midwife-delivered pregnancies. The critical difference was hand hygiene, and this proved to be a seminal finding in the field of infection prevention. Growing evidence of the importance of hand hygiene led to the first national hand hygiene guidelines in the 1980s and the development of international guidance on hand hygiene in healthcare. The World Health Organization (WHO) has developed an internationally used framework for hand hygiene education, called the *5 Moments for Hand Hygiene*. This program provides a structure for recognizing critical moments where hand hygiene can influence a transmission event, including before and after touching a patient, before a clean or aseptic procedure, after a body fluid exposure risk, and after touching patient surroundings (Table 216.1). Use of this or similar frameworks provides a structure for staff education around the practice of hand hygiene and serves as an auditing tool to assess rates of compliance with optimal practice.

Hand hygiene itself is the act of either handwashing (placing hands under running water and using friction with or without a soap product) or using a waterless hygiene product (e.g., alcohol-based foams or gels) to remove the burden of surface flora from the skin and nails of the hand. Alcohol-based hand hygiene products are widely available, are quick and easy to use, and allow for repeated in-the-moment use, such that they are the preferred method for hand hygiene for most healthcare situations. However, because they do not remove visible dirt or debris, handwashing with soap and water is recommended over alcohol-based products after dirty tasks when visible soiling is likely, such as after changing a diaper or using the restroom. Alcohol-based products are also not the preferred agents for certain hardy microbes such as norovirus or *Clostridioides difficile* spores, especially in outbreak settings.

Personal Protective Equipment

Personal protective equipment (PPE) is equipment worn to prevent or reduce exposure to potential hazards in the workplace, including infectious diseases. In the healthcare setting, PPE is targeted to prevent exposure of healthcare personnel's skin, eyes, respiratory tract, and mucous membranes to potential infectious agents but is also used to protect patients from the colonizing flora and respiratory secretions of healthcare personnel. Various types of PPE may be used in different settings, with the specific type of PPE tied to the **precautions** that are indicated for a specific patient and/or a specific pathogen. The five primary components of PPE include **gowns**, **gloves**, **masks**, **eye protection**, and **respirators (e.g., N95 or Powered Air-Purifying Respirator)**. Gowns can either be reusable (launderable) or disposable and are designed to prevent contamination of the provider's clothing, particularly from those infectious agents that are spread through a contact mechanism. Depending on the setting, gowns may be required to be resistant to liquid soaking in order to maximize their effectiveness.

Gloves are used most commonly as a component of standard precautions when performing a task where there is a reasonable expectation of soiling of the hands (e.g., changing a diaper or examining a wound). Importantly, glove use is not required for every moment of patient contact (e.g., routine physical exam), and glove use is not a substitute for effective hand hygiene in breaking the chain of transmission. Therefore gloves should never be used as the only element of infection prevention. Hand hygiene before donning of gloves and after removal of gloves is a critical and necessary step in breaking the chain of transmission.

Face masks and eye protection are intended to prevent exposure of a provider's mouth, nose, and eyes from expectorated and aerosolized pathogens. Protection of the eyes can include clear shields attached

Table 216.1 Recommendations for Application of Standard Precautions for Care of All Patients in All Healthcare Settings

COMPONENT	RECOMMENDATIONS
Hand hygiene	Before and after each patient contact, regardless of whether gloves are used. After contact with blood, body fluids, secretions, excretions, or contaminated items; immediately after removing gloves; before and after entering patient rooms. Alcohol-containing antiseptic hand rubs preferred except when hands are visibly soiled with blood or other proteinaceous material or if exposure to spores (e.g., *Clostridium difficile, Bacillus anthracis)* or nonenveloped viruses (norovirus) is likely to have occurred; in these cases, soap and water is required.
PERSONAL PROTECTIVE EQUIPMENT (PPE)	
Gloves	For touching blood, body fluids, secretions, excretions, or contaminated items; for touching mucous membranes and nonintact skin. Employ hand hygiene before and after glove use.
Gown	During procedures and patient-care activities when contact of clothing or exposed skin with blood, body fluids, secretions, or excretions is anticipated.
Mask, eye protection (goggles), face shield	During procedures and patient-care activities likely to generate splashes or sprays of blood, body fluids, or secretions, such as suctioning and endotracheal intubation, to protect healthcare personnel. For patient protection, use of a mask by the person inserting an epidural anesthesia needle or performing myelograms when prolonged exposure of the puncture site is likely to occur.
Soiled patient-care equipment	Handle in a manner that prevents transfer of microorganisms to others and to the environment. Wear gloves if equipment is visibly contaminated. Perform hand hygiene.
ENVIRONMENT	
Environmental control	Develop procedures for routine care, cleaning, and disinfection of environmental surfaces, especially frequently touched surfaces in patient-care areas.
Textiles (linens) and laundry	Handle in a manner that prevents transfer of microorganisms to others and the environment.
PATIENT CARE	
Injection practices (use of needles and other sharps)	Do not recap, bend, break, or manipulate used needles; if recapping is required, use a one-handed scoop technique only. Use needle-free safety devices when available, placing used sharps in puncture-resistant container. Use a sterile, single-use, disposable needle and syringe for each injection. Single-dose medication vials preferred when medications may be administered to more than one patient.
Patient resuscitation	Use mouthpiece, resuscitation bag, or other ventilation devices to prevent contact with mouth and oral secretions.
Patient placement	Prioritize for single-patient room if patient is at increased risk for transmission, is likely to contaminate the environment, is unable to maintain appropriate hygiene, or is at increased risk for acquiring infection or developing adverse outcome after infection.
Respiratory hygiene/cough etiquette (source containment of infectious respiratory secretions in symptomatic patients) beginning at initial point of encounter, such as triage or reception areas in emergency department or physician office	Instruct symptomatic persons to cover nose/mouth when sneezing or coughing; use tissues with disposal in no-touch receptacles. Employ hand hygiene after soiling of hands with respiratory secretions. Wear surgical mask if tolerated or maintain spatial separation (>3 ft if possible).

Adapted from Kimberlin DW, Brady MT, Jackson MA, et al., eds. *Red Book 2018–2021: Report of the Committee on Infectious Diseases,* 31st ed. Elk Grove Village, IL: American Academy of Pediatrics; 2018:148–150.

directly to surgical masks, separate face shields, or goggles, but protection of both forward-facing and lateral aspects of the ocular region is required.

In the setting of a true aerosolized pathogen, respirator use is indicated. Respirator masks include National Institute of Occupational Safety and Health (NIOSH)–approved N95s, so-called because they filter out up to 95% of particles in the air when used appropriately. Other respirator options that meet international standards include KN95 masks, but these may not meet NIOSH standards and should not be used in lieu of an N95. The use of fitted face mask respirators such as the N95 requires a fit-testing program to ensure that healthcare personnel are using a correctly sized and fitted mask at all times. Alternatives to a fitted respiratory mask include the powered air purifying respirator (PAPR), which uses a motor and fan to provide constant pressurized air flow from under a loosely fitting hood over the entire head.

Precautions and Isolation

Precautions and *isolation* are terms to describe in a specific patient-care setting which equipment, practices, and procedures should be used to best prevent against a transmission event related to a known or suspected pathogen.

Standard precautions are used in any setting in which patient care occurs to prevent transmission of a potential pathogen to or from a healthcare worker, regardless of suspected or confirmed infection status of the patient. These include consistent hand hygiene and use of barrier PPE (gown, glove, mask) as required based on risk of exposure

to blood and body fluids, including expectorations and respiratory secretions (e.g., routine use of mask and eye protection during endotracheal intubation).

Isolation procedures, or **transmission-based precautions**, are targeted to prevent transmission of known or suspected pathogens or in the setting of specific syndromes (e.g., infectious diarrhea, upper respiratory tract symptoms). **Contact isolation** typically includes gloves and gown in addition to standard precautions and is used to limit the spread of pathogens by direct contact with a patient (e.g., patients with norovirus). **Droplet isolation** includes protection of mucosal surfaces from expectorated large droplets and should include face mask and eye protection. Some pathogens may spread efficiently by both contact and droplet (e.g., rhinovirus), and thus these two isolation types may be combined as **droplet and contact**.

Airborne isolation is used for pathogens that are readily aerosolized and requires the use of eye protection and use of an appropriate respirator (either N95 or PAPR depending on the employee). Additionally, patients with airborne infections require placement in specialized airborne infection isolation rooms (AIIRs), which have specialized air handling that can maintain negative pressure compared with the surrounding environment and have increased air turnovers per unit time.

ENVIRONMENT, DISINFECTION, AND STERILIZATION

A critical component of preventing transmission of infectious pathogens in healthcare settings includes appropriate environmental cleaning, elimination of potential reservoirs, and disinfection and sterilization of medical equipment.

Maintaining cleanliness (and, where appropriate, sterility) of all patient care spaces, equipment, and medical devices requires an institutional focus on the environment of care that highlights accountability and highly reliable policies and procedures. For each individual healthcare worker, cleanliness of personal medical equipment used in patient care is key. This includes personal stethoscopes, which should be cleaned whenever they are visibly soiled and should be disinfected with an appropriate topical agent (e.g., alcohol) between each use. Similarly, shared patient devices such as thermometers, otoscopes, and ophthalmoscopes should either have disposable single-use covers or should have a cleaning protocol that is adhered to after each patient use.

Higher-level cleaning and disinfection, known as high-level disinfection, are required for reusable items that contact mucous membranes or nonintact skin (e.g., endoscopes), and sterilization is required for critical items that enter sterile tissue or the vascular system (e.g., surgical tools).

VISITATION AND PATIENT AND CAREGIVER MANAGEMENT

In pediatric healthcare settings, unlike adult settings, patients frequently are accompanied by parents, caregivers, and family members throughout their healthcare experience. Visitor and caregiver management is a critical tool in preventing healthcare transmission events in these settings. Limitation of total numbers of visitors at a bedside may be indicated in the setting of local or seasonal outbreaks of disease, such as during influenza season. Similarly, age-based limitations are commonly used to keep siblings of patients away from the healthcare setting, particularly during the winter respiratory viral season. Visitor screening at points of entry can be effective in identifying caregivers and siblings who may not be presenting for care but have evident symptoms of infection and may need to be excluded from the healthcare setting.

OCCUPATIONAL HEALTH AND CLINICIAN EDUCATION

Typically, infection prevention and control programs work closely with occupational or employee health programs because both departments have a responsibility for keeping healthcare workers safe from workplace hazards, including infection. Occupational health and IPC programs may work together to develop on-boarding requirements for vaccination for common diseases and programs for seasonal vaccination for influenza. Annual and as-needed education for healthcare workers is an important role of IPC programs, including education on best practices for hand hygiene, use of PPE, and promoting understanding of patient isolation categories.

SPECIAL POPULATIONS

Immunocompromised Hosts

Immunocompromised hosts include those patients with inborn disorders of immunity and patients with iatrogenically caused immune deficits (e.g., patients undergoing chemotherapy, solid organ, or bone marrow transplant or those using immune-modulating therapies). Immunocompromised hosts pose a special infection prevention problem, as they are typically more susceptible to infections that may be common and benign in other patients and more susceptible to infections that are highly unusual in hosts with intact immune systems, such as invasive mold.

The environment of care for these patients may have additional considerations over and above the norm. **Positive pressure ventilation** can be used to provide a protective environment for such patients during periods of highest risk (e.g., immediately after bone marrow transplantation). A focus on air handling capability, including high-efficiency particulate absorbing (HEPA) filtration, is critically important, especially in settings where construction or renovation is ongoing, as this increases the risk of aerosolization of fungal and mold spores.

Patients with Indwelling Medical Devices

Indwelling medical devices such as pacemakers, orthopedic hardware, intracranial shunts, and indwelling venous catheters pose a special infection risk because of disruption of normal immunologic barriers (e.g., skin) that can allow for communication between sterile and nonsterile spaces and because of the presence of foreign material, which can present a nidus for biofilm formation. IPC programs are frequently involved in quality improvement projects around the optimal insertion and maintenance of such devices, both in the healthcare setting and at home.

Surveillance and Reporting

In addition to the primary prevention work of an IPC program, another core element includes response to transmission events, which critically includes a surveillance and reporting mechanism. IPC programs typically monitor for events of infection within the healthcare setting, such as surgical site infection or new diagnoses of viral respiratory infection so as to generate data about current trends, detect clusters and outbreaks, and guide future policy. Most states require reporting of healthcare-associated events such as infections to a state- and/or federal-level body such as NHSN.

Preparedness, Bioresponse, and Public Health

An important additional element of IPC work is preparedness and planning for community-based outbreaks or epidemics that can affect healthcare operations. Planning for low-likelihood, high-risk pathogens such as Ebola virus requires a multidisciplinary planning team, including hospital operations, IPC, clinical teams, transport services, and others. Scheduled periodic retraining of a core group of healthcare workers can increase their comfort in managing the care of these patients and in decreasing the risk of PPE and isolation breaches that could lead to an event of transmission.

In addition to internal systemwide planning, interfacing with public health bodies is an important responsibility of IPC teams. This responsibility includes reporting of notifiable diseases (e.g., sexually transmitted infections [STIs], tuberculosis, measles), which may require a broader public health response in the community. In the absence of positive test results, individual clinician suspicion of a disease is frequently the initial trigger for public health notification, and so an understanding of reporting requirements is important for each healthcare worker.

IPC is increasingly a complex and specialized area of expertise within healthcare operations. However, at its heart it requires the active participation and commitment of every member of the healthcare team. As such, the best way to keep patients safe is to approach every moment of patient interaction as an opportunity to create a safe and clean environment of care.

Chapter 217

Childcare and Communicable Diseases

Gail V. Carter-Hamilton and Susan E. Coffin

More than 20 million children <5 years old attend a childcare facility. These facilities can include part-day or full-day programs at nursery schools or preschools and full-day programs based in either a licensed childcare center or another person's home. Regardless of the age at entry, children entering childcare settings are more prone to infections, largely from the exposure to greater numbers of children.

Childcare facilities can be classified based on the number of children enrolled, ages of attendees, health status of the attendees, and type of setting. As defined in the United States, **childcare facilities** consist of childcare centers, small and large family childcare homes, and facilities for ill children or for children with special needs. Centers are licensed and regulated by state governments and care for a larger number of children than are typically cared for in family homes. In contrast, **family childcare homes** are designated as small (1-6 children) or large (7-12 children), may be full-day or part-day, and may be designed for either daily or sporadic attendance. Family childcare homes generally are not licensed or registered, depending on state requirements.

Although many children who attend childcare facilities are cared for in family childcare homes, most studies of infectious diseases in infants and toddlers have been conducted in childcare centers. Almost any organism has the potential to be spread and to cause disease in a childcare setting. Epidemiologic studies have established that children in childcare facilities are 2-18 times more likely to acquire a variety of infectious diseases than children not enrolled in childcare (Table 217.1).

Children who attend childcare facilities are more likely to receive more courses of antimicrobial agents for longer periods and to acquire antibiotic-resistant organisms. Transmission of infectious agents in group care depends on the age and immune status of the children, season, hygiene practices, crowding, and environmental characteristics of the facilities. The pathogen characteristics, including infectivity, survivability in the environment, and virulence, also influence transmission in childcare settings. Rates of infection, duration of illness, and risk for hospitalization tend to decrease among children in childcare facilities after the first 6 months of attendance and decline to levels observed among homebound children after 3 years of age. Adult caregivers are also at increased risk for acquiring and transmitting infectious diseases, particularly in the first year of working in these settings.

EPIDEMIOLOGY

Respiratory tract infections and **gastroenteritis** are the most common diseases associated with childcare. These infections occur in children and their household contacts and in childcare workers and can spread into the community. The severity of illness caused by a given respiratory and enteric pathogen depends on the person's underlying health status, the inoculum, and prior exposures to the pathogen, either by infection or immunization. Some organisms, such as hepatitis A virus (HAV), can cause subclinical disease in young children and produce overt and sometimes serious disease in older children and adults. Other diseases, such as otitis media and varicella, usually affect children rather than adults. Both infections and infestations of the skin and hair may be acquired through contact with contaminated linens or through close personal contact, which is inevitable in childcare settings.

RESPIRATORY TRACT INFECTIONS

Respiratory tract infections account for the majority of childcare-related illnesses. Children <2 years old who attend childcare centers have more upper and lower respiratory tract infections than do age-matched children not in childcare. The organisms responsible for these illnesses are similar to those that circulate in the community and include respiratory syncytial virus (RSV), parainfluenza viruses, influenza viruses, human metapneumoviruses, adenoviruses, rhinoviruses, endemic and epidemic coronaviruses, parvovirus B19, and *Streptococcus pneumoniae.*

Upper respiratory tract infections, including **otitis media**, are among the most common manifestations of these infections. The risk for developing otitis media is 2-3 times greater among children who attend childcare centers than among children cared for at home. Most prescriptions for antibiotics for children <3 years old in childcare are to treat otitis media. These children also are at increased risk for recurrent

Table 217.1 Infectious Diseases in the Childcare Setting

DISEASE	INCREASED INCIDENCE WITH CHILDCARE
RESPIRATORY TRACT INFECTIONS	
Otitis media	Yes
Sinusitis	Probably
Pharyngitis	Probably
Pneumonia	Yes
GASTROINTESTINAL TRACT INFECTIONS	
Diarrhea (rotavirus, norovirus, calicivirus, astrovirus, enteric adenovirus, *Giardia lamblia, Cryptosporidium, Shigella, Escherichia coli* O157:H7, and *Clostridium difficile*)	Yes
Hepatitis A	Yes
SKIN DISEASES	
Impetigo	Probably
Scabies	Probably
Pediculosis	Probably
Tinea (ringworm)	Probably
INVASIVE BACTERIA INFECTIONS	
Haemophilus influenzae type b	No*
Neisseria meningitidis	Probably
Streptococcus pneumoniae	Yes
ASEPTIC MENINGITIS	
Enteroviruses	Probably
HERPESVIRUS INFECTIONS	
Cytomegalovirus	Yes
Varicella-zoster virus	Yes
Herpes simplex virus	Probably
BLOOD-BORNE INFECTIONS	
Hepatitis B	Few case reports
HIV	No cases reported
Hepatitis C	No cases reported
VACCINE-PREVENTABLE DISEASES	
Measles, mumps, rubella, diphtheria, pertussis, tetanus	Not established
Polio	No
H. influenzae type b	No*
Varicella	Yes
Rotavirus	Yes
COVID-19	Yes

*Not in the post–vaccine era; *yes* in the pre–vaccine era.

otitis media, further increasing the use of antimicrobial agents in this population. Studies have demonstrated reductions in both otitis media and antibiotic use subsequent to pneumococcal vaccination implementation. Pharyngeal carriage of group A *Streptococcus* occurs earlier among children in childcare; systemic illness may occur including pneumonia, empyema, septic arthritis, or osteomyelitis. **Influenza** vaccination of younger infants reduces influenza infection and secondary sequelae in both the children and the adults who care for them in their home and in childcare settings. After adoption of the acellular pertussis vaccine, increases in clusters and outbreaks of infection caused by *Bordetella pertussis* have led to the recognition of less durable immunity, with older children and adults serving as reservoirs of infection.

Transmission of these organisms typically occurs through either direct or indirect contact with the respiratory droplets of an infected child. In childcare settings, contamination of surfaces occurs frequently as children mouth toys, drool, and cough or sneeze. Additionally, some respiratory pathogens are spread through large droplets that typically can travel 3-6 feet. However, intimate contact between children is a routine part of the play and care of young children, thus facilitating transmission. The most common surfaces from which airborne droplets can be spread are the hands, so the most efficient form of infection control in the childcare setting is good hand hygiene.

GASTROINTESTINAL TRACT INFECTIONS

Acute infectious **diarrhea** is 2-3 times more common among children in childcare than among children cared for in their homes. Outbreaks of diarrhea, which occur frequently in childcare centers, are usually caused by enteric viruses, such as norovirus, caliciviruses, enteric adenoviruses, and astroviruses, or by enteric parasites such as *Giardia lamblia* or *Cryptosporidium*. A dramatic and sustained decline in the burden of rotavirus infection has been demonstrated since introduction of the rotavirus vaccination program in 2006, and this trend is likely reflected in the population of children attending childcare and early childhood education programs. Bacterial **enteropathogens** such as *Shigella* and *Escherichia coli* O157:H7 and, less often *Campylobacter, Clostridium difficile,* and *Bacillus cereus* also have caused outbreaks of diarrhea in childcare settings. *Salmonella* rarely is associated with outbreaks of diarrhea in childcare settings because person-to-person spread of this organism is uncommon.

Outbreaks of **HAV infection** in children enrolled in childcare facilities have resulted in community-wide outbreaks. HAV infection is typically mild or asymptomatic in young children and often is identified only after symptomatic illness becomes apparent among either older children or adult contacts of children in childcare. Enteropathogens and HAV are transmitted in childcare facilities by the fecal-oral route and can also be transmitted through contaminated food or water. Children in diapers constitute a high risk for the spread of gastrointestinal infections through the fecal-oral route. As such, enteric illness and HAV infection are more common in centers that care for children who are not toilet-trained and where proper hygienic practices are not followed. The most common enteropathogens, such as norovirus and *G. lamblia,* are characterized by low infective doses and high rates of asymptomatic excretion among children in childcare, characteristics that facilitate transmission and outbreaks.

SKIN DISEASES

The most recognized skin infections or infestations in children in childcare are impetigo caused by *Staphylococcus aureus* or group A *Streptococcus*, pediculosis, scabies, tinea capitis, tinea corporis, and molluscum contagiosum. Many of these diseases are spread by contact with infected linens, clothing, hairbrushes, and hats and through direct personal contact; they more often affect children >2 years old. The magnitude of these infections and infestations in children in childcare is not known.

Parvovirus B19, which causes fifth disease (erythema infectiosum), is spread through the respiratory route and has been associated with outbreaks in childcare centers. The rash of fifth disease is a systemic manifestation of parvovirus B19 infection; the child is no longer contagious once the rash is present (see Chapter 298). The greatest health hazard is for pregnant women and immunocompromised hosts because of their respective risks for fetal loss and aplastic crisis.

INVASIVE ORGANISMS AND SYSTEMIC INFECTIONS

Before universal immunization, *Haemophilus influenzae* type b invasive disease was more common among children in childcare than children in homecare. Although the largest burden of invasive *H. influenzae* infection in the pediatric population still occurs in children <5 years old, infection is now primarily caused by nontypeable *H. influenzae* or non–type b encapsulated strains of *H. influenzae;* there have been no reported outbreaks of nontypeable or type b *H. influenzae* in >5 years in the United States.

Data suggest that the risk for primary disease caused by *Neisseria meningitidis* is higher among children in childcare than among children in homecare. Childcare attendance is also associated with nasopharyngeal carriage of penicillin-resistant *S. pneumoniae* and invasive pneumococcal disease, especially among children with a history of recurrent otitis media and use of antibiotics. Secondary spread of *S. pneumoniae* and *N. meningitidis* has been reported, indicating the potential for outbreaks to occur in this setting. Routine use of pneumococcal conjugate vaccine has decreased the incidence of invasive disease and reduced carriage of serotypes of *S. pneumoniae* contained in the vaccine both in the vaccinated child and in younger siblings. A vaccine against serogroup B meningococcus has been introduced for routine use in children <2 years old in the United Kingdom. It is anticipated that infant vaccination against meningococcus will be adopted in the near future. Outbreaks of aseptic meningitis have been reported among children in childcare centers and among their parents and their teachers.

HERPESVIRUSES

As many as 70% of diapered children who become infected with **cytomegalovirus** (CMV) shed virus in urine and saliva for prolonged periods. CMV-infected children often transmit the virus to other children with whom they have contact and to their care providers and their mothers at a rate of 8–20% per year. Transmission occurs as a result of contact with either saliva or urine. The overwhelming majority of primary infections with and reactivation of CMV in otherwise healthy children results in asymptomatic shedding of CMV; nonetheless, this shedding can pose a health risk for previously uninfected pregnant childcare providers or immunocompromised persons. A licensed CMV vaccine is not yet available, but research is ongoing, with recent trials demonstrating tolerability and immunogenicity of candidate CMV vaccines (see Chapter 302).

Varicella often is transmitted in childcare centers, but routine use of varicella vaccine has reduced this risk. Vaccinated children who become infected with varicella often have mild, atypical symptoms and signs of disease that can result in delayed recognition and spread of infection to susceptible contacts. The role of childcare facilities in the spread of **herpes simplex virus**, especially during episodes of gingivostomatitis, requires further clarification.

BLOOD-BORNE PATHOGENS

Hepatitis B virus (HBV) transmission has been reported rarely in childcare settings, and transmission of hepatitis C virus (HCV), hepatitis D virus (HDV), and HIV has not been reported in a childcare setting. However, it is impossible to identify every child who might have a blood-borne infection such as hepatitis B, C, or D, or HIV, and it is critical that standard precautions be observed routinely to reduce the risk for transmitting these viruses and other pathogens.

Concerns have been raised about the risk of HIV transmission in childcare settings and the acquisition of opportunistic infections by HIV-infected children who attend childcare, but experience has revealed that this risk is minimal. Children with HIV infection enrolled in childcare facilities should be kept up to date on their vaccines and monitored for exposure to infectious diseases.

Transmission of blood-borne pathogens can theoretically occur when there is contact between blood or body fluids and a mucous membrane or an open wound. Blood-borne pathogens are unlikely to spread by toddler **biting** in a group setting. Most bites do not break the skin, and if a bite does break the skin, the mouth of the biter does not stay on the victim long enough for blood to transfer from the biter to the victim. If there are concerns about transmission of HBV, HCV, or HIV infection, it is recommended to check the status of the biter rather than the bite victim as part of the initial evaluation process.

ANTIBIOTIC USE AND BACTERIAL RESISTANCE

Antibiotic resistance has become a major global problem and threatens the health of children who attend childcare facilities because the incidence of infection by organisms resistant to frequently used antimicrobial agents has increased dramatically. It is estimated that children in childcare are 2-4 times more likely to receive an antibiotic and that they receive longer courses of antibiotics compared with age-matched children in homecare. This frequency of antibiotic use combined with the propensity for person-to-person transmission of pathogens in a crowded environment has resulted in an increased prevalence of antibiotic-resistant bacteria in the respiratory and intestinal tracts, including *S. pneumoniae, H. influenzae, Moraxella catarrhalis, E. coli* O157:H7, and *Shigella* spp.

Methicillin-resistant *S. aureus* **(MRSA)** has historically been found primarily in the healthcare setting but is now prevalent in the community setting. Traditional childcare center attendance is cited as a risk factor for colonization with MRSA, and carriage is associated with increased risk of infection and transmission. Population-based surveillance has demonstrated a rise in both invasive and noninvasive MRSA infections in community settings over the past 2 decades. Currently, large-scale studies investigating the epidemiology of *S. aureus* in the childcare setting are limited.

PREVENTION

Written policies designed to prevent or to control the spread of infectious agents in a childcare center should be available and should be reviewed regularly. All programs should use a health consultant to help with development and implementation of infection prevention and control (IPC) policies (see Chapter 216). Standards for environmental and personal hygiene should include maintenance of current immunization records for both children and staff, appropriate policies for exclusion of ill children and caretakers, targeting of potentially contaminated areas for frequent cleaning, adherence to appropriate procedures for changing diapers, appropriate handling of food, management of pets, and surveillance for and reporting of communicable diseases. Staff whose primary function is preparing food should not change diapers. Appropriate and thorough **hand hygiene** is the most important factor for reducing infectious diseases in the childcare setting. Strategies for improving adherence to these standards should be implemented. Children at risk for introducing an infectious disease should not attend childcare until they are no longer contagious (Tables 217.2 and 217.3).

Routine vaccination is proven to improve the health of children in childcare settings. In the United States, there are 17 diseases and organisms against which all children should be immunized unless there are contraindications: diphtheria, pertussis, tetanus, measles, mumps, rubella, polio, hepatitis A and hepatitis B, varicella, *H. influenzae* type b, *S. pneumoniae,* rotavirus, *N. meningitidis,* influenza, COVID-19, and human papillomavirus (see Chapter 215). Rates of immunization among children in licensed childcare facilities are high, in part because of laws in almost all states that require age-appropriate immunizations of children who attend licensed childcare programs. Vaccines against influenza, *H. influenzae* type b, hepatitis B, rotavirus, varicella, *S. pneumoniae,* COVID-19, and hepatitis A are of particular benefit to children in childcare centers.

Childcare providers should receive all immunizations that are recommended routinely for adults, including tetanus and diphtheria toxoids and acellular pertussis (Tdap) booster, influenza, and COVID-19 vaccines and should have a preemployment health evaluation, with a tuberculin skin test or interferon-γ release blood assay. Local public health authorities should be notified of cases of reportable communicable disease that occur in children or providers in childcare settings.

STANDARDS

Every state has specific standards for licensing and reviewing childcare centers and family childcare homes. The American Academy of Pediatrics, American Public Health Association, and National Resource

Table 217.2 Disease- or Condition-Specific Recommendations for Exclusion of Children in Out-of-Home Childcare

CONDITION	MANAGEMENT OF CASE	MANAGEMENT OF CONTACTS
COVID-19	Return to class after 10 days from onset and no fever for at least 24 hr without antipyretics.	Varies and evolving but many include being tested ≥5 days from exposure, wearing a mask, checking for symptoms, stay at home if symptoms develop (see latest recommendations at CDC) (see also Chapter 311).
Clostridium difficile	Exclusion until stools are contained in the diaper or child is continent and stool frequency is no more than two stools above that child's normal frequency for the time the child is in the program. Stool consistency does not need to return to normal to be able to return to childcare. Neither test of cure nor repeat testing should be performed for asymptomatic children in whom *C. difficile* was diagnosed previously.	Symptomatic contacts should be excluded until stools are contained in the diaper or child is continent and stool frequency is no more than two stools above that child's normal frequency for the time the child is in the program. Testing is not required for asymptomatic contacts.
Hepatitis A virus (HAV) infection	Serologic testing to confirm HAV infection in suspected cases. Exclusion until 1 wk after onset of illness.	In facilities with diapered children, if one or more cases confirmed in child or staff attendees or two or more cases in households of staff or attendees, hepatitis A vaccine (HepA) or immune globulin intramuscular (IGIM) should be administered within 14 days of exposure to all unimmunized staff and attendees. In centers without diapered children, HepA or IGIM should be administered to unimmunized classroom contacts of index case. Asymptomatic IGIM recipients may return after receipt of IGIM.
Impetigo	No exclusion if treatment has been initiated and as long as lesions on exposed skin are covered.	No intervention unless additional lesions develop.
Measles	Exclusion until 4 days after beginning of rash and when the child is able to participate.	Immunize exposed children without evidence of immunity within 72 hr of exposure. Children who do not receive vaccine within 72 hr or who remain unimmunized after exposure should be excluded until at least 2 wk after onset of rash in the last case of measles.

Continued

Table 217.2 Disease- or Condition-Specific Recommendations for Exclusion of Children in Out-of-Home Childcare—cont'd

CONDITION	MANAGEMENT OF CASE	MANAGEMENT OF CONTACTS
Mumps	Exclusion until 5 days after onset of parotid gland swelling.	In outbreak setting, people without documentation of immunity should be immunized or excluded. Immediate readmission may occur after immunization. Unimmunized people should be excluded for 26 or more days after onset of parotitis in last case. A second dose of MMR vaccine (or MMRV, if age appropriate) should be offered to all students (including those in postsecondary school) and to all healthcare personnel born in or after 1957 who have only received one dose of MMR vaccine. A second dose of MMR also may be considered during outbreaks for preschool-age children who have received one MMR dose. People previously vaccinated with two doses of a mumps-containing vaccine who are identified by public health as at increased risk for mumps because of an outbreak should receive a third dose of a mumps-containing vaccine to improve protection against mumps disease and related complications.
Pediculosis capitis (head lice) infestation	Treatment at end of program day and readmission on completion of first treatment. Children should not be excluded or sent home early from school because of head lice, because this infestation has low contagion within classrooms.	Household and close contacts should be examined and treated if infested. No exclusion necessary.
Pertussis	Exclusion until completion of 5 days of the recommended course of antimicrobial therapy if pertussis is suspected. Children and providers who refuse treatment should be excluded until 21 days have elapsed from cough onset.	Immunization and chemoprophylaxis should be administered as recommended for household contacts. Symptomatic children and staff should be excluded until completion of 5 days of antimicrobial therapy. Untreated adults should be excluded until 21 days after onset of cough.
Rubella	Exclusion for 7 days after onset of rash for postnatal infection.	During an outbreak, children without evidence of immunity should be immunized or excluded for 21 days after onset of rash of the last case in the outbreak. Pregnant contacts should be evaluated.
Infection with *Salmonella* serotypes Typhi or Paratyphi	Exclusion until three consecutive stool cultures obtained at least 48 hr after cessation of antimicrobial therapy are negative, stools are contained in the diaper or child is continent, and stool frequency is no more than two stools above that child's normal frequency for the time the child is in the program.	When *Salmonella* serotype Typhi infection is identified in a child care staff member, local or state health departments may be consulted regarding regulations for length of exclusion and testing, which may vary by jurisdiction.
Infection with nontyphoidal *Salmonella* spp., *Salmonella* of unknown serotype	Exclusion until stools are contained in the diaper or child is continent and stool frequency is no more than two stools above that child's normal frequency for the time the child is in the program. Stool consistency does not need to return to normal to be able to return to childcare. Negative stool culture results *not* required for nonserotype Typhi or Paratyphi *Salmonella* spp.	Symptomatic contacts should be excluded until stools are contained in the diaper or child is continent and stool frequency is no more than two stools above that child's normal frequency for the time the child is in the program. Stool cultures are not required for asymptomatic contacts.
Scabies	Exclusion until after treatment given.	Close contacts with prolonged skin-to-skin contact should receive prophylactic therapy. Bedding and clothing in contact with skin of infected people should be laundered.
Infection with Shiga toxin–producing *Escherichia coli* (STEC), including *E. coli* O157:H7	Exclusion until two stool cultures (obtained at least 48 hr after any antimicrobial therapy, if administered, has been discontinued) are negative, stools are contained in the diaper or child is continent, and stool frequency is no more than two stools above that child's normal frequency. Some state health departments have less stringent exclusion policies for children who have recovered from less virulent STEC infection.	Meticulous hand hygiene; stool cultures should be performed for any symptomatic contacts. In outbreak situations involving virulent STEC strains, stool cultures of asymptomatic contacts may aid in controlling spread. Center(s) with cases should be closed to new admissions during STEC outbreak.
Shigellosis	Exclusion until treatment complete and one or more posttreatment stool cultures are negative for *Shigella* spp., stools are contained in the diaper or child is continent, and stool frequency is no more than two stools above that child's normal frequency for the time the child is in the program. Some states may require more than one negative stool culture.	Meticulous hand hygiene; stool cultures should be performed for any symptomatic contacts.

Table 217.2 Disease- or Condition-Specific Recommendations for Exclusion of Children in Out-of-Home Childcare—cont'd

CONDITION	MANAGEMENT OF CASE	MANAGEMENT OF CONTACTS
Staphylococcus aureus skin infections	Exclusion only if skin lesions are draining and cannot be covered with a watertight dressing.	Meticulous hand hygiene; cultures of contacts are not recommended.
Streptococcal pharyngitis	Exclusion until at least 12 hr after treatment has been initiated.	Symptomatic contacts of documented cases of group A streptococcal infection should be tested and treated if test results are positive.
Tuberculosis	Most children younger than 10 yr are not considered contagious. For those with active disease, exclusion until determined to be noninfectious by physician or health department authority. No exclusion for latent tuberculosis infection (LTBI).	Local health department personnel should be informed for contact investigation.
Varicella	Exclusion until all lesions have crusted or, in immunized people without crusts, until no new lesions appear within a 24-hr period.	For people without evidence of immunity, varicella vaccine should be administered, ideally within 3 days, but up to 5 days after exposure, or when indicated, varicella-zoster immune globulin (VariZIG) should be administered up to 10 days after exposure; if VariZIG is not available, intravenous immunoglobulin (IGIV) should be considered as an alternative. If vaccine cannot be administered and VariZIG/IGIV is not indicated, preemptive oral acyclovir or valacyclovir can be considered.

From Kimberlin DW, Barnett ED, Lynfield R, Sawyer MH, eds. *Red Book: 2021–2024 Report of the Committee on Infectious Diseases*, 32nd ed. Itasca, IL: American Academy of Pediatrics; 2021, Table 2.3, pp. 128–132.

Table 217.3 Recommendations for Inclusion or Exclusion of Childcare*

CHILDREN NEED NOT BE EXCLUDED FOR A MINOR ILLNESS UNLESS ANY OF THE FOLLOWING EXISTS:

- The illness prevents the child from participating comfortably in program activities.
- The illness results in a greater care need than the childcare staff can provide without compromising the health and safety of the other children.
- The child has any of the following conditions: fever, unusual lethargy, irritability, persistent crying, difficulty breathing, or other signs of possible severe illness.
- Diarrhea (defined as an increased number of stools compared with the child's normal pattern, with increased stool water and/or decreased form) that is not contained by diapers or toilet use.
- Vomiting two or more times in the previous 24 hours, unless the vomiting is determined to be caused by a noncommunicable condition and the child is not in danger of dehydration.
- Mouth sores associated with an inability of the child to control his or her saliva, unless the child's physician or local health department authority states that the child is noninfectious.
- Rash with fever or behavior change, until a physician has determined the illness to not be a communicable disease.
- Purulent conjunctivitis (defined as pink or red conjunctiva with white or yellow eye discharge, often with matted eyelids after sleep and eye pain or redness of the eyelids or skin surrounding the eye), until examined by a physician and approved to readmission, with or without treatment.
- Tuberculosis, until the child's physician or local health department authority states that the child is noninfectious.
- Impetigo, until 24 hours after treatment has been initiated.
- Streptococcal pharyngitis, until 24 hours after treatment has been initiated and unless the child has been afebrile for 24 hours.
- Head lice (pediculosis), until the morning after the first treatment.
- Scabies, until after treatment has been completed.
- Varicella, until the sixth day after the onset of rash or sooner if all lesions have dried and crusted.
- Pertussis (which is confirmed by laboratory or suspected based on symptoms of the illness or because of cough onset within 14 days of having face-to-face contact with a person in a household or classroom who has a laboratory-confirmed case of pertussis), until 5 days of appropriate antibiotic therapy (currently: erythromycin) has been completed (total course of treatment is 14 days).
- Mumps, until 9 days after onset of parotid gland swelling.
- Hepatitis A virus infection, until 1 week after onset of illness and jaundice, if present, has disappeared or until passive immunoprophylaxis (immune serum globulin) has been administered to appropriate children and staff in the program, as directed by the responsible health department.

Certain conditions do not constitute a prior reason for excluding a child from childcare unless the child would be excluded by the above criteria or the disease is determined by a health authority to contribute to transmission of the illness at the program. These conditions include the following: a symptomatic excretion of an enteropathogen; nonpurulent conjunctivitis (defined as pink conjunctiva with a clear, watery eye discharge and without fever, eye pain, or eyelid redness); rash without fever and without behavior change; cytomegalovirus infection; hepatitis B virus carrier state; and HIV infection.

*Child and caregiver-specific exclusion policies reflect the present state of knowledge.
From Centers for Disease Control and Prevention: https://dchealth.dc.gov/sites/default/files/dc/sites/doh/publication/attachments/Recommendations%20for%20Inclusion%20or%20Exclusion%20CDC.pdf

Center jointly publish comprehensive health and safety performance standards that can be used by pediatricians and other healthcare professionals to guide decisions about management of infectious diseases in childcare facilities (available at http://nrckids.org/CFOC). Additionally, the **National Association for the Education of Young Children (NAEYC)**, a professional organization supporting early childhood education efforts and volunteer accreditation, is gaining recognition as a resource for health and safety standards for childcare facilities (http://www.naeyc.org/). Specific standards set by all states can be reviewed at the U.S. Department of Health and Human Services' **National Center on Early Childhood Quality Assurance** website (https://childcareta.acf.hhs.gov/licensing).

Chapter 218

Health Advice for Children Traveling Internationally

John C. Christenson and James G. Carlucci

Children are traveling internationally with increasing frequency and to more exotic destinations that pose unique injury and disease risks. Compared to adults, children are *less* likely to receive pretravel advice and *more* likely to be seen by a medical provider or be hospitalized on return for a travel-related illness. Primary care providers are confronted with the challenge of trying to ensure safe, healthy travel for their patients, whether travel is occurring for purposes of tourism, study abroad, visiting friends and relatives, or volunteerism. Whenever possible, health professionals are encouraged to consult with **travel medicine specialists**, especially when uncertain about pretravel advice, unique travel medicine vaccines (e.g., yellow fever, Japanese encephalitis, typhoid, rabies), and recommendations for malaria medications.

Travel medicine is a unique specialty, and experienced travel medicine practitioners provide specialized guidance on the infectious and noninfectious risks based on age, itinerary, duration, season, purpose of travel, and underlying traveler characteristics (health and vaccination status). A **pretravel consultation** includes the essential elements of (1) safety and preventive counseling against injuries and diseases, (2) routine, recommended, and required vaccinations, based on individual risk assessment, (3) counseling and medications for self-treatment of traveler's diarrhea, and (4) when indicated by itinerary, malaria chemoprophylaxis (Table 218.1).

In the United States, recommendations and vaccine requirements for travel to different countries are provided by the Centers for Disease Control and Prevention (CDC) and are available online at https://wwwnc.cdc.gov/travel/page/yellowbook-home (Table 218.2). Some travel vaccines and medications may not be recommended based on specifics of travel itinerary, trip duration, or patient characteristics. Alternatively, some vaccinations are not approved for younger children because of lack of data or limited immunologic response but may still confer potential benefit to the young traveler with off-label vaccine administration. In both scenarios, consultation or referral to a knowledgeable travel medicine practitioner is encouraged, especially if uncertainty exists regarding pretravel recommendations.

THE PEDIATRIC TRAVEL MEDICINE CONSULTATION

Parents of traveling children should seek medical consultation at least 1 month before departure to review the travel itinerary, obtain safety and preventive counseling, ensure adequate vaccinations (routine, recommended, and required), receive necessary medications for chronic health conditions, and obtain important medications for self-treatment of traveler's diarrhea and, when indicated, malaria chemoprophylaxis with counseling. Advice, vaccinations, and medications should be emphasized as important measures, with the provider goal of keeping the child healthy during travel rather than to discourage traveling.

Pediatric Travelers Visiting Friends and Relatives

Compared to most children traveling internationally, the **pediatric visiting-friends-and-relatives (VFR) traveler** is the most vulnerable population uniquely at risk for travel-related illnesses. VFR travelers may include immigrants, refugees, migrants, students, or displaced persons who are traveling back to their country of origin for the purposes of visiting friends and relatives. Pediatric VFR travelers are typically children accompanying their parents or family members back to their ancestral country, where relational, social, and cultural connections remain. Compared to tourist travelers, VFR travelers are more likely to travel for longer durations, visit more remote destinations, travel by higher-risk local transportation modes, experience closer contact with the local population, and use fewer insect, food, and water precautions. Adult and pediatric VFR travelers are also less likely to perceive a risk of travel-related illnesses, seek pretravel advice, receive travel immunizations, or use effective malaria prophylaxis on arrival in the destination country. VFR travel comprises ~60% of imported malaria in U.S. children (i.e., malaria acquired outside the United States), and pediatric VFR travelers are reported to be 25 times more likely than tourist travelers to acquire malaria. Among all travelers, unvaccinated pediatric VFR travelers remain at higher risk for contracting and having symptomatic illness caused by hepatitis A virus. Several studies suggest that VFR travelers are at disproportionate risk of acquiring typhoid fever and possibly tuberculosis as well.

SAFETY AND PREVENTIVE COUNSELING TOPICS

Health and Evacuation Insurance, Underlying Health Conditions, and Medications

Parents should be made aware that their medical insurance policy might not provide coverage for hospitalizations or medical emergencies in foreign countries and is unlikely to cover the high cost of an emergency medical evacuation. Supplemental **travel medical insurance** and **evacuation insurance** may be purchased and are especially recommended for prolonged travel itineraries, for remote destinations, and for children with higher-risk preexistent health conditions going to countries where inpatient care at a level comparable to the traveler's home country may not be available. Information regarding medical and evacuation insurance providers can be found at the U.S. Department of State International Travel advisory website (https://travel.state.gov/content/travel/en/international-travel/before-you-go/your-health-abroad/insurance-providers-overseas.html) and the CDC Travel Health website (https://wwwnc.cdc.gov/travel/page/insurance).

Parents of children with medical conditions should take with them a brief medical summary and a sufficient supply of prescription medications for their children, with bottles that are clearly identified by prescription labels. For children requiring care by specialists, an international directory for that specialty can be consulted. A directory of physicians worldwide who speak English and who have met certain qualifications is available from the International Society of Travel Medicine (https://www.istm.org). If medical care is needed urgently when abroad, sources of information include the U.S. embassy or consulate, hotel managers, travel agents catering to foreign tourists, and missionary hospitals.

A travel health kit consisting of prescription medications and nonprescription items, such as acetaminophen, an antihistamine, oral rehydration solution packets, antibiotic ointment, bandages, insect repellent (DEET or picaridin), and sunscreen, is highly recommended for all children. Children with persistent asthma should have bronchodilators and oral corticosteroids prescribed for treatment of any acute asthma exacerbations encountered during overseas travel. Children with a history of angioedema, anaphylaxis, or severe allergies to food or insects should have an epinephrine autoinjector (EpiPen) and antihistamines available for use during travel.

Parents and family members should be aware of the prevalence of *counterfeit medication* and lack of quality control of medications in many areas of the world, particularly in low- and middle-income countries. Critical medications, including insulin and newly prescribed antimalarials, should be purchased before international travel and packed in original prescription containers.

Safety and Injury Prevention

Motor vehicle accidents are a leading cause of traumatic injuries, hospitalizations, and deaths, both in pediatric and adult travelers. Differences in traffic patterns and regulations (e.g., right- vs. left-hand traffic and pedestrian right of way) should be emphasized to children, and the use of safety belts should be reinforced. When possible, child safety seats should be taken on the trip. Parents should also be aware of additional risks for small children that may exist overseas, such as open balconies, windows without screens or bars, exposed wires and electrical outlets, paint chips, pest and rodent poison, and stray animals.

Table 218.1 Checklist of Items to Address in the Pretravel Consultation

CATEGORY	ISSUES THAT SHOULD BE ADDRESSED
Patient risk assessment	Obtain history: itinerary, type of travel, personal medical history, age, underlying diseases, allergies, current medications, pregnancy status, previous vaccination status
Immunizations	Update routine immunizations Provide routine travel immunizations Provide destination-specific immunizations
Malaria prophylaxis	If indicated: Provide malaria education and advice; discuss bite-avoidance measures Prescribe antimalaria prophylaxis
Traveler's diarrhea	Prescribe oral rehydration therapy and loperamide (Imodium)* Prescribe appropriate antibiotic (see Table 218.4)
Prevention against mosquito bites	Give advice regarding mosquito-borne disease Discuss personal protection measures
Rabies prevention	Give advice regarding behavior near animals Discuss measures to take if bitten or scratched by an animal—seek urgent medical advice Administer vaccine when indicated
Prevention of sexually transmitted diseases	Provide education regarding safe sex
Zika virus	Discuss potential risk of congenital Zika syndrome for pregnant women or women/men planning to conceive after return from an endemic area

Some of the recommendations are indicated only for specific destinations or specific at-risk groups.
*Contraindicated in bacterial diarrhea, dysentery.
Modified from Matson KB, Siraj DS. Travel medicine. In Kellerman RD, Rakel DP, Heidelbaugh JJ, Lee EM, eds. *Conn's Current Therapy 2023*. Philadelphia: Elsevier; 2023: Table 2, p. 1474.

Water-related activities also are associated with significant injuries in pediatric travelers, and pools and oceanfronts are often unsupervised and without lifeguards at overseas destinations. Injuries to children on **flights** are also well-documented. Children should not sit in aisle seats, as they can be injured by aisle traffic, service carts, and falling objects from overhead storage bins.

Animal Contact

Among travelers, attacks from domestic or stray animals are much more likely to occur than attacks from wild animals. Wounds from animal bites present a risk for bacterial infections, tetanus, and rabies. **Dogs** are responsible for >95% of all **rabies** transmission in Asia, Africa, and Latin America. Globally, the World Health Organization (WHO) estimates that approximately 59,000 human deaths result from rabies each year, with the vast majority of cases occurring in South Asia, Southeast Asia, and Africa. Rabies transmission is reported less frequently after bites from cats and other carnivores, monkeys, and bats. Macaque monkeys native to Asia and North Africa can be found in urban centers and tourist sites and pose a risk for rabies and herpes B virus infections after bites and scratches.

Young children are more likely to be bitten and experience more severe facial wounds because of their short stature. They are at higher risk for rabies exposure from dogs and other animals during travel and require greater supervision. Parents should always encourage their children to report bite injuries and to avoid petting, feeding, or handling dogs, monkeys, and stray animals. Before travel, tetanus vaccinations need to be current for all travelers. Children, long-term travelers, expatriates, and all individuals likely to come into contact with animals in a rabies-endemic region (primarily Africa and South and Southeast Asia) should consider preexposure vaccination for rabies before international travel (see Rabies later). Bite or scratch wounds should be washed thoroughly and for a prolonged time (≥15 minutes) with copious water and soap. Local wound care will substantially reduce the risk of canine and other mammalian rabies transmission. Rabies **postexposure vaccination** and rabies immunoglobulin is likely indicated in most cases, and medical care should be sought emergently. Antibiotics (e.g., amoxicillin-clavulanate) may need to be administered to a child to prevent secondary infections, especially for animal bites involving the hands and head/neck areas.

ROUTINE CHILDHOOD VACCINATIONS REQUIRED FOR PEDIATRIC TRAVEL

Parents should allow at least 4 weeks before departure for optimal administration of vaccines to their children. All children who travel should be immunized according to the routine childhood immunization schedule with all vaccines appropriate for their age. The immunization schedule can be accelerated to maximize protection for traveling children, especially for unvaccinated or incompletely vaccinated children (see Fig. 215.1 in Chapter 215). Routine and catch-up childhood vaccine schedules can be found at the CDC website (https://www.cdc.gov/vaccines/schedules/).

Live-attenuated viral vaccines should be administered concurrently or ≥4 weeks apart to minimize immunologic interference. Intramuscular Immunoglobulin administration interferes with the immune response to measles immunization and possibly to varicella immunization. If a child requires measles or varicella immunization, the vaccines should be given either 2 weeks before or 3 months after immunoglobulin administration (longer with higher doses of intravenous immunoglobulin). Immunoglobulin does not interfere with the immune response to oral typhoid, poliovirus, or yellow fever vaccines.

Vaccine products produced in eggs (yellow fever, influenza) may be associated with hypersensitivity responses, including anaphylaxis in persons with known severe **egg sensitivity**. Screening by inquiring about adverse effects when eating eggs is a reasonable way to identify those at risk for anaphylaxis from receiving influenza or yellow fever vaccines. Although measles and mumps vaccines are produced in chick embryo cell cultures, children with egg allergy are at very low risk for anaphylaxis with these vaccines.

Diphtheria-Tetanus-Pertussis

Children traveling internationally should be fully vaccinated with diphtheria and tetanus toxoids and acellular pertussis (DTaP), having completed the fourth or fifth booster dose by 4-6 years of age. A single dose of an adolescent/adult preparation of tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine is recommended at 11-12 years of age for those who have completed the recommended primary DTaP (or DTP) series.

Adolescents and adults should receive a single Tdap booster if >5 years have elapsed since the last dose, since a tetanus-containing booster (Td or Tdap) may not be readily available for tetanus-prone wounds during international travel or in remote settings (e.g., adventure travel, wilderness).

Haemophilus influenzae Type b

Haemophilus influenzae type b (Hib) remains a leading cause of meningitis in children 6 months to 3 years of age in many low- and middle-income countries. Before they travel, all unimmunized children <5 years old should be vaccinated against Hib (see Chapter 215). A single dose of Hib vaccine should also be administered to unvaccinated or

partially vaccinated children ≥5 years old if they have anatomic or functional asplenia, sickle cell disease, HIV infection, leukemia, malignancy, or other immunocompromising condition. Unvaccinated children >5 years old do not need vaccination unless they have a high-risk condition.

Hepatitis A

Hepatitis A is a routine childhood vaccine in the United States but requires special considerations in the traveling pediatric patient. Protection from hepatitis A in specific children may also involve the provision of immunoglobulin. For these reasons, hepatitis A vaccination is covered later in Specialized Pediatric Travel Vaccinations.

Hepatitis B

Hepatitis B can be a travel-associated infection. Hepatitis B is highly prevalent throughout much of the world, including areas of South America, sub-Saharan Africa, Eastern and Southeastern Asia, and most of the Pacific basin. In certain parts of the world, 8–15% of the population may be chronically infected. Disease can be transmitted by blood transfusions not screened for hepatitis B surface antigen, exposure to unsterilized needles, close contact with local children who have open skin lesions, and sexual exposure. Exposure to hepatitis B is more likely for travelers residing for prolonged periods in endemic areas. Partial protection may be provided by one or two doses, but ideally three doses should be given before travel. For unvaccinated adolescents, a three-dose hepatitis B vaccine series should be administered, with a minimum interval of 4 weeks between the first and second doses, 8 weeks between the second and third doses, and at least 16 weeks between the first and third doses.

All unvaccinated children and adolescents should receive the accelerated hepatitis B vaccine series before travel. Because one or two doses provide some protection, hepatitis B vaccination should be initiated even if the full series cannot be completed before travel.

Respiratory Viruses

Infections by respiratory viruses such as influenza and SARS-CoV-2 are well recognized as a cause of morbidity among adult and pediatric travelers. Disease caused by these viruses can be prevented through vaccination. The risk for exposure to influenza during international travel varies depending on the time of year, destination, and close contact with infected persons. During the peak of the SARS-CoV-2 pandemic, the use of lockdowns and quarantine, masks, and physical distancing used in many countries to control the spread of SARS-CoV-2 greatly altered the epidemiology of influenza and other respiratory viruses, resulting in few reported infections More recently, influenza appears to have returned to its "traditional" seasonality.

Influenza vaccination is recommended for all children older than 6 months of age and for adults. Vaccines against SARS-CoV-2 are also available (for persons ≥ 6 months of age) and are recommended to prevent severe disease, hospitalization, and death. **Oseltamivir** can be used to treat (and prevent) influenza infections. Antivirals are available to treat serious SARS-CoV-2 infections, especially for high-risk individuals.

There are no available vaccines effective against avian influenza strains such as influenza A H5N1 and H7N9, which have become a great concern worldwide. Because these strains of influenza virus are spread through contact with infected birds, precautions include avoiding direct contact with birds or surfaces with bird droppings, avoiding poultry farms or bird markets, eating only well-cooked poultry or products, and washing hands frequently. **Oseltamivir** is the antiviral of choice to treat infections caused by these viruses.

Measles-Mumps-Rubella

Measles is still endemic in many low- and middle-income countries and in some industrialized nations. It remains a leading cause of vaccine-preventable death in much of the world. Vaccine status for measles is important for all traveling children, particularly if they are traveling to low- and middle-income countries or areas with measles outbreaks. Measles vaccine, preferably in combination with mumps and rubella vaccines (MMR), should be given to all children at 12-15 months and at 4-6 years of age, unless there is a contraindication (see Chapter 215). In children traveling internationally, the second vaccination can be given as soon as 4 weeks after the first to induce immunity among those children who did not respond to the first MMR vaccine.

Children 6-12 months old traveling to low- and middle-income countries should be vaccinated early. The monovalent measles vaccine is not available in the United States, so MMR can be administered. Early vaccination (i.e., 6-12 months of age) will provide some immunity to measles, but antibody response may not be durable or lasting. Therefore any MMR vaccine administered before 12 months of age should not be counted toward the routine vaccination schedule; children vaccinated early for purposes of international travel must be revaccinated on or after their first birthday with two doses separated by at least 4 weeks. Infants <6 months old are generally protected by maternal antibodies (assuming the mother has previously been immunized against measles or had natural infection) and would not need early MMR vaccination before travel.

Pneumococcal Vaccines

Streptococcus pneumoniae is the leading cause of childhood **bacterial pneumonia** and is among the leading causes of bacteremia and bacterial meningitis in children in low- and middle-income and industrialized nations. Preparing a child to travel internationally includes routine or catch-up vaccination with 20-valent pneumococcal conjugate vaccine (PCV20) and, for children with certain high-risk conditions, use of 23-valent pneumococcal polysaccharide vaccine (PPSV23). A single dose of PCV20 should be administered to previously unvaccinated children 6-18 years old with underlying high-risk medical conditions, including anatomic or functional asplenia (including sickle cell disease), HIV infection, a congenital immunodeficiency or immunocompromising condition, chronic heart or lung disease, chronic renal failure or nephrotic syndrome, diabetes mellitus, cerebrospinal fluid leak, or cochlear implant. The Advisory Committee on Immunization Practices (ACIP) also recommends that high-risk children ≥2 years old receive the PPSV23 vaccine ≥8 weeks after their last PCV13 dose. ACIP recommendations on prevention of pneumococcal disease among infants and children using PCV13 and PPSV23 can be found at http://www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/pneumo.html.

Polio Vaccine

Poliomyelitis (wild type) was eradicated from the Western Hemisphere in 1991. Polio remains endemic in two countries—Afghanistan and Pakistan—with additional surrounding countries at risk for importation of polio. Unfortunately, many other countries throughout the world, mainly Africa, are experiencing infections by vaccine-derived poliovirus. The poliovirus vaccination schedule in the United States is a four-dose, all-inactivated poliovirus (IPV) regimen (see Chapter 215). Traveling infants should begin the IPV series as early as 6 weeks of age (for an accelerated dosing schedule for children, see Fig. 215.1 and Table 215.1). Length of immunity conferred by IPV immunization is not known; a single booster dose of IPV is therefore recommended for previously vaccinated adolescents and adults traveling to polio-endemic areas if approximately 10 years have elapsed since they completed their primary series. Oral poliovirus vaccine is no longer available in the United States.

Varicella

All children ≥12 months old who have no history of varicella vaccination or chickenpox should be vaccinated unless there is a contraindication to vaccination (see Chapter 215). Unlike measles vaccine (see earlier), varicella vaccine is not approved or recommended for traveling children 6-12 months of age. Infants <6 months old are generally protected by maternal antibodies. All children now require two doses, the first at 12 months of age and the second at 4-6 years. The second dose can be given as soon as 3 months after the first dose. For unvaccinated children ≥13 years old, the first and second doses can be separated by 4 weeks.

SPECIALIZED PEDIATRIC TRAVEL VACCINATIONS

Table 218.2 summarizes the dosages and age restrictions of vaccines specifically given to children traveling internationally.

Cholera

Cholera is present in many low- and middle-income countries, but the risk for infection among travelers to these countries is extremely low. Travelers entering countries reporting cholera outbreaks are at minimal risk of acquiring cholera if they take adequate safe food and water precautions and practice frequent handwashing. No country or territory currently requires cholera vaccination as a condition for entry. Of note, a live-attenuated, single-dose oral suspension vaccine is licensed in the United States to prevent disease in travelers 2-64 years of age visiting endemic regions.

Hepatitis A Vaccination and Preexposure Immunoglobulin

Hepatitis A virus (HAV) is endemic in most of the world, and travelers are at risk, even if their travel is restricted to the usual tourist routes. HAV infection can result from eating shellfish harvested from sewage-contaminated waters, eating unwashed vegetables or fruits, or eating food prepared by an asymptomatic HAV carrier. Young children infected with hepatitis A are often asymptomatic but can transmit infection to unvaccinated older children and adults, who are more likely to develop clinical hepatitis. Few areas carry no risk of HAV infection, and therefore immunization is recommended for all travelers. Hepatitis A vaccine (HepA) is recommended in the United States for universal immunization of all children ≥12 months old, administered as two doses 6 months apart. A single dose of HepA vaccine given to travelers will provide adequate protection. Protective immunity develops within 2 weeks after the initial vaccine dose. A combined three-dose HepA and hepatitis B vaccine (Twinrix, GlaxoSmithKline) is available in the United States but is licensed for use only in individuals >18 years old. Pediatric combination hepatitis A–hepatitis B vaccine (HepA-HepB) (Twinrix-Junior, GlaxoSmithKline) is licensed for use in children 1-18 years old in Canada and Europe. In many countries, a combination hepatitis A–typhoid fever vaccine is available for persons >16 years of age.

Children <1 year old are at lower risk of clinical HAV infection, especially if they are breastfed or residing in areas with safe water for formula reconstitution. Some experts recommend use of preexposure intramuscular immunoglobulin for children <6 months who are traveling internationally to higher-risk destinations, particularly low-income destinations or regions where hygienic or sanitary conditions are limited. However, administration of immunoglobulin diminishes the immunogenicity of live-virus vaccines, in particular measles vaccine, that may be needed for infant travelers. Vaccination against measles should occur ≥2 weeks before any immunoglobulin administration, and a 3-month interval is suggested between immunoglobulin administration and subsequent measles immunization.

Because measles-endemic countries frequently overlap with higher-risk travel destinations for HAV infection, HepA vaccine is recommended for infant travelers 6-11 months of age. Several studies demonstrate that infants as young as 6 months will develop antibodies after HepA, especially if there are no interfering maternal antibodies from prior maternal vaccination or disease. There is potential for a more durable immune response to the HepA vaccination, especially in later infancy, when potential interfering maternal antibody concentrations are lower. If early HepA vaccination is given rather than immunoglobulin to infant travelers (age 6-11 months), it should not count toward the routine two-dose vaccine series. Similar to MMR vaccination, an informed decision should be made with the parents, balancing the risk of travel-associated disease and vaccine adverse events with the potential protective benefit to the traveling infant.

Japanese Encephalitis

Japanese encephalitis is a disease transmitted by mosquitoes in many areas of Asia, especially in rural farming areas. Although it is a leading cause of vaccine-preventable encephalitis in children in many Asian countries and parts of western Pacific countries, the risk of disease to nonimmune travelers is low. A map showing where Japanese encephalitis transmission occurs can be found at https://wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/japanese-encephalitis.

Most human infections with **Japanese encephalitis virus (JEV)** are asymptomatic, and <1% of individuals develop clinical disease. With symptomatic disease, the fatality rate is 20–30%, and the incidence of neurologic or psychiatric sequelae in survivors is 30–50%. The risk of JEV disease for pediatric travelers is unknown, but among all travelers, it is estimated to be less than 1 case per 1 million travelers to Asia. However, if residing in a rural area with active JEV transmission in the rainy season, the risk may increase to 5-50 cases per 100,000 population per year. Risk of Japanese encephalitis neurologic disease after mosquito-bite transmission is thought to be higher in children than in adults. The disease occurs primarily from June to September in temperate zones and throughout the entire year in tropical zones. Vaccination is recommended for travelers planning visits >1 months to rural areas of Asia, where the disease is endemic, especially areas of rice or pig farming. Vaccination is recommended for shorter visits to such areas if the traveler will often be outdoors or where increased disease activity is reported. Risk for infection can be greatly reduced by following the standard precautions to avoid mosquito bites.

The inactivated Vero cell culture–derived Japanese encephalitis vaccine (Ixiaro) has replaced the older inactivated mouse brain–derived vaccine (JE-VAX), which is no longer manufactured. Japanese encephalitis vaccine efficacy is >95% in adults who receive two doses administered 7-28 days apart. The licensed range for Japanese encephalitis vaccine has been extended to include children as young as 2 months, with a dose administered on days 0 and 28.

Meningococcal Vaccines

Meningococcal vaccines currently available in the United States include two quadrivalent conjugate A/C/Y/W-135 vaccines, MenACWY-CRM (Menveo) and MenACWY-TT (MenQuadfi), and two meningococcal B vaccines (Bexsero, Trumenba).

Children traveling to those equatorial countries in sub-Saharan Africa (i.e., the "meningitis belt") where the incidence of meningococcal disease (especially group A) is highest should receive a *Neisseria meningitidis* quadrivalent vaccine, especially if travel is prolonged or occurs during the dry season of December to June. Risk is greatest in the meningitis belt of sub-Saharan Africa, with rates of meningococcal disease in endemic regions reaching up to 1,000 cases per 100,000 population per year. Vaccination programs for resident populations with a monovalent group A vaccine in highly endemic areas have resulted in a decrease in cases of invasive disease. In recent years, other serogrups have become more prevalent. Conjugate A/C/Y/W-135 vaccines are available to pediatric travelers ≥2 months of age, but the dosing schedule varies by product and age, as outlined in Table 218.2. Booster doses of conjugate A/C/Y/W-135 should occur every 3-5 years for travelers returning to endemic areas, depending on the age of the pediatric traveler. Providers may also want to consider meningococcal vaccination for other pediatric travelers, especially if there is remote or rural travel within low-income countries with limited healthcare access, because meningococcal outbreaks can occur anywhere in the world. Proof of receipt of quadrivalent meningococcal vaccination is also necessary for individuals traveling to Saudi Arabia for the annual Hajj or Umrah pilgrimage.

Serogroups A and C are most often associated with epidemics of meningitis in sub-Saharan Africa, especially in the meningitis belt of equatorial Africa during the dry season months (December to June). Serogroups Y and W-135 have also been found in meningococcal outbreaks. Serogroup B is associated with more sporadic cases of invasive meningococcal disease in industrialized countries, including the United States. Routine vaccination of travelers with meningococcal B vaccine is currently not recommended. Additional vaccine information on meningococcal vaccination regimens and booster intervals can be found at the CDC website (https://wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/meningococcal-disease).

Rabies

Rabies is endemic in many countries in Africa, Asia, and Central and South America. Children are at particular risk because they are less likely to report bites and because facial bites are more common in children. Rabies has the potential for an extended latency period (months) and is uniformly fatal once the clinical symptoms emerge. **Preexposure prophylaxis** is recommended for ambulatory children with extended

Table 218.2 Travel Vaccine Summary Table

VACCINE	TRADE NAME (MFR)	AGE	DOSE	ROUTE	SCHEDULE	BOOSTER
Cholera CVD 103-HgR vaccine	Vaxchora (PaxVax)	18-64 yr	100 mL (reconstituted)	Oral	1 dose[1]	Undetermined[2]
Hepatitis A vaccine, inactivated	Havrix (GlaxoSmithKline)	1-18 yr	0.5 mL (720 ELISA units)	IM	0 and 6-12 mo	None
		≥19 yr	1.0 mL (1,440 ELISA units)	IM	0 and 6-12 mo	None
Hepatitis A vaccine, inactivated	Vaqta (Merck & Co., Inc.)	1-18 yr	0.5 mL (25 U)	IM	0 and 6-18 mo	None
		≥19 yr	1.0 mL (50 U)	IM	0 and 6-18 mo	None
Hepatitis B vaccine, recombinant with novel adjuvant (1018)	Heplisav-B (Dynavax Technologies Corp.)	>18	0.5 mL (20 μg HBsAg and 3,000 μg of 1018)	IM	0, 1 mo	None
Hepatitis B vaccine, recombinant[2,3]	Engerix-B (GlaxoSmithKline)	0-19 yr	0.5 mL (10 μg HBsAg)	IM	0, 1, 6 mo	None
		0-10 yr (accelerated)	0.5 mL (10 μg HBsAg)	IM	0, 1, 2 mo	12 mo
		11-19 yr (accelerated)	1 mL (20 μg HBsAg)	IM	0, 1, 2 mo	12 mo
		≥20 yr (primary)	1 mL (20 μg HBsAg)	IM	0, 1, 6 mo	None
		≥20 yr (accelerated)	1 mL (20 μg HBsAg)	IM	0, 1, 2 mo	12 mo
Hepatitis B vaccine, recombinant[2,3]	Recombivax HB (Merck & Co., Inc.)	0-19 yr (primary)	0.5 mL (5 μg HBsAg)	IM	0, 1, 6 mo	None
		11-15 yr (adolescent accelerated)	1 mL (10 μg HBsAg)	IM	0, 4-6 mo	None
		≥20 yr (primary)	1 mL (10 μg HBsAg)	IM	0, 1, 6 mo	None
Combined hepatitis A and hepatitis B vaccine	Twinrix (GlaxoSmithKline)	≥18 yr (primary)	1.0 mL (720 ELU HAV + 20 μg HBsAg)	IM	0, 1, 6 mo	None
		≥18 yr (accelerated)	1.0 mL (720 ELU HAV + 20 μg HBsAg)	IM	0, 7, and 21-30 days	12 mo
Japanese encephalitis vaccine, inactivated	Ixiaro (Valneva)	2 mo to 2 yr	0.25 mL	IM	0, 28 days	≥1 year after primary series[4]
		3-17 yr	0.5 mL	IM	0, 28 days	≥1 yr after primary series[4]
		18-65 yr	0.5 mL	IM	0, 7-28 days	≥1 yr after primary series[4]
		>65 yr	0.5 mL	IM	0, 28 days	≥1 yr after primary series[4]
Meningococcal polysaccharide tetanus toxoid conjugate vaccine (MenACWY-TT)[5]	MenQuadfi (Sanofi Pasteur)	≥2 yr	0.5 mL	IM	1 dose[6]	If at continued risk[7]
Meningococcal oligosaccharide diphtheria CRM_{197} conjugate vaccine (MenACWY-CRM)[5]	Menveo (GSK)	2-12 mo	0.5 mL	IM	0, 2, 4, 10 mo	If at continued risk[7]
		7-23 yr	0.5 mL	IM	0, 3 mo (second dose administered in second year of life)	
		≥2 yr	0.5 mL	IM	1 dose[6]	

Table 218.2 Travel Vaccine Summary Table—cont'd

VACCINE	TRADE NAME (MFR)	AGE	DOSE	ROUTE	SCHEDULE	BOOSTER
Polio vaccine, inactivated	IPOL (Sanofi Pasteur)	≥18 yr	0.5 mL	SC or IM	1 dose if patient has completed a pediatric series	Repeat boosters may be needed for long-term travelers to polio-affected countries; see Chapter 296
Rabies vaccine (human diploid cell)	Imovax (Sanofi Pasteur)	Any	1 mL	IM	Preexposure series: days 0, 7, and 21 or 28 days	None; see Chapter 320 for postexposure immunization
Rabies vaccine (purified chick embryo cell)	RabAvert (Novartis)	Any	1 mL	IM	Preexposure series: days 0, 7, and 21 or 28 days	None; see Chapter 320 for postexposure immunization
Typhoid vaccine (oral, live, attenuated)	Vivotif (PaxVax)	≥6 yr	1 capsule[8]	Oral	0, 2, 4, 6 days	Repeat primary series after 5 yr
Typhoid vaccine (Vi capsular polysaccharide)	Typhim Vi (Sanofi Pasteur)	≥2 yr	0.5 mL	IM	1 dose	2 yr
Yellow fever	YF-Vax (Sanofi Pasteur)	≥9 mo[9]	0.5 mL[10]	SC	1 dose	Not recommended for most[11]

[1]Must be administered in a healthcare setting.
[2]In a clinical trial, vaccine efficacy was 90% at 10 days postvaccination and declined to 80% at 3 months postvaccination in prevention of severe diarrhea after oral cholera challenge. Long- term immunogenicity is unknown. Clinicians advising travelers who are at continued or repeated risk over an extended period may consider revaccination, although the appropriate interval and efficacy are unknown.
[3]Consult the prescribing information for differences in dosing for hemodialysis and other immunocompromised patients.
[4]If potential for Japanese encephalitis virus exposure continues.
[5]If an infant is receiving the vaccine before travel, two doses may be administered as early as 8 wk apart.
[6]People with HIV, anatomic or functional asplenia, and persistent complement component deficiencies (C3, C5-9, properdin, factor D, and factor H or people taking eculizumab [Soliris]) should receive a two-dose primary series 8-12 wk apart.
[7]Revaccination with meningococcal conjugate vaccine (MenACWY-D or MenACWY-CRM) is recommended after 3 yr for children who received their last dose at <7 yr of age. Revaccination with meningococcal conjugate vaccine is recommended after 5 yr for people who received their last dose at ≥7 yr of age and every 5 yr thereafter for people who are at continued risk.
[8]Must be kept refrigerated at 35.6°F to 46.4°F (2°C to 8°C); administer with cool liquid no warmer than 98.6°F (37°C).
[9]Ages 6-8 mo and ≥60 yr are precautions and age <6 mo is a contraindication to the use of yellow fever vaccine.
[10]YF Vax is available in single-dose and multiple-dose (five-dose) vials.
[11]For full details regarding revaccination, see https://wwwnc.cdc.gov/travel/page/yellow-book-resources.
ACIP, Advisory Committee on Immunization Practices; ELU, ELISA units of inactivated HAV; HAV, hepatitis A virus; HBsAg, hepatitis B surface antigen; IM, intramuscular; U, units HAV antigen; SC, subcutaneous.
From Centers for Disease Control and Prevention (CDC). International travel with infants and children: Yellow Book 2024. Atlanta: CDC, 2024. https://wwwnc.cdc.gov/travel/yellowbook

travel to high-risk regions, especially expatriate children and younger children traveling to or living in rural areas where enzootic dog rabies is endemic. Rabies preexposure vaccination should also be considered for adventure travelers (e.g., hikers, bikers), individuals likely to come into contact with rabies vectors (e.g., students working with animal or bat conservation), or travelers with itineraries to rabies-endemic regions where timely, effective **postexposure prophylaxis** might not be available after an animal bite. Most animal bites in a rabies-endemic area should be considered a medical emergency, especially bites from stray dogs, other carnivores, and bats. Immediate and copious wound irrigation should be followed by prompt administration of appropriate postexposure rabies prophylaxis at a medical facility. Postexposure prophylaxis is required even for persons who received preexposure vaccination. Algorithms for preexposure and postexposure vaccination are the same regardless of patient age.

Numerous rabies vaccine formulations exist around the world. In the United States, two rabies vaccines are available: human diploid cell vaccine (HDCV; Imovax, Sanofi Pasteur, SA) and purified chick embryo cell vaccine (PCEC; RabAvert, Novartis). Preexposure prophylaxis is given intramuscularly (HDCV or PCEC) as two doses (1 mL) on days 0 and 7. For previously unvaccinated individuals, postexposure prophylaxis is given as four doses (1 mL) of HDCV or PCEC vaccine intramuscularly on days 0, 3, 7, and 14. A fifth dose is recommended at day 28 for immunocompromised individuals. For previously vaccinated individuals, only two doses (1 mL) intramuscularly on days 0 and 3 are recommended. Previously unvaccinated persons should also receive rabies immunoglobulin (RIG, 20 IU/kg), with as much of the dose as possible infiltrated around the wound site at the time of initial postexposure prophylaxis. Previously vaccinated persons do not require RIG. Unpurified or purified equine RIG preparations are still used in some low- and middle-income countries and are associated with a higher risk for severe reactions, including serum sickness and anaphylaxis. Purified cell culture–derived vaccines also are not always available abroad; travelers should be aware that any rabies vaccines derived from neural tissue carry an increased risk for adverse reactions, often with neurologic sequelae. If rabies prophylaxis is initiated abroad, neutralizing titers should be checked on return and immunization completed with a cell culture–derived vaccine. If rabies prophylaxis cannot be provided abroad, children with high-risk bites (e.g., stray dog) should be emergently transported to a site where they can receive prophylaxis, because the vaccinations should be started as soon as possible after the bite and ideally within 24 hours. Infants and

young children respond well to rabies vaccine, and both preexposure and postexposure vaccinations can be given at any age, using the same dose and schedule as adults. Individual travelers simultaneously receiving mefloquine or chloroquine may have limited immune reactions to intradermal (ID) rabies vaccine and should be vaccinated intramuscularly. The ID administration route is not currently recommended in the United States.

Tuberculosis

The risk for tuberculosis in the typical traveler is low. Pretravel and posttravel testing for tuberculosis is controversial and should be done on an individualized basis depending on the itinerary, duration, and activities (e.g., working in a hospital setting). Immunization with bacille Calmette-Guérin (BCG) is even more controversial. BCG vaccine has variable efficacy in reducing severe tuberculosis disease in infants and young children, is not available in the United States, and is generally not recommended for pediatric travelers. However, parents traveling with young children who plan to reside in countries with high endemic rates of tuberculosis may consider vaccination once in country to prevent disseminated disease. Infection with *Mycobacterium bovis* can be prevented through avoiding consumption of unpasteurized dairy products.

Typhoid

Salmonella Typhi infection, or **typhoid fever**, is common in many low- and middle-income countries in Asia, Africa, and Latin America (see Chapter 244). Typhoid vaccination is recommended for most children ≥2 years old who are traveling to the Indian subcontinent because the incidence of typhoid is 10-100 times higher for travelers to the Indian subcontinent than all other travel destinations. Vaccination should be strongly considered for other travelers to low- and middle-income countries, particularly if they are VFR travelers, lack access to reliable clean water and food, are traveling for a prolonged duration, or are adventurous eaters.

Two typhoid vaccines, the intramuscular (IM) Vi-polysaccharide vaccine and the oral Ty21a strain live-attenuated vaccine, are recommended for use in children in the United States. Both produce a protective response in 50–80% of recipients. The Ty21a vaccine may offer partial protection against *Salmonella* Paratyphi, another cause of enteric fever. Travelers who have had prior diagnoses of typhoid fever should still receive vaccination because past infection does not confer long-term immunity.

The IM Vi-polysaccharide vaccine is licensed for use in children ≥2 years old. It can be given any time before departure, but it should ideally be administered 2 weeks before travel, with a booster needed 2-3 years later. The oral Ty21a vaccine can only be used in children ≥6 years old and is given in four doses over 1 week. Enteric-coated capsules are to be swallowed with a cool or room-temperature drink, at least 1 hour before a meal, every other day until the four doses are completed. Oral typhoid capsules must remain refrigerated (not frozen). Capsules should never be broken open, because vaccine efficacy depends on capsules being swallowed whole in order to pass through the acidic stomach contents. The oral vaccine is associated with an immune response lasting 5-7 years (depending on national labeling). Antibiotics inhibit the immune response to the oral Ty21a vaccine; the vaccine should not be given within 72 hours of antibiotic treatment, and antibiotics should be avoided until 7 days after completing the vaccine series. Studies demonstrate that mefloquine, chloroquine, and atovaquone-proguanil can be given concurrently with the oral Ty21a vaccine without affecting the immunogenicity of the vaccine. Oral Ty21a vaccine should not be given to immunocompromised children; these children should receive the IM Vi-polysaccharide vaccine.

Yellow Fever

Yellow fever (see Chapter 316) is a mosquito-borne viral illness resembling other viral hemorrhagic fevers (see Chapter 317) but with more prominent hepatic involvement. Yellow fever is present in tropical areas of South America and Africa.

Yellow fever vaccination is indicated in children >9 months old traveling to an endemic area. Many countries require yellow fever vaccination by law for travelers arriving from endemic areas, and some African countries require evidence of vaccination from all entering travelers. Current recommendations can be obtained by contacting state or local health departments or the Division of Vector-Borne Infectious Diseases of the CDC (800-232-4636; https://wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/yellow-fever.

Most countries accept a medical waiver for children who are too young to be vaccinated (i.e., <6 months of age) and for persons with a contraindication to vaccination. Children with asymptomatic HIV infection may be vaccinated if exposure to yellow fever virus (YFV) cannot be avoided.

Yellow fever vaccine (0.5 mL subcutaneously), a *live-attenuated vaccine* (17D strain) developed in chick embryos, is safe and highly effective in children >9 months old, but in young infants is associated with a greatly increased risk for vaccine-associated encephalitis (0.5-4/1,000) and other severe reactions. Yellow fever vaccine should *never* be given to infants <6 months old; infants 6-8 months old should be vaccinated only in consultation with the CDC or a travel medicine expert to assess the current epidemiology, travel itinerary and duration, and whether the risk of YFV exposure is greater than vaccine risks. In children >9 months old, adverse effects are rare, although vaccine-associated neurotropic and viscerotropic disease associated with the vaccine has been reported. The risk of these reactions is higher in those with thymic disease, altered immune status, multiple sclerosis, or age <9 months (neurotropic disease) or >60 years. Yellow fever vaccination is generally contraindicated in pregnancy and for nursing mothers, unless extended travel to a yellow fever–endemic area is unavoidable.

Children with immunodeficiency or an immunosuppressed state, a thymic disorder or dysfunction (e.g., DiGeorge syndrome), or a history of anaphylactic reactions to eggs *should not receive* yellow fever vaccine. Long-lived immunity develops with this vaccine, perhaps even lasting for a lifetime. Effective July 2016, the WHO and countries following international health regulations no longer require revaccination every 10 years (i.e., a single lifetime dose is now accepted); however, individuals traveling to high-risk areas with active yellow fever transmission and who anticipate frequent or prolonged stays should still consider being reimmunized every 10 years.

TRAVELER'S DIARRHEA

Ingestion of contaminated food or water makes travel-associated diarrhea the most common health complaint among international travelers. Traveler's diarrhea, characterized by a twofold or greater increase in the frequency of unformed bowel movements, occurs in as many as 40% of all travelers overseas (see Chapter 387.1). Children, especially those <3 years old, have a higher incidence of diarrhea, more severe symptoms, and more prolonged symptoms than adults, with a reported attack rate of 60% for those <3 years old in one study.

An important risk factor for traveler's diarrhea is the country of destination. High-risk areas (attack rates of 25–50%) include low- and middle-income countries of Latin America, Africa, the Middle East, and Asia. Intermediate risk occurs in Mediterranean countries, China, and Israel. Low-risk areas include North America, Northern Europe, Australia, and New Zealand. Fecal-oral diarrheal pathogens that children acquire during travel are similar to those acquired by adults and include enterotoxigenic and enteroaggregative *Escherichia coli*, *Campylobacter, Salmonella* (nontyphoidal serotypes predominate), and *Shigella* spp. Enteric protozoa are a much less common cause of traveler's diarrhea than bacterial pathogens; *Giardia lamblia* is the most likely protozoal cause of persistent diarrhea. Less common travel-associated protozoa include *Cryptosporidium* spp., *Entamoeba histolytica,* and *Cyclospora*. Viral infections, particularly rotavirus and norovirus infections, may also cause travel-associated diarrhea in children. Clinicians should be aware that not all diarrheal illness in children is food-borne or water-borne; for example, febrile children with malaria may also present with vomiting and/or nonbloody diarrhea and may be misdiagnosed as having traveler's diarrhea.

Guidance on Prevention of Traveler's Diarrhea

Food and water hygiene remain important measures to reduce the incidence of traveler's diarrhea in children. However, creating long lists of foods to avoid or offering the popular, simple advice of "Boil it, peel it, cook it, or forget it!" is generally an ineffective method of reducing traveler's diarrhea. Most studies show that these types of dietary directives are difficult to keep and may have little impact on the incidence of traveler's diarrhea. In adult studies, the risk of developing traveler's diarrhea appears to be more associated with *where a person eats rather than what they eat*. Eating in a relative's or friend's home is generally safer than eating in a restaurant, where restaurant kitchen hygiene and proper refrigeration may be lacking and employee handwashing may be sporadic.

In general, travel medicine providers can give some commonsense food and water advice to family travelers. Boiled or bottled water, hot beverages, and canned or bottled beverages are generally safe to consume. Ice should be avoided. In low- and middle-income countries, tap water is generally unsafe for drinking or brushing teeth. Boiling water for ≥1 minute (or 3 minutes at altitudes >2,000 meters) remains a reliable method of disinfecting water. Food that is thoroughly cooked and served hot is almost always safe to eat. Dry foods, such as pastry items, breads, and cookies, are generally safe to eat. Unpasteurized milk or other dairy products (cheese) should always be avoided. Breastfeeding should be encouraged for young children, especially infants <6 months old, to reduce exposure to contaminated water or formula. All children should be reminded to wash their hands before eating and after playing around soil or animals. Chemoprophylactic agents for traveler's diarrhea are not recommended for children.

Management of Traveler's Diarrhea

Dehydration is the greatest threat presented by a diarrheal illness in a small child. Parents should be made aware of the symptoms and signs of dehydration and given instructions on how to prepare and administer rehydration solutions. Prepackaged WHO **oral rehydration solution** packets, which are available at stores or pharmacies in almost all low- and middle-income countries, should be part of a child's travel kit. Oral rehydration solution should be mixed as directed with bottled or boiled water and given slowly, as tolerated, to the child while symptoms persist.

Antimotility agents such as diphenoxylate (Lomotil) and loperamide (Imodium) should be avoided in infants and young children. The American Academy of Pediatrics (AAP) does not recommend their routine use in acute gastroenteritis. Use of antimotility agents may be beneficial in older children and adolescents with afebrile, nonbloody traveler's diarrhea. In general, antimotility agents should not distract parents from giving frequent oral rehydration solution, because ongoing intestinal fluid losses likely continue despite a decrease in stooling. Bismuth subsalicylate for acute gastroenteritis should be avoided because of concern for toxicity and Reye syndrome.

Presumptive Antibiotic Treatment

Oral rehydration is the mainstay of treatment for pediatric traveler's diarrhea. However, antibiotics should be prescribed for the pediatric traveler, with parental instructions to start presumptive treatment early in the diarrheal illness (Tables 218.3 and 218.4). Systemic antibiotics can shorten the duration and severity of diarrheal illness, especially if presumptive antibiotics are initiated immediately after the onset of traveler's diarrhea. For children, the drug of choice is **azithromycin** (10 mg/kg once daily for up to 3 days, with a maximum daily dose of 500 mg). **Ciprofloxacin** (10 mg/kg per dose twice daily for up to 3 days, maximum dose of 500 mg twice daily) is an alternative but should not be prescribed for travelers to the Indian subcontinent or Southeast Asia, where fluoroquinolone resistance is common. Shiga toxin–producing *E. coli,* such as *E. coli* O157:H7, is an extremely uncommon cause of pediatric traveler's diarrhea in nonindustrialized countries, and the benefit of presumptive antibiotic therapy in traveling children, even with bloody diarrhea, typically outweighs the low risk of developing hemolytic-uremic syndrome. Parents need to be aware that the use of antibiotics for the treatment of traveler's diarrhea has been associated with colonization with highly resistant organisms such as extended-spectrum β-lactamase–producing Enterobacteriaceae. These organisms could later cause infections once back home.

Azithromycin is highly effective against most bacterial pathogens that cause traveler's diarrhea and is the preferred antibiotic among many travel experts. Azithromycin can be prescribed in powder form that can be reconstituted with safe water into a liquid suspension when needed. Amoxicillin, trimethoprim-sulfamethoxazole (cotrimoxazole), and erythromycin should *not* be prescribed for self-treatment of traveler's diarrhea, because of widespread resistance among diarrheal pathogens. Traveler's diarrhea that results in bloody stools, persistently high fevers, systemic chills and rigors, severe or localizing abdominal pain, or continued fluid losses should prompt additional medical evaluation.

Table 218.3 Traveler's Diarrhea Empiric Treatment Recommendations

Therapy of mild traveler's diarrhea: diarrhea that is tolerable, is not distressing, and does not interfere with planned activities.

- Antibiotic treatment is not recommended in patients with mild traveler's diarrhea.
- Loperamide or BSS may be considered in the treatment of mild traveler's diarrhea in older children.

Therapy of moderate traveler's diarrhea: diarrhea that is distressing or interferes with planned activities.

- Antibiotics may be used to treat cases of moderate traveler's diarrhea.
- Fluoroquinolones may be used to treat moderate traveler's diarrhea depending on resistance patterns of country or region.
- Azithromycin may be used to treat moderate traveler's diarrhea.
- Rifaximin may be used to treat moderate, noninvasive traveler's diarrhea.
- Loperamide may be used as adjunctive therapy for moderate to severe traveler's diarrhea. Antimotility agents alone are not recommended for patients with bloody diarrhea or those who have diarrhea and fever.
- Loperamide may be considered for use as monotherapy in moderate traveler's diarrhea in older children.

Therapy of severe traveler's diarrhea: diarrhea that is incapacitating or completely prevents planned activities: all dysentery is considered severe.

- Antibiotics should be used to treat severe traveler's diarrhea.
- Azithromycin is preferred to treat severe traveler's diarrhea.
- Fluoroquinolones may be used to treat severe, nondysenteric traveler's diarrhea depending on resistance patterns of country or region.
- Rifaximin may be used to treat severe, nondysenteric traveler's diarrhea.*
- Single-dose antibiotic regimens may be used to treat traveler's diarrhea.

*These treatment recommendations were developed before the approval of rifamycin SV in the United States. Because it is in the same category of antimicrobial drug as rifaximin and because they have the same mechanism of action, rifamycin SV can be considered as an alternative to rifaximin.

Modified from Centers for Disease Control and Prevention (CDC). International travel with infants and children: Yellow Book 2024. Atlanta: CDC, 2020. Box 2-04 and Table 2-10. https://wwwnc.cdc.gov/travel/yellowbook/2024/preparing/travelers-diarrhea#treatment

INSECT-BORNE INFECTIONS

Insect-borne infections for which traveling children are most at risk include malaria, dengue, chikungunya, yellow fever, Zika, and Japanese encephalitis, depending on the area of travel. **Malaria** is transmitted by nighttime biting *Anopheles* mosquitoes, whereas **dengue** occurs from mosquito species *(Culex, Aedes)* that are predominantly active during the day. Families should be encouraged to protect children against daytime and nighttime biting mosquitoes, because many regions of the world where malaria is found also have diseases transmitted by daytime

Table 218.4 Acute Diarrhea Adult Antibiotic Treatment Recommendations*

ANTIBIOTIC*	DOSE	DURATION
Azithromycin†,‡	1,000 mg	Single or divided dose§
	500 mg daily	3 days
Levofloxacin	500 mg daily	1-3 days§
Ciprofloxacin	750 mg	Single dose§
	500 mg bid	3 days
Ofloxacin	400 mg bid	1-3 days§
Rifamycin SV‖	388 mg bid	3 days
Rifaximin‖	200 mg tid	3 days

*See also Chapter 387.1. Lower weight-based dosing should be used where appropriate.
*Antibiotic regimens may be combined with loperamide 4 mg initially followed by 2 mg after each loose stool, not to exceed 16 mg in a 24-hr period. This is the adult dose of loperamide, which might be appropriate for older children and adolescents, but antimotility agents are generally not recommended for younger children, and if they are used then lower doses may be more appropriate.
†Use empirically as first-line in Southeast Asia or other areas if fluoroquinolone-resistant bacteria are suspected.
‡Preferred regimen for dysentery or febrile diarrhea.
§If symptoms are not resolved after 24 hr, continue daily dosing for up to 3 days.
‖Do not use if clinical suspicion for *Campylobacter, Salmonella, Shigella,* or other causes of invasive diarrhea. Use may be reserved for patients unable to receive fluoroquinolones or azithromycin.
From Centers for Disease Control and Prevention (CDC). International travel with infants and children: Yellow Book 2024. Atlanta: CDC, 2024. Table 2-09. https://wwwnc.cdc.gov/travel/yellowbook/2024/preparing/travelers-diarrhea#table 209

biting mosquitoes (dengue, Zika, chikungunya). Zika can also be sexually transmitted, so sexually active adolescents and young adults need to be advised on these additional risks when traveling to Zika-endemic regions. In addition to insect bite prevention using insect repellents, methods of contraception should be discussed with the traveler. Ticks, fleas, lice, and other arthropods are also known to transmit rickettsial, borrelial, and parasitic pathogens, but transmission can be prevented by close attention to measures to mitigate exposures that are appropriate when outdoors, close inspection for ticks once returning indoors, and use of insect repellents on skin and clothing with products containing DEET and permethrin, respectively.

Exposure to insect bites can be reduced by wearing appropriate attire and using insect repellents containing *N,N*-diethyl-*m*-toluamide (**DEET**) or picaridin. The AAP recommends avoiding DEET-containing repellents in children <2 months old. Rare cases of neurologic events have been reported in very young children with exposure to inappropriate, frequent applications of DEET-containing repellents (>10 times/day) or who licked off DEET. Concentrations of 25–30% DEET need be applied every 4-6 hours, as needed, whereas 5–7% DEET provides only 1-2 hours of protection time. DEET concentrations >40–50% do not confer a substantially longer protection time for children and are not recommended.

Picaridin is fragrance-free, effective, and generally well tolerated on exposed skin and faces. It has similar efficacy to DEET but with less inhalational or dermal irritation. Picaridin at concentrations of 20% or higher provides adequate protection against *Anopheles* mosquitoes that have potential to transmit malaria. When applying sunscreen and insect repellent, sunscreen should be applied first, followed by DEET or picaridin.

Spraying or treating clothing with **permethrin**, a synthetic pyrethroid, is a safe and effective method of further reducing insect bites in children. Permethrin can be applied directly to clothing, bed nets, shoes, and hats and should be allowed to dry fully before use. As an insecticide, permethrin should never be applied to skin. Permethrin-treated garments retain both repellency and insecticidal activity, even with repeated laundering. Clothing will eventually need to be retreated to maintain repellency, according to the product label. Bed nets, particularly permethrin-impregnated bed nets, also decrease the risk of insect bites, and their use is highly recommended in malarial areas.

MALARIA CHEMOPROPHYLAXIS

Malaria, a mosquito-borne infection, is the leading parasitic cause of death in children worldwide (see Chapter 334). Of the five *Plasmodium* species that infect humans, *Plasmodium falciparum* causes the greatest morbidity and mortality. Each year, >8 million U.S. citizens visit parts of the world where malaria is endemic (sub-Saharan Africa, Central and South America, India, Southeast Asia, Oceania). Children accounted for 15–20% of imported malaria cases in a WHO study in Europe. Given travel of young children with their families to endemic countries, physicians in industrialized countries are increasingly required to give advice on prevention, diagnosis, and treatment of malaria. **Risk factors** for severe malaria and death include inadequate adherence to chemoprophylaxis, delay in seeking diagnosis and medical care, and nonimmune status, but the case-fatality rate of imported malaria remains <1% in children from nonendemic countries. The CDC maintains updated information at https://wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/malaria, as well as a malaria hotline for physicians (770-488-7788). It is important to check this updated information, because recommendations for prophylaxis and treatment are often modified as a result of changes in the risk for developing malaria in different areas of the world, changing *Plasmodium* resistance patterns, and the availability of new antimalarial medications.

Avoidance of mosquitoes and **barrier protection** from mosquitoes are an important part of malaria prevention for travelers to endemic areas. The *Anopheles* mosquito feeds from dusk to dawn. Travelers should remain in well-screened areas, wear clothing that covers most of the body, sleep under a bed net (ideally impregnated with permethrin), and use insect repellents with DEET during these hours. Parents should be discouraged from taking a young child on a trip that will entail evening or nighttime exposure in areas endemic for *P. falciparum*.

Chemoprophylaxis is the cornerstone of malaria prevention for nonimmune children and adults who travel to malaria-endemic areas *but is not a replacement for other protective measures*. Travelers often do not take malaria prophylaxis as prescribed or at all. They are more likely to use prophylactic antimalarial drugs if their physicians provide appropriate recommendations and education before departure. However, in one survey, only 14% of persons who sought medical advice obtained correct information about malaria prevention and prophylaxis. Families with children visiting friends and relatives are particularly less likely to take malaria prophylaxis or seek pretravel medical advice.

Resistance of *P. falciparum* to the traditional chemoprophylactic agent, **chloroquine**, is widespread, and in most areas of the world other agents must be used (Table 218.5). Factors that must be considered

Table 218.5 Antimalarial Chemoprophylaxis for Children

AREA	DRUG	ADULT DOSE	PEDIATRIC DOSE	ADVANTAGES	DISADVANTAGES	COMMENTS
Chloroquine-resistant area	Mefloquine*,†	250 mg salt (228 mg base) tablets One tablet weekly	Weight <10 kg: 5 mg salt (4.6 mg base)/kg/week	Once-weekly dosing	Bitter taste No pediatric formulation Side effects of sleep disturbance, vivid dreams	Children going to malaria-endemic area for ≥4 wk Children unlikely to take daily medication
			Weight 10-19 kg: ¼ tablet/week			
			Weight 20-30 kg: ½ tablet/week			
			Weight 31-45 kg: ¾ tablet/week			
			Weight >45 kg: 1 tablet/week			
	Doxycycline‡	100 mg tablet One tablet daily	2.2 mg/kg daily (max: 100 mg)	Known safety profile Readily available in most pharmacies	Prolonged (>21 days) courses should not be given to children <8 yr old Daily dosing Must take with food or causes stomach upset Photosensitivity Yeast superinfections	Children ≥8 yr old going to area for <4 wk who cannot take or cannot obtain atovaquone-proguanil
	Atovaquone-proguanil§ (Malarone)	250/100 adult tablet One tablet daily	Pediatric tablet: 62.5 mg atovaquone/25 mg proguanil	Pediatric tablet formulation available Generally well tolerated	Daily dosing Expensive Can cause stomach upset	Children going to malaria-endemic area for <4 wk
			Weight 5-8 kg: ½ pediatric tablet once daily			
			Weight >8-10 kg: ¾ pediatric tablet once daily			
			Weight >10-20 kg: 1 pediatric tablet once daily			
			Weight >20-30 kg: 2 pediatric tablets once daily			
			Weight >30-40 kg: 3 pediatric tablets once daily			
			Weight >40 kg: 1 adult tablet once daily			
Chloroquine-susceptible area	Chloroquine phosphate	500 mg salt (300 mg base) One tablet weekly	8.3 mg/kg salt (5 mg/kg base) weekly, up to maximum adult dose of 500 mg salt	Once-weekly dosing Generally well tolerated Safe in pregnancy	Bitter taste No pediatric formulation	Best medication for children traveling to areas with *Plasmodium falciparum* or *P. vivax* that is chloroquine susceptible
	Hydroxychloroquine	400 mg of salt (310 mg of base)	6.5 mg/kg of salt (5 mg/kg of base) once weekly, up to maximum adult dose of 400 mg of salt	Safe in pregnancy		Alternative when chloroquine is unavailable for travelers to areas with *P. falciparum* or *P. vivax* that is chloroquine susceptible

Continued

Table 218.5 Antimalarial Chemoprophylaxis for Children—cont'd

AREA	DRUG	ADULT DOSE	PEDIATRIC DOSE	ADVANTAGES	DISADVANTAGES	COMMENTS
Terminal prophylaxis (antirelapse therapy) for regions predominantly with *P. vivax* and *P. ovale*.	Primaquine	26.3 mg salt (15 mg base) tablets; 2 tablets once daily for 14 days after departure from malarious area.	0.8 mg/kg of salt form (0.5 mg/kg of base) once daily for 14 days after departure from malarious area	Reduce risk for relapses by *P. vivax* and *P. ovale*.	May cause hemolysis in persons with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Contraindicated in pregnancy and breastfeeding mothers.	Must confirm G6PD sufficiency before administration.
Short-term prophylaxis for regions with predominantly *Plasmodium vivax*	Primaquine	26.3 mg salt (15 mg base) tablets; 2 tablets. Begin 1-2 days before travel to malarious areas, continue for 7 days after leaving area.	0.8 mg/kg of salt form (0.5 mg/kg of base). Begin 1-2 days before travel to malarious areas, continue for 7 days after leaving area.	Reduce risk for relapses by *P. vivax*.	May cause hemolysis in persons with G6PD deficiency. Contraindicated in pregnancy and breastfeeding mothers.	Must confirm G6PD sufficiency before administration.
Terminal prophylaxis (antirelapse therapy) for regions predominantly with *P. vivax*	Tafenoquine **(Krintafel)**	150 mg tablets; ≥16 yr: 2 tablets, single dose	Not recommended	Single dose	May cause hemolysis in persons with G6PD deficiency. Contraindicated in pregnancy and breastfeeding mothers.	Must confirm G6PD sufficiency before administration.
Prophylaxis against all *Plasmodium* spp.	Tafenoquine **(Arakoda)**	100 mg tablets; ≥18 yr: 2 tablets, daily for 3 days before travel. Weekly during travel (starting 1 wk after last pretravel dose). Once 1 wk after travel	Not recommended	Effective against all *Plasmodium* spp.	May cause hemolysis in persons with G6PD deficiency. Contraindicated in pregnancy and breastfeeding mothers.	Must confirm G6PD sufficiency before administration.

*Chloroquine and mefloquine should be started 1-2 wk before departure and continued for 4 wk after last exposure.
†Mefloquine resistance exists in western Cambodia and along the Thailand-Cambodia and Thailand-Myanmar borders. Travelers to these areas should take doxycycline or atovaquone-proguanil. See text for precautions about mefloquine use.
‡Doxycycline should be started 1-2 days before departure and continued for 4 wk after last exposure. Do not use in children <8 yr old or in pregnant women.
§Atovaquone-proguanil (Malarone) should be started 1-2 days before departure and continued for 7 days after last exposure; should be taken with food or a milky drink. Not recommended in pregnant women, children who weigh <5 kg, and women breastfeeding infants who weigh <5 kg. Contraindicated in individuals with severe renal impairment (creatinine clearance <30 mL/min).
Drugs used for chloroquine-resistant areas can also be used in chloroquine-susceptible areas.

in choosing appropriate chemoprophylaxis medications and dosing schedules include age of the child, travel itinerary (including whether the child will be traveling to areas of risk within a particular country and whether chloroquine-resistant *P. falciparum* is present in the country), vaccinations being given, allergies or other known adverse reactions to antimalarial agents, and the availability of medical care during travel.

Children traveling to areas with chloroquine-resistant *P. falciparum* can be given mefloquine, atovaquone-proguanil, or doxycycline (if >8 years old) as malaria prophylaxis. For trips shorter than 4 weeks, atovaquone-proguanil is the preferred medication, because it is given for only a short period before and after travel. Atovaquone-proguanil or doxycycline is also preferred for travel of any duration to western Cambodia and the Thailand-Cambodia and Thailand-Myanmar borders because of mefloquine resistance in these areas. For periods of travel >4 weeks to all other areas with chloroquine-resistant *P. falciparum,* mefloquine is the preferred medication because it can be taken weekly.

Mefloquine is FDA approved only for children weighing >15 kg, but the CDC recommends mefloquine prophylaxis for all children regardless of weight because the risk for acquiring severe malaria outweighs the risk for potential mefloquine toxicity. Adults taking mefloquine prophylaxis have a 10–25% incidence of sleep disturbance and dysphoria and, less frequently, more serious neuropsychiatric symptoms. These side effects appear to be less common in children. Other potential side effects of mefloquine therapy include nausea and vomiting.

The lack of a liquid or suspension formulation for all antimalarial agents can make administration difficult. For children who cannot take tablets, parents should take a chloroquine or mefloquine prescription

to a compounding pharmacy, which can pulverize the tablets and place exact dosages into gel capsules. Parents can then open the gel capsules and sprinkle the powder into food. Disguising these medications, which have a bitter taste, is important; chocolate syrup has been used successfully as a vehicle for the medication. Persons with depression, neuropsychiatric disorders, seizure disorders, or cardiac conduction defects should not take mefloquine.

Atovaquone-proguanil fixed combination (Malarone) is an effective and safe chemoprophylaxis for travelers to chloroquine-resistant malaria-endemic areas. Adverse effects are infrequent and mild (abdominal pain, vomiting, and headache) and infrequently result in discontinuation of the medication. Atovaquone-proguanil prophylaxis must be taken every day with food, so it is better suited for prophylaxis during short periods of exposure. Recent data allow dosing down to 5 kg body weight, although the use of atovaquone-proguanil in children weighing 5-10 kg is considered off-label.

Daily **doxycycline** is an alternative chemoprophylaxis regimen for chloroquine-resistant *P. falciparum* malaria. Doxycycline has been used extensively and is highly effective. Use in children <8 years old should be avoided, as courses >21 days are usually required and safety data are limited in this age-group. Adverse effects (nausea, vomiting, photosensitivity, vaginal candidiasis) are relatively uncommon. Persons given doxycycline prophylaxis should be warned to decrease exposure to direct sunlight, wear protective clothing (long sleeves and brimmed hat), and use sunscreen to minimize the possibility of photosensitivity.

Primaquine has also been used successfully as chemoprophylaxis, especially in areas of high prevalence of *Plasmodium vivax* and *Plasmodium ovale,* but there are limited data about its use in nonimmune children. Primaquine prophylaxis for children should only be given in consultation with the CDC or a travel medicine specialist.

Chloroquine, chloroquine-proguanil, and azithromycin do not provide adequate protection for children traveling to a chloroquine-resistant malaria-endemic area.

In areas of the world where *P. falciparum* remains fully chloroquine-sensitive (Haiti, the Dominican Republic, Central America west of the Panama Canal, and some countries in the Middle East), weekly chloroquine is the drug of choice for malaria chemoprophylaxis. Updated information on chloroquine susceptibility and recommended malaria prophylaxis is available at https://wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/malaria.

On leaving an area endemic for *P. vivax* or *P. ovale* after a prolonged visit (usually >3 months), travelers should consider terminal prophylaxis with primaquine (0.5 mg/kg base) daily, up to a maximum dose of 30 mg base or 52.6 mg salt, for 14 days, to eliminate extraerythrocytic forms of *P. vivax* and *P. ovale* and prevent relapses. Screening for glucose-6-phosphate dehydrogenase (G6PD) deficiency is mandatory before primaquine treatment, because primaquine is contraindicated in G6PD-deficient persons because it can cause severe hemolysis.

Small amounts of antimalarial drugs are secreted into breast milk. The amounts of transferred drug are not considered to be either harmful or sufficient to provide adequate prophylaxis against malaria. Prolonged infant exposure to doxycycline through breast milk is not advisable.

Self-treatment of presumptive malaria during travel remains controversial. It should never be substituted for seeking appropriate medical care, but it can be considered in special circumstances such as travel to remote areas, intolerance of prophylaxis, or refusal of chemoprophylaxis by the traveler. Self-treatment medication should be different from the prescribed chemoprophylaxis. The CDC or a travel medicine specialist should be consulted if self-treatment medication is being considered for a traveler.

THE RETURNING TRAVELER

Posttravel evaluations are part of travel medicine and continuing care. Physicians unfamiliar with diseases that occur in low- and middle-income countries often misdiagnose the cause of illness in a child returning from travel abroad. Among returning patients identified from the GeoSentinel Surveillance Network sites who were ill, the most common disorders (in descending order of frequency) included malaria, giardiasis, dengue fever, campylobacteriosis, cutaneous larva migrans, enteric fever, spotted fever (rickettsiosis), chikungunya fever, hepatitis A, and influenza. Returning pediatric travelers who are severely ill or with continued fevers should be seen in consultation with a pediatric travel medicine or infectious diseases specialist. The cause of fever may be suggested by the geographic area (Table 218.6) and incubation period (Table 218.7).

Among all persons returning from travel (children and adults), three major patterns of illness have been noted (Table 218.8). The etiology of each of these disease presentations in part depends on the country or geographic region visited (see Table 218.6). Table 218.9 provides suggestive clues to a diagnosis.

Table 218.6 Common Causes of Fever by Geographic Area

GEOGRAPHIC AREA	COMMON TROPICAL DISEASE-CAUSING FEVER	OTHER INFECTIONS CAUSING OUTBREAKS OR CLUSTERS IN TRAVELERS
Caribbean	Chikungunya, dengue, malaria (Haiti), Zika	Acute histoplasmosis, leptospirosis
Central America	Chikungunya, dengue, malaria (primarily *Plasmodium vivax*), Zika	Leptospirosis, histoplasmosis, coccidioidomycosis
South America	Chikungunya, dengue, malaria (primarily *P. vivax*), Zika	Bartonellosis, leptospirosis, enteric fever, histoplasmosis
Southcentral Asia	Dengue, enteric fever, malaria (primarily non–*P. falciparum*)	Chikungunya
Southeast Asia	Dengue, malaria (primarily non–*P. falciparum*)	Chikungunya, leptospirosis
Sub-Saharan Africa	Malaria (primarily *P. falciparum*), tick-borne rickettsiae (main cause of fever in southern Africa), acute schistosomiasis, dengue	

https://wwwnc.cdc.gov/travel/yellowbook/2024/posttravel-evaluation/general-approach-to-the-returned-traveler
From Centers for Disease Control and Prevention (CDC). International travel with infants and children: Yellow Book 2024. Wilson ME. Post-travel evaluation. Atlanta: CDC, 2024. Table 11-09.

Table 218.7 Common Infections by Incubation Period

DISEASE	USUAL INCUBATION PERIOD (RANGE)	DISTRIBUTION
INCUBATION <14 DAYS		
Chikungunya	2-4 days (1-14 days)	Tropics, subtropics
Dengue	4-8 days (3-14 days)	Topics, subtropics
Encephalitis, arboviral (Japanese encephalitis, tick-borne encephalitis, West Nile virus, other)	3-14 days (1-20 days)	Specific agents vary by region
Enteric fever (typhoid/paratyphoid)	7-18 days (3-60 days)	Especially in Indian subcontinent
Acute HIV	10-28 days (10 days to 6 weeks)	Worldwide
Influenza	1-3 days	Worldwide, can also be acquired while traveling
Legionellosis	5-6 days (2-10 days)	Widespread
Leptospirosis	7-12 days (2-26 days)	Widespread, most common in tropical areas
Malaria, *Plasmodium falciparum*	6-30 days (98% onset within 3 mo of travel)	Tropics, subtropics
Malaria, *Plasmodium vivax*	8 days to 12 mo (almost half have onset >30 days after completion of travel)	Widespread in tropics and subtropics
Spotted-fever rickettsiae	Few days to 2-3 wk	Causative species vary by region
Zika virus infection	3-14 days	Widespread in Latin America, endemic through much of Africa, Southeast Asia, and Pacific Islands
INCUBATION 14 DAYS TO 6 WEEKS		
Encephalitis, arboviral; enteric fever; acute HIV; leptospirosis; malaria	See above incubation periods for relevant diseases.	See above distribution for relevant diseases
Amebic liver abscess	Weeks to months	Most common in resource-poor countries
Hepatitis A	28-30 days (15-50 days)	Most common in resource-poor countries
Hepatitis E	26-42 days (2-9 wk)	Widespread
Acute schistosomiasis (Katayama syndrome)	4-8 wk	Most common in sub-Saharan Africa
INCUBATION >6 WK		
Amebic liver abscess, hepatitis E, malaria, acute schistosomiasis	See above incubation periods for relevant diseases.	See above distribution for relevant diseases
Hepatitis B	90 days (60-150 days)	Widespread
Leishmaniasis, visceral	2-10 mo (10 days to years)	Asia, Africa, Latin America, Southern Europe, and the Middle East
Tuberculosis	Primary, weeks; reactivation, years	Global distribution, rates, and levels of resistance vary widely

https://wwwnc.cdc.gov/travel/yellowbook/2024/posttravel-evaluation/general-approach-to-the-returned-traveler
From Centers for Disease Control and Prevention (CDC). International travel with infants and children: Yellow Book 2024. Fairley JK. General approach to the returned traveler. Atlanta: CDC, 2024. Table 11-02.

Fever is a particularly worrisome symptom. Children with a febrile/systemic illness after recent travel to a malarial destination should be promptly evaluated for malaria, especially if having traveled to sub-Sahara Africa and Papua New Guinea. *P. falciparum* malaria will generally present within 1-2 months after return from travel to a malaria-endemic area, but can occur within the first year after return. In contrast, symptoms of *P. vivax* or *P. ovale* malaria are typically later in onset after travel (i.e., several months), are milder in disease severity, and may occur in a relapsing pattern if undiagnosed or improperly treated. Other symptoms of malaria can be nonspecific and include chills, malaise, headache, myalgias, vomiting, diarrhea, cough, and possible seizures. Children are more likely than adults to have higher fevers and also gastrointestinal symptoms, hepatomegaly, splenomegaly, and severe anemia. Thrombocytopenia (without increased bleeding) and fever in a child returning from an endemic area are highly suggestive of malaria.

Thick and thin blood smears need to be performed for diagnosis *if* malaria is clinically suspected. If results are negative initially, two or more additional smears should be done 12-24 hours after the initial smears. The diagnostic yield of blood smears may be higher if obtained during a febrile episode. Rapid malaria antigen tests (BinaxNOW Malaria) are also available, are FDA-approved, and are sensitive for diagnosing *P. falciparum* malaria. At times, a polymerase chain reaction (PCR) assay is necessary to confirm the malarial parasite species. Treatment should be initiated immediately once the diagnosis is confirmed or empirically if presentation is severe with suspected malaria. Treatment should be determined in consultation with a pediatric infectious disease specialist and/or the CDC for updated information on the drugs of choice, which are similar to those for adults (see Chapter 334). Great caution should be used with young children, nonimmune patients, and pregnant patients with *P. falciparum* malaria, and hospitalization of these

Table 218.8 Patterns of Illness in Returning International Travelers

SYSTEMIC FEBRILE ILLNESS
Malaria
Dengue
Zika
Enteric fever (typhoid/paratyphoid)
Chikungunya virus
Spotted fever rickettsiae

Giardiasis (acute, persistent, or recurrent)
Entamoeba histolytica
Cryptosporidium spp.
Cyclospora cayetanensis
Presumed viral enteritis
DERMATOLOGIC MANIFESTATIONS
Rash with fever (dengue)
Arthropod-related dermatitis (insect bites)
Cutaneous larva migrans (*Ancylostoma braziliense*)
Bacterial skin infections—pyoderma, impetigo, ecthyma, erysipelas
Myiasis (tumbu and botfly)
Scabies
Tungiasis
Superficial mycosis
Animal bites
Leishmaniasis
Rickettsial diseases
Marine envenomation/dermatitis
Photoallergic dermatitis and phytophotodermatitis

Table 218.9 Common Clinical Findings and Associated Infections

COMMON CLINICAL FINDINGS	INFECTIONS TO CONSIDER AFTER TRAVEL
Fever and rash	Dengue, chikungunya, Zika, rickettsial infections, enteric fever (skin lesions may be sparse or absent), acute HIV infection, measles
Fever and abdominal pain	Enteric fever, amebic liver abscess
Undifferentiated fever and normal or low white blood cell count	Dengue, malaria, rickettsial infection, enteric fever, chikungunya, Zika
Fever and hemorrhage	Viral hemorrhagic fevers (dengue and others), meningococcemia, leptospirosis, rickettsial infections
Fever and arthralgia or myalgia, sometimes persistent	Chikungunya, dengue, Zika
Fever and eosinophilia	Acute schistosomiasis, drug hypersensitivity reaction, fascioliasis and other parasitic infections (rare)
Fever and pulmonary infiltrates	Common bacterial and viral pathogens, legionellosis, acute schistosomiasis, Q fever, leptospirosis
Fever and altered mental status	Cerebral malaria, viral or bacterial meningoencephalitis, African trypanosomiasis, scrub typhus
Mononucleosis syndrome	Epstein-Barr virus (EBV) infection, cytomegalovirus (CMV) infection, toxoplasmosis, acute HIV infection
Fever persisting >2 wk	Malaria, enteric fever, EBV infection, CMV infection, toxoplasmosis, acute HIV infection, acute schistosomiasis, brucellosis, tuberculosis, Q fever, visceral leishmaniasis (rare)
Fever with onset >6 wk after travel	*Plasmodium vivax* or *P. ovale* malaria, acute hepatitis (B, C, or E), tuberculosis, amebic liver abscess

From Centers for Disease Control and Prevention (CDC). International travel with infants and children: Yellow Book 2024. Wilson ME. Post-travel evaluation. Atlanta: CDC, 2024. Table 11-4. https://wwwnc.cdc.gov/travel/yellowbook/2024/posttravel-evaluation/general-approach-to-the-returned-traveler.

patients should be strongly considered until reliable improvement is observed.

Enteric (typhoid) fever should be considered in children with persistent or recurrent fevers, especially after return from the Indian subcontinent. Multiple blood cultures and a stool culture may both be necessary for diagnosis of enteric fever. **Dengue** is another cause of fever and systemic illness in ill travelers, particularly when returning from Southeast Asia, the Caribbean, Central and South America, or the Indian subcontinent. Many bacterial and protozoal causes of acute traveler's diarrhea may also result in fever and systemic symptoms in children. Additional travel-associated febrile, diarrheal, and dermatologic illnesses exist, of which the most common etiologies can be found in Tables 218.8 and 218.9.

THE ADOLESCENT TRAVELER

The preparation of an adolescent interested in traveling abroad can pose a challenge for most clinicians. Study abroad, gap year, humanitarian volunteer work, adventure, and tourism are among many reasons for travel to countries with limited resources. Although many travel-related problems discussed in this chapter are relevant to this group, other high-risk activities such as sexual intercourse, alcohol consumption, driving, use of illicit drugs, and adventure travel (e.g., mountain climbing, white water rafting, kayaking, biking) require special attention and discussion with the traveler and parents/guardians. Topics such as HIV exposure, sexually transmitted infections, sexual assault, and unplanned pregnancy may require specific preventive strategies such as condom use, contraception, and postexposure HIV prophylaxis.

Chapter 219

Fever

Linda S. Nield and Deepak Kamat

Fever is defined as a rectal temperature ≥38°C (100.4°F), and a fever >40°C (104°F) is called **hyperpyrexia**. Traditionally, body temperature fluctuates in a defined normal range (36.6–37.9°C [97.9–100.2°F] rectally), so that the highest point is reached in the early evening and the lowest point is reached in the morning. Any abnormal rise in body temperature should be considered a symptom and sign of an underlying condition.

PATHOGENESIS

Body temperature is regulated by thermosensitive neurons located in the preoptic or anterior hypothalamus that respond to changes in blood temperature, as well as by cold and warm receptors located in skin and muscles. Thermoregulatory responses include redirecting blood to or from cutaneous vascular beds, increased or decreased sweating, regulation of extracellular fluid (ECF) volume by arginine vasopressin, and behavioral responses, such as seeking a warmer or cooler environmental temperature.

Three different mechanisms can produce fever: pyrogens, heat production exceeding heat loss, and defective heat loss. The first mechanism involves endogenous and exogenous pyrogens that raise the hypothalamic temperature set point. **Endogenous pyrogens** include the cytokines interleukin (IL)-1 and IL-6, tumor necrosis factor (TNF)-α, and interferon (IFN)-β and IFN-γ. Stimulated leukocytes and other cells produce lipids that also serve as endogenous pyrogens. The best-studied lipid mediator is prostaglandin E_2, which attaches to the prostaglandin receptors in the hypothalamus to produce the new temperature set point. Along with infectious diseases, drugs, malignancy, and inflammatory diseases can cause fever through the production of endogenous pyrogens. Some substances produced within the body are not pyrogens but are capable of stimulating endogenous pyrogens. Such substances include antigen-antibody complexes in the presence of complement components, lymphocyte products, bile acids, and androgenic steroid metabolites. **Exogenous pyrogens** come from outside the body and consist of mainly infectious pathogens and drugs. Microbes, microbial toxins, or other products of microbes are the most common exogenous pyrogens, which stimulate macrophages and other cells to produce endogenous pyrogens. **Endotoxin** is one of the few substances that can directly affect thermoregulation in the hypothalamus and stimulate endogenous pyrogen release. Many drugs cause fever, and the mechanism for increasing body temperature varies with the class of drug. Drugs that are known to cause fever include vancomycin, amphotericin B, and allopurinol.

Heat production exceeding heat loss is the second mechanism that leads to fever; examples include salicylate poisoning and malignant hyperthermia. **Defective heat loss**, the third mechanism, may occur in children with ectodermal dysplasia or victims of severe heat exposure.

ETIOLOGY

The causes of fever can be organized into four main categories: *infectious, inflammatory, neoplastic,* and *miscellaneous.* Self-limited viral infections (common cold, influenza, gastroenteritis) and uncomplicated bacterial infections (otitis media, pharyngitis, sinusitis) are the most common causes of acute fever. The body temperature rarely rises above potentially lethal levels (42°C [107.6°F]) in the neurologically intact child unless extreme hyperthermic environmental conditions are present or other extenuating circumstances exist, such as underlying malignant hyperthermia or thyrotoxicosis.

The pattern of the fever can provide clues to the underlying etiology. Viral infections typically are associated with a slow decline of fever over several days, whereas bacterial infections are often associated with a prompt resolution of fever after effective antimicrobial treatment. Although antimicrobials can result in rapid elimination of bacteria, if tissue injury has been extensive, the inflammatory response and fever can continue for days after all microbes have been eradicated.

Intermittent fever is an exaggerated circadian rhythm that includes a period of normal temperatures on most days; extremely wide fluctuations may be termed **septic** or **hectic fever**. **Sustained fever** is persistent and does not vary by >0.5°C (0.9°F)/day. **Remittent fever** is persistent and varies by >0.5°C/day. **Relapsing fever** is characterized by febrile periods separated by intervals of normal temperature; **tertian fever** occurs on the first and third days (malaria caused by *Plasmodium vivax*), and **quartan fever** occurs on the first and fourth days (malaria caused by *Plasmodium malariae*). Diseases characterized by relapsing fevers should be distinguished from infectious diseases that tend to relapse (Table 219.1). **Biphasic fever** indicates a single illness with two distinct periods (**camelback fever** pattern); poliomyelitis is the classic example. A biphasic course is also characteristic of other enteroviral infections, leptospirosis, dengue fever, yellow fever, Colorado tick fever, spirillary rat-bite fever (caused by *Spirillum minus*), and the African hemorrhagic fevers (Marburg, Ebola, and Lassa fevers). The term **periodic fever** is used narrowly to describe fever syndromes with a regular periodicity (cyclic neutropenia and periodic fever, aphthous

Lyme disease *(Borrelia burgdorferi)*
Lymphocytic choriomeningitis (LCM) infection
Malaria
Melioidosis *(Pseudomonas pseudomallei)*
Noninfluenza respiratory viral infection
Oroya fever *(Bartonella bacilliformis)*
Q fever *(Coxiella burnetii)*
Rat-bite fever (*Spirillum minus*)
Relapsing fever *(Borrelia recurrentis)*
Syphilis *(Treponema pallidum)*
Tuberculosis
Typhoid fever *(Salmonella typhi)*
Visceral leishmaniasis
Yellow fever
NONINFECTIOUS CAUSES
Behçet disease
Crohn disease
Leukocytoclastic vasculitis syndromes
Sweet syndrome
Systemic lupus erythematosus and other autoimmune disorders
Weber-Christian disease (panniculitis)
Others
PERIODIC FEVER SYNDROMES (SEE CHAPTER 204)
Cyclic neutropenia
Familial Mediterranean fever
Hyper–immunoglobulin D syndrome
Muckle-Wells syndrome
Periodic fever, aphthous stomatitis, pharyngitis, and adenopathy (PFAPA)
Tumor necrosis factor receptor–associated periodic syndrome [TRAPS])
Others

MIS-C, multisystem inflammatory syndrome in children.

stomatitis, pharyngitis, adenopathy) or more broadly to include disorders characterized by recurrent episodes of fever that do not follow a strictly periodic pattern (familial Mediterranean fever, TNF receptor–associated periodic syndrome [Hibernian fever], hyper-IgD syndrome, Muckle-Wells syndrome) (see Chapter 204). **Factitious fever**, or self-induced fever, may be caused by intentional manipulation of the thermometer or injection of pyrogenic material.

The **double quotidian fever** (or fever that peaks twice in 24 hours) is classically associated with juvenile idiopathic arthritis. In general, a single isolated fever spike is not associated with an infectious disease. Such a spike can be attributed to the infusion of blood products and some drugs, as well as some procedures or manipulation of a catheter on a colonized or infected body surface. Similarly, temperatures in excess of 41°C (105.8°F) are most often associated with a noninfectious cause. Causes for very high temperatures (>41°C [105.8°F]) include central fever (resulting from central nervous system dysfunction involving the hypothalamus or spinal cord injury), malignant hyperthermia, malignant neuroleptic syndrome, drug fever, or heat stroke. Temperatures that are lower than normal (<36°C [96.8°F]) can be associated with overwhelming sepsis but are more often related to cold exposure, hypothyroidism, autonomic instability, central nervous system lesions, or overuse of antipyretics.

CLINICAL FEATURES

The clinical features of fever can range from no symptoms to extreme malaise. Children might complain of feeling hot or cold, display facial flushing, and experience shivering. Fatigue and irritability may be evident. Parents often report that the child looks ill or pale and has a decreased appetite. The underlying etiology also produces accompanying symptoms. Although the underlying etiologies can manifest in varied ways clinically, there are some predictable features. For example, **fever with petechiae** in an ill-appearing patient indicates the high possibility of life-threatening conditions such as meningococcemia, Rocky Mountain spotted fever, or acute bacterial endocarditis. The unusual symptom of loss of smell and taste can accompany fever in COVID-19.

Changes in heart rate, most frequently tachycardia, accompany fever. Normally heart rate rises by 10 beats/min per 1°C (1.8°F) rise in temperature for children >2 months old. Relative tachycardia, when the pulse rate is elevated disproportionately to the temperature, is usually caused by noninfectious diseases or infectious diseases in which a toxin is responsible for the clinical manifestations. **Relative bradycardia** (temperature-pulse dissociation), when the pulse rate remains low in the presence of fever, can accompany typhoid fever, brucellosis, leptospirosis, or drug fever. Bradycardia in the presence of fever also may be a result of a conduction defect resulting from cardiac involvement with acute rheumatic fever, Lyme disease, viral myocarditis, or infective endocarditis.

EVALUATION

Most acute febrile episodes in a normal host can be diagnosed by a careful history and physical examination and require few, if any, laboratory tests. Because infection is the most likely etiology of acute fever, the evaluation should initially be geared to discovering an underlying infectious cause (Table 219.2 and Chapter 220). The details of the history should include the onset and pattern of fever and any accompanying signs and symptoms. The patient often displays signs or symptoms that provide clues to the cause of the fever. Exposures to other ill persons at home, daycare, and school should be noted, along with any recent travel, animal exposures, or medications. The past medical history should include information about underlying immune deficiencies or other major illnesses and receipt of childhood vaccines.

Physical examination should begin with a complete evaluation of vital signs, which should include pulse oximetry, because hypoxia may indicate lower respiratory infection. In the acutely febrile child, the physical examination should focus on any localized complaints, but a complete head-to-toe screen is recommended, because clues to the underlying diagnosis may be found. For example, palm and sole lesions may be discovered during a thorough skin examination and provide a clue for infection with coxsackievirus.

Table 219.2 Evaluation of Acute Fever

Thorough history: onset, other symptoms, exposures (daycare, school, family, pets, playmates, other ill individuals), travel, medications, other underlying disorders, immunizations
Physical examination: complete, with focus on localizing symptoms
Laboratory studies on a case-by-case basis:
- Blood: complete blood count, culture, C-reactive protein, procalcitonin, sedimentation rate
- Cerebrospinal fluid: cell count, culture, glucose, Gram stain, NAAT for herpes simplex virus, protein
- Nasopharyngeal: NAAT for respiratory viruses
- Pharyngeal: NAAT and culture for group A *Streptococcus*
- Stool: calprotectin, culture, NAAT for enteric pathogens
- Urine: culture, gross and microscopic analysis, NAAT for genital pathogens
- Others (such as chest radiograph or other radiologic imaging)

NAAT, Nucleic acid amplification test.

If a fever has an obvious cause, laboratory evaluation may not be required, and management is tailored to the underlying cause with as-needed reevaluation. If the cause of the fever is not apparent, further diagnostic evaluation should be considered on a case-by-case basis. The history of presentation and abnormal physical examination findings guide the evaluation. The child with respiratory symptoms and hypoxia may require a chest radiograph, rapid antigen testing for respiratory syncytial virus or influenza, or polymerase chain reaction (PCR) testing for SARS-CoV-2. The child with pharyngitis can benefit from PCR testing for group A *Streptococcus* and a throat culture. Dysuria, back pain, or a history of vesicoureteral reflux should prompt a urinalysis and urine culture, and bloody diarrhea should prompt a stool culture. A complete blood count and blood culture should be considered in the ill-appearing child, along with cerebrospinal fluid studies if the child has neck stiffness or if the possibility of meningitis is considered. Well-defined high-risk groups require a more extensive evaluation on the basis of age, associated disease, or immunodeficiency status and might warrant prompt antimicrobial therapy before a pathogen is identified. Fever in neonates and young infants (0-3 months old), fever in older children, and fever of unknown origin are discussed in Chapters 220, 221, and 222, respectively.

MANAGEMENT

Although fever is a common parental worry, no evidence supports the belief that high fever can result in brain damage or other bodily harm, except in rare instances of febrile status epilepticus and heat stroke. *Treating fever in self-limiting illnesses for the sole reason of bringing the body temperature back to normal is not necessary in the otherwise healthy child.* Most evidence suggests that fever is an adaptive response and should be treated only in select circumstances. In humans, increased temperatures are associated with decreased microbial replication and an increased inflammatory response. Although fever can have beneficial effects, it also increases oxygen consumption, carbon dioxide production, and cardiac output and can exacerbate cardiac insufficiency in patients with heart disease or chronic anemia (e.g., sickle cell disease), pulmonary insufficiency in patients with chronic lung disease, and metabolic instability in patients with diabetes mellitus or inborn errors of metabolism. Children between 6 months and 5 years of age are at increased risk for simple febrile seizures. *The focus of the evaluation and treatment of febrile seizures is aimed at determining the underlying cause of the fever.* Children with idiopathic epilepsy also often have an increased frequency of seizures associated with a fever. High fever during pregnancy may be teratogenic.

Fever with temperatures <39°C (102.2°F) in healthy children generally does not require treatment. However, as temperatures become higher, patients tend to become more uncomfortable, and treatment of fever is then reasonable. If a child is included in one of the high-risk groups previously discussed or if the child's caregiver is concerned that the fever is adversely affecting the child's behavior and causing discomfort, treatment may be given to hasten the resolution of the fever.

Other than providing symptomatic relief, antipyretic therapy does not change the course of infectious diseases. Encouraging good hydration is the first step to replacing fluids that are lost related to the increased metabolic demands and insensible losses of fever. Antipyretic therapy is beneficial in high-risk patients and patients with discomfort. **Hyperpyrexia** (>41°C [105.8°F]) indicates high probability of a hypothalamic disorder or central nervous system injury (hemorrhage, other etiology) and should be treated with antipyretics. Some studies show that hyperpyrexia may be associated with a significantly increased risk of serious bacterial infection, but other studies have not substantiated this relationship. The most common antipyretics are **acetaminophen 10-15 mg/kg/dose every 4 hours and ibuprofen in children >6 months old at 5-10 mg/kg/dose every 8 hours**. Antipyretics reduce fever by reducing production of prostaglandins. If used appropriately, antipyretics are safe; potential adverse effects include liver damage (acetaminophen) and gastrointestinal or kidney disturbances (ibuprofen). To reduce fever most safely, the caregiver should choose one type of medication and clearly record the dose and time of administration so that overdosage does not occur, especially if multiple caregivers are involved in the management. Physical measures such as tepid baths and cooling blankets are not considered effective to reduce fever. Evidence is also scarce for the use of complementary and alternative medicine interventions.

Fever caused by specific underlying etiologies resolves when the condition is properly treated. Examples include administration of intravenous immunoglobulin to treat Kawasaki disease or the administration of antibiotics to treat bacterial infections.

Chapter 220

Fever Without a Focus in the Neonate and Young Infant

Laura Brower and Samir S. Shah

Fever is a common reason for neonates and young infants to undergo medical evaluation in the hospital or ambulatory setting. For this age-group (0-3 months), **fever without a focus** refers to a rectal temperature of 38°C (100.4°F) or greater without other presenting signs or symptoms. The evaluation of these patients can be challenging because of the difficulty distinguishing between a serious infection (bacterial or viral) and a self-limited viral illness. The etiology and evaluation of fever without a focus depend on the age of the child. Three age-groups are typically considered: neonates 0-28 days, young infants 29-90 days, and children 3-36 months.

ETIOLOGY AND EPIDEMIOLOGY

Serious bacterial infection (SBI) occurs in 7–13% of neonates and young infants with fever. In this group, the most common SBIs are urinary tract infection (UTI; 5–13%), bacteremia (1–2%), and meningitis (0.2–0.5%). The risk for SBI is highest in those appearing ill (in contrast to well appearing) and those with risk factors and is inversely related to postnatal age. The term **invasive bacterial infection (IBI)**, which refers to bacteremia and meningitis, recognizes that infants with UTIs may be managed differently (e.g., often with oral antibiotics) than those with bacteremia or meningitis. *Escherichia coli* is the most common organism causing SBI, followed by group B *Streptococcus* (GBS). The frequency of GBS infections has decreased as a consequence of increased screening of pregnant women and use of intrapartum antibiotic prophylaxis. Other, less common organisms include *Klebsiella* spp., *Enterococcus* spp., *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Staphylococcus aureus* (Table 220.1). *Listeria monocytogenes* is a rare cause of neonatal infections, potentially related to changes in public health education and improvements in food safety. Additional details about specific bacteria are available in the following chapters: *E. coli* (see Chapter 246), GBS (see Chapter 230), *S. pneumoniae* (see Chapter 228), *N. meningitidis* (see Chapter 237), *S. aureus* (see Chapter 227.1), and *L. monocytogenes* (see Chapter 234). Specific bacterial infections that can present with fever in this age-group, although often with symptoms other than isolated fever, include pneumonia (see Chapter 449), gastroenteritis (see Chapter 387), osteomyelitis (see Chapter 725), septic arthritis (see Chapter 726), omphalitis (see Chapter 144), cellulitis, and other skin and soft tissue infections (see Chapter 706).

Herpes simplex virus **(HSV)** infections (see Chapter 299) should also be considered in febrile neonates, particularly those under 28 days old, given the high rate of mortality and significant morbidity among survivors. Neonatal HSV is rare, with a prevalence of 0.2–0.3% among febrile neonates. Most of these infections are caused by HSV type 2, though HSV type 1 can also cause neonatal infection. Neonates with disseminated disease and skin, eye, and mouth (SEM) disease typically present at 5-12 days of life. Neonates with central nervous system (CNS) disease generally present at 16-19 days. Perinatally acquired HSV occasionally manifests beyond 28 days of age, although most cases beyond 28 days of age represent postnatal acquisition.

In febrile infants who *appear well,* viral illnesses are much more common than bacterial or serious viral infections. The most common viruses include respiratory syncytial virus (RSV; see Chapter 307), enteroviruses (see Chapter 297), influenza viruses (see Chapter 305), parainfluenza viruses (see Chapter 306), human metapneumovirus (see Chapter 308), adenovirus (see Chapter 309), parechoviruses (see Chapter 297), and rhinovirus (see Chapter 310).

CLINICAL MANIFESTATIONS

In neonates and young infants, bacterial and viral infections can present with isolated fever or nonspecific symptoms, making diagnosis of serious illnesses challenging. Some neonates and young infants will have signs of systemic illness at presentation, including abnormal temperature (hypothermia <36°C [96.8°F], fever ≥38°C [100.4°F]), abnormal respiratory examination (tachypnea >60 breaths/min, respiratory distress, apnea), abnormal circulatory examination (tachycardia >180 beats/min, delayed capillary refill >3 seconds, weak or bounding pulses), abnormal abdominal examination, abnormal neurologic

Chapter 220

Fever Without a Focus in the Neonate and Young Infant

Laura Brower and Samir S. Shah

Fever is a common reason for neonates and young infants to undergo medical evaluation in the hospital or ambulatory setting. For this age-group (0-3 months), **fever without a focus** refers to a rectal temperature of 38°C (100.4°F) or greater without other presenting signs or symptoms. The evaluation of these patients can be challenging because of the difficulty distinguishing between a serious infection (bacterial or viral) and a self-limited viral illness. The etiology and evaluation of fever without a focus depend on the age of the child. Three age-groups are typically considered: neonates 0-28 days, young infants 29-90 days, and children 3-36 months.

ETIOLOGY AND EPIDEMIOLOGY

Serious bacterial infection (SBI) occurs in 7–13% of neonates and young infants with fever. In this group, the most common SBIs are urinary tract infection (UTI; 5–13%), bacteremia (1–2%), and meningitis (0.2–0.5%). The risk for SBI is highest in those appearing ill (in contrast to well appearing) and those with risk factors and is inversely related to postnatal age. The term **invasive bacterial infection (IBI)**, which refers to bacteremia and meningitis, recognizes that infants with UTIs may be managed differently (e.g., often with oral antibiotics) than those with bacteremia or meningitis. *Escherichia coli* is the most common organism causing SBI, followed by group B *Streptococcus* (GBS). The frequency of GBS infections has decreased as a consequence of increased screening of pregnant women and use of intrapartum antibiotic prophylaxis. Other, less common organisms include *Klebsiella* spp., *Enterococcus* spp., *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Staphylococcus aureus* (Table 220.1). *Listeria monocytogenes* is a rare cause of neonatal infections, potentially related to changes in public health education and improvements in food safety. Additional details about specific bacteria are available in the following chapters: *E. coli* (see Chapter 246), GBS (see Chapter 230), *S. pneumoniae* (see Chapter 228), *N. meningitidis* (see Chapter 237), *S. aureus* (see Chapter 227.1), and *L. monocytogenes* (see Chapter 234). Specific bacterial infections that can present with fever in this age-group, although often with symptoms other than isolated fever, include pneumonia (see Chapter 449), gastroenteritis (see Chapter 387), osteomyelitis (see Chapter 725), septic arthritis (see Chapter 726), omphalitis (see Chapter 144), cellulitis, and other skin and soft tissue infections (see Chapter 706).

Herpes simplex virus **(HSV)** infections (see Chapter 299) should also be considered in febrile neonates, particularly those under 28 days old, given the high rate of mortality and significant morbidity among survivors. Neonatal HSV is rare, with a prevalence of 0.2–0.3% among febrile neonates. Most of these infections are caused by HSV type 2, though HSV type 1 can also cause neonatal infection. Neonates with disseminated disease and skin, eye, and mouth (SEM) disease typically present at 5-12 days of life. Neonates with central nervous system (CNS) disease generally present at 16-19 days. Perinatally acquired HSV occasionally manifests beyond 28 days of age, although most cases beyond 28 days of age represent postnatal acquisition.

In febrile infants who *appear well,* viral illnesses are much more common than bacterial or serious viral infections. The most common viruses include respiratory syncytial virus (RSV; see Chapter 307), enteroviruses (see Chapter 297), influenza viruses (see Chapter 305), parainfluenza viruses (see Chapter 306), human metapneumovirus (see Chapter 308), adenovirus (see Chapter 309), parechoviruses (see Chapter 297), and rhinovirus (see Chapter 310).

CLINICAL MANIFESTATIONS

In neonates and young infants, bacterial and viral infections can present with isolated fever or nonspecific symptoms, making diagnosis of serious illnesses challenging. Some neonates and young infants will have signs of systemic illness at presentation, including abnormal temperature (hypothermia <36°C [96.8°F], fever ≥38°C [100.4°F]), abnormal respiratory examination (tachypnea >60 breaths/min, respiratory distress, apnea), abnormal circulatory examination (tachycardia >180 beats/min, delayed capillary refill >3 seconds, weak or bounding pulses), abnormal abdominal examination, abnormal neurologic

Table 220.1 Bacterial Pathogens in Neonates and Young Infants with Urinary Tract Infection, Bacteremia, or Meningitis

FREQUENCY	URINARY TRACT INFECTION	BACTEREMIA AND MENINGITIS
Common	*Escherichia coli*	*Escherichia coli* Group B *Streptococcus*
Less common	*Klebsiella* spp. *Enterococcus* spp.	*Listeria monocytogenes* *Streptococcus pneumoniae* *Staphylococcus aureus* *Klebsiella* spp.
Rare	Group B *Streptococcus* *Staphylococcus aureus* *Pseudomonas aeruginosa* *Enterobacter* spp. *Citrobacter* spp. *Proteus mirabilis*	*Neisseria meningitidis* *Salmonella* spp. *Enterobacter* spp. *Enterococcus* spp. *Cronobacter sakazakii* *Haemophilus influenzae* *Citrobacter*

examination (lethargy, irritability, alterations in tone), or abnormal skin examination (rash, petechiae, cyanosis). Infants with **septic arthritis** or **osteomyelitis** may appear well except for signs around the involved joint or bone or may only manifest with *pseudoparalysis* (disuse) and *paradoxical irritability* (infant experiences pain during attempts to comfort the child).

DIAGNOSIS

Historically, all neonates <60 or <90 days of age were hospitalized; underwent laboratory evaluation of the blood, urine, and cerebrospinal fluid (CSF); and received empirical antibiotics. Additionally, some patients had stool cultures, had chest radiographs, had HSV evaluation, and/or received empirical antiviral agents. Under this approach, many infants without SBI or serious viral infection received evaluation, treatment, and hospitalization. Protocols were subsequently developed to identify infants at lower risk of SBI, who may be managed outside the hospital setting. The most current protocol is the American Academy of Pediatrics (AAP) guideline, which considers UTIs separately from bacteremia and meningitis (Table 220.2). Despite protocols, substantial variation continues to exist in the approach to and management

Table 220.2 Management of Fever Without Source in Infants 0-36 Months Old

GROUP	MANAGEMENT
Any toxic-appearing child 0–36 mo and temperature ≥38°C (100.4°F)	Hospitalize, cultures (blood, urine, CSF) plus other tests*, parenteral antibiotics
WELL-APPEARING CHILD	
Child <22 days and temperature ≥38°C (100.4°F)	Hospitalize, cultures (blood, urine, CSF) plus other tests*, parenteral antibiotics
Child 22–60 days and temperature ≥38°C (100.4°F)	**Three-Step Process** 1. Determine risk based on history, physical examination, and laboratory studies. Low risk: • Uncomplicated medical history • Well-appearing physical examination • Normal laboratory studies • Urine: negative leukocyte esterase and nitrite, ≤5 WBC/hpf centrifuged and <10 WBC/hpf uncentrifuged • Inflammatory markers: temperature ≤38.5°C, procalcitonin ≤0.5 ng/mL, CRP ≤20 mg/L, absolute neutrophil count ≤4,000-5,200/mm^3 • Stool studies if diarrhea (no RBC and <5 WBC/hpf) 2. If child *fulfills all low-risk criteria*, use age to determine need for LP, parenteral antimicrobials, and hospital observation. • **Age 22-28 days**: Obtain UA, blood culture, inflammatory markers. May perform LP. May administer parenteral antimicrobials. Observe in hospital. • **Age 29-60 days old**: Obtain UA, blood culture, inflammatory markers. Need not perform LP. Need not administer antimicrobials. Observe closely at home with follow-up within 24-36 hr. 3. If child does not fulfill all low-risk criteria, use age and lab results to determine need for LP, antimicrobials, and hospital observation. • **Age 22-28 days** with abnormal UA and normal inflammatory markers: May perform LP. Administer parenteral antimicrobials. Observe in hospital. • **Age 22-28 days** with abnormal inflammatory markers: Perform LP. If CSF pleocytosis, CSF uninterpretable, or abnormal UA, administer parenteral antimicrobials and observe in hospital. If CSF and UA are normal, may observe at home after parenteral antimicrobials or observe in the hospital with or without parenteral antimicrobials. • **Age 29-60 days** with abnormal UA and normal inflammatory markers: Administer oral antimicrobials. May observe closely at home with follow-up in 12-24 hr. • **Age 29-60 days** with abnormal inflammatory markers: May perform LP. If CSF pleocytosis, administer parenteral antimicrobials and observe in hospital. If CSF is normal, may administer parenteral or oral antimicrobials and may observe closely in hospital or at home. If CSF is not available or uninterpretable, administer parenteral antimicrobials and may observe closely in hospital or at home.
Child 2-36 mo and temperature 38–39°C (100.4–102.2°F)	Reassurance that diagnosis is likely self-limited viral infection, but advise return with persistence of fever, temperatures >39°C (102.2°F), and/or new signs and symptoms.
Child 2-36 mo and temperature >39°C (102.2°F)	**Two-Step Process** 1. Determine immunization status. 2. If received conjugate pneumococcal and *Haemophilus influenzae* type b vaccines, obtain urine studies (urine WBC, leukocyte esterase, nitrite, and culture) for all females, all males <6 mo old, all uncircumcised males <2 yr, and all children with recurrent urinary tract infections. If did not receive conjugate pneumococcal and *H. influenzae* type b vaccines, manage according to the 1993 Guidelines (see Baraff et al. *Ann Emerg Med.* 1993;22:1198–1210).

*Other tests may include chest radiograph, stool studies, herpes simplex and other virus polymerase chain reaction.
CSF, Cerebrospinal fluid; hpf, high-powered field; LP, lumbar puncture; RBC, red blood cell; UA, urinalysis; WBC, white blood cell.
Modified from Huppler A. Fever. In: Kliegman RM, Toth H, Bordini BJ, Basel D, eds. *Nelson Pediatric Symptom-Based Diagnosis*, 2nd ed. Philadelphia: Elsevier; 2023: Table 52.5, p. 971; with data from Pantell RH, Roberts KB, Adams WG, et al. Evaluation and management of well appearing febrile infants 8 to 60 days old. *Pediatrics.* 2021;148(2):e2021052228.

of the febrile infant. *It must be emphasized that these criteria apply to the well-appearing child; those who appear critically ill (septic) require prompt evaluation, resuscitation, and empiric antibiotic therapy (within 1 hour).*

In the past, experts advocated that all neonates ≤28 days old undergo a complete evaluation for serious infection, receive empirical antimicrobials, and be hospitalized. In prior risk criteria, one allowed neonates ≤28 days to be designated as "low risk" and managed outside the hospital without antimicrobials. In one study, <1% of low-risk infants ≤28 days old had SBI; however, in another study applying the other criteria to neonates, 3–4% of those classified as low risk had SBI. In the current protocols, neonates 22-28 days who meet certain low-risk criteria can be managed outside the hospital; in one study, the risk of bacteremia in this age-group was lower than in infants <22 days (1.6% vs 3.3–5.3%).

Young febrile infants ≥29 days old who *appear ill* (with signs of systemic illness) require complete evaluation for serious infection, empiric antimicrobials, and hospitalization; however, well-appearing infants can be managed safely as outpatients using low-risk criteria as indicated in Table 220.2. With each of these approaches, infants must have a normal physical examination, must be able to reliably obtain close follow-up, and must meet certain laboratory and/or radiographic criteria. Based on these protocols, all infants meeting the previous criteria would undergo lumbar puncture (LP), whereas low-risk infants meeting other criteria and following the current protocols would not. There is substantial variation in clinical practice in the performance of LPs in well-appearing infants >28 days. When deciding whether to perform an LP in this age-group, clinicians should consider multiple factors, including the home situation and the ability to contact the family.

The protocols discussed in Table 220.2 were initially developed for use in the emergency department (ED). Infants evaluated in the office setting may warrant a different approach when a relationship between the physician and family already exists to facilitate clear communication and timely follow-up. In one large study of febrile infants <3 months old who were initially evaluated for fever in the office setting, clinicians hospitalized only 36% of infants but initiated antibiotics in 61 of the 63 infants with bacteremia or bacterial meningitis. These findings suggest that, with very close follow-up (including multiple in-person visits or frequent contacts by telephone), some febrile infants perceived to be at low risk for **invasive bacterial infection** (bacteremia and meningitis) on the basis of history, physical examination, and normal but limited laboratory testing can be managed in an office-based setting. It is important to note that 3% of infants with SBI did not initially receive empiric antibiotics, necessitating careful consideration of risks and benefits of selective rather than universal testing and empiric antibiotic treatment of febrile infants evaluated in the office setting.

Viral Respiratory Illness

Several studies have demonstrated a decreased risk of SBI in infants with positive testing for influenza, RSV, and other respiratory viral illnesses, although the risk of UTI remains significant. In one prospective study, the risk of SBI in neonates <28 days old was not altered by RSV status. Given these data, young febrile infants with bronchiolitis may not require LP, particularly if they can be closely observed or have close follow-up.

Urinary Tract Infection and Bacterial Meningitis

In the past, infants with abnormal findings on urinalysis (UA) would undergo complete evaluation for infection, including LP. In well-appearing infants >28 days old with an abnormal UA, some evidence suggests that the risk of bacterial meningitis is extremely low: <0.5%. For neonates 0-28 days, the risk of concomitant bacterial meningitis with UTI is 1–2%.

CSF pleocytosis in the absence of bacterial meningitis (i.e., **sterile pleocytosis**) has been reported in ~23% infants with UTI. The cause is uncertain, with some studies attributing this phenomenon to traumatic LPs or undetected viral infection rather than inflammation in the context of systemic illness.

LABORATORY DIAGNOSIS

Complete Blood Count

The peripheral complete blood cell count (CBC) and differential are frequently obtained by providers when evaluating febrile neonates and infants. The white blood cell (WBC) count alone cannot accurately predict SBI risk. In one series, isolated use of the WBC cutoffs of outside 5,000-15,000 WBCs/mm^3 would miss at least 33% of infants with bacteremia and 40% of those with meningitis. A prospective study found no increased risk of SBI in febrile, well-appearing infants with leukopenia (WBC count <5,000/mm^3). The WBC count combined with other factors may help determine an infant's risk of SBI, but it should not be used in isolation to predict infection risk. The absolute neutrophil count (ANC) has also been used in evaluating the risk of serious infection. Two recent large studies derived ANC cutoffs of greater than 4,000 and 5,200 per mm^3 for use in specific protocols; however, these protocols used ANC in conjunction with other markers.

Blood Culture

The ability to identify pathogens in the blood depends on the volume of blood, the timing of the blood culture in relation to antimicrobial administration, and, to a lesser degree, the number of blood cultures obtained. A negative blood culture does not exclude the possibility of bacterial meningitis; in one study, 38% of infants with culture-proven bacterial meningitis had negative blood cultures. For additional information on the time to positivity of blood cultures in neonates and young infants, see "Discharge from the Hospital."

Urinalysis

Different methods can assist in making a presumptive diagnosis of UTI while awaiting results of a urine culture. *Traditional* UA consists of dipstick biochemical analysis of urine for nitrites or leukocyte esterase (LE) and microscopic examination of the urine for WBCs and bacteria. One study found that the traditional UA had a higher negative predictive value (NPV) than dipstick alone (99.2% vs 98.7%), but that dipstick alone had a higher positive predictive value (PPV, 66.8% for dipstick alone vs 51.2% for traditional UA). *Enhanced* UA includes hemocytometer cell count (to decrease variability of urine cell counts) and Gram stain on uncentrifuged urine. The enhanced UA has a higher sensitivity but comparable specificity to traditional UA. However, the enhanced UA has not been studied in the most common protocols for evaluation of the febrile infant, and many institutions/office practices do not perform this test.

Cerebrospinal Fluid

CSF evaluation consists of culture and Gram stain, cell count, glucose, and protein. Polymerase chain reaction (PCR) testing may also be sent based on the clinical scenario, usually for enterovirus or HSV (some include bacterial pathogens). Normal CSF parameters vary by age of the infant and should be interpreted in combination with other clinical and historical risk factors, given that some infants with normal CSF parameters may rarely have CNS infections (Table 220.3). The CSF Gram stain can be a useful adjunct to other CSF parameters given the high specificity of the test (99.3–99.9%; i.e., relatively few false-positive results), although the range of reported sensitivity is much broader (67–94.1%).

The interpretation of CSF can be challenging in the setting of a traumatic LP, where the CSF is contaminated with peripheral blood. Some clinicians assume a ratio of WBCs to red blood cells (RBCs) of 1:500 in the CSF. Others advocate calculating the expected CSF WBCs based on the peripheral blood WBCs and RBCs and then using the observed-to-predicted ratio of CSF WBCs to aid in the identification of bacterial meningitis. This calculation assumes that the ratio of WBCs to RBCs in the peripheral blood remains constant after introduction into the CSF. Next-generation molecular testing is helpful in identifying the most

*Data from Byington CL, Kendrick J, Sheng X. Normative cerebrospinal fluid profiles in febrile infants. *J Pediatr*. 2011;158(1):130–134. All infants had nontraumatic lumbar puncture (LP) and no evidence of bacterial or viral infection.

†Data from Chadwick SL, Wilson JW, Levin JE, Martin JM. Cerebrospinal fluid characteristics of infants who present to the emergency department with fever: establishing normal values by week of age. *Pediatr Infect Dis J*. 2011;30(4):e63–e67. All infants were excluded if they had identified viral or bacterial meningitis, positive blood or urine cultures, a ventriculoperitoneal shunt, recent neurosurgery/antibiotics/seizure, or a traumatic LP.

‡Data from Kestenbaum LA, Ebberson J, Zorc JJ, et al. Defining cerebrospinal fluid white blood cell count reference values in neonates and young infants. *Pediatrics*. 2010;125(2):257–264. Infants were excluded for traumatic LP, serious bacterial infection, congenital infection, seizure, presence of ventricular shunt, or positive CSF testing for enterovirus.

§Data from Shah SS, Ebberson J, Kestenbaum LA, et al. Age-specific reference values for cerebrospinal fluid protein concentration in neonates and young infants. *J Hosp Med*. 2011;6(1):22–27. Infants were excluded for traumatic LP, serious bacterial infection, congenital infection, seizure, presence of a ventricular shunt, positive CSF testing for enterovirus, or elevated serum bilirubin.

#Data from Thomson J, Sucharew H, Cruz AT, et al. Cerebrospinal fluid reference values for young infants undergoing lumbar puncture. *Pediatrics*. 2018;141(3):e20173405. Infants were excluded for missing any component of the CSF profile, traumatic LP, serious bacterial infection, viral CNS infection, non-CNS HSV disease, or prolonged hospital length of stay.

common bacterial and viral pathogens despite a traumatic LP; results are often available within a few hours.

One retrospective cohort study concluded that an observed/predicted CSF WBC ratio of ≤0.01 was helpful in predicting the absence of bacterial meningitis; however, another retrospective cohort study and one case series of traumatic LPs concluded that adjustment of CSF WBC count does not improve the accuracy of diagnosis of meningitis in patients with traumatic LPs. Clinicians may consider hospitalization and empirical antimicrobials in patients with traumatic LPs given the challenge of interpreting the CSF WBC count when there is blood contamination of the specimen.

Treatment with antibiotics before LP can complicate the interpretation of CSF cultures. CSF cultures are negative relatively rapidly after antibiotic administration, within 2 hours for *N. meningitidis* and 4-24 hours for *S. pneumoniae*. Next-generation molecular testing is not affected by prior antibiotic treatment, thus enhancing a diagnosis despite prior antibiotic therapy. In patients with bacterial meningitis, CSF glucose increases to normal range, often within 4-24 hours of antibiotic administration, whereas CSF protein concentrations, despite decreasing, remain abnormal for >24 hours after antibiotic administration. Changes in CSF WBC count and ANC are minimal in the first 24 hours of antibiotic therapy. Therefore CSF findings can provide relevant management information even in the setting of antibiotic administration before LP.

Herpes Simplex Virus Testing

No consensus exists on which neonates should be tested and empirically treated for HSV infection. Historical and clinical features that

should raise concern for HSV include exposure to individuals infected with HSV, particularly mothers with primary HSV infections or first-time genital infections, seizure or abnormal neurologic examination, vesicular rash, ill appearance, apnea, hypothermia, petechial rash/excessive bleeding, hepatic failure, or a history of a scalp electrode. However, neonates with HSV can present *without any high-risk* clinical or historical features, particularly with early isolated CNS disease. Published approaches to neonatal HSV include (1) testing and empirical treatment of all neonates <21 days old who are evaluated for infection; (2) testing and empirical treatment of neonates with the presence of high-risk clinical features for HSV; and (3) testing and empirical treatment for all neonates with high-risk features plus testing the CSF of all neonates <21 days old while deferring empirical acyclovir in those without high-risk features, unless the CSF HSV PCR test is positive.

The AAP Committee on Infectious Diseases recommends that neonates undergoing evaluation for HSV have the following laboratory studies performed: surface cultures or PCR of the conjunctiva, mouth or nasopharynx, rectum, and any vesicles; CSF PCR (sensitivity: 75–100%); whole blood PCR; and serum levels of alanine transaminase (ALT). HSV PCR testing of the mouth, conjunctiva, nasopharynx, rectum, and vesicles has been shown to be more sensitive than culture, with comparable specificity, although no direct comparisons have been performed in neonates.

Enterovirus Testing

Enterovirus is a common and typically benign cause of fever in febrile infants, although it can be difficult to distinguish from SBI on initial presentation. Enterovirus PCR testing of the CSF is a sensitive and rapid means to diagnose infection. One retrospective study of patients with CSF enterovirus testing found no cases of bacterial meningitis in patients with positive enterovirus PCR; this study did not include neonates ≤28 days old. Several studies have demonstrated shorter length of stay, fewer antibiotics, and lower cost among infants with positive CSF enterovirus test results. These results suggest that during local enterovirus seasons, and if PCR testing is available, testing for enterovirus may be of benefit in the evaluation of febrile infants and neonates. Some centers have implemented multiplex PCR panels, which permit testing for multiple viruses, including enterovirus and HSV (and bacteria) simultaneously.

Other Inflammatory Markers

Investigations have examined the utility of inflammatory markers such as C-reactive protein (CRP) and serum procalcitonin (PCT) in the diagnosis of SBI and, more specifically, IBI (bacteremia and meningitis) (see Table 220.2). One meta-analysis reported that PCT is superior to WBC count and CRP for the detection of IBI in children <3 years old, whereas another found that PCT was inferior to prediction rules in identifying SBI in young infants. A prospective multicenter cohort study of febrile infants 7-91 days old determined that the PCT was better at identifying patients with IBI than CRP, WBC count, or ANC. Building on these results, clinical prediction rules for febrile infants, such as the **Step-by-Step** approach, incorporate PCT and CRP, along with age ≤21 days, ill appearance, ANC >10,000/mm^3, and pyuria in a stepwise approach to determine which patients are at high risk for IBI; only 0.7% of infants who met none of those criteria had IBI. In the approach from the AAP, inflammatory markers are recommended for all infants 22 days and older as part of risk stratification. If available, this approach recommends PCT along with either CRP or ANC. If PCT is unavailable, then CRP, ANC, and elevation in temperature should be considered as markers of inflammation (see Table 220.2).

Other Diagnostic Studies

Older infants with positive RSV and influenza testing have a very low risk of SBI beyond UTI. One large case-based survey demonstrated decreased admission rates and antibiotic use for infants with positive respiratory viral tests, and another study demonstrated that implementation of a care algorithm incorporating viral testing led to a shorter length of stay and antibiotic course.

Chest radiographs are unlikely to be clinically useful in the evaluation of the febrile infant without respiratory symptoms. Studies that have examined routine use of radiographs have found limited utility because in infants without respiratory symptoms, most results will be normal and abnormal results can be difficult to interpret.

TREATMENT

Antimicrobials

Ill-appearing and high-risk infants and those <22 days old hospitalized for evaluation for SBI should receive antimicrobial therapy. Commonly used regimens include (1) a third-generation cephalosporin (typically cefepime or ceftazidime), (2) a third-generation cephalosporin and ampicillin, or (3) an aminoglycoside and ampicillin.

Ampicillin is the preferred treatment of GBS and covers *L. monocytogenes* and many *Enterococcus* spp. and some *E. coli*. For neonates 0-28 days, options 2 or 3 have been recommended, given the risk of *L. monocytogenes*. For young infants >28 days, option 1 (third-generation cephalosporin: ceftriaxone) is a reasonable choice. For ill-appearing infants or those with positive CSF Gram stains, additional antibiotics may include vancomycin or broad-spectrum antibiotics such as carbapenems. Local epidemiology and resistance patterns may assist in these choices. Neonates with concern for HSV should be empirically treated with high-dose acyclovir (60 mg/kg/day).

Treatment duration and route of antimicrobial administration depend on the infection. Additional details based on specific infections and organisms are available in the following chapters: meningitis (see Chapter 148), UTI (see Chapter 575), *E. coli* (see Chapter 246), GBS (see Chapter 230), and HSV (see Chapter 299).

Discharge from the Hospital

Traditionally, infants remained in the hospital receiving antimicrobial therapy until bacterial cultures were negative for 48 hours or even longer. Multiple studies have suggested that shorter culture observation periods (i.e., 24 or 36 hours) may be reasonable because most pathogens in the blood grow within this time frame when automated blood culture monitoring systems are used. In one multicenter retrospective cross-sectional study, 91% of blood cultures were positive by 24 hours and 96% by 36 hours. Fewer studies have evaluated the *time to positivity* of CSF and urine cultures, but in one large study of febrile infants 28-90 days old, all positive CSF cultures grew within 24 hours (median time to positivity, 18 hours). For blood cultures, 1.3% grew after 24 hours (median time to positivity, 16 hours), and for urine cultures, 0.9% grew after 24 hours (median time to positivity, 16 hours). In one multicenter study including infants <60 days old, 82% of CSF cultures were positive by 24 hours and 86% by 36 hours. For neonates undergoing evaluation for HSV, it is reasonable to await results of HSV testing before discharge to home. For patients with identified bacterial infections or HSV infections, the duration of the hospital stay will be determined by the specific pathogen and site of infection.

PROGNOSIS

Most well-appearing neonates and young infants with fever recover completely and relatively quickly, depending on the etiology of the fever. Most infection-related mortality and long-term morbidity result from HSV infection and bacterial meningitis. For HSV, reported mortality rates range from 27% to 31% for disseminated disease and from 4% to 6% for CNS disease. Of those who survive, 83% of patients with disseminated disease and 31% of those with CNS disease will have normal development at 12 months old. The mortality of bacterial meningitis varies by pathogen but ranges from 4% to 15%. In one study of children who had meningitis as infants, 84% had normal development at age 5 years.

Chapter 221

Fever in the Older Child

Laura Brower and Samir S. Shah

Fever is the most common reason for a child to seek medical care. While most infants and children have benign viral causes of fever, a small proportion will have more serious infections. Unlike fever in young infants, pediatricians can rely more readily on symptoms and physical examination findings to establish a diagnosis in older children. Laboratory testing and radiographic studies are not routinely indicated but may be helpful when diagnostic uncertainty exists or the patient appears critically ill. Occult infections, such as urinary tract infection (UTI), may be present, and testing for such infections should be guided by demographic and contextual factors such as patient age, patient gender, and environmental exposures.

DIAGNOSIS

The many potential causes of fever in older infants and children can be broadly categorized into viral and bacterial infections, further organized by body region, as well as the less common inflammatory, oncologic, endocrine, and medication-induced causes (Table 221.1).

Viral Infections

Viral infections are the most common cause of fever, and the prevalence of specific viral infections varies by season. Typically, in the summer and early fall, enteroviruses (e.g., coxsackieviruses) predominate, usually presenting as hand-foot-and-mouth disease, herpangina, aseptic meningitis, or a variety of other manifestations. In the late fall and winter, viral upper and lower respiratory tract infections caused by respiratory viruses such as respiratory syncytial virus (RSV) and influenza and gastroenteritis caused by gastrointestinal (GI) viruses such as norovirus and rotavirus are common. Parainfluenza viruses are a common cause of **laryngotracheobronchitis (croup)** and occur primarily in the fall and spring, affecting mostly infants and toddlers. Varicella is a less common cause of fever than in the past because of childhood vaccination but still occurs, with the highest incidence in winter and early spring. Coronavirus disease 2019 (COVID-19) caused by SARS-CoV-2 can cause fever alone or with either upper or lower respiratory tract symptoms in young children, though asymptomatic infections also occur.

Bacterial Infections

Common bacterial infections include acute **otitis media** and **streptococcal pharyngitis (strep throat)**. Acute otitis media is diagnosed by the presence of a bulging, erythematous, and nonmobile tympanic membrane upon insufflation. Streptococcal pharyngitis occurs most frequently in the late fall and winter and is uncommon before age 3 years. The presence of focal auscultatory findings, including crackles, suggests a lower respiratory tract infection, such as bacterial pneumonia, but may also be present among children with **bronchiolitis** and viral pneumonia. **Atypical pneumonia** caused by mycoplasma typically occurs in school-age children and is often associated with headache, sore throat, malaise, and low-grade fever. The presence of neck pain (especially with neck extension for those with retropharyngeal abscess), drooling, or muffled voice may indicate a deep neck infection such as a **retropharyngeal abscess**, which occurs in infants and young children, or a **peritonsillar abscess**, which typically affects older children. Skin and soft tissue infections such as cellulitis and abscess may also present with fever, with the buttocks a common area for abscesses in young children. Bone and joint infections such as **osteomyelitis** and **septic arthritis** may present with fever and refusal to bear weight or limp in the young child. Invasive bacterial infections, including **sepsis** and **bacterial meningitis**, must be considered in young children presenting with fever. Although uncommon, these infections are potentially life-threatening and require prompt recognition and treatment. Ill appearance, lethargy, and tachycardia are typically present among children with severe sepsis, and petechiae may be an early finding among children with meningococcemia or other invasive bacterial diseases. Figures 221.1 and 221.2 show age-related diagnoses and organisms producing bacterial sepsis in infants and children. Children with fever who are immunosuppressed, such as children receiving chemotherapy or those with sickle cell disease, are at higher risk for invasive bacterial infection.

Infants and children age 2-24 months merit special consideration because they have limited verbal skills, are at risk for occult bacterial infections, and may be otherwise asymptomatic except for fever (see Chapter 220).

Occult Urinary Tract Infection

Among children 2-24 months old without symptoms or physical examination findings that identify another focal source of infection, the prevalence of UTI may be as high as 5–10%. The highest risk of UTI occurs in females and uncircumcised males, with a very low rate of infection (<0.5%) in circumcised males. Table 221.2 lists clinical risk factors for UTI.

Occult Bacteremia

Occult bacteremia is defined as a positive blood culture for a pathogen in a well-appearing child without an obvious source of infection. In the 1990s, before vaccination programs against *Haemophilus influenzae* type b (Hib) and *Streptococcus pneumoniae*, up to 5% of young children age 2 to 24 (up to 36) months with fever ≥39°C (102.2°F) had occult bacteremia, most often caused by *S. pneumoniae*. Currently, the prevalence of occult bacteremia is far less than 1% in febrile, well-appearing young children. Most cases of pneumococcal occult bacteremia are transient, with a minority of these children developing new focal infections, sepsis, or other sequelae. Unimmunized and incompletely immunized young children remain at higher risk for occult bacteremia because of pneumococcus (see Chapter 228). Bacteremia caused by Hib or meningococcus should not be considered benign because subsequent serious invasive infection may rapidly follow the bacteremia.

GENERAL APPROACH

The general approach to fever in the older child begins with an assessment of the child's overall appearance and vital signs. A detailed history of the present illness and a thorough physical examination should be performed to identify the cause of the fever.

Overall Appearance and Vital Signs

Children who are ill or appear toxic or who have abnormal vital signs (e.g., tachycardia, tachypnea, hypotension) require rapid assessment, including a focused physical examination to evaluate for the possibility of an invasive bacterial infection. A more detailed history and physical exam can be performed in the well-appearing child.

Symptoms

A thorough history should be obtained from the caregiver (and patient, when appropriate), including a characterization of the fever and any other associated symptoms. The degree and duration of the fever should be assessed, and the method of taking the temperature should be ascertained (e.g., forehead, axillary, oral, rectal). For children with prolonged fever, it is important to determine whether the fever has been episodic or persistent. Patients with prolonged fever may harbor occult infections, UTI, or bone or soft tissue infections or may have an inflammatory or oncologic condition. Additionally, Kawasaki disease and multisystem inflammatory syndrome in children (MIS-C) should be considered among children with prolonged fever, and a careful evaluation for other stigmata associated with these conditions is warranted (see Chapter 208).

After characterizing the fever, it is important to ask systematically about the presence of symptoms that may identify an etiology for the fever, including symptoms of common viral infections such as rhinorrhea, cough, vomiting, and diarrhea. Additionally, symptoms should be elicited for each body system: headache, ear pain, sore throat, neck pain or swelling, difficulty breathing, chest pain, abdominal pain, rash or changes in skin color, extremity pain or difficulty with ambulation (including refusal to bear weight in a

Factitious

young child), and overall activity level. In older children, the presence of dysuria, urinary frequency, or back pain may indicate UTI. Assessment of oral intake and urine output is also critical because dehydration may accompany common childhood infections and is associated with higher rates of morbidity. The presence of weight loss or night sweats may indicate leukemia, lymphoma, or tuberculosis. Additionally, a thorough social history should be performed, inquiring about attendance at daycare, any travel, and any sick contacts at daycare, school, or in the household.

Physical Examination

A complete physical examination includes particular attention to body systems with associated symptoms (e.g., thorough exam of oropharynx for child with sore throat). A complete physical

Epidemiology of blood culture-proven bacterial sepsis in children in Switzerland: a population-based cohort study. Lancet Child Adolesc. 2017;1:124–133, Fig. 4.)*

examination is particularly important in young children <24 months old who have limited verbal skills to communicate localized pain. In older children the physical exam may proceed systematically from head to toe, but in younger children, who may be fearful of the exam, it is important to auscultate the heart and lungs first before proceeding to potentially painful or distressing aspects of the examination (e.g., inspection of ears or oropharynx). In addition to a careful evaluation of each body system, a complete examination should include an assessment of neck pain and mobility, which may be limited in children with **meningitis**. Additionally, the examiner should palpate carefully for the presence of **lymphadenopathy**, which may be present with infectious and oncologic causes of fever. Erythema and exudate of the tonsils with palatal petechiae suggest streptococcal pharyngitis. Erythema, bulging, and decreased mobility of the tympanic membrane are the cardinal signs of acute otitis media. Diffuse crackles and wheezes on auscultation of the lungs occur with acute viral bronchiolitis, whereas focal crackles or decreased breath sounds are more consistent with bacterial pneumonia. Focal tenderness in the right lower quadrant of the abdomen suggests **appendicitis**, and suprapubic tenderness may indicate UTI **(cystitis)**. Any focal bony tenderness may reflect a diagnosis of osteomyelitis, whereas erythema, swelling, and limitation of range of motion suggest a diagnosis of septic arthritis. Abnormal gait or pain with ambulation without focal findings may also reflect a bone or joint infection. A careful skin examination should also be performed. The presence of petechiae may suggest meningococcal or other invasive bacterial infection, whereas viral exanthems are typically associated with a blanching macular or maculopapular rash.

EVALUATION

Laboratory Testing

Laboratory testing is not routinely indicated in the well-appearing child without a focus of infection on examination. Urine testing should be considered based on the child's age, duration of fever, and risk factors for UTI (see Table 221.2). In general, the decision to perform laboratory testing should be guided by the overall appearance and vital signs of the child, the presence of specific symptoms or physical examination findings, and the child's age.

For children who are ill or appear toxic or who have vital sign abnormalities indicative of an invasive bacterial infection (tachycardia, hypotension), rapid laboratory evaluation should be performed. Testing may include a blood culture and possibly urine and cerebrospinal fluid (CSF) cultures, depending on the age of the child and the presence or absence of physical exam findings indicative of UTI or bacterial meningitis. Markers of inflammation, such as procalcitonin or C-reactive protein may also be considered. Complete blood counts (CBCs) identify leukocytosis or leukopenia, anemia, and thrombocytosis or thrombocytopenia. Children with infectious mononucleosis may have lymphocyte predominance and the presence of atypical lymphocytes. Children

who are immunosuppressed or who have a central venous catheter should also undergo diagnostic testing and receive prompt antimicrobial therapy, given their higher risk of invasive bacterial infection.

For well-appearing children with symptoms or signs indicative of a viral upper respiratory or GI infection, routine viral testing is not generally indicated. **Influenza** testing may be indicated within 48 hours of symptom onset in certain higher-risk populations, with immunosuppression, chronic respiratory or cardiac disease, sickle cell disease, hospitalization, and age <2 years influencing the decision to treat with an antiviral agent. Testing for **SARS-CoV-2** may be indicated based on local prevalence and symptoms (fever, cough, congestion, loss of taste or smell, shortness of breath, body aches, fatigue, headache, sore throat, nausea, vomiting, or diarrhea). Viral testing may also be useful with prolonged fever to identify a source of the fever and avoid extensive evaluation for inflammatory conditions such as Kawasaki disease or MIS-C.

Rapid strep testing of the oropharynx is indicated for children ≥3 years old with signs of streptococcal pharyngitis on examination. Although strep throat is uncommon in children <3 years old, this group should undergo rapid strep testing if they have signs of strep throat on exam and a household contact with streptococcal pharyngitis (see Chapter 229).

Febrile children 2 months to 2 years old with several of the risk factors for UTI listed in Table 221.2, particularly females and uncircumcised males, should undergo evaluation with urine dipstick, urine microscopy, and urine culture. Females and uncircumcised males 2-6 months old with high fever or fever that lasts ≥2 days may undergo urine testing even in the presence of respiratory tract infection, given the higher risk of UTI in this younger group (see Chapter 575).

Given the very low risk of occult bacteremia, routine performance of blood testing (e.g., CBC, blood culture) is not indicated in the vast majority of immunized children with fever. Unimmunized and underimmunized children <2 years old remain at higher risk of occult pneumococcal bacteremia, and CBC, blood culture, and/or inflammatory markers may be considered in this population in the absence of another source of infection.

Imaging

The presence of focal crackles or decreased breath sounds on auscultation in the febrile child is suggestive of **pneumonia**. Current guidelines recommend presumptive antibiotic treatment for pneumonia based on clinical grounds and reserve the use of chest radiography for children with hypoxemia or significant respiratory distress and for those who fail outpatient therapy. Chest radiography is indicated for hospitalized children to assess for complicated pneumonia, including **empyema**. The performance of other imaging should be dictated by physical exam findings. The presence of drooling and neck or throat pain in an infant or toddler may be suggestive of a retropharyngeal abscess, which is usually confirmed by imaging that may include a lateral radiograph of the soft tissue of the neck or computed tomography (CT) if clinical suspicion is high. Ultrasonography (US) may be performed to assess for **appendicitis** in children with fever and focal right lower quadrant pain or abdominal pain that is severe. However, definitive imaging, including CT or MRI, may be required if US is nondiagnostic or if clinical suspicion is high.

†Adapted from Shaikh N, Hoberman A, Hum SW, et al. Development and validation of a calculator for estimating the probability of urinary tract infection in young febrile children. *JAMA Pediatr*. 2018;172(6):550–556 and UTICalc Version 3.0, University of Pittsburgh 2021, https://uticalc.pitt.edu/

MANAGEMENT

General Management Principles

Management should be guided by the presence of specific symptoms by history or signs on physical examination. Based on the child's age and duration of fever, management may also be guided by focused diagnostic testing, such a urinalysis and selective urine culture testing among young febrile children (Fig. 221.3 and see Table 221.2). Supportive care, including the use of antipyretics and adequate hydration, should be reviewed with the patient and caregiver for all children with fever. Children with viral infections generally require supportive care only, except for children at higher risk of severe or complicated disease with **influenza virus** (see Chapter 305) or SARS-CoV-2 (see Chapter 311). Antibiotics should

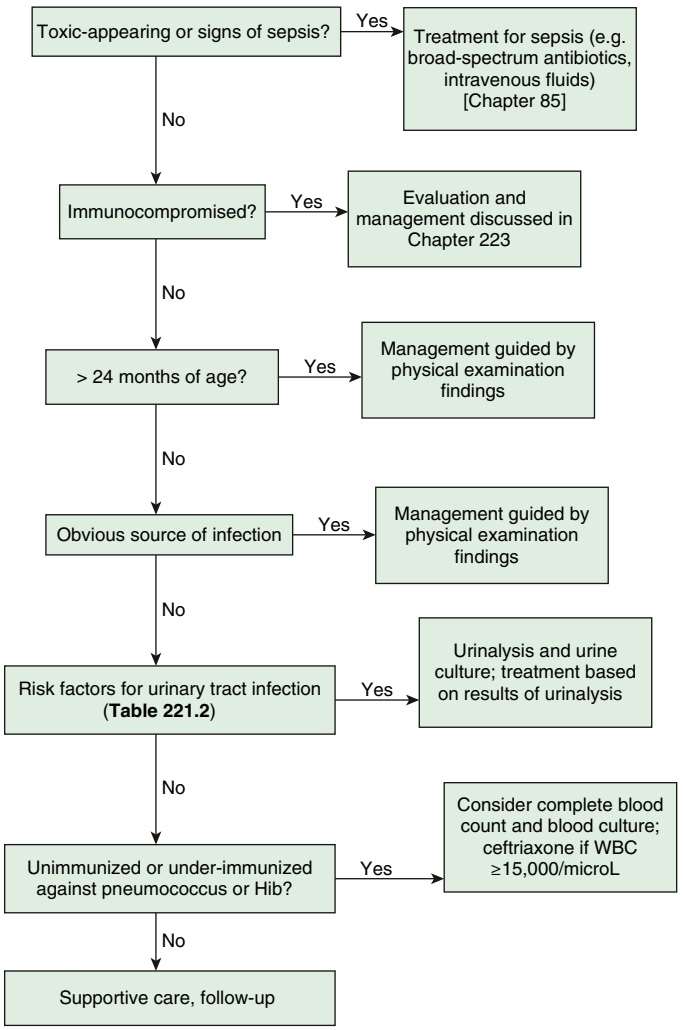

Fig. 221.3 Algorithm for evaluation and management of fever in infants and children >2 mo of age. Hib, *Haemophilus influenzae* type b; WBC, white blood cell count.

be reserved for children with evidence of bacterial infection on physical examination. A wait-and-see approach can be considered for children with acute **otitis media**, in whom a prescription for antibiotics can be provided to the family but instructions given to not fill the prescription unless severe or worsening symptoms develop (see Chapter 680). Oral antibiotics can be prescribed to young children with UTI, although children who cannot tolerate oral intake, are vomiting or dehydrated, or appear toxic require parenteral antibiotics and hospitalization.

Blood tests, including CBC and blood culture, should be considered to evaluate for occult **bacteremia** in the unimmunized child. One management strategy for these children is to administer a parenteral antibiotic (e.g., ceftriaxone) if leukocytosis (white blood cell count ≥15,000/μL), elevated absolute neutrophil count (≥10,000/μL), or elevated inflammatory markers (procalcitonin >0.5 ng/mL) are present while awaiting results of blood culture. Children who appear toxic or who have signs of either sepsis or bacterial meningitis require emergent treatment with parenteral antibiotics as well as adjunct therapies to support the child's hemodynamics (see Chapter 85).

Importantly, anticipatory guidance should be provided to all families of children with fever, including the criteria to return to care and the importance of fever control and adequate hydration.

Other Considerations

Children who are unimmunized or underimmunized are at higher risk of invasive bacterial infection, as are children who are immunocompromised. Management of fever in these children is described further in Chapter 223. Additionally, the approach to fever in the returning traveler should be focused on identifying commonly encountered infections based on the region of travel (see Chapter 218).

Chapter 222

Fever of Unknown Origin

Andrew P. Steenhoff

Fever of unknown origin **(FUO)** is a diagnostic dilemma for pediatricians because it is often difficult to distinguish clinically between benign and potentially life-threatening causes. Pediatricians face the important challenge of not missing the diagnosis of a serious illness or an easily treatable condition that can result in increased morbidity. Fortunately, FUO is usually an uncommon presentation of a common disease, with most of these common diseases being easily treatable.

The classification of FUO is best reserved for children with a temperature >38°C (100.4°F) documented by a healthcare provider and for which the cause could not be identified after at least 8 days of evaluation (Table 222.1). It is important to differentiate FUO from **fever without a source (FWS)**. FWS is fever where the source has not yet been identified and is differentiated from FUO by the duration of the fever. FWS can progress to FUO if no cause is elicited after 7 days of evaluation.

ETIOLOGY

The many causes of FUO in children are infectious, rheumatologic (connective tissue or autoimmune), autoinflammatory, oncologic, neurologic, genetic, factitious, and iatrogenic processes (Table 222.2). Although oncologic disorders should be seriously considered, most children with malignancies do not have fever alone. The possibility of **drug fever** should be considered if the patient is receiving any drug. Drug fever is usually sustained and not associated with other symptoms. Discontinuation of the drug is associated with resolution of the fever, generally within 72 hours, although certain drugs, such as iodides, are excreted for a prolonged period, with fever that can persist for as long as 1 month after drug withdrawal.

Most fevers of unknown origin result from atypical presentations of common diseases. In some cases, the presentation as an FUO is characteristic of the disease (e.g., juvenile idiopathic arthritis), but the definitive diagnosis can be established only after prolonged observation, because initially there are no associated or specific findings on physical examination, and all laboratory results are negative or normal.

In the United States the systemic infectious diseases most commonly implicated in children with FUO are bacterial enterocolitis, including salmonellosis, as well as tuberculosis, rickettsial diseases, syphilis, Lyme disease, cat-scratch disease, atypical prolonged presentations of common viral diseases such as adenovirus infection, Epstein-Barr virus (EBV) infection, cytomegalovirus (CMV) infection, viral hepatitis, coccidioidomycosis, histoplasmosis, malaria, *Angiostrongylus cantonensis* infection, and toxoplasmosis. Less common infectious causes of FUO include tularemia, brucellosis, leptospirosis, and rat-bite fever. Acquired immunodeficiency syndrome (AIDS) alone is not usually responsible for FUO, although febrile illnesses often occur in patients with AIDS as a result of opportunistic infections (see Table 222.1).

Juvenile idiopathic arthritis (JIA) and **systemic lupus erythematosus** (SLE) are the connective tissue diseases most often associated with FUO. **Inflammatory bowel disease** (IBD) and **Kawasaki disease** are also frequently reported as causes of FUO. If **factitious fever** (inoculation of pyogenic material or manipulation of the thermometer by the patient or parent) is suspected, the presence and pattern of fever should be documented in the hospital. Prolonged and continuous observation of the patient, which can include electronic or video surveillance, is imperative. FUO lasting >6 months is uncommon in children and suggests granulomatous, autoinflammatory, or autoimmune disease. Repeat interval evaluation is required, including history, physical examination, laboratory evaluation, and imaging studies.

Historically, 90% of pediatric FUO cases in the United States had an identifiable cause: approximately 50% infectious, 10–20% collagen vascular, and 10% oncologic. Other studies had variable results: 20–44% infectious, 0–7% collagen vascular, 2–3% oncologic, and up to 67% undiagnosed. The reason for the paradoxical increase in undiagnosed cases of FUO ironically is likely caused by improved infectious and autoimmune diagnostic techniques. The advent of polymerase chain reaction (PCR), improved culture techniques, and better understanding of atypical viral and bacterial pathogenesis and autoimmune processes likely contribute to *earlier* diagnosis of these conditions and fewer children with these conditions *advancing* to the category of FUO. By contrast, causes of FUO remain primarily infectious in low and middle income settings where there is a higher infectious disease burden and advanced diagnostic techniques are more limited.

DIAGNOSIS

The evaluation of FUO requires a thorough history and physical examination supplemented by a few screening laboratory tests and additional laboratory and imaging evaluation informed by the history or abnormalities on examination or initial screening tests (see Table 222.2). Occasionally the **fever pattern** helps make a diagnosis (Fig. 222.1). Nonetheless, most diseases causing an FUO do not have a typical fever pattern.

History

A detailed fever history should be obtained, including onset, frequency, duration, response or nonresponse to therapy, recurrence, and associated symptoms. Repetitive chills and temperature spikes are common in children with **septicemia** (regardless of cause), particularly when associated with kidney disease, liver or biliary disease, infective endocarditis, malaria, brucellosis, rat-bite fever, or a loculated collection of pus.

The age of the patient is helpful in evaluating FUO. Children >6 years old often have a respiratory or genitourinary tract infection, localized infection (abscess, osteomyelitis), JIA, or rarely, leukemia. Adolescent patients are more likely to have IBD, autoimmune processes, lymphoma, or tuberculosis in addition to the causes of FUO found in younger children.

A history of exposure to wild or domestic **animals** should be solicited. The incidence of **zoonotic infections** in the United States is

be reserved for children with evidence of bacterial infection on physical examination. A wait-and-see approach can be considered for children with acute **otitis media**, in whom a prescription for antibiotics can be provided to the family but instructions given to not fill the prescription unless severe or worsening symptoms develop (see Chapter 680). Oral antibiotics can be prescribed to young children with UTI, although children who cannot tolerate oral intake, are vomiting or dehydrated, or appear toxic require parenteral antibiotics and hospitalization.

Blood tests, including CBC and blood culture, should be considered to evaluate for occult **bacteremia** in the unimmunized child. One management strategy for these children is to administer a parenteral antibiotic (e.g., ceftriaxone) if leukocytosis (white blood cell count ≥15,000/μL), elevated absolute neutrophil count (≥10,000/μL), or elevated inflammatory markers (procalcitonin >0.5 ng/mL) are present while awaiting results of blood culture. Children who appear toxic or who have signs of either sepsis or bacterial meningitis require emergent treatment with parenteral antibiotics as well as adjunct therapies to support the child's hemodynamics (see Chapter 85).

Importantly, anticipatory guidance should be provided to all families of children with fever, including the criteria to return to care and the importance of fever control and adequate hydration.

Other Considerations

Children who are unimmunized or underimmunized are at higher risk of invasive bacterial infection, as are children who are immunocompromised. Chapter 222

Fever of Unknown Origin

Andrew P. Steenhoff

Fever of unknown origin **(FUO)** is a diagnostic dilemma for pediatricians because it is often difficult to distinguish clinically between benign and potentially life-threatening causes. Pediatricians face the important challenge of not missing the diagnosis of a serious illness or an easily treatable condition that can result in increased morbidity. Fortunately, FUO is usually an uncommon presentation of a common disease, with most of these common diseases being easily treatable.

The classification of FUO is best reserved for children with a temperature >38°C (100.4°F) documented by a healthcare provider and for which the cause could not be identified after at least 8 days of evaluation (Table 222.1). It is important to differentiate FUO from **fever without a source (FWS)**. FWS is fever where the source has not yet been identified and is differentiated from FUO by the duration of the fever. FWS can progress to FUO if no cause is elicited after 7 days of evaluation.

ETIOLOGY

The many causes of FUO in children are infectious, rheumatologic (connective tissue or autoimmune), autoinflammatory, oncologic, neurologic, genetic, factitious, and iatrogenic processes (Table 222.2). Although oncologic disorders should be seriously considered, most children with malignancies do not have fever alone. The possibility of **drug fever** should be considered if the patient is receiving any drug. Drug fever is usually sustained and not associated with other symptoms. Discontinuation of the drug is associated with resolution of the fever, generally within 72 hours, although certain drugs, such as iodides, are excreted for a prolonged period, with fever that can persist for as long as 1 month after drug withdrawal.

Most fevers of unknown origin result from atypical presentations of common diseases. In some cases, the presentation as an FUO is characteristic of the disease (e.g., juvenile idiopathic arthritis), but the definitive diagnosis can be established only after prolonged observation, because initially there are no associated or specific findings on physical examination, and all laboratory results are negative or normal.

In the United States the systemic infectious diseases most commonly implicated in children with FUO are bacterial enterocolitis, including salmonellosis, as well as tuberculosis, rickettsial diseases, syphilis, Lyme disease, cat-scratch disease, atypical prolonged presentations of common viral diseases such as adenovirus infection, Epstein-Barr virus (EBV) infection, cytomegalovirus (CMV) infection, viral hepatitis, coccidioidomycosis, histoplasmosis, malaria, *Angiostrongylus cantonensis* infection, and toxoplasmosis. Less common infectious causes of FUO include tularemia, brucellosis, leptospirosis, and rat-bite fever. Acquired immunodeficiency syndrome (AIDS) alone is not usually responsible for FUO, although febrile illnesses often occur in patients with AIDS as a result of opportunistic infections (see Table 222.1).

Juvenile idiopathic arthritis (JIA) and **systemic lupus erythematosus** (SLE) are the connective tissue diseases most often associated with FUO. **Inflammatory bowel disease** (IBD) and **Kawasaki disease** are also frequently reported as causes of FUO. If **factitious fever** (inoculation of pyogenic material or manipulation of the thermometer by the patient or parent) is suspected, the presence and pattern of fever should be documented in the hospital. Prolonged and continuous observation of the patient, which can include electronic or video surveillance, is imperative. FUO lasting >6 months is uncommon in children and suggests granulomatous, autoinflammatory, or autoimmune disease. Repeat interval evaluation is required, including history, physical examination, laboratory evaluation, and imaging studies.

Historically, 90% of pediatric FUO cases in the United States had an identifiable cause: approximately 50% infectious, 10–20% collagen vascular, and 10% oncologic. Other studies had variable results: 20–44% infectious, 0–7% collagen vascular, 2–3% oncologic, and up to 67% undiagnosed. The reason for the paradoxical increase in undiagnosed cases of FUO ironically is likely caused by improved infectious and autoimmune diagnostic techniques. The advent of polymerase chain reaction (PCR), improved culture techniques, and better understanding of atypical viral and bacterial pathogenesis and autoimmune processes likely contribute to *earlier* diagnosis of these conditions and fewer children with these conditions *advancing* to the category of FUO. By contrast, causes of FUO remain primarily infectious in low and middle income settings where there is a higher infectious disease burden and advanced diagnostic techniques are more limited.

DIAGNOSIS

The evaluation of FUO requires a thorough history and physical examination supplemented by a few screening laboratory tests and additional laboratory and imaging evaluation informed by the history or abnormalities on examination or initial screening tests (see Table 222.2). Occasionally the **fever pattern** helps make a diagnosis (Fig. 222.1). Nonetheless, most diseases causing an FUO do not have a typical fever pattern.

History

A detailed fever history should be obtained, including onset, frequency, duration, response or nonresponse to therapy, recurrence, and associated symptoms. Repetitive chills and temperature spikes are common in children with **septicemia** (regardless of cause), particularly when associated with kidney disease, liver or biliary disease, infective endocarditis, malaria, brucellosis, rat-bite fever, or a loculated collection of pus.

The age of the patient is helpful in evaluating FUO. Children >6 years old often have a respiratory or genitourinary tract infection, localized infection (abscess, osteomyelitis), JIA, or rarely, leukemia. Adolescent patients are more likely to have IBD, autoimmune processes, lymphoma, or tuberculosis in addition to the causes of FUO found in younger children.

A history of exposure to wild or domestic **animals** should be solicited. The incidence of **zoonotic infections** in the United States is

Table 222.1 Summary of Definitions and Major Features of Four Subtypes of Fever of Unknown Origin (FUO)

FEATURE	CLASSIC FUO	HEALTHCARE-ASSOCIATED FUO	IMMUNE-DEFICIENT FUO	HIV-RELATED FUO
Definition	>38°C (100.4°F), >3 wk, >2 visits, or 1 wk in hospital	≥38°C (100.4°F), >1 wk, not present or incubating on admission	≥38°C (100.4°F), >1 wk, negative cultures after 48 hr	≥38°C (100.4°F), >3 wk for outpatients, >1 wk for inpatients, HIV infection confirmed
Patient location	Community, clinic, or hospital	Acute care hospital	Hospital or clinic	Community, clinic, or hospital
Leading causes	Cancer, infections, inflammatory conditions, undiagnosed, habitual hyperthermia	Healthcare-associated infections, postoperative complications, drug fever	Majority caused by infections, but cause documented in only 40–60%	HIV itself, typical and atypical mycobacteria, CMV, lymphomas, toxoplasmosis, cryptococcosis, immune reconstitution inflammatory syndrome (IRIS)
History emphasis	Travel, contacts, animal and insect exposure, medications, immunizations, family history, cardiac valve disorder	Operations and procedures, devices, anatomic considerations, drug treatment	Stage of chemotherapy, drugs administered, underlying immunosuppressive disorder	Drugs, exposures, risk factors, travel, contacts, stage of HIV infection
Examination emphasis	Fundi, oropharynx, temporal artery, abdomen, lymph nodes, spleen, joints, skin, nails, genitalia, rectum or prostate, lower-limb deep veins	Wounds, drains, devices, sinuses, urine	Skinfolds, IV sites, lungs, perianal area	Mouth, sinuses, skin, lymph nodes, eyes, lungs, perianal area
Investigation emphasis	Imaging, biopsies, sedimentation rate, skin tests	Imaging, bacterial cultures	CXR, bacterial cultures	Blood and lymphocyte count; serologic tests; CXR; stool examination; biopsies of lung, bone marrow, and liver for cultures and cytologic tests; brain imaging
Management	Observation, outpatient temperature chart, investigations, avoidance of empirical drug treatments	Depends on situation	Antimicrobial treatment protocols	Antiviral and antimicrobial protocols, vaccines, revision of treatment regimens, good nutrition
Time course of disease	Months	Weeks	Days	Weeks to months
Tempo of investigation	Weeks	Days	Hours	Days to weeks

CMV, Cytomegalovirus; CXR, chest radiograph; HIV, human immunodeficiency virus; IV, intravenous line.
Adapted from Mackowak PA, Durack DT. Fever of unknown origin. In: Mandell GL, Bennett, JE, Dolin R, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, 7th ed. Philadelphia: Elsevier; 2010: Table 51-1.

increasing, and these infections are often acquired from pets that are not overtly ill. Immunization of dogs against specific disorders such as **leptospirosis** can prevent canine disease but does not always prevent the animal from carrying and shedding leptospires, which may be transmitted to household contacts. A history of ingestion of rabbit or squirrel meat might provide a clue to the diagnosis of oropharyngeal, glandular, or typhoidal **tularemia**. A history of tick bite or travel to tick- or parasite-infested areas should be obtained.

Any history of **pica** should be elicited. Ingestion of dirt is a particularly important clue to infection with *Toxocara canis* (visceral larva migrans) or *Toxoplasma gondii* (toxoplasmosis).

A history of unusual dietary habits or travel as early as the birth of the child should be sought. Tuberculosis, malaria, histoplasmosis, and coccidioidomycosis can reemerge years after visiting or living in an endemic area. It is important to identify prophylactic immunizations and precautions taken by the patient against ingestion of contaminated water or food during foreign travel. Rocks, dirt, and artifacts from geographically distant regions that have been collected and brought into the home as souvenirs can serve as vectors of disease.

A **medication** history should be pursued rigorously. This history should elicit information about nonprescription preparations and topical agents, including eyedrops, that may be associated with atropine-induced fever.

The genetic background of a patient also is important. Descendants of the Ulster Scots may have FUO because they are afflicted with nephrogenic diabetes insipidus. **Familial dysautonomia** (Riley-Day syndrome), a disorder in which hyperthermia is recurrent, is more common among Jews than among other population groups. Ancestry from the Mediterranean region should suggest **familial Mediterranean fever**. Both familial Mediterranean fever and hyper-IgD syndrome are inherited as autosomal recessive disorders. Tumor necrosis factor receptor–associated periodic syndrome and Muckle-Wells syndrome are inherited as autosomal dominant traits.

Pseudo-FUO is defined as successive episodes of benign, self-limited infections with fever that the parents perceive as one prolonged fever episode. This needs to be carefully ruled out before undertaking an unnecessary evaluation. Usually, pseudo-FUO starts with a well-defined infection (frequently viral) that resolves but is followed by other febrile viral illnesses that may be less well defined. Diagnosis of pseudo-FUO usually requires a careful history, focusing on identifying afebrile periods between febrile episodes. If pseudo-FUO is suspected and the patient does not appear ill, keeping a *fever diary* can be helpful.

RHEUMATOLOGIC DISEASES
Autoimmune hepatitis
Behçet syndrome
Chronic noninfectious osteomyelitis (CNO)
Juvenile dermatomyositis
Juvenile idiopathic arthritis* ± macrophage activation syndrome
Rheumatic fever
Systemic lupus erythematosus*
Vasculitis syndromes (granulomatous, nongranulomatous)

HYPERSENSITIVITY DISEASES
Drug fever, including DRESS
Hypersensitivity pneumonitis
Hypersensitivity vasculitis/reactive arthritis*
Serum sickness
Weber-Christian disease

NEOPLASMS
Atrial myxoma
Cholesterol granuloma
Hodgkin lymphoma
Inflammatory pseudotumor
Langerhans cell histiocytosis
Leukemia
Lymphoma*
Pheochromocytoma
Neuroblastoma
Wilms tumor

GRANULOMATOUS DISEASES
Crohn disease
Granulomatous hepatitis
Polyangiitis with granulomatosis
Sarcoidosis

FAMILIAL AND HEREDITARY DISEASES
Anhidrotic ectodermal dysplasia
Autoimmune lymphoproliferative syndrome (ALPS)
Autonomic neuropathies
Fabry disease
Familial dysautonomia
Familial Hibernian fever
Familial Mediterranean fever and the many other autoinflammatory (periodic fever) diseases (see Chapter 204)
Hypertriglyceridemia
Ichthyosis
Sickle cell crisis
Spinal cord/brain injury

MISCELLANEOUS
Addison disease
Allergic alveolitis
Castleman disease
Cyclic neutropenia
Diabetes insipidus (non-nephrogenic and nephrogenic)
Erythema multiforme
Factitious fever
Hemophagocytic lymphohistiocytosis (HLH)
Hypereosinophilia syndromes
Hypothalamic-central fever
Infantile cortical hyperostosis
Inflammatory bowel disease*
Kawasaki disease*
Kikuchi-Fujimoto disease
Metal fume fever
Multisystem inflammatory syndrome in children (MIS-C)
Pancreatitis
Poisoning
Pulmonary embolism
Rosai-Dorfman disease
Thrombotic thrombocytopenia purpura
Thrombophlebitis
Thyrotoxicosis, thyroiditis

*Most common identified causes of FUO in children.
DRESS, Drug reaction with eosinophilia and systemic symptoms.
Modified from Huppler AR. Fever. In: Kliegman RM, Toth H, Bordini BJ, Basel D, eds. *Nelson Pediatric Symptom-Based Diagnosis*, 2nd ed. Philadelphia: Elsevier; 2023: Table. 52.9, pp. 980–981.

Physical Examination

A complete physical examination is essential to search for any clues to the underlying diagnosis, and often it is worthwhile to repeat a detailed examination on different days to detect signs that may have changed or been missed (Tables 222.3-222.5). The child's general appearance, including **sweating** during fever, should be noted. The continuing absence of sweat in the presence of an elevated or changing body temperature suggests dehydration caused by vomiting, diarrhea, or central or nephrogenic diabetes insipidus. It also should suggest anhidrotic ectodermal dysplasia, familial dysautonomia, or exposure to atropine.

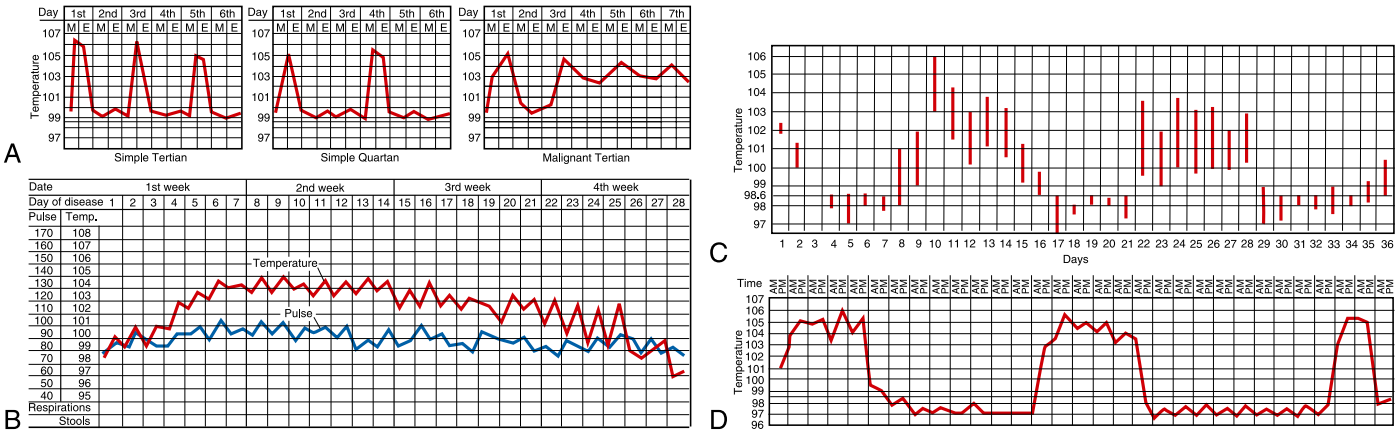

Fig. 222.1 Distinctive fever patterns. **A,** Malaria. **B,** Typhoid fever (demonstrating relative bradycardia). **C,** Hodgkin disease (Pel-Ebstein fever pattern). **D,** Borreliosis (relapsing fever pattern). *(From Woodward TE. The fever pattern as a clinical diagnostic aid. In Mackowiak PA, ed. Fever: Basic Mechanisms and Management, 2nd ed. Philadelphia: Lippincott-Raven; 1997:215–236.)*

Table 222.3 Subtle Physical Findings with Special Significance in Patients with Fever of Unknown Origin

BODY SITE	PHYSICAL FINDING	DIAGNOSIS
Head	Sinus tenderness	Sinusitis
Temporal artery	Nodules, reduced pulsations	Temporal arteritis
Oropharynx	Ulceration	Disseminated histoplasmosis, SLE, IBD, Behçet syndrome, periodic fever syndromes
	Tender tooth	Periapical abscess, sinus referred pain
	Loose teeth	Langerhans cell histiocytosis, leukemia
Fundi or conjunctivae	Choroid tubercle	Disseminated granulomatosis*
	Petechiae, Roth spots	Endocarditis
Thyroid	Enlargement, tenderness	Thyroiditis
Heart	Murmur	Infective or marantic endocarditis
	Relative bradycardia	Typhoid fever, malaria, leptospirosis, psittacosis, central fever, drug fever
Abdomen	Enlarged iliac crest lymph nodes, splenomegaly	Lymphoma, endocarditis, disseminated granulomatosis*
	Audible abdominal aortic or renal artery bruit	Large vessel vasculitis such as Takayasu arteritis
	Costovertebral tenderness	Chronic pyelonephritis, perinephric abscess
Rectum	Perirectal fluctuance, tenderness	Abscess
	Prostatic tenderness, fluctuance	Abscess
Genitalia	Testicular nodule	Periarteritis nodosa, cancer
	Epididymal nodule	Disseminated granulomatosis
Spine	Spinal tenderness	Vertebral osteomyelitis
	Paraspinal tenderness	Paraspinal collection
Lower extremities	Deep venous tenderness	Thrombosis or thrombophlebitis
Upper or lower extremities	Pseudoparesis	Syphilitic bone disease
Skin and nails	Petechiae, splinter hemorrhages, subcutaneous nodules, clubbing	Vasculitis, endocarditis

*Includes tuberculosis, histoplasmosis, coccidioidomycosis, sarcoidosis, granulomatosis with polyangiitis, and syphilis.
Adapted from Mackowak PA, Durack DT. Fever of unknown origin. In: Mandell GL, Bennett, JE, Dolin R, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, 7th ed. Philadelphia: Elsevier; 2010: Table 51-8.

Table 222.4 Examples of Potential Diagnostic Clues to Infections Presenting as Fever of Unknown Origin

ETIOLOGY	HISTORICAL CLUES	PHYSICAL CLUES
Anaplasmosis	Transmitted by bite of *Ixodes* tick in association with outdoor activity in northern-central and eastern United States	Fever, headache, arthralgia, myalgia, pneumonitis, thrombocytopenia, lymphopenia, elevated liver enzymes
Babesiosis	Transmitted by bite of *Ixodes* tick in association with outdoor activity in northeastern United States	Arthralgias, myalgias, relative bradycardia, hepatosplenomegaly, anemia, thrombocytopenia, elevated liver enzymes
Bartonellosis	Recent travel to Andes Mountains (Oroya fever; *Bartonella bacilliformis*), association with homelessness in urban settings *(Bartonella quintana)* or scratch of infected kitten or feral cat *(Bartonella henselae)*	Conjunctivitis, retroorbital pain, anterior tibial bone pain, macular rash, nodular plaque lesions, regional lymphadenopathy
Blastomycosis	Contact with soil adjacent to Mississippi and Ohio River valleys, Saint Lawrence River in New York and Canada, and North American Great Lakes or exposure to infected dogs	Arthritis, atypical pneumonia, pulmonary nodules, and/or fulminant adult respiratory distress syndrome; verrucous, nodular, or ulcerative skin lesions; prostatitis
Brucellosis	Associated with contact or consumption of products from infected goats, pigs, camels, yaks, buffalo, or cows and with abattoir work	Arthralgias, hepatosplenomegaly, suppurative musculoskeletal lesions, sacroiliitis, spondylitis, uveitis, hepatitis, pancytopenia
Coccidioidomycosis	Exposure to soil or dust in southwestern United States	Arthralgias, pneumonia, pulmonary cavities, pulmonary nodules, erythema multiforme, erythema nodosum
Ehrlichiosis	Transmitted by bite of *Amblyomma, Dermacentor,* or *Ixodes* tick in association with outdoor activity in midwestern and southeastern United States	Pneumonitis, hepatitis, thrombocytopenia, lymphopenia
Enteric fever (*Salmonella enterica* serovar Typhi)	Recent travel to a low- or middle-income country (LMIC) with consumption of potentially contaminated food or water	Headache, arthritis, abdominal pain, relative bradycardia, hepatosplenomegaly, leukopenia
Histoplasmosis	Exposure to bat or blackbird excreta in roosts, chicken houses, or caves in region surrounding Ohio and Mississippi River valleys	Headache, pneumonia, pulmonary cavities, mucosal ulcers, adenopathy, erythema nodosum, erythema multiforme, hepatitis, anemia, leukopenia, thrombocytopenia
Leptospirosis	Occupational exposure among workers in sewers, rice and sugarcane fields, and abattoirs; recreational water sports and exposure to contaminated waters or infected dogs	Bitemporal and frontal headache, calf and lumbar muscle tenderness, conjunctival suffusion, hepatic and renal failure, hemorrhagic pneumonitis
Leishmaniasis (visceral disease)	Associated with recent travel to areas endemic for sand flies	Hepatosplenomegaly, lymphadenopathy, and hyperpigmentation of face, hand, foot, and abdominal skin (kala-azar)
Malaria	Recent travel to endemic areas in Asia, Africa, and Central/South America	Fever, headaches, nausea, emesis, diarrhea, hepatomegaly, splenomegaly, anemia
Psittacosis *(Chlamydia psittaci)*	Associated with contact with birds, especially psittacine birds	Fever, pharyngitis, hepatosplenomegaly, pneumonia, blanching maculopapular eruptions; erythema multiforme, marginatum, and nodosum
Q fever *(Coxiella burnetii)*	Associated with farm, veterinary, or abattoir work; consumption of unpasteurized milk; contact with infected sheep, goats, or cattle	Atypical pneumonia, hepatitis, hepatomegaly, relative bradycardia, splenomegaly
Rat-bite fever *(Streptobacillus moniliformis)*	Recent bite or scratch by rat, mouse, or squirrel; ingestion of food or water contaminated by rat excrement	Headaches, myalgias, polyarthritis, and maculopapular, morbilliform, petechial, vesicular, or pustular rash over the palms, soles, and extremities
Relapsing fever *(Borrelia recurrentis)*	Associated with poverty, crowding, and poor sanitation (louse-borne) or with camping (tick-borne), particularly in the Grand Canyon	High fever with rigors, headache, delirium, arthralgias, myalgias, and hepatosplenomegaly
Rocky Mountain spotted fever	Associated with outdoor activity in the South Atlantic or southeastern United States and exposure to *Dermacentor* tick bites	Headache, petechial rash involving the extremities, palms, and soles
Tuberculosis	Recent contact with tuberculosis; recent immigration from endemic country; work or residence in homeless shelters, correctional facilities, or healthcare facilities	Night sweats, weight loss, atypical pneumonia; on chest x-ray, hilar adenopathy is most common in younger children, with cavitary pulmonary lesions seen in youth.
Tularemia	Associated with bites by *Amblyomma* or *Dermacentor* ticks, deer flies, and mosquitoes or direct contact with tissues of infected animals such as rabbits, squirrels, deer, raccoons, cattle, sheep, and swine	Ulcerated skin lesions at a bite site, pneumonia, relative bradycardia, lymphadenopathy, conjunctivitis

Continued

Table 222.4 Examples of Potential Diagnostic Clues to Infections Presenting as Fever of Unknown Origin—cont'd

ETIOLOGY	HISTORICAL CLUES	PHYSICAL CLUES
Whipple disease (*Tropheryma whipplei*)	Potential association with exposure to sewage	Chronic diarrhea, arthralgia, weight loss, malabsorption, malnutrition

Adapted from Wright WF, Mackowiak PA. Fever of unknown origin. In: Bennett JE, Blaser MJ, Dolin R, et al., eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, 8th ed. Philadelphia: Saunders; 2015: Table 56-9.

Table 222.5 Discriminating Features of Noninfectious Causes of Fever of Unknown Origin

CAUSES OF FEVER	EXPOSURE OR CONDITION	FEATURES	DIAGNOSTIC METHOD
Kikuchi-Fujimoto disease		Regional or generalized lymphadenopathy; elevated inflammatory markers	Biopsy or histology
Inflammatory pseudotumor	History of nonspecific illness (presumed host-controlled infection)	Insidious; malaise, weight loss, vague abdominal pain or tenderness; anemia; elevated inflammatory markers	Abdominal CT; biopsy or histology
Kawasaki disease (incomplete)		Asynchronous or incomplete features of Kawasaki disease; elevated inflammatory markers; thrombocytosis	Clinical constellation; echocardiogram
Juvenile idiopathic arthritis	Familial, sporadic	Hepatosplenomegaly, lymphadenopathy, exanthem; anemia, elevated inflammatory markers	Clinical constellation
Systemic lupus erythematosus	Familial, sporadic	Malaise, weight loss; then multisystem involvement (kidneys, joints, skin)	Serum antinuclear antibody, anti–double-stranded DNA, anti–smooth muscle antibody
Hemophagocytic lymphohistiocytosis	Familial, virus, or rheumatologic (macrophage activation syndrome) induced	Severe, rapidly progressive illness; hepatomegaly, lymphadenopathy, exanthem; cytopenias; extreme elevations of inflammatory markers	Ferritin, triglyceride levels, gene panel, other diagnostic criteria; erythrophagocytosis by macrophages; natural killer cell, $CD8^+$ T-lymphocyte dysfunction
Vasculitis syndromes	Familial, sporadic	Specific hallmarks (renal, neurologic, stomatitis or perianal ulcers, uveitis, pulmonary)	Clinical constellation; specific autoantibodies; biopsy or histology
Sarcoidosis	Geography; race	Fatigue, weight loss, leg pain; anemia; elevated inflammatory markers; mediastinal lymphadenopathy; uveitis	Clinical constellation; biopsy or histology; soluble interleukin-2 receptor level
Inflammatory bowel disease	Familial; sporadic	Linear growth failure, subtle gastrointestinal symptoms or abdominal tenderness; perirectal skin tag; iron-deficiency anemia; elevated inflammatory markers	Abdominal CT; barium study
Lymphoreticular malignancy		Weight loss, fatigue; nonarticular bone pain; lymphadenopathy; cytopenias	Bone marrow or tissue biopsy
Drug hypersensitivity	Prescription or nonprescription drug exposure	Preserved sense of well-being; exanthems; eosinophilia; organ dysfunction (renal, cardiac, pulmonary)	Clinical constellation; withdrawal of drug
Factitious fever or Munchausen syndrome by proxy	Predisposing parent-patient dynamic	Discordant temperature and vital signs; discordant parent-measured temperature and urine temperature; normal inflammatory markers	Clinical constellation; verification of temperature in medical setting
Hypothalamic dysfunction, diabetes insipidus, dysautonomia, or absent corpus callosum	Underlying condition; genetic syndrome; anatomic abnormality	Normal inflammatory markers; hypernatremia; no response to nonsteroidal antiinflammatory drugs	Clinical constellation; laboratory tests and imaging

Modified from Long SS, Prober CG, Fischer M, eds. *Principles and Practice of Pediatric Infectious Diseases*, 5th ed. Philadelphia: Elsevier; 2018: Table 15.2, p. 121.

The general activity of the patient and the presence or absence of rashes should also be noted.

A careful ophthalmic examination is important. Red, weeping eyes may be a sign of connective tissue disease, particularly polyarteritis nodosa. Palpebral **conjunctivitis** in a febrile patient may be a clue to measles, coxsackievirus infection, tuberculosis, infectious mononucleosis, lymphogranuloma venereum, or cat-scratch disease. In contrast, bulbar conjunctivitis in a child with FUO suggests Kawasaki disease or leptospirosis. Petechial conjunctival **hemorrhages** suggest infective endocarditis. Uveitis suggests sarcoidosis, JIA, SLE, Kawasaki disease,

Behçet disease, and vasculitis. **Chorioretinitis** suggests CMV, toxoplasmosis, and syphilis. **Proptosis** suggests an orbital tumor, thyrotoxicosis, metastasis (neuroblastoma), orbital infection, granulomatosis with polyangiitis, or orbital pseudotumor.

The ophthalmoscope should also be used to examine nail-fold capillary abnormalities that are associated with connective tissue diseases such as juvenile dermatomyositis and systemic scleroderma. Immersion oil or lubricating jelly is placed on the skin adjacent to the nailbed, and the capillary pattern is observed with the ophthalmoscope set on +40.

FUO is sometimes caused by **hypothalamic dysfunction**. A clue to this disorder is failure of pupillary constriction because of absence of the sphincter constrictor muscle of the eye. This muscle develops embryologically when hypothalamic structure and function also are undergoing differentiation.

Fever resulting from familial dysautonomia may be suggested by lack of tears, an absent corneal reflex, or a smooth tongue with absence of fungiform papillae. Tenderness to tapping over the sinuses or the upper teeth suggests sinusitis. Recurrent oral candidiasis may be a clue to various disorders of the immune system, especially involving the T lymphocytes. Hyperactive deep tendon reflexes can suggest thyrotoxicosis as the cause of FUO.

Hyperemia of the pharynx, with or without exudate, suggests streptococcal infection, EBV infection, CMV infection, toxoplasmosis, salmonellosis, tularemia, Kawasaki disease, gonococcal infection, or leptospirosis.

The muscles and bones should be palpated carefully. Point tenderness over a bone can suggest occult osteomyelitis or bone marrow invasion from neoplastic disease. Tenderness over the trapezius muscle may be a clue to subdiaphragmatic abscess. Generalized muscle tenderness suggests dermatomyositis, trichinosis, polyarteritis, Kawasaki disease, or *Mycoplasma* or arboviral infection.

Rectal examination can reveal perirectal lymphadenopathy or tenderness, which suggests a deep pelvic abscess, iliac adenitis, or pelvic osteomyelitis. A guaiac test should be obtained; occult blood loss can suggest granulomatous colitis or ulcerative colitis as the cause of FUO.

Laboratory Evaluation

The laboratory evaluation of the child with FUO and whether inpatient or outpatient are determined on a case-by-case basis. Hospitalization may be required for laboratory or imaging studies that are unavailable or impractical in an ambulatory setting, for more careful observation, or for temporary relief of parental anxiety. The **tempo** of diagnostic evaluation should be adjusted to the tempo of the illness; haste may be imperative in a critically ill patient, but if the illness is more chronic, the evaluation can proceed in a systematic manner and can be carried out in an outpatient setting. If there are no clues in the patient's history or on physical examination that suggest a specific infection or area of suspicion, it is unlikely that diagnostic studies will be helpful. In this common scenario, continued surveillance and repeated reevaluations of the child should be employed to detect any new clinical findings.

Although ordering a large number of diagnostic tests in every child with FUO according to a predetermined list is discouraged, certain studies should be considered in the evaluation. A complete blood cell count (CBC) with a white blood cell (WBC) differential and a urinalysis should be part of the initial laboratory evaluation. An absolute neutrophil count (ANC) of <5,000/μL is evidence against indolent bacterial infection other than typhoid fever. Conversely, in patients with a polymorphonuclear leukocyte (PMN) count of >10,000/μL or a nonsegmented PMN count of >500/μL, a severe bacterial infection is highly likely. Direct examination of the blood smear with Giemsa or Wright stain can reveal organisms of malaria, trypanosomiasis, babesiosis, or relapsing fever.

An erythrocyte sedimentation rate (ESR) >30 mm/hr indicates inflammation and the need for further evaluation for infectious, autoimmune, autoinflammatory, or malignant diseases, tuberculosis, Kawasaki disease, or autoimmune disease. A low ESR does not eliminate the possibility of infection or JIA. C-reactive protein (CRP) is another acute-phase reactant that becomes elevated and returns to normal more rapidly than the ESR. Experts recommend checking either ESR or CRP, because there is no evidence that measuring both in the same patient with FUO is clinically useful.

Blood cultures should be obtained aerobically. Anaerobic blood cultures have an extremely low yield and should be obtained only if there are specific reasons to suspect anaerobic infection. Multiple or repeated blood cultures may be required to detect bacteremia associated with infective endocarditis, osteomyelitis, or deep-seated abscesses. Polymicrobial bacteremia suggests factitious or self-induced infection or gastrointestinal (GI) pathology. The isolation of leptospires, *Francisella,* or *Yersinia* requires selective media or specific conditions not routinely used. Therefore it is important to inform the laboratory what organisms are suspected in a particular case. Urine culture should be obtained in all cases. Next-generation sequencing of tissue or whole blood or plasma may identify undetected or unculturable bacteria, fungi, or viruses.

Tuberculin skin testing (TST) should be performed with intradermal placement of 5 units of purified protein derivative that has been kept appropriately refrigerated. In children >2 years old, it is reasonable to test for tuberculosis using an interferon-γ release assay (IGRA).

Imaging studies of the chest, sinuses, mastoids, or GI tract may be indicated by specific historical or physical findings. Radiographic evaluation of the GI tract for IBD may be helpful in evaluating selected children with FUO and no other localizing signs or symptoms.

Examination of the bone marrow can reveal leukemia; metastatic neoplasm; mycobacterial, fungal, or parasitic infection; histiocytosis; hemophagocytosis; or storage diseases. If a bone marrow aspirate is performed, cultures for bacteria, mycobacteria, and fungi should be obtained.

Serologic tests can aid in the diagnosis of EBV infection, CMV infection, toxoplasmosis, salmonellosis, tularemia, brucellosis, leptospirosis, cat-scratch disease, Lyme disease, rickettsial disease, and on some occasions JIA. The clinician should be aware that the reliability and the sensitivity and specificity of these tests vary; for example, serologic tests for Lyme disease outside of reference laboratories have been generally unreliable.

MRI scans may be helpful in detecting abdominal abscesses and osteomyelitis, especially if the focus cannot be localized to a specific limb or multifocal disease is suspected. ^{18}F-fluorodeoxyglucose positron emission tomography (PET) combined with MRI or CT is a helpful imaging modality and contributed to an ultimate diagnosis in 48% of children in a Dutch study. Echocardiograms can demonstrate vegetation on the leaflets of heart valves, suggesting infective endocarditis. Ultrasonography (US) can identify intraabdominal abscesses of the liver, subphrenic space, pelvis, or spleen.

Total-body CT or MRI (both with contrast) is usually the first imaging study of choice; both permit detection of neoplasms and collections of purulent material without the use of surgical exploration or radioisotopes. CT and MRI are helpful in identifying lesions of the head, neck, chest, retroperitoneal spaces, liver, spleen, intraabdominal and intrathoracic lymph nodes, kidneys, pelvis, and mediastinum. CT- or US-guided aspiration or biopsy of suspicious lesions has reduced the need for exploratory laparotomy or thoracotomy. MRI is particularly useful for detecting osteomyelitis or myositis if there is concern about a specific limb. Diagnostic imaging can be helpful in confirming or evaluating a suspected diagnosis. With CT scans, however, the child is exposed to large amounts of radiation. PET-CT or MRI may help localize an occult tumor.

Biopsy is occasionally helpful in establishing a diagnosis of FUO. Bronchoscopy, laparoscopy, mediastinoscopy, and GI endoscopy can provide direct visualization and biopsy material when organ-specific manifestations are present. When employing any of the more invasive testing procedures, the risk/benefit ratio for the patient must always be considered before proceeding further. A diagnostic approach to an FUO is noted in Figure 222.2.

MANAGEMENT

The ultimate treatment of FUO is tailored to the underlying diagnosis. Fever and infection in children are not synonymous, and **antimicrobial agents** should only be used when there is evidence of infection, with avoidance of empirical trials of medication. An exception may be the use of antituberculous treatment in critically ill children with

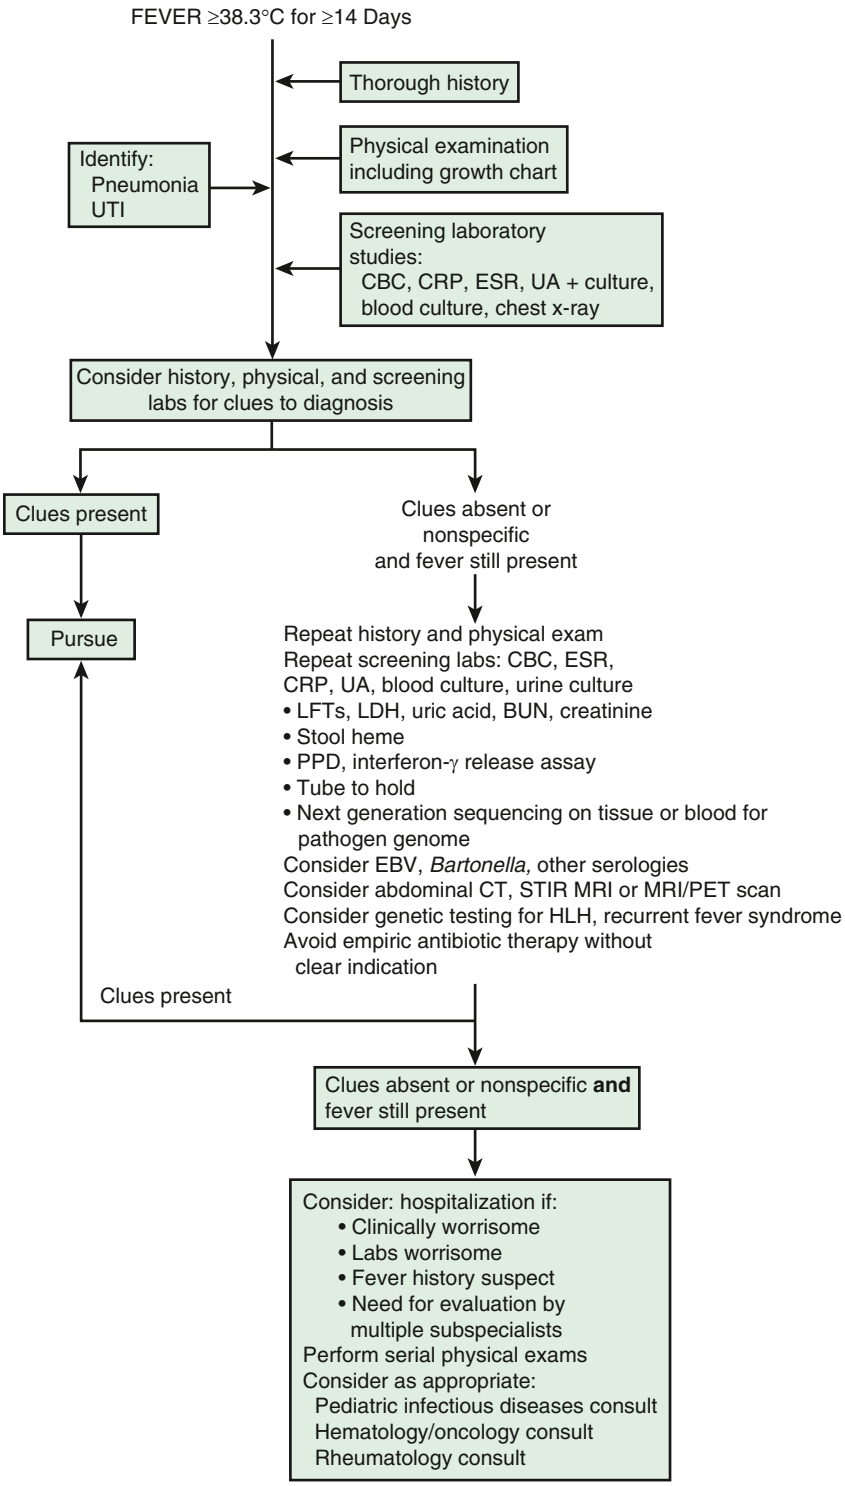

Fig. 222.2 Algorithmic approach to the evaluation of fever of unknown origin (FUO). EBV, Epstein-Barr virus; HLH, hemophagocytic lymphohistiocytosis; LDH, lactate dehydrogenase; LFT, liver function test; PPD, purified protein derivative; STIR, short tau inversion recovery rapid MRI; UTI, urinary tract infection. *(Modified from Huppler AR. Fever. In Kliegman RM, Toth H, Bordini BJ, Basel D, eds. Nelson Pediatric Symptom-Based Diagnosis, 2nd ed. Philadelphia: Elsevier; 2023, Fig. 52.2, p. 982.)*

suspected disseminated tuberculosis. Empirical trials of other antimicrobial agents may be dangerous and can obscure the diagnosis of infective endocarditis, meningitis, parameningeal infection, or osteomyelitis. After a complete evaluation, **antipyretics** may be indicated to control fever associated with adverse symptoms.

PROGNOSIS

Children with FUO have a better prognosis than adults. The outcome in a child depends on the primary disease process. In many cases, no diagnosis can be established, and fever abates spontaneously. In as many as 25% of children in whom fever persists, the cause of the fever remains unclear even after thorough evaluation.

In a series of 69 patients referred for "prolonged" unexplained fever, 10 were not actually having fever, and 11 had diagnoses that were readily apparent at the initial visit. The remaining 48 were classified as having FUO. The median duration of reported fever for these patients was 30 days. Fifteen received a diagnosis, and 10 (67%) had confirmed infections: acute EBV or CMV infection ($n = 5$; with 1 patient developing hemophagocytic lymphohistiocytosis), cat-scratch disease (3), and histoplasmosis (2). The other 5 patients had inflammatory conditions (systemic JIA, 2; IBD, 1), central fever (1), or malignancy (acute lymphoblastic leukemia, 1).

Chapter 223

Infections in Immunocompromised Persons

Marian G. Michaels, Hey Jin Chong, and Michael Green

Infection develops when the host immune system fails to protect adequately against potential pathogens (see also Chapters 165, 166, and 180). For individuals with an intact immune system, infection occurs in the setting of naïveté to the microbe and absence of or inadequate preexisting microbe-specific immunity, or when protective barriers of the body such as the skin have been breached. Healthy children are able to meet the challenge of most infectious agents with an immunologic armamentarium capable of preventing significant disease. Once an infection begins to develop, an array of immune responses is set into action to control the disease and prevent it from reappearing. In contrast, immunocompromised children might not have this same capability. Depending on the level and type of immune defect, the affected child might not be able to contain the pathogen or develop an appropriate immune response to prevent recurrence.

Primary immunodeficiencies are compromised states that result from genetic defects affecting one or more arms of the immune system. **Acquired**, or **secondary**, **immunodeficiencies** may result from infection (e.g., infection with **HIV**), from malignancy, or as a consequence of immunomodulating or immunosuppressing medications. The latter include medications that affect T cells (corticosteroids, calcineurin inhibitors, tumor necrosis factor [TNF] inhibitors, chemotherapy), neutrophils (myelosuppressive agents, idiosyncratic or immune-mediated neutropenia), specific immunoregulatory cells (TNF blockers, interleukin-2 inhibitors), or all immune cells (chemotherapy). Perturbations of the mucosal and skin barriers or the normal microbial flora can also be characterized as secondary immunodeficiencies, predisposing the host to infections, if only temporarily.

The pathogens causing infections among *immunocompetent* hosts are also responsible for infections among children with *immunodeficiencies*. In addition, less virulent or opportunistic organisms, including normal skin flora, commensal bacteria of the oropharynx or gastrointestinal (GI) tract, environmental fungi, and common community viruses of low-level pathogenicity, can cause severe, life-threatening illnesses in immunocompromised patients (Table 223.1). Close communication with the diagnostic laboratory is critical to ensure that the laboratory does not disregard normal flora and organisms normally considered contaminants as being unimportant.

Table 223.1 Most Common Causes of Infections in Immunocompromised Children

BACTERIA, AEROBIC
Acinetobacter
Bacillus
Burkholderia cepacia
Citrobacter
Corynebacterium
Enterobacter spp.
Enterococcus faecalis
Enterococcus faecium
Escherichia coli
Klebsiella spp.
Listeria monocytogenes
Mycobacterium spp.
Neisseria meningitidis
Nocardia spp.
Pseudomonas aeruginosa
Staphylococcus aureus
Staphylococcus, coagulase-negative
Streptococcus pneumoniae
Streptococcus, viridans group
BACTERIA, ANAEROBIC
Bacillus
Clostridium
Fusobacterium
Peptococcus
Peptostreptococcus
Propionibacterium
Veillonella
FUNGI
Aspergillus
Candida albicans
Other *Candida* spp.
Cryptococcus neoformans
Fusarium spp.
Pneumocystis jirovecii
Zygomycoses *(Mucor, Rhizopus, Rhizomucor)*
VIRUSES
Adenoviruses
Cytomegalovirus
Epstein-Barr virus
Herpes simplex virus
Human herpesvirus 6
Polyomavirus (BK)
Respiratory and enteric community-acquired viruses
Varicella-zoster virus
PROTOZOA
Cryptosporidium parvum
Giardia lamblia
Toxoplasma gondii

223.1 Infections Occurring with Primary Immunodeficiencies

Marian G. Michaels, Hey Jin Chong, and Michael Green

Currently, more than 450 genes involving inborn errors of immunity have been identified, accounting for a wide array of diseases presenting with susceptibility to infection, allergy, autoimmunity, and autoinflammation, as well as malignancy (see Chapters 165 and 166).

ABNORMALITIES OF THE PHAGOCYTIC SYSTEM

Children with abnormalities of the phagocytic and neutrophil system have problems with bacteria and environmental fungi. Disease manifests as recurrent infections of the skin, mucous membranes, lungs, liver, and bones. Dysfunction of this arm of the immune system can be a result of inadequate numbers, abnormal movement properties, or aberrant function of neutrophils (see Chapter 168).

Neutropenia is defined as an absolute neutrophil count (ANC) of <1,000 cells/mm^3 and can be associated with significant risk for developing severe bacterial and fungal disease, particularly when prolonged or when the ANC is <500 cells/mm^3. Although acquired neutropenia secondary to bone marrow suppression from a virus or medication is common, practitioners should be cognizant of genetic causes of neutropenia. **Primary congenital neutropenia** most often manifests during the first year of life with cellulitis, perirectal abscesses, or stomatitis from *Staphylococcus aureus* or *Pseudomonas aeruginosa.* Episodes of severe disease, including bacteremia or meningitis, are also possible. Bone marrow evaluation shows a failure of maturation of myeloid precursors. Many of the neutropenic syndromes respond to colony-stimulating factor. Cyclic neutropenia can be associated with autosomal dominant inheritance or de novo sporadic gene variations

and manifests as fixed cycles of severe neutropenia between periods of normal granulocyte numbers. Often the ANC has normalized by the time the patient presents with symptoms, thus hampering the diagnosis. The cycles classically occur every 21 days (range: 14-36 days), with neutropenia lasting 3-6 days. Most often the disease is characterized by recurrent aphthous ulcers and stomatitis during the periods of neutropenia. However, life-threatening necrotizing myositis or cellulitis and systemic disease can occur, especially with *Clostridium septicum* or *Clostridium perfringens*.

Leukocyte adhesion deficiencies (LADs) are caused by defects of neutrophil aggregation and attachment to endothelial surfaces, rendering them unable to enter sites of infection (see Chapter 168). In the most severe form, there is a total absence of CD18, seen in LAD type 1, but genetic defects in fucose metabolism (LAD type 2) and FERMT3 (LAD type 3) have also been described. Generally, children with LAD have a history of delayed cord separation and recurrent infections of the skin, oral mucosa, and genital tract beginning early in life. Ecthyma gangrenosum also occurs. Because the defect involves leukocyte migration and adherence, the ANC in the peripheral blood is usually *extremely elevated,* but a key hallmark of LAD is that pus is not found at the site of infection. The mainstay of treatment is aggressive antibiotic use, with curative therapy being hematopoietic stem cell transplantation (HSCT).

Chronic granulomatous disease (CGD) is an inherited neutrophil dysfunction syndrome, which can be either X-linked or autosomal recessive, although spontaneous genetic changes can also occur (see Chapter 170). Neutrophils and other myeloid cells have defects in their nicotinamide-adenine dinucleotide phosphate oxidase function, decreasing superoxide production and thereby impairing intracellular killing. Accordingly, microbes that destroy their own hydrogen peroxide *(S. aureus, Serratia marcescens, Burkholderia cepacia, Nocardia* spp., *Aspergillus)* cause recurrent infections in these children. Less common but considered pathognomonic are *Granulibacter bethesdensis, Francisella philomiragia, Chromobacterium violaceum,* and *Paecilomyces* infections. Infections have a predilection to involve the lungs, liver, and bone. **Mulch pneumonitis** can be seen in patients with known CGD but also can be a unique presenting feature in adults with autosomal recessive CGD. Mulch pneumonitis can resemble hypersensitivity pneumonitis, and bronchoscopy may yield *Aspergillus* but often may not identify a clear organism. Treatment with antifungals and corticosteroids for the inflammation is recommended. *S. aureus* abscesses can occur in the liver despite prophylaxis. In addition, these children can present with recurrent abscesses affecting the skin, perirectal region, or lymph nodes. Sepsis can occur but is more common with certain gram-negative organisms such as *C. violaceum* and *F. philomiragia*.

Prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX), recombinant human interferon-γ, and oral antifungal agents with activity against *Aspergillus* spp., such as itraconazole or newer azoles, substantially reduces the incidence of severe infections. Patients with life-threatening infections are also reported to benefit from aggressive treatment with white blood cell transfusions along with antimicrobial agents directed against the specific pathogen. In addition, HSCT can be curative, and gene therapy trials are also a consideration. It is important to remember that patients with CGD do not make pus, and thus drainage alone for liver abscesses is not effective. Instead, patients should be treated with intravenous (IV) antibiotics as well as IV corticosteroids, with surgical resection considered if these measures fail.

DEFECTIVE SPLENIC FUNCTION, OPSONIZATION, OR COMPLEMENT ACTIVITY

Children who have congenital asplenia or splenic dysfunction associated with polysplenia or hemoglobinopathies, such as sickle cell disease, as well as those who have undergone splenectomy are at risk for serious infections from encapsulated bacteria and blood-borne protozoa such as *Plasmodium* and *Babesia.* Prophylaxis against bacterial infection with penicillin or amoxicillin should be considered for these patients, particularly children <5 years of age. The most common causative bacterial organisms include *Staphylococcus pneumoniae, Haemophilus influenzae* type b (Hib), and *Salmonella,* which can cause sepsis, pneumonia, meningitis, and osteomyelitis. Defects in the early complement components, particularly C2 and C3, may also be associated with severe infection from these bacteria. **Terminal complement defects** (C5, C6, C7, C8, and C9) are associated with recurrent infections with *Neisseria.* Patients with complement deficiency also have an increased incidence of autoimmune disorders. Vaccines for *S. pneumoniae,* Hib, and *N. meningitidis* should be administered to all children with abnormalities in opsonization or complement pathways (see Chapters 173 and 174).

B-CELL DEFECTS (HUMORAL IMMUNODEFICIENCIES)

Antibody deficiencies account for the majority of primary immunodeficiencies among humans (see Chapters 165 and 166). Patients with defects in the B-cell arm of the immune system fail to develop appropriate antibody responses, with abnormalities that range from complete **agammaglobulinemia** to isolated failure to produce antibody against a specific antigen or organism. Complete antibody deficiencies found in children with **X-linked agammaglobulinemia (XLA)** or other rarer autosomal recessive **agammaglobulinemia** predispose to infections with encapsulated organisms such as *S. pneumoniae* and Hib. Other bacteria can also be problematic in these children (see Table 223.1). Patients with XLA can also have neutropenia, with one case series showing 12 of 13 patients with XLA having neutropenia as part of the initial presentation. Because of the neutropenia, patients with XLA can present with *Pseudomonas* septicemia. Viral infections can also occur, with rotavirus leading to chronic diarrhea. Enteroviruses can disseminate and cause a chronic meningoencephalitis syndrome in these patients. Paralytic polio can develop after immunization with live polio vaccine. Protozoan infections such as giardiasis can be severe and persistent.

Children with agammaglobulinemia are usually asymptomatic until 5-6 months of age, when maternally derived antibody levels begin to wane. Around 6 months of age these children begin to develop recurrent episodes of otitis media, bronchitis, pneumonia, bacteremia, and meningitis. Many of these infections respond quickly to antibiotics, delaying the recognition of antibody deficiency, with studies showing some patients diagnosed in their teens. Children with B-cell defects can develop bronchiectasis over time after chronic or recurrent pulmonary infections and require lifelong IgG replacement therapy. Careful physical examination identifies lack of tonsils in these children, and lymphocyte subsets should confirm the lack of circulating B cells.

Selective IgA deficiency is the most common antibody deficiency and leads to a lack of production of secretory antibody at the mucosal membranes (see Chapter 166). Even though most patients have no increased risk for infections, some have mild to moderate disease at sites of mucosal barriers. Accordingly, recurrent sinopulmonary infection and GI disease are the major clinical manifestations. These patients also have an increased incidence of allergies and autoimmune disorders compared with the normal population.

Common variable immunodeficiency (CVID) is considered an antibody deficiency, with ~30% of cases found to have a monogenic cause. Diagnosis can be made in children over the age of 4, with low IgG as well as low IgM or IgA and lack of protective vaccine titers. These patients develop sinopulmonary and GI infections with common organisms, although they can have more severe presentations than their immunocompetent counterparts. They also have increased risk of autoimmunity and malignancy and often require IgG replacement.

Hyper-IgM syndrome encompasses a group of genetic defects associated with immunoglobulin class-switch recombination. The most common type is caused by a defect in the CD40 ligand on the T cell, leading to inability of the B cell to class-switch (see Chapter 166). Similar to other patients with humoral defects, these patients are at risk for bacterial sinopulmonary infections. However, unlike a true pure antibody defect, besides being important in T-cell–B-cell interactions, CD40 ligand is also important in the interaction between T cells and macrophages/monocytes, predisposing to opportunistic infections such as *Pneumocystis jirovecii* pneumonia (PJP) and *Cryptosporidium* intestinal infection.

T-CELL DEFECTS (CELL-MEDIATED IMMUNODEFICIENCIES)

Children with primary T-cell–mediated immunodeficiencies can present early in life and are susceptible to viral, fungal, and protozoan infections. Clinical manifestations include chronic diarrhea,

mucocutaneous candidiasis, and recurrent pneumonia, rhinitis, and otitis media. In thymic hypoplasia **(DiGeorge syndrome)**, hypoplasia or aplasia of the thymus and parathyroid glands occurs during fetal development in association with the presence of other congenital abnormalities. Hypocalcemia and cardiac anomalies can be the presenting features of DiGeorge syndrome, which should prompt evaluation of the T-cell system.

Chronic mucocutaneous candidiasis (CMC) is a group of immunodeficiencies leading to susceptibility to fungal infections of the skin, nails, oral cavity, and genitals. Most frequently caused by *Candida* spp., dermatophyte infections with *Microsporum, Epidermophyton,* and *Trichophyton* have also been described. Interestingly, patients with CMC do not have an increased risk for histoplasmosis, blastomycosis, or coccidioidomycosis. Despite chronic cutaneous and mucosal infection with *Candida* spp., these patients often lack a delayed hypersensitivity to skin tests for *Candida* antigen. Several gene defects have been identified in people with CMC, including *STAT1* gain-of-function pathologic gene variations, *IL17R* defects, *CARD9* deficiency, and *ACT1* deficiency. Although patients with CMC generally do not develop invasive candidiasis, patients with CMC as a feature of an inborn error or immunity certainly do develop invasive *Candida* infection. Endocrinopathies, autoimmunity, and life-threatening vascular abnormalities can be seen as well, making genetic testing important in the prognosis and management of patients with CMC.

COMBINED B-CELL AND T-CELL DEFECTS

Patients with defects in both the B-cell and T-cell components of the immune system have variable manifestations depending on the extent of the defect (see Chapter 165). Complete or almost complete immunodeficiency is found with **severe combined immunodeficiency disorder (SCID)**, whereas partial defects can be present in such states as **ataxia-telangiectasia**, **Wiskott-Aldrich syndrome**, **hyper-IgE syndrome**, and **X-linked lymphoproliferative disorder**. Rather than one disorder, SCID represents a heterogeneous group of genetic defects that present in the first year of life with recurrent and typically severe infections caused by a variety of bacteria, fungi, and viruses. Failure to thrive, chronic diarrhea, mucocutaneous or systemic candidiasis, PJP, or cytomegalovirus (CMV) infections are common early in life. Passive maternal antibody is relatively protective against the bacterial pathogens during the first few months of life, but thereafter patients are susceptible to both gram-positive and gram-negative organisms. Exposure to live-virus vaccines can also lead to disseminated disease; accordingly, the use of live vaccines (including rotavirus vaccine) is contraindicated in patients with suspected or proven SCID. Without stem cell transplantation or gene therapy, most affected children succumb to infections within the first year of life.

Children with **ataxia-telangiectasia** develop recurrent sinopulmonary infections from both bacteria and respiratory viruses and are particularly susceptible to chronic lung infections because of their immunodeficiency and their muscular weakness leading to poor airway clearance. In addition, these children experience an increased incidence of malignancies and neurologic complications, with most patients being wheelchair bound by the second decade of life. **Wiskott-Aldrich syndrome** is an X-linked recessive disease associated with eczema, thrombocytopenia, reduced number of CD3 lymphocytes, moderately suppressed mitogen responses, and impaired antibody response to polysaccharide antigens. Accordingly, infections with *S. pneumoniae* or Hib can be seen.

Hyper-IgE syndrome (HIES) is characterized by elevated levels of IgE, infections, and eczema, with the most common cause being the result of dominant negative gene variation in *STAT3*. Pathogenic gene variants in *TYK2, PGM3, ZNF341, CARD11,* and *IL6ST* have also been reported to cause this phenotype. Patients can present with recurrent episodes of *S. aureus* abscesses of the skin, lungs, and musculoskeletal system. These abscesses were initially described as "cold" in that they did not have the characteristic warmth and rubor typically seen in immunocompetent patients and thereby are easily missed, delaying therapy. Patients can also develop infections caused by *Candida* and, depending on the gene defect, severe viral infections. Patients with *STAT3* HIES should receive prophylaxis against *S. aureus* with aggressive management of eczema as well.

223.2 Infections Occurring with Acquired Immunodeficiencies

Marian G. Michaels, Hey Jin Chong, and Michael Green

Immunodeficiencies can be secondarily acquired from infections or other underlying disorders, such as malignancy, cystic fibrosis, diabetes mellitus, sickle cell disease, or malnutrition. Immunosuppressive medications used to prevent rejection after organ transplantation, to prevent graft-versus-host disease (GVHD) after stem cell transplantation, or to treat malignancies may also leave the host vulnerable to infections. Similarly, medications used to control rheumatologic or other autoimmune diseases may be associated with an increased risk for developing infection. Surgical removal of the spleen likewise puts a person at increased risk for infections. Further, any process that disrupts the normal mucosal and skin barriers (e.g., burns, surgery, indwelling catheters) may lead to an increased risk for infection.

ACQUIRED IMMUNODEFICIENCY FROM INFECTIOUS AGENTS

Infection with HIV, the causative agent of **AIDS**, remains globally an important infectious cause of acquired immunodeficiency (see Chapter 322). Left untreated, HIV infection has profound effects on many parts of the immune system but in particular T-cell–mediated immunity that leads to susceptibility to the same types of infections as with primary T-cell immunodeficiencies.

Other organisms can also lead to temporary alterations of the immune system. Very rarely, transient neutropenia associated with community-acquired viruses can lead to significant disease with bacterial infections. Secondary infections can occur because of impaired immunity or disruption of normal mucosal immunity, as exemplified by the increased risk for pneumonia from *S. pneumoniae* or *S. aureus* after influenza infection and group A streptococcal cellulitis and fasciitis after varicella.

MALIGNANCIES

The immune systems of children with malignancies are compromised by the therapies used to treat the cancer and, at times, by direct effects of the cancer itself. The type, duration, and intensity of anticancer therapy remain the major risk factors for infections in these children and often affect multiple arms of the immune system. The presence of mucous membrane abnormalities, indwelling catheters, malnutrition, prolonged exposure to antibiotics, and frequent hospitalizations adds to the risk for infection in these children.

Even though several arms of the immune system can be affected, the major abnormality predisposing to infection in children with cancer is **neutropenia**. The depth and duration of neutropenia are the primary predictors of the risk of infection in children being treated for cancer. Patients are at particular risk for bacterial and fungal infections if the ANC decreases to <500 cells/mm^3, and the risk is highest in those with counts <100 cells/mm^3. Counts of >500 cells/mm^3 but <1,000 cells/mm^3 incur some increased risk for infection, but not nearly as great. The lack of neutrophils can lead to a diminution of inflammatory response, limiting the ability to localize sites of infection and potentially leaving fever as the only manifestation of infection. Accordingly, the absence of physical signs and symptoms does not reliably exclude the presence of infection, resulting in the need for empirical antibiotics (Fig. 223.1). Because patients with **fever and neutropenia** might only have subtle signs and symptoms of infection, the presence of fever warrants an intensive investigation, including a thorough physical examination with careful attention to the oropharynx, lungs, perineum and anus, skin, nailbeds, and intravascular catheter insertion sites (Table 223.2).

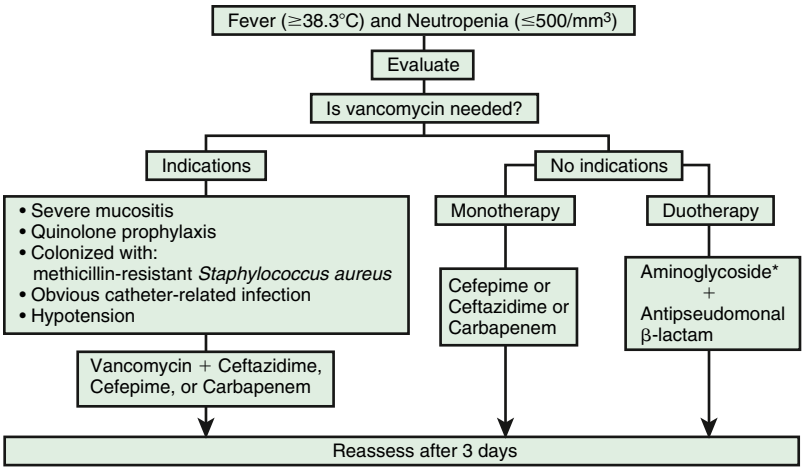

Fig. 223.1 Algorithm for the initial management of the febrile neutropenic patient. Monotherapy can be considered with cefepime, imipenem/cilastatin, meropenem, piperacillin-tazobactam, or ticarcillin–clavulanic acid. *Aminoglycoside antibiotics should be avoided if the patient is also receiving nephrotoxic, ototoxic, or neuromuscular blocking agents; has renal or severe electrolyte dysfunction; or is suspected of having meningitis (because of poor blood-brain perfusion). *(Adapted from Freifeld AG, Bow EJ, Sepkowitz KA, et al. Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America. Clin Infect Dis. 2011;52:e56–e93.)*

A comprehensive laboratory evaluation, including a complete blood cell count, serum creatinine, blood urea nitrogen, and serum transaminases, should be obtained. Blood cultures should be taken from each port of any **central venous catheter** (CVC) and from a peripheral vein and repeated if the original culture is negative. Although peripheral vein sampling is often omitted with continued fevers and neutropenia, it should be obtained before the initial antibiotic administration and reconsidered in children with one or more positive cultures from a CVC, facilitating localization (line vs systemic) of the source of the infection. Other microbiologic studies should be done if there are associated clinical symptoms, including a nasal aspirate for viruses in patients with upper respiratory findings; stool for viruses such as rotavirus or norovirus and for *Clostridium difficile* toxin in patients with diarrhea; urinalysis and culture in young children or in older patients with symptoms of urgency, frequency, dysuria, or hematuria; and biopsy and culture of cutaneous lesions. Chest radiographs should be obtained in any patient with lower respiratory tract symptoms, although pulmonary infiltrates may be absent in children with severe neutropenia. Sinus films should be obtained for children >2 years of age if rhinorrhea is prolonged. Abdominal CT scans should also be considered in children with profound neutropenia and abdominal pain to evaluate for the presence of typhlitis. Chest CT scan should be considered for children not responding to broad-spectrum antibiotics who have continued fever and neutropenia for >96 hours. Although some have considered the use of fungal biomarkers (e.g., galactomannan, β-D-glucan, fungal polymerase chain reaction [PCR]), these assays have poor positive predictive values, and their use is not routinely recommended. Biopsies for cytology, Gram stain, and culture should be considered if abnormalities are found during endoscopic procedures or if lung nodules are identified radiographically.

Past studies demonstrated that before the routine institution of empirical antimicrobial therapy for fever and neutropenia, 75% of children with fever and neutropenia were ultimately found to have a documented site of infection, suggesting that most children with fever and neutropenia will have an underlying infection (see Table 223.2). Current data suggest that bacteremia is present in ~20% of febrile neutropenic pediatric patients with leukemia; ~90% have bacterial disease (Fig. 223.2). Currently, gram-positive cocci are the most common pathogens identified in these patients; however, gram-negative organisms such as *P. aeruginosa, Escherichia coli,* and *Klebsiella* can cause life-threatening infection and must be considered in the empirical treatment regimen. Other multidrug-resistant Enterobacterales are increasingly recovered in these children. Although coagulase-negative staphylococci often cause infections in these children in association with CVCs, these infections are typically indolent, and a short delay in treatment usually does not lead to a detrimental outcome. Other gram-positive bacteria, such as *S. aureus* and *S. pneumoniae,* can cause more fulminant disease and require prompt institution of therapy. Viridans streptococci are particularly important potential pathogens in patients with the oral mucositis that is often associated with use of cytarabine and in patients who experience selective pressure from treatment with certain antibiotics such as quinolones. Infection caused by this group of organisms can present with an acute septic shock syndrome. Also, patients with prolonged neutropenia are at increased risk for opportunistic fungal infections (fungemia or tissue invasion), with *Candida* spp. and *Aspergillus* spp. being the most commonly identified fungi. Other fungi that can cause serious disease in these children include zygomycetes, *Fusarium* spp., and dematiaceous molds. In patients with repeatedly negative blood cultures but persistent fevers, next-generation sequencing in blood or plasma may help identify bacterial, viral, fungal, or protozoan pathogens.

FEVER AND NEUTROPENIA

The use of empirical antimicrobial treatment as part of the management of fever and neutropenia decreases the risk of progression to sepsis, septic shock, acute respiratory distress syndrome, organ dysfunction, and death. In 2017 the International Pediatric Fever and Neutropenia Guideline Panel updated a comprehensive guideline for the management of neutropenic children with cancer or after HSCT (see Fig. 223.1).

First-line antimicrobial therapy should take into consideration the types of microbes anticipated and the local resistance patterns encountered at each institution as well as the level of risk for severe infection associated with a given patient. In addition, antibiotic choices may be limited by specific circumstances, such as the presence of drug allergy and renal or hepatic dysfunction. Guidelines for the management of fever and neutropenia in children with cancer and/or undergoing HSCT conclude that the use of oral antimicrobial therapy as either initial or stepdown therapy can be considered in low-risk children who can tolerate oral antibiotics and in whom careful monitoring can be ensured. However, the guideline emphasizes that oral medication use may present major challenges in children, including the availability of liquid formulations of appropriate antibiotics, cooperation of young children, and the presence of mucositis potentially interfering with absorption. Accordingly, decisions to implement this approach should be reserved for a select subset of these children presenting with fever and neutropenia and institutions with an appropriate infrastructure to follow them as outpatients.

The decision to initially use IV monotherapy versus an expanded regimen of antibiotics depends on the severity of illness of the patient, history of previous colonization with resistant organisms, and obvious presence of catheter-related infection. Glycopeptide addition (such as vancomycin) to the initial empirical regimen should be implemented if the patient has hypotension or other evidence of septic shock, an obvious catheter-related infection, a history of colonization with methicillin-resistant *S. aureus,* or the patient is at high risk for infection with viridans streptococci (severe mucositis, acute myelogenous leukemia, or prior use of quinolone prophylaxis). Otherwise, use of monotherapy with an antipseudomonal β-lactam, such as piperacillin-tazobactam, a fourth-generation cephalosporin, or a carbapenem can be considered. Ceftazidime should not be used as monotherapy if concern exists for gram-positive organisms or resistant gram-negative bacteria. The addition of a second anti–gram-negative bacterial agent (e.g., aminoglycoside) for empirical therapy can be considered in patients who are clinically unstable when multidrug-resistant organisms are suspected.

Table 223.2 Host Defense Defects and Common Pathogens by Time After Bone Marrow or Hematopoietic Stem Cell Transplantation

TIME PERIOD	HOST DEFENSE DEFECTS	CAUSES	COMMON PATHOGENS
Pretransplant	Neutropenia Abnormal anatomic barriers	Underlying disease Prior chemotherapy	Aerobic gram-negative bacilli
Preengraftment	Neutropenia Abnormal anatomic barriers	Chemotherapy Radiation Indwelling catheters	Aerobic gram-positive cocci Aerobic gram-negative bacilli *Candida* *Aspergillus* Herpes simplex virus (in previously infected patients) Community-acquired viral pathogens
Postengraftment	Abnormal cell-mediated immunity Abnormal anatomic barriers	Chemotherapy Immunosuppressive medications Radiation Indwelling catheters Unrelated cord blood donor	Gram-positive cocci Aerobic gram-negative bacilli Cytomegalovirus Adenoviruses Community-acquired viral pathogens *Pneumocystis jirovecii*
Late posttransplant	Delayed recovery of immune function (cell-mediated, humoral, and abnormal anatomic barriers)	Time required to develop donor-related immune function Graft-versus-host disease	Varicella-zoster virus *Streptococcus pneumoniae*

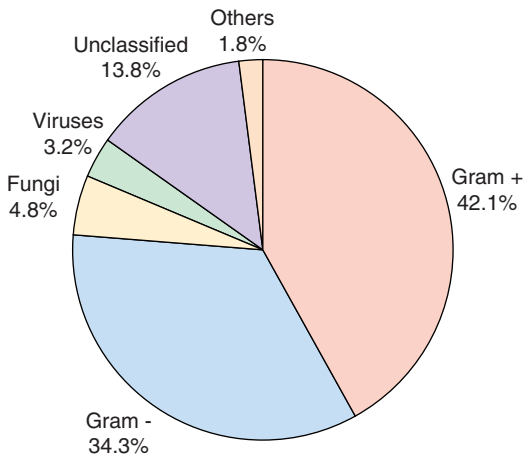

Fig. 223.2 Pathogens involved in the microbiologically documented infections in pediatric oncology patients with febrile neutropenia. *(From Boeriu E, Borda A, Dumitru D, et al. Diagnosis and management of febrile neutropenia n pediatric oncology patients – a systematic review. Diagnostics. 2022;12:1800.)*

Regardless of the regimen chosen initially, it is critical to evaluate the patient carefully and continually for response to therapy, development of secondary infections, and adverse effects. Management recommendations for these children are evolving. Patients who have negative blood cultures at 48 hours, who have been afebrile for at least 24 hours, and who have evidence of bone marrow recovery can have all antibiotics discontinued. However, if symptoms persist or evolve, IV antibiotics should be continued. Continuation of antibiotics in children whose fever has abated and who are clinically well but continue to have depression of neutrophils is more controversial. Pediatric guidelines advocate for discontinuing antibiotics in low-risk patients at 72 hours for children who have negative blood cultures and who have been afebrile for at least 24 hours regardless of bone marrow recovery, as long as careful follow-up is ensured.

Next-generation sequencing (NGS) during episodes of fever and neutropenia may enhance pathogen detection when blood cultures and other tests are negative. NGS has the advantage of detecting bacteria, fungi, viruses and polymicrobial infections. When fever persists despite empiric antibiotics, NGS results may help modify antimicrobial therapy based on the pathogens identified.

Patients without an identified etiology but with **persistent fever** should be reassessed daily. At day 3-5 of persistent fever and neutropenia, those remaining clinically well may continue on the same regimen, although consideration should be given to discontinuing vancomycin or double gram-negative bacterial coverage if they were included initially. Patients who remain febrile with clinical instability warrant escalation of therapy with the addition of a glycopeptide, if it was not included initially and risk factors exist, and modification of the empirical antibacterial regimen to cover potential antimicrobial resistance and anaerobic infections in these children. If fever persists for >96 hours, the addition of an **antifungal agent** with antimold activity should be considered, particularly for those at high risk for invasive fungal infection (those with acute myelogenous leukemia or relapsed acute lymphocytic leukemia or who are receiving highly myelosuppressive chemotherapies for other cancers or with allogeneic HSCT). Liposomal amphotericin products and echinocandins have been studied in children; voriconazole, itraconazole, and posaconazole have been successfully used in adults, with increasing experience in children. Azoles may have substantial drug-drug interactions; however, their use has not been thoroughly evaluated. Studies comparing caspofungin with liposomal amphotericin for children with malignancies and fever and neutropenia have shown that caspofungin is noninferior.

The use of **antiviral agents** in children with fever and neutropenia is not warranted without specific evidence of viral disease. Active herpes simplex or varicella-zoster lesions merit treatment to decrease the time of healing; even if these lesions are not the source of fever, they are potential portals of entry for bacteria and fungi. CMV is a rare cause of fever in children with cancer and neutropenia. If CMV infection is suspected, assays to evaluate viral load in the blood and organ-specific infection should be obtained. Ganciclovir, foscarnet, or cidofovir may be considered while evaluation is pending, although ganciclovir can cause bone marrow suppression and foscarnet and cidofovir can be nephrotoxic. If influenza is identified, specific treatment with an antiviral agent (oseltamivir, zanamivir) should be administered. The possibility of severe acute respiratory syndrome–coronavirus type 2 (SARS-CoV-2) infection should be evaluated by PCR, and treatment should be considered based on current recommendations and local availability of antiviral therapies.

The use of **hematopoietic growth factors** shortens the duration of neutropenia but has not been proved to reduce morbidity or mortality. Accordingly, guidelines do not endorse the routine use of hematopoietic growth factors in patients with established fever and neutropenia, although the recommendations do note that hematopoietic growth factors can be considered as prophylaxis in those with neutropenia at high risk for fever.

Prophylaxis with levofloxacin has been shown to decrease bacteremia for children with acute leukemia receiving intensive chemotherapy and may also be effective in those undergoing allogenic HSCT. However, monitoring for breakthrough bacteremia and for quinolone resistance is important.

FEVER WITHOUT NEUTROPENIA

Infections occur in children with cancer in the absence of neutropenia. Most often, these infections are viral in etiology. However, *P. jirovecii* can cause pneumonia regardless of the neutrophil count. Administration of prophylaxis against *Pneumocystis* is an effective preventive strategy and should be provided to all children undergoing active treatment for malignancy. First-line therapy remains TMP-SMX, with second-line alternatives including pentamidine, atovaquone, dapsone, or dapsone-pyrimethamine. Environmental fungi such as *Cryptococcus, Histoplasma,* and *Coccidioides* can also cause disease. *Toxoplasma gondii* is an uncommon but occasional pathogen in children with cancer. Infections caused by pathogens encountered in healthy children (*S. pneumoniae,* group A streptococcus) can also occur in children with cancer regardless of the granulocyte count.

TRANSPLANTATION

Transplantation of hematopoietic stem cells and solid organs (including heart, liver, kidney, lungs, pancreas, and intestines) is increasingly used as therapy for a variety of disorders. Children undergoing transplantation are at risk for infections caused by many of the same microbial agents that cause disease in children with primary immunodeficiencies. Although the types of infections after transplantation generally are similar among all recipients of these procedures, some differences exist between patients depending on the type of transplantation performed, the type and amount of immunosuppression given, and the child's preexisting immunity to specific pathogens.

Stem Cell Transplantation

Infections after HSCT can be classified as occurring during the **pretransplantation period**, **preengraftment period** (0-30 days after transplantation), **postengraftment period** (30-100 days), or **late posttransplantation period** (>100 days). Specific defects in host defenses predisposing to infection vary within each of these periods (see Table 223.2). In addition, risk is affected by type of transplant (autologous, allogeneic, T-cell depleted, cord blood) along with the quality of the donor-recipient match. Neutropenia and abnormalities in cell-mediated and humoral immune function occur predictably during specific periods after transplantation. In contrast, breaches of anatomic barriers caused by indwelling catheters and mucositis secondary to radiation or chemotherapy create defects in host defenses that may be present any time after transplantation.

Pretransplantation Period

Children come to HSCT with a heterogeneous history of underlying diseases, chemotherapy exposure, degree of immunosuppression, and previous infections. Approximately 12% of all infections among adult HSCT recipients occur during the pretransplantation period. These infections are often caused by aerobic gram-negative bacilli and manifest as localized infections of the skin, soft tissue, and urinary tract. Importantly, the development of infection during this period does not delay or adversely affect the success of engraftment.

Preengraftment Period

Bacterial infections predominate in the preengraftment period (0-30 days). **Bacteremia** is the most common documented infection and occurs in as many as 50% of all HSCT recipients during the first 30 days after transplantation. Bacteremia is typically associated with the presence of either mucositis or an indwelling catheter but may also be seen with pneumonia. Similarly, >40% of children undergoing HSCT experience one or more infections in the preengraftment period. Gram-positive cocci, gram-negative bacilli, yeast, and, less frequently, other fungi cause infection during this period. *Aspergillus* has been identified in 4–20% of HSCT recipients, most often after 3 weeks of neutropenia. Infections caused by the emerging fungal pathogens *Fusarium* and *Pseudallescheria boydii* are associated with the prolonged neutropenia during the preengraftment period.

Viral infections also occur during the preengraftment period. Among adults, reactivation of herpes simplex virus (HSV) is the most common viral disease observed, but this is less common among children. A history of HSV infection or seropositivity indicates the need for prophylaxis. Nosocomial exposure to community-acquired viral pathogens, including SARS-CoV-2, respiratory syncytial virus (RSV), influenza virus, adenovirus, rotavirus, and norovirus, represents another important source of infection during this period. There is growing evidence that community-acquired viruses cause increased morbidity and mortality for HSCT recipients during this period. Adenovirus is a particularly important viral pathogen that can occur early, although it typically presents after engraftment.

Postengraftment Period

The predominant defect in host defenses in the postengraftment period is altered cell-mediated immunity. Accordingly, organisms historically categorized as *opportunistic pathogens* predominate during this period. The risk is especially accentuated 50-100 days after transplantation, when host immunity is lost and donor immunity is not yet established. *P. jirovecii* presents during this period if patients are not maintained on appropriate prophylaxis. Reactivation of *T. gondii,* a rare cause of disease among HSCT recipients, can also occur after engraftment. Hepatosplenic candidiasis often presents during the postengraftment period, although seeding likely occurs during the neutropenic phase.

Cytomegalovirus (CMV) is an important cause of morbidity and mortality among HSCT recipients. Unlike patients undergoing solid organ transplantation (SOT), where primary infection from the donor causes the greatest harm, CMV reactivation in an HSCT recipient whose donor is naïve to the virus can also cause severe disease. Disease risk from CMV after HSCT is also increased in recipients of cord blood transplants or matched unrelated T-cell–depleted transplants and those with GVHD. **Adenovirus**, another important viral pathogen, has been recovered from up to 5% of adult and pediatric HSCT recipients and causes invasive disease in approximately 20% of cases. Children receiving matched unrelated donor organs or unrelated cord blood cell transplants have an incidence of adenovirus infection as high as 14% during this early postengraftment period. **Polyomaviruses** such as BK virus have been increasingly recognized as a cause of renal dysfunction and hemorrhagic cystitis after bone marrow transplantation. Infections with other herpesviruses (Epstein-Barr virus [EBV] and human herpesvirus 6) as well as community-acquired pathogens are associated with excess morbidity and mortality during this period, similar to the preengraftment period.

Late Posttransplantation Period

Infection is unusual after 100 days in the absence of chronic GVHD. However, the presence of chronic GVHD significantly affects anatomic barriers and is associated with defects in humoral, splenic, and cell-mediated immune function. Viral infections, including primary infection with or reactivation of varicella-zoster virus (VZV), are responsible for >40% of infections during this period. This may decrease over time, as the Oka varicella vaccine strain has a lower rate of reactivation than wild-type varicella. Pandemic SARS-CoV-2 has also been noted to have more severe outcomes in children after HSCT. Bacterial infections, particularly of the upper and lower respiratory tract, account for approximately 30% of infections. These infections may be associated with deficiencies in immunoglobulin production, especially IgG2. Fungal infections account for <20% of confirmed infections during the late posttransplantation period.

Solid Organ Transplantation

Factors predisposing to infection after organ transplantation include those that either existed before transplantation or are secondary to intraoperative events or posttransplantation therapies (Table 223.3). Some of these additional risks cannot be prevented, and some risks acquired during or after the operation depend on decisions or actions of members of the transplant team. Organ recipients are at risk for infection from potential exposure to pathogens in the donor organ. Although some donor-derived infections can be anticipated through donor screening, many pathogens are not routinely screened for, and strategies defining when and how to screen for all but a small subset of potential pathogens have not been identified or implemented. Similar to other children who have undergone surgical procedures, surgical site infections are a frequent cause of infection early after transplantation. Beyond this, the need for immunosuppressive agents to prevent rejection is the major factor predisposing to infection after transplantation. Despite efforts to

Table 223.3 Risk Factors for Infections After Solid Organ Transplantation in Children

PRETRANSPLANTATION FACTORS
Age of patient
Underlying disease, malnutrition
Specific organ transplanted
Previous exposures to infectious agents
Previous immunizations
Presence of infection in the donor
INTRAOPERATIVE FACTORS
Duration of transplant surgery
Exposure to blood products
Technical problems

POSTTRANSPLANTATION FACTORS
Immunosuppression
Induction immunosuppression type
Maintenance immunosuppression
Augmented treatment for rejection
Indwelling catheters
Nosocomial exposures
Community exposures

optimize immunosuppressive regimens to prevent or treat rejection with minimal impairment of immunity, all current regimens interfere with the ability of the immune system to prevent infection. The primary target of the majority of these immunosuppressive agents in organ recipients is the cell-mediated immune system, but regimens can and do impair many other aspects of the transplant recipient's immune system as well.

Timing

The timing of specific types of infections is generally predictable, regardless of which organ is transplanted. Infectious complications typically develop in one of three intervals: early (0-30 days after transplantation), intermediate (30-180 days), or late (>180 days); most infections present in the first 180 days after transplantation. Table 223.4 should be used as a general guideline to the types of infections encountered, but the timing of the presentation may be modified with the introduction of newer immunosuppressive therapies and by the use of prophylaxis.

Early infections are usually the result of a complication of the transplant surgery itself, the unexpected acquisition of a bacterial or fungal pathogen from the donor, or the presence of an indwelling catheter. In contrast, infections during the intermediate period typically result from a complication of the immunosuppression, which tends to be at its greatest intensity during the first 6 months after transplantation. This is the period of greatest risk for infections caused by opportunistic pathogens such as CMV, EBV, and *P. jirovecii*. Anatomic abnormalities, such as bronchial stenosis and biliary stenosis, that develop as a result of the transplant surgery can also predispose to recurrent infection in this period.

Infections developing late after transplantation typically result from uncorrected anatomic abnormalities, chronic rejection, or exposure to community-acquired pathogens. Augmented immunosuppression as treatment for late acute cellular rejection or chronic rejection can increase the risk for late presentations with CMV, EBV, and other potential opportunistic infections. Acquisition of infection from community-acquired pathogens such as RSV can result in severe infection secondary to the immunocompromised state of the transplant recipient during the early and intermediate periods. Compared with the earlier periods, community-acquired infections in the late period are usually benign because immunosuppression is typically maintained at significantly lower levels. However, certain pathogens such as VZV and EBV may be associated with severe disease even at this late period.

Bacterial and Fungal Infections

Although there are important graft-specific considerations for bacterial and fungal infections after transplantation, some principles are generally applicable to all transplant recipients. Bacterial and fungal infections after organ transplantation are usually a direct consequence of the surgery, a breach in an anatomic barrier, a foreign body, or an abnormal anatomic narrowing or obstruction. With the exception of infections related to the use of indwelling catheters, sites of bacterial infection tend to occur at or near the transplanted organ. Infections after abdominal transplantation (liver, intestine, or renal) usually occur in the abdomen or at the surgical wound. The pathogens are typically enteric gram-negative bacteria, *Enterococcus*, and occasionally *Candida*. Infections after thoracic transplantation (heart, lung) usually occur in the lower respiratory tract or at the surgical wound. Pathogens associated with these infections include *S. aureus* and gram-negative bacteria. Patients undergoing lung transplantation for cystic fibrosis

Table 223.4 Timing of Infectious Complications After Solid Organ Transplantation

EARLY PERIOD (0-30 DAYS)
Bacterial Infections
Gram-negative enteric bacilli
• Small bowel, liver, neonatal heart
Pseudomonas, Burkholderia, Stenotrophomonas, Alcaligenes
• Cystic fibrosis lung
Gram-positive organisms
• All transplant types
Fungal Infections
• All transplant types
Viral Infections
Herpes simplex virus
• All transplant types
Nosocomial respiratory viruses
• All transplant types
MIDDLE PERIOD (1-6 MO)
Viral Infections
Cytomegalovirus
• All transplant types
• Seronegative recipient of seropositive donor
Epstein-Barr virus
• All transplant types (small bowel the highest-risk group)
• Seronegative recipient
Varicella-zoster virus
• All transplant types
• Opportunistic infections
Pneumocystis jirovecii
• All transplant types
Toxoplasma gondii
• Seronegative recipient of cardiac transplant from a seropositive donor are highest risk group
Bacterial Infections
Pseudomonas, Burkholderia, Stenotrophomonas, Alcaligenes
• Cystic fibrosis lung
Gram-negative enteric bacilli
• Small bowel
LATE PERIOD (>6 MO)
Viral Infections
Epstein-Barr virus
• All transplant types, but less risk than middle period
Varicella-zoster virus
• All transplant types
Community-acquired viral infections
• All transplant types
Bacterial Infections
Pseudomonas, Burkholderia, Stenotrophomonas, Alcaligenes
• Cystic fibrosis lung
• Lung transplants with chronic rejection
Gram-negative bacillary bacteremia
• Small bowel
Fungal Infections
Aspergillus
• Lung transplants with chronic rejection

Adapted from Green M, Michaels MG. Infections in solid organ transplant recipients. In: Long SS, Prober CG, Fischer M, eds. *Principles and Practice of Pediatric Infectious Diseases*, 5th ed. Philadelphia: Elsevier; 2018: Table 95-1.

experience a particularly high rate of infectious complications because they are often colonized with *P. aeruginosa* or *Aspergillus* before transplantation. Even though the infected lungs are removed, the sinuses and upper airways remain colonized with these pathogens, and subsequent reinfection of the transplanted lungs can occur. Children receiving organ transplants are often hospitalized for long periods and receive many antibiotics; thus recovery of multidrug-resistant bacteria is common after all types of organ transplantation. Infections caused by *Aspergillus* are less common but occur after all types of organ transplantation and are associated with high rates of morbidity and mortality.

Viral Infections

Viral pathogens, especially herpesviruses, are a major source of morbidity and mortality after SOT. In addition, BK virus is a major cause of renal disease after kidney transplantation. Although SARS-CoV-2 has affected pediatric SOT recipients less than adult recipients, disease severity is increased compared with nonimmunosuppressed children. The patterns of disease associated with individual viral pathogens are generally similar among all organ transplant recipients. However, the incidence, mode of presentation, and severity differ according to the type of organ transplanted and, for many viral pathogens, pretransplant serologic status of the recipient.

Viral pathogens can be generally categorized as latent pathogens, which cause infection through reactivation in the host or acquisition from the donor (e.g., CMV, EBV) or as community-acquired viruses (e.g., SARS-CoV-2, RSV, influenza). For CMV and EBV, primary infection occurring after transplantation is associated with the greatest degree of morbidity and mortality. The highest risk is seen in a naïve host who receives an organ from a donor who previously was infected with one of these viruses. This mismatched state is frequently associated with severe disease. However, even if the donor is negative for CMV and EBV, primary infection can be acquired from a close contact or through blood products. Secondary infections (reactivation of a latent strain within the host or superinfection with a new strain) tend to result in milder illness unless the patient is highly immunosuppressed, which can occur in the setting of treatment of significant rejection.

CMV is one of the most commonly recognized transplant viral pathogens. Disease from CMV has decreased significantly with the use of preventive strategies, including antiviral prophylaxis, most commonly using ganciclovir or oral valganciclovir, as well as viral load monitoring to inform preemptive antiviral therapy. Some centers have implemented a sequential approach where surveillance viral load monitoring follows a relatively short period of chemoprophylaxis. Clinical manifestations of CMV disease can range from a syndrome of fatigue and fever to tissue-invasive disease that most often affects the liver, lungs, and GI tract.

Infection caused by **EBV** is another important complication of SOT. Clinical symptoms range from a mild mononucleosis syndrome to disseminated **posttransplant lymphoproliferative disorder (PTLD)**. EBV-associated PTLD is more common among children than adults, because primary EBV infection in the immunosuppressed host is more likely to lead to uncontrolled proliferative disorders, including posttransplant lymphoma.

Other viruses, such as adenovirus, also have the capacity to be donor associated, but appear to be less common. The unexpected development of donor-associated viral pathogens, including hepatitis B virus, hepatitis C virus, and HIV, is rare today because of intensive donor screening. However, the changing epidemiology of some viruses (e.g., dengue, chikungunya, Zika) raises concerns for the *donor-derived transmission* of these emerging viral pathogens.

Community-acquired viruses, including those associated with respiratory tract infection (SARS-CoV-2, RSV, influenza virus, adenovirus, parainfluenza virus) and GI infection (enteroviruses, norovirus, and rotavirus), can cause important disease in children after organ transplantation. In general, risk factors for more severe infection include young age, acquisition of infection early after transplantation, and augmented immune suppression. Infection in the absence of these risk factors frequently results in a clinical illness that is comparable to that seen in immunocompetent children. However, some community-acquired viruses, such as adenovirus, can be associated with graft dysfunction even when acquired late after transplantation.

Although children with SARS-CoV-2 infection after transplantation fare better than adult counterparts, they are at risk for more severe symptoms early after transplant and if they have comorbidities. Immunization remains one of the best preventive strategies against severe disease even though efficacy is less compared to nonimmunosuppressed children.

Opportunistic Pathogens

Children undergoing SOT are also at risk for symptomatic infections from pathogens that do not usually cause clinical disease in immunocompetent hosts. Although these typically present in the intermediate period, these infections can also occur late in patients, requiring prolonged and high levels of immunosuppression. *P. jirovecii* is a well-recognized cause of pneumonia after SOT, although routine prophylaxis has essentially eliminated this problem. *T. gondii* can complicate cardiac transplantations because of tropism of the organism for cardiac muscle and risk for donor transmission; less often, it complicates other types of organ transplantation.

223.3 Prevention of Infection in Immunocompromised Persons

Marian G. Michaels, Hey Jin Chong, and Michael Green

Although infections cannot be completely prevented in children who have defects in one or more arms of their immune system, measures can be taken to decrease the risks for infection. Replacement immunoglobulin is a benefit to children with primary B-cell deficiencies. Interferon (IFN)-γ, TMP-SMX, and oral antifungal agents have long been used to reduce the number of infections occurring in children with CGD, although the relative benefit of INF-γ has been questioned. Children who have depressed cellular immunity resulting from primary diseases, advanced HIV infection, or immunosuppressive medications benefit from prophylaxis against *P. jirovecii.* Strategies for safe living for all children with immunocompromising conditions should be emphasized, including hand hygiene, avoidance of community members with communicable infections, and attention to local environmental risk factors. These strategies were stressed and employed during the era of pandemic SARS-CoV-2 circulation. Immunizations prevent many infections and are particularly important for children with compromised immune systems who do not have a contraindication or inability to respond. For children rendered immunocompromised because of medication or splenectomy, immunizations should be administered before treatment whenever possible. This timing allows for superior response to vaccine antigens, avoids the risk of live vaccines, which may be contraindicated depending on the immunosuppression, and importantly, provides protection before the immune system is compromised.

Although immunodeficient children are a heterogeneous group, some principles of prevention are generally applicable. The use of inactivated vaccines does not lead to an increased risk for adverse effects, although their efficacy may be reduced because of an impaired immune response. In most cases, children with immunodeficiencies should receive all the recommended inactivated vaccines. Live-attenuated vaccinations can cause disease in some children with immunologic defects, and therefore alternative immunizations should be used whenever possible, such as inactivated influenza vaccine rather than live-attenuated influenza vaccine or inactivated typhoid vaccine rather than the oral live typhoid vaccine for travelers. In general, live-virus vaccines should not be used in children with primary T-cell abnormalities; efforts should be made to ensure that close contacts are all immunized to decrease the risk of exposure. In some patients in whom wild-type viral infection can be severe, immunizations, even with live-virus vaccine, are warranted in the immunosuppressed child. For example, children with HIV infection and a CD4 level of >15% should receive vaccinations against measles and varicella. In addition, growing evidence suggests that select transplant recipients can safely receive live vaccines as well. Some vaccines should be given to children with immunodeficiencies in addition to routine

vaccinations. As an example, children with asplenia or splenic dysfunction should receive meningococcal vaccine and both the conjugate and the polysaccharide pneumococcal vaccines. Influenza and SARS-CoV-2 vaccination is recommended for all eligible individuals (>6 months old for influenza) and should be emphasized for immunocompromised children and all household contacts to minimize risk for transmission to the immunocompromised child.

Chapter 224

Infection Associated with Medical Devices

Hana Hakim and Joshua Wolf

Use of implanted synthetic and prosthetic devices has revolutionized pediatric practice by providing long-term venous access, limb-salvage surgery, and successful treatment of hydrocephalus, urinary retention, and renal failure. However, infectious complications of these devices remain a major concern and account for a significant number of healthcare-acquired infections (HAIs) and attributable morbidity and mortality among hospitalized patients. Several federal and hospital programs in the United States and elsewhere focus on prevention initiatives to reduce device-related HAI rates, most frequently central line–associated bloodstream infection (CLABSI), catheter-associated urinary tract infection (CAUTI), and ventilator-associated pneumonia (VAP). HAIs are typically defined as infections that occur at least 2 days after admission to the hospital and that were not incubating at the time of admission. Device-associated infections are related to the development of **biofilms**, organized communities of microorganisms on the device surface protected from the immune system and from antimicrobial therapy. A number of factors are important to the development of infection, including host susceptibility, device composition, duration of implantation, and exposure to colonizing or contaminating organisms.

INTRAVASCULAR ACCESS DEVICES

Intravascular access devices range from short, stainless steel needles or plastic cannulae inserted for brief periods to multilumen, implantable, synthetic plastic catheters that are expected to remain in use for years. Infectious complications include local skin and soft tissue infections, such as exit site, tunnel tract, and device pocket infections, and **catheter-related bloodstream infections (CRBSIs)**. The use of central venous devices has improved the quality of life of high-risk patients but has also increased the risk of infection.

Catheter Types

Short-term peripheral cannulae are most often used in pediatric patients, and infectious complications occur infrequently. The rate of peripheral CRBSIs in children is <0.15%. Patient age <1 year, duration of use >144 hours (6 days), and some infusates are associated with increased risk for catheter-related infection. Catheter-associated phlebitis is more common (1–6%) but is rarely infective and can be treated conservatively by cannula removal.

Central venous catheters (CVCs), which terminate in a central vein such as the superior or inferior vena cava, are widely used in both adult and pediatric patients and are responsible for the majority of catheter-related infections. These catheters are frequently used in patients with chronic illnesses such as oncologic, gastrointestinal, and cardiovascular diseases and in critically ill patients, including neonates, who have many other risk factors for nosocomial infection. Patients in an intensive care unit (ICU) with a CVC in place have a fivefold greater risk for developing a nosocomial bloodstream infection than those without. Other risk factors that have been associated with increased incidence of CLABSIs include prolonged hospital stay, total parenteral nutrition, use of multiple concurrent CVCs or a CVC with multiple lumens, and use of short-term nontunneled CVC.

The use of peripherally inserted central catheters, which are inserted into a peripheral vein and terminate in a central vein, has increased in pediatric patients. Infection rates seem to be similar to long-term tunneled CVCs, ranging between 2.0 and 3.51 per 1,000 catheter-days, but other complications such as fracture, dislodgment, and occlusion are more common.

When prolonged intravenous (IV) access is required, a cuffed silicone rubber (Silastic) or polyurethane catheter may be inserted into the superior vena cava through the subclavian, cephalic, or jugular vein. The extravascular segment of the catheter passes through a subcutaneous (SC) tunnel before exiting the skin, usually on the superior aspect of the chest (e.g., Broviac or Hickman catheter). A cuff around the catheter near the exit site induces a fibrotic reaction to seal the tunnel. Totally implanted devices comprise a tunneled central catheter attached to an SC reservoir or port with a self-sealing silicone septum immediately under the skin that permits repeated percutaneous needle access.

The incidence of local (exit site, tunnel, and pocket) infection with long-term catheters is 0.2-2.8/1,000 catheter-days. The incidence of external tunneled CRBSI is 0.5-11.0/1,000 catheter-days. The incidence of CRBSI in implantable devices is much lower at 0.3-1.8/1,000 catheter-days; however, treatment with total parenteral nutrition (TPN) eliminates this risk reduction because of a much greater relative increase in infection rate in ports. The risk for CRBSI is increased among premature infants, young children, and TPN patients.

Catheter-Associated Skin and Soft Tissue Infection

A number of local infections can occur in the presence of a CVC. The clinical manifestations of local infection include erythema, tenderness, and purulent discharge at the exit site or along the SC tunnel tract of the catheter. **Exit site infection** denotes infection localized to the exit site, without significant tracking along the tunnel, often with purulent discharge. **Tunnel tract infection** indicates infection in the SC tissues tracking along a tunneled catheter, which may also include serous or serosanguineous discharge from a draining sinus along the path. **Pocket infection** indicates suppurative infection of an SC pocket containing a totally implanted device. Bloodstream infection may coexist with local infection.

The diagnosis of local infection is established clinically, but a Gram-stained smear and culture of any exit site drainage should be performed to identify the microbiologic cause. The source is usually contamination by skin or gastrointestinal flora, and the most common organisms are *Staphylococcus aureus,* coagulase-negative staphylococci, *Pseudomonas aeruginosa, Candida* spp., and mycobacteria. Green discharge is strongly suggestive of mycobacterial infection, and appropriate stains and culture should be performed.

Treatment of local infection related to a short-term CVC should include device removal. Exit site infection may resolve with device removal alone, but systemic symptoms should initially be managed with antimicrobial therapy. In the case of long-term CVCs, exit site infections usually respond to local care with topical or systemic antibiotics alone. However, tunnel or pocket infections require removal of the catheter and systemic antibiotic therapy in almost all cases. When a tunneled CVC is removed as a result of tunnel infection, the cuff should also be removed and sent for culture if possible. In cases of mycobacterial infection, wide surgical debridement of the tissues is usually required for cure.

Catheter-Related Bloodstream Infection

CRBSI occurs when microorganisms attached to the CVC are shed into the bloodstream, leading to bacteremia. The term **catheter-related bloodstream infection** is reserved for a bloodstream infection that is demonstrated by CVC tip culture or other techniques to have been caused by colonization of the device. In contrast, the more general term **central line–associated bloodstream infection (CLABSI)** is typically

used for surveillance and can refer to any bloodstream infection that occurs in a patient with a CVC, unless there is an identified alternative source. On the device, the organisms are embedded in biofilms as organized communities. Colonization may be present even in the absence of symptoms or positive cultures.

Organisms may contaminate the external surface of the CVC during insertion or the intraluminal surface through handling of the catheter hub or contaminated infusate. Most cases of CRBSI appear to be caused by intraluminal colonization, but external colonization may play a greater role in infections related to recently inserted (<30 days) catheters or in immunocompromised patients. In most populations, gram-positive cocci predominate, with about half of infections caused by coagulase-negative staphylococci. Gram-negative enteric bacteria are isolated in approximately 20–30% of episodes, and fungi account for 5–10% of episodes.

Fever without an identifiable focus is the most common clinical presentation of CRBSI; local soft tissue symptoms and signs are usually absent. Onset of fever or rigors during or soon after flushing of a catheter is highly suggestive of CRBSI. Symptoms and signs of complicated infection, such as septic thrombophlebitis, endocarditis, and ecthyma gangrenosum, may also be present.

Blood cultures collected before beginning antibiotic therapy are generally positive from both the CVC and the peripheral blood. It is important not to collect cultures unless infection is suspected, as blood culture contamination may occur and can lead to inappropriate therapy. To help interpret positive cultures with common skin contaminants, blood cultures should be collected from at least two sites, preferably including all lumens of a CVC, before initiation of antibiotic therapy.

Tests to differentiate CRBSI from other sources of bacteremia in the presence of a CVC include culture of the catheter tip, quantitative blood cultures, and **differential time to positivity** of blood cultures drawn from different sites. Definitive diagnosis of CRBSI can be important to identify those patients who might benefit from catheter removal. Although CVC tip culture can identify CRBSI, it precludes salvage of the catheter. The most readily available technique to confirm CRBSI without catheter removal is calculation of differential time to positivity between blood cultures drawn through a catheter and from a peripheral vein or separate lumen. During CRBSI, blood obtained through the responsible lumen will usually indicate growth at least 2-3 hours before peripheral blood or uncolonized lumens because of a higher intraluminal microorganism burden. Identical volumes of blood must be collected simultaneously from each site, and a continuously monitored blood culture system is required. Specificity of this test is good (94–100%), and sensitivity is good when a peripheral blood culture is available (approximately 90%) but poorer when comparing two lumens of a CVC (64%). Where available, quantitative blood culture showing at least a threefold higher number of organisms from central compared with peripheral blood is similarly diagnostic.

Treatment of CRBSI related to **long-term vascular access devices** (e.g., Hickman, Broviac, totally implantable devices) with systemic antibiotics is successful for many bacterial infections without removal of the device. Antibiotic therapy should be directed to the isolated pathogen and given for a total of 10-14 days from the date of blood culture clearance. Until pathogen identification and susceptibility testing are available, empirical therapy, based on local antimicrobial susceptibility data and usually including **vancomycin** plus an antipseudomonal aminoglycoside (e.g., gentamicin), penicillin (e.g., piperacillin-tazobactam), or cephalosporin (e.g., ceftazidime or cefepime), is generally indicated. An echinocandin or azole antifungal should be initiated if fungemia is suspected. Patients who have a recent history of CRBSI with a resistant organism treated without CVC removal who subsequently develop severe sepsis should generally receive initial empirical therapy directed against that organism, because relapse is common.

Antibiotic lock or dwell therapy, with administration of solutions of high concentrations of antibiotics or ethanol that remain in the catheter for up to 24 hours, has been proposed to improve outcomes when used as an adjuvant to systemic therapy. Antibiotic locks are recommended in patients receiving dialysis who may not have antibiotics frequently delivered through the CVC, but evidence does not suggest that routine use of lock therapy is beneficial in other patient populations, and it may cause harm. Ethanol lock therapy increases the risk of CVC occlusion, and lock therapy can result in delays to necessary CVC removal.

If blood cultures remain positive after 72 hours of appropriate therapy, or if a patient deteriorates clinically, the device should be removed. Failure of CRBSI salvage therapy is common and can be serious in infections caused by *S. aureus* (approximately 50%), *Candida* spp. (>70%), and *Mycobacterium* spp. (>70%). Other indications for removing a long-term catheter include severe sepsis, suppurative thrombophlebitis, and endocarditis. Prolonged therapy (4-6 weeks) is indicated for persistent bacteremia or fungemia after catheter removal, because this may represent unrecognized infective endocarditis or thrombophlebitis. The decision to attempt catheter salvage should weigh the risk and clinical impact of persistent or relapsed infection against the risk of surgical intervention.

CRBSI may be complicated by other intravascular infections such as septic thrombophlebitis or endocarditis. The presence of these conditions may be suggested by preexisting risk factors (e.g., congenital heart disease), signs and symptoms, or persistent bacteremia or fungemia 72 hours after device removal and appropriate therapy. Screening for these complications in otherwise low-risk children, even those with *S. aureus* infection, is not recommended, because the overall frequency is low, and the tests can be difficult to interpret and may lead to inappropriate therapy.

Prevention of Infection

Consistent implementation of evidence-based prevention bundles has been essential to reduce HAI CLABSI rates. Prevention of CLABSI starts with preinsertion planning for the type and number of CVC lumens and selection of the venous site for CVC insertion. Insertion bundle elements include meticulous hand hygiene, aseptic skin preparation using 2% chlorhexidine gluconate, and use of maximal sterile barrier precautions in an operating room–like environment. Maintenance bundles guide the daily safe care of CVCs to prevent infections, including protecting the CVC from gross contamination with excretions or body fluids, evidence-based techniques to access and scrub the CVC hub and connectors, and assessing and changing the CVC site dressing. Regular assessment of the need for the catheter should be part of the daily medical and nursing care team discussions. In general, children with external CVCs are discouraged from swimming because of concern of subsequent CRBSI. However, existing evidence regarding risk of CRBSI related to swimming is limited. It is important to educate patient caregivers about the potential risk and the importance of maintaining a secured CVC with water-resistant dressing if patients choose to swim. Catheters should routinely be removed as soon as they are no longer needed. Although prevalence of infection increases with prolonged duration of catheter use, routine replacement of a required CVC, either at a new site or over a guide wire, results in significant morbidity and is not recommended. Other practices that have been associated with reduction in CLABSI rates include use of a chlorhexidine-impregnated sponge at the exit site and daily bathing of ICU patients with 2% chlorhexidine gluconate. Use of antibiotic, taurolidine, or ethanol lock solutions; heparin with preservatives; and alcohol-impregnated caps, as well as antimicrobial-impregnated/coated catheters may be appropriate in high-risk populations. There is no evidence that routine replacement of short-term peripheral catheters prevents phlebitis or other complications in children, so they should only be replaced when clinically indicated (e.g., phlebitis, dysfunction, dislodgment).

URINARY CATHETERS

Urinary catheters are a frequent cause of HAIs, with approximately 14 infections per 1,000 admissions, resulting in increasing duration of hospitalization, cost of patient care, morbidity, and mortality. Rates of CAUTI are highest among ICU patients. As with other devices, microorganisms adhere to the urinary catheter surface and establish a biofilm that allows proliferation. The physical presence of the catheter reduces the normal host defenses by preventing complete emptying of the bladder, thus providing a medium for growth, distending the urethra, and blocking periurethral glands. Almost all patients catheterized

for >30 days develop bacteriuria. The mechanism of the infection can be either from organisms colonizing the patient's perineal or rectal area or from organisms contaminating the hands of healthcare providers or contaminating equipment such as a collection bag. The organism burden in CAUTI is typically ≥100,000 colony-forming units/mL. Lower thresholds may be used where there is a high index of suspicion, but these episodes usually represent colonization rather than infection. Urine culture should only be performed in catheterized patients when infection is suspected, because asymptomatic colonization is ubiquitous and may lead to overtreatment and subsequent development of bacterial resistance. Gram-negative bacilli and *Enterococcus* spp. are the predominant organisms isolated in CAUTI; coagulase-negative staphylococci are implicated in approximately 15% of cases. Symptomatic UTIs should be treated with antibiotics and catheter removal. Catheter colonization with *Candida* spp. is common but rarely leads to invasive infection, and treatment does not have a long-term impact on colonization. Treatment for asymptomatic candiduria or bacteriuria is not recommended, except in neonates, immunocompromised patients, and those with urinary tract obstruction.

All urinary catheters introduce a risk for infection and thus should be used only when necessary and for the minimum required duration. Existing evidence supports the benefit of using alternatives to indwelling urethral catheters to prevent CAUTI, including external catheters in male patients, intermittent catheterization, or suprapubic catheters in selected patients. Hand hygiene and aseptic technique are part of the insertion bundles of interventions aimed at preventing CAUTI. Evidence-based urinary catheter maintenance practices are essential to prevent hospital-acquired CAUTI, including perineal hygiene, a closed drainage system, maintenance of unobstructed urine flow, and keeping the collection bag below the level of the bladder. Technologic advances have led to the development of silver- or antibiotic-impregnated urinary catheters that are associated with lower rates of infection. Prophylactic antibiotics do not significantly reduce the infection rates for long-term catheters but clearly increase the risk for infection with antibiotic-resistant organisms.

MECHANICAL VENTILATORS

Endotracheal intubation and mechanical ventilation are lifesaving technologies to support patients with respiratory failure and patients undergoing surgical procedures. However, VAP has contributed to prolonged hospital stay and increased costs in patients in medical and surgical ICUs. VAP is more frequently reported in adult than in pediatric patients. The mechanism of VAP is through microaspiration of colonizing oropharyngeal organisms to the lower respiratory tract and its associated host inflammatory response. Common pathogens causing VAP include gram-negative bacilli (e.g., *Escherichia coli, Klebsiella pneumoniae, Enterobacter* spp., and *P. aeruginosa*) and gram-positive cocci (e.g., *S. aureus* and *Streptococcus* spp.). Risk factors for VAP include medications that increase gastric pH (e.g., H_2 blockers, antacids, proton pump inhibitors), decreased level of consciousness, use of paralytics or muscle relaxant agents, and prolonged intubation. Progressive or acute-onset respiratory deterioration requiring increased mechanical setting support in a patient who has been intubated for more than 2 days should raise the suspicion of VAP. Chest diagnostic imaging and cultures of lower respiratory specimens (e.g., endotracheal aspiration or bronchoalveolar lavage) should be considered.

Evidence-based practices to prevent VAP include use of noninvasive ventilation (e.g., continuous positive airway pressure [CPAP], bilevel positive airway pressure [BiPAP]) when possible to avoid endotracheal intubation and prevention of microaspiration by elevating the head of the bed, controlling cuff pressure, minimizing and early weaning of sedation, and maintaining closed ventilator circuits. Oral care with chlorhexidine gluconate for oropharyngeal decontamination has been included as an element in several VAP prevention bundles. Evidence regarding the efficacy and safety of other interventions such as use of probiotics or silver-coated endotracheal tubes has been inconclusive.

CEREBROSPINAL FLUID SHUNTS

Cerebrospinal fluid (CSF) shunting is required for the treatment of many children with **hydrocephalus**. The usual procedure uses a silicone rubber device with a proximal portion inserted into the ventricle, a unidirectional valve, and a distal segment that diverts the CSF from the ventricles to either the peritoneal cavity (**ventriculoperitoneal** [VP] shunt) or right atrium (**ventriculoatrial** [VA] shunt). The incidence of shunt infection ranges from 1% to 20% (average, 10%). The highest rates are reported in young infants, patients with prior shunt infections, and certain etiologies of hydrocephalus. Most infections result from intraoperative contamination of the surgical wound by skin flora. Accordingly, coagulase-negative staphylococci are isolated in more than half the cases. *S. aureus* is isolated in approximately 20% and gram-negative bacilli in 15% of cases.

Four distinct clinical syndromes have been described: colonization of the shunt, infection associated with wound infection, distal infection with peritonitis, and infection associated with meningitis. The most common type of infection is **colonization of the shunt**, with nonspecific symptoms that reflect shunt malfunction as opposed to frank infection. Symptoms associated with colonized VP shunts include lethargy, headache, vomiting, a full fontanel, and abdominal pain. Fever is often absent or may be low-grade (<39°C or 102.2°F). Symptoms usually occur within months of the surgical procedure. Colonization of a VA shunt results in more severe systemic symptoms, and specific symptoms of shunt malfunction are often absent. Septic pulmonary emboli, pulmonary hypertension, and infective endocarditis are frequently reported complications of VA shunt colonization. Chronic VA shunt colonization may cause hypocomplementemic glomerulonephritis from antigen-antibody complex deposition in the glomeruli, commonly called *shunt nephritis;* clinical findings include hypertension, microscopic hematuria, elevated blood urea nitrogen and serum creatinine levels, and anemia.

Diagnosis is by Gram stain, microscopy, biochemistry, and culture of CSF. CSF should be obtained by direct aspiration of the shunt before administration of antibiotics, because CSF obtained from either lumbar or ventricular puncture is often sterile. It is unusual to observe signs of ventriculitis, and CSF findings can be only minimally abnormal. Blood culture results are usually positive in VA shunt colonization but negative in cases of VP colonization.

Wound infection presents with obvious erythema, swelling, discharge, or dehiscence along the shunt tract and most often occurs within days to weeks of the surgical procedure. *S. aureus* is the most common isolate. In addition to the physical findings, fever is common, and signs of shunt malfunction eventually ensue in most cases.

Distal infection of VP shunts with **peritonitis** presents with abdominal symptoms, usually without evidence of shunt malfunction. The pathogenesis is likely related to perforation of the bowel at VP shunt placement or translocation of bacteria across the bowel wall. Thus gram-negative isolates predominate, and mixed infection is common. The infecting organisms are often isolated from only the distal portion of the shunt.

Common pathogens responsible for community-acquired **meningitis**, including *Streptococcus pneumoniae, Neisseria meningitidis,* and *Haemophilus influenzae* type b, cause bacterial meningitis in patients with shunts only rarely, and the clinical presentation is similar to that for acute bacterial meningitis in other children (see Chapter 643.1).

Treatment of shunt colonization includes removal of the shunt and systemic antibiotic therapy directed against the isolated organisms. Treatment without removal of the shunt is rarely successful and should not be routinely attempted. After collection of appropriate samples for culture, empirical therapy is usually with vancomycin plus an antipseudomonal agent with relatively good CSF penetration, such as ceftazidime or meropenem. Definitive therapy should be directed toward the isolate and should account for poor penetration of most antibiotics into the CSF across noninflamed meninges. Accordingly, intraventricular antibiotics may be indicated but are usually reserved unless there is evidence of treatment failure. If the isolate is susceptible, a parenteral antistaphylococcal penicillin with or without intraventricular vancomycin is the treatment of choice. If the organism is resistant to penicillins, systemic vancomycin and possibly intraventricular vancomycin are recommended. In gram-negative infections, a third-generation cephalosporin with or without an intraventricular aminoglycoside is

optimal. When using intraventricular antibiotics, monitoring CSF levels is necessary to avoid toxicity.

Removal of the colonized device is required for cure, and final replacement should be delayed until clearance of CSF cultures is documented. Many neurosurgeons immediately remove the shunt and place an external ventricular drain to relieve intracranial pressure (ICP), with a second-stage shunt replacement once CSF sterilization has been confirmed. Others opt initially to exteriorize the distal end of the shunt and replace the shunt in a single-stage procedure once CSF cultures remain sterile for 48-72 hours. Daily CSF cultures should be collected until clearance has been documented on two to three consecutive specimens, and antibiotics should be continued for at least 10 days after documented sterilization of the CSF. Gram-negative organisms may require a longer duration of therapy (up to 21 days). The CSF white cell count generally increases for the first 3-5 days of appropriate therapy, and that alone should not prompt concern for treatment failure. Distal shunt infection with peritonitis and wound infection are managed in a similar fashion.

Treatment of **bacterial meningitis** with typical community-acquired pathogens such as meningococcus or pneumococcus usually requires only systemic antibiotic therapy. Shunt replacement is not required in the absence of device malfunction, poor clinical response, persistent CSF culture positivity, or relapse of infection after antibiotic therapy.

Prevention of Infection

Prevention of shunt infection includes meticulous cutaneous preparation and surgical technique. Systemic and intraventricular antibiotics, antibiotic-impregnated shunts, and soaking the shunt tubing in antibiotics are used to reduce the incidence of infection, with varying success. Systemic prophylactic antibiotics given before and during shunt insertion can reduce the risk for infection and should be used routinely but should not be continued for more than 24 hours postoperatively. Antibiotic-impregnated catheters also appear to reduce the risk of infection and may be used in high-risk patients where the devices are available.

PERITONEAL DIALYSIS CATHETERS

During the first year of peritoneal dialysis for end-stage renal disease, 65% of children will have one or more episodes of peritonitis. Bacterial entry comes from luminal or periluminal contamination of the catheter or by translocation across the intestinal wall. Hematogenous infection is rare. Infants and young children who are in diapers are at highest risk for peritoneal dialysis catheter–associated infections. Infections can be localized at the exit site or associated with peritonitis, or both. Organisms responsible for peritonitis include coagulase-negative staphylococci (30–40%), *S. aureus* (10–20%), streptococci (10–15%), *E. coli* (5-10%), *Pseudomonas* spp. (5–10%), other gram-negative bacteria (5–15%), *Enterococcus* spp. (3–6%), and fungi (2–10%). *S. aureus* is more common in localized exit site or tunnel tract infections (42%). Most infectious episodes are caused by a patient's own flora, and carriers of *S. aureus* have increased rates of infection compared with noncarriers.

The clinical manifestations of peritonitis may be subtle and include low-grade fever with mild abdominal pain or tenderness. Cloudy peritoneal dialysis fluid may be the first and predominant sign. With peritonitis, the peritoneal fluid cell count is usually >100 white blood cells/μL. When peritonitis is suspected, the effluent dialysate should be submitted for a cell count, Gram stain, and culture. The Gram stain is positive in up to 40% of cases of peritonitis.

Patients with cloudy fluid and clinical symptoms should receive empirical therapy, preferably guided by results of a Gram stain. If no organisms are visualized, vancomycin and either an aminoglycoside or a third- or fourth-generation cephalosporin with antipseudomonal activity should be given by the intraperitoneal route. Blood levels should be measured for glycopeptides and aminoglycosides. Patients without cloudy fluid and with minimal symptoms may have therapy withheld pending culture results. Once the cause is identified by culture, changes in the therapeutic regimen may be needed. Oral **rifampin** may be added as adjunctive therapy for susceptible *S. aureus* isolates but should not be used as a standalone agent and must prompt consideration of drug interactions. Candidal peritonitis should be treated with catheter removal and intraperitoneal or oral **fluconazole** or an IV **echinocandin** such as caspofungin or micafungin, depending on the *Candida* spp.; catheter retention has been associated with almost inevitable relapse and higher risk of mortality in adult studies. The duration of therapy for peritonitis is a minimum of 14 days, with longer treatment of 21-28 days for episodes of *S. aureus, Pseudomonas* spp., and resistant gram-negative bacteria and 28-42 days for fungi. Repeat episodes of peritonitis with the same organism within 4 weeks of previous therapy should lead to consideration of catheter removal or attempt at salvage with administration of a fibrinolytic agent and a longer course of up to 6 weeks of antibiotic therapy.

In all cases, if the infection fails to clear after appropriate therapy or if a patient's condition is deteriorating, the catheter should be removed. Exit site and tunnel tract infections may occur independently of peritonitis or may precede it. Appropriate antibiotics should be administered on the basis of Gram stain and culture findings and are typically given systemically only, unless peritonitis is also present. Some experts recommend that the peritoneal catheter be removed if *Pseudomonas* spp. or fungal organisms are isolated.

Prevention of Infection

In addition to usual hygienic practices such as hand hygiene and aseptic care of the catheter exit site, regular application of **mupirocin** or **gentamicin** cream to the catheter exit site reduces exit site infections and peritonitis. Some practitioners recommend against the use of gentamicin cream because of the risk of infection with gentamicin-resistant bacteria. Systemic antibiotic prophylaxis should be considered at catheter insertion, if there is accidental contamination, and at dental procedures. Antifungal prophylaxis with oral nystatin or fluconazole should be considered during antibiotic therapy to prevent fungal infection.

IMPLANTABLE ORTHOPEDIC DEVICES

Implantable orthopedic devices are used infrequently in children. Orthopedic device infection most often follows introduction of microorganisms at surgery through airborne contamination or direct inoculation, hematogenous spread, breakdown of overlying skin, or contiguous spread from an adjacent infection. Early postoperative infection occurs within 2-4 weeks of surgery, with manifestations typically including fever, pain, and local symptoms of wound infection. Chronic infection presents >1 month after surgery and is often caused by organisms of low virulence that contaminated the implant at surgery or by failure of wound healing. Typical manifestations include pain and deterioration in function. Local symptoms such as erythema, swelling, or drainage may also occur. Acute hematogenous infections are most often observed ≥2 years after surgery and may be more common in children with immunocompromise. Options for treatment include conservative management with operative debridement and irrigation and retention of the prosthesis, followed by a 3- to 6-month course of antimicrobial therapy, or more radical intervention with removal and replacement of all hardware—as either a one- or two-stage exchange with a shorter course of antibiotic therapy (2-6 weeks). If the prosthesis is retained, suppressive oral antibiotic therapy may be considered after an initial treatment course, especially in patients who are undergoing intensive time-limited treatment such as chemotherapy. As with other long-term implanted devices, the most common organisms are coagulase-negative staphylococci and *S. aureus*. With prior antibiotic therapy, the prosthesis culture may be negative; in these situations, molecular techniques to identify the organism are available, but sensitivity and specificity are poorly understood.

Orthopedic hardware such as screws and plates are more commonly encountered in children than true implantable orthopedic devices. The management of infections associated with these kinds of hardware is similar to other orthopedic device infections, but because the hardware is typically temporary, it should generally be removed as soon as feasible.

Systemic antibiotic prophylaxis, antibiotic-containing bone cement, and operating rooms fitted with laminar airflow have been proposed to reduce infection. To date, results from clinical studies are conflicting.

Section 3
Antibiotic Therapy

Chapter 225
Principles of Antibacterial Therapy

Mark R. Schleiss

Antibacterial therapy in infants and children presents many challenges. A daunting problem is the paucity of pediatric data regarding pharmacokinetics and optimal dosages; as a consequence, pediatric recommendations are frequently extrapolated from adult studies. A second challenge is the need for the clinician to consider important differences among pediatric age-groups with respect to the pathogenic species most often responsible for bacterial infections. Age-appropriate antibiotic dosing and toxicities must be considered, taking into account the developmental status and physiology of infants and children. Finally, the style of how a pediatrician uses antibiotics in children, particularly young infants, has some important differences compared with how antibiotics are used in adult patients.

Specific antibiotic therapy is optimally driven by a **microbiologic diagnosis**, predicated on isolation of the pathogenic organism from a sterile body site and supported by antimicrobial susceptibility testing. However, given the inherent difficulties that can arise in collecting specimens from pediatric patients and given the high risk of mortality and disability associated with serious bacterial infections in very young infants, much of pediatric infectious diseases practice is based on clinical diagnoses and **empirical** use of antibacterial agents, often administered before and/or without identification of the specific pathogen. Although there is an ever-increasing emphasis on **antimicrobial stewardship**, driven by the importance of using empirical therapy sparingly (to avoid selecting for resistant organisms), there are some settings in which antimicrobials must be administered before the presence of a specific bacterial pathogen is proven. This is particularly relevant to the care of the febrile or ill-appearing neonate or young infant under 30 days of age.

Several key considerations influence decision-making regarding the appropriate empirical use of antibacterial agents in infants and children. It is important to know the age-specific differential diagnosis with respect to likely pathogens. This information affects the choice of antimicrobial agent and also the dose, dosing interval, and route of administration (oral vs parenteral). A complete history and physical examination, combined with appropriate laboratory and radiographic studies, are necessary to identify specific diagnoses, information that in turn affects the choice, dosing, and degree of urgency of administration of antimicrobial agents. The vaccination history may confer reduced risk for some invasive infections (i.e., *Haemophilus influenzae* type b, *Streptococcus pneumoniae, Neisseria meningitidis*), but a history of vaccination does not necessarily eliminate risk. The threat of serious bacterial infection in pediatric practice is also affected by the child's immunologic status, which may be compromised by immaturity (neonates), underlying disease, and immunosuppressive medications used to treat other disorders (see Chapter 223). Infections in immunocompromised children may result from bacteria that are not considered pathogenic in immunocompetent children. The presence of foreign bodies (medical devices) also increases the risk of bacterial infections (see Chapter 224). The likelihood of central nervous system (CNS) involvement must be considered in all pediatric patients with serious bacterial infections, because many bacteremic pathogens in childhood carry a significant risk of hematogenous spread to the CNS.

The patterns of **antimicrobial resistance** in the community and for the potential causative pathogen being empirically covered must also be considered. Resistance to penicillin and cephalosporins is frequent among strains of *S. pneumoniae,* often necessitating the use of other classes of antibiotics. Similarly, the striking emergence of community-acquired methicillin-resistant *Staphylococcus aureus* **(MRSA)** infections has complicated antibiotic choices, both when this pathogen is isolated in culture and for empirical coverage of skin and soft tissue infections. Extended-spectrum β-lactamase **(ESBL)**–producing gram-negative bacteria (Enterobacteriaceae) have reduced the effectiveness of penicillins and cephalosporins. Furthermore, carbapenem-resistant Enterobacteriaceae **(CRE)** are an increasing problem among hospitalized patients, particularly in children with an epidemiologic connection to regions of the world, such as India, where such strains are frequently encountered.

Antimicrobial resistance occurs through many modifications of the bacterial genome (Tables 225.1 and 225.2). Mechanisms include enzyme inactivation of the antibiotic, decreased cell membrane permeability to intracellularly active antibiotics, efflux of antibiotics out of the bacteria, protection or alteration of the antibiotic target site, excessive production of the target site, and bypassing the antimicrobial site of action. CRISPR (clustered regularly interspaced short palindromic repeats) elements in bacteria have also been shown to be related to emergence of antimicrobial resistance. CRISPRs are detectable in many bacterial genomes, protecting their genomes from attack by foreign DNA during transformation, phage invasion, or plasmid insertion. The mechanism of protection is mediated by insertion of small sequences of the invading DNA between palindromic repeats within the CRISPR element. Upon re-exposure to similar DNA sequences from phage or invading bacteria, the existing sequence within the CRISPR is transcribed into a small RNA that associates with CRISPR-associated nucleases, blocking integration of the targeted foreign DNA. Deletion of CRISPR elements in *Enterococcus* is inversely related to antibiotic resistance, and CRISPR-deficient strains are selected for in the context of healthcare-associated infections. CRISPR deficiency allows for evolution of significantly larger genomes, and the attendant insertion of large sequences of DNA in turn enables expression of multiple antibiotic-resistance genes.

Antimicrobial resistance has reached *crisis proportions,* driven by the emergence of new resistance mechanisms (e.g., carbapenemases, including *Klebsiella pneumoniae*–associated carbapenemases, or **KPCs**) and by overuse of antibiotics, both in healthcare and in other venues, such as agribusiness and animal husbandry. This increase in antibiotic resistance has rendered some bacterial infections encountered in clinical practice virtually untreatable. Accordingly, there is an urgent need to develop new antimicrobials and to rediscover some older antibiotics that have been out of use in recent decades but still retain activity against resistant organisms. It is vital that practitioners use antibiotics only when truly indicated, with the narrowest feasible antimicrobial spectrum, to help thwart emergence of resistance. In addition, advocacy for **vaccines**, particularly conjugate pneumococcal vaccine, can also decrease the selective pressure that excessive antimicrobial use exerts on resistance.

Effective antibiotic action requires achieving therapeutic levels of the drug at the site of infection. Other factors to consider include the impact of pH on antibiotic activity; for example, an antibiotic may penetrate an abscess with adequate levels but may be inactive in the acidic milieu of the abscess cavity. Although measuring the level of antibiotic at the site of infection is not always possible, one may measure the serum level and use this level as a surrogate marker to achieve the desired effect at the tissue level. Various target serum levels are appropriate for different antibiotic agents and are assessed by the peak and trough serum levels and the area under the therapeutic drug level curve (Fig. 225.1). These levels in turn are a reflection of the route of administration, drug absorption (IM, PO), volume of distribution, and drug elimination half-life, as well as drug-drug interactions that might

enhance or impede enzymatic inactivation of an antibiotic or result in antimicrobial synergism or antagonism (Fig. 225.2).

AGE- AND RISK-SPECIFIC USE OF ANTIBIOTICS IN CHILDREN

Neonates

The causative pathogens associated with neonatal infections are typically acquired around the time of delivery. Thus empirical antibiotic selection must take into account the importance of these organisms (see Chapter 148). Among the causes of neonatal sepsis in infants, **group B *Streptococcus*** (GBS) is the most common. Although intrapartum antibiotic prophylaxis administered to women at increased risk for transmission of GBS to the infant has greatly decreased the incidence of this infection in neonates, particularly with respect to so-called *early-onset disease,* GBS infections are still frequently encountered in clinical practice (see Chapter 230). Gram-negative enteric organisms acquired from the maternal birth canal, in particular *Escherichia coli,* are also common causes of neonatal sepsis. Although less common, *Listeria monocytogenes* is an important pathogen to consider, in particular because this organism is intrinsically resistant to cephalosporin antibiotics, which are often used as empirical therapy for serious bacterial infections in young children. *Salmonella* bacteremia and **meningitis** on a global basis is a well-recognized infection in infants. All these organisms can be associated with meningitis in the neonate; therefore lumbar puncture should always be considered in the setting of bacteremic infections in this age-group, and antibiotic management should include agents capable of crossing the blood-brain barrier if meningitis cannot be excluded.

Older Children

Antibiotic choices in toddlers and young children were once driven by the high risk of this age-group to invasive disease caused by *H. influenzae* type b (**Hib**; see Chapter 240). With the advent of conjugate vaccines against Hib, invasive disease has declined dramatically. However, outbreaks still occur and have been observed in the context of parental refusal of vaccines. Therefore the use of antimicrobials that are active against Hib remains important in many clinical settings, particularly if meningitis is a consideration. Other important pathogens to consider in this age-group include *E. coli*, *S. pneumoniae, N. meningitidis,* and *S. aureus*. Strains of *S. pneumoniae* that are resistant to penicillin and cephalosporin antibiotics are frequently encountered in clinical practice. Similarly, MRSA is highly prevalent in children in the outpatient setting. Antibiotic resistance in *S. pneumoniae* and MRSA is a result of mutations that confer alterations in penicillin-binding proteins, the molecular targets of penicillin and cephalosporin activity (see Table 225.1).

Depending on the specific clinical diagnosis, other pathogens encountered among older children include *Moraxella catarrhalis*, nontypeable (nonencapsulated) strains of *H. influenzae*, and *Mycoplasma pneumoniae*, which cause upper respiratory tract infections and pneumonia; group A *Streptococcus*, which causes pharyngitis, skin and soft tissue infections, osteomyelitis, septic arthritis, and rarely, bacteremia with toxic shock syndrome; *Kingella kingae*, which causes bone and joint infections and bacteremia; viridians group streptococci and Enterococcus, which cause endocarditis; and *Salmonella* spp., which cause enteritis, bacteremia, osteomyelitis, and septic arthritis. Vector-borne bacterial infections, including infections with *Borrelia burgdorferi*, *Rickettsia rickettsii*, and *Anaplasma phagocytophilum*, are increasingly recognized in certain regions, with an emerging increase in prevalence related to global climate change. Zoonotic exposures, pet ownership, and uncommon dietary intake may suggest less common pathogens such as *Coxiella burnetii, Brucella abortus, Bartonella henselae, Yersinia pestis, L. monocytogenes,* and *Francisella tularensis,* all of which have unique antibiotic susceptibility profiles. These complexities

Table 225.1 Mechanisms of Resistance to β-Lactam Antibiotics

I. Alter target site (PBP)
  A. Decrease affinity of PBP for β-lactam antibiotic
    1. Modify existing PBP
      a. Create mosaic PBP
        (1) Insert nucleotides obtained from neighboring bacteria (e.g., penicillin-resistant *Streptococcus pneumoniae*)
        (2) Mutate structural gene of PBP(s) (e.g., ampicillin-resistant β-lactamase–negative *Haemophilus influenzae*)
    2. Import new PBP (e.g., *mecA* in methicillin-resistant *Staphylococcus aureus*)
II. Destroy β-lactam antibiotic
  A. Increase production of β-lactamases, carbapenemases
    1. Acquire more efficient promoter
      a. Mutate existing promoter
      b. Import new promoter
    2. Deregulate control of β-lactamase production
      a. Mutate regulator genes (e.g., *ampD* in "stably derepressed" *Enterobacter cloacae*)
  B. Modify structure of resident β-lactamase
    1. Mutate structural gene (e.g., ESBLs in *Klebsiella pneumoniae*)
  C. Import new β-lactamase(s) with different spectrum of activity
III. Decrease concentration of β-lactam antibiotic inside cell
  A. Restrict its entry (loss of porins)
  B. Pump it out (efflux mechanisms)

ESBLs, Extended-spectrum β-lactamases; PBP, penicillin-binding protein.

*Aminoglycoside-modifying enzymes confer antibiotic resistance through three general reactions: N-acetylation, O-nucleotidylation, and O-phosphorylation. For each of these general reactions, there are several different enzymes that attack a specific amino or hydroxyl group. The nomenclature for these enzymes lists the molecular site where the modification occurs after the type of enzymatic activity. An aminoglycoside acetyltransferase (AAC) that acts at the 3′ site is designated AAC(3′).There may be more than one enzyme that catalyzes the same reaction, however, and Roman numerals may be necessary (e.g., AAC[3′]-IV).
A, Amikacin; AAC, aminoglycoside acetyltransferase; ANT, aminoglycoside nucleotidyltransferase; APH, aminoglycoside phosphotransferase; Ar, arbekacin, E, Enterobacteriaceae; Ent, enterococci, FQ, fluoroquinolone (acetylates the piperazine ring in some fluoroquinolones), G, gentamicin; K, kanamycin; PR, *Providencia-Proteus*; PS, pseudomonads; SA, staphylococci; SR, streptococci; T, tobramycin.
Adapted from Opal SM, Pop-Vicas A. Molecular mechanisms of antibiotic resistance in bacteria. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases,* 9th ed. Philadelphia: Elsevier; 2020: Table 18-5.

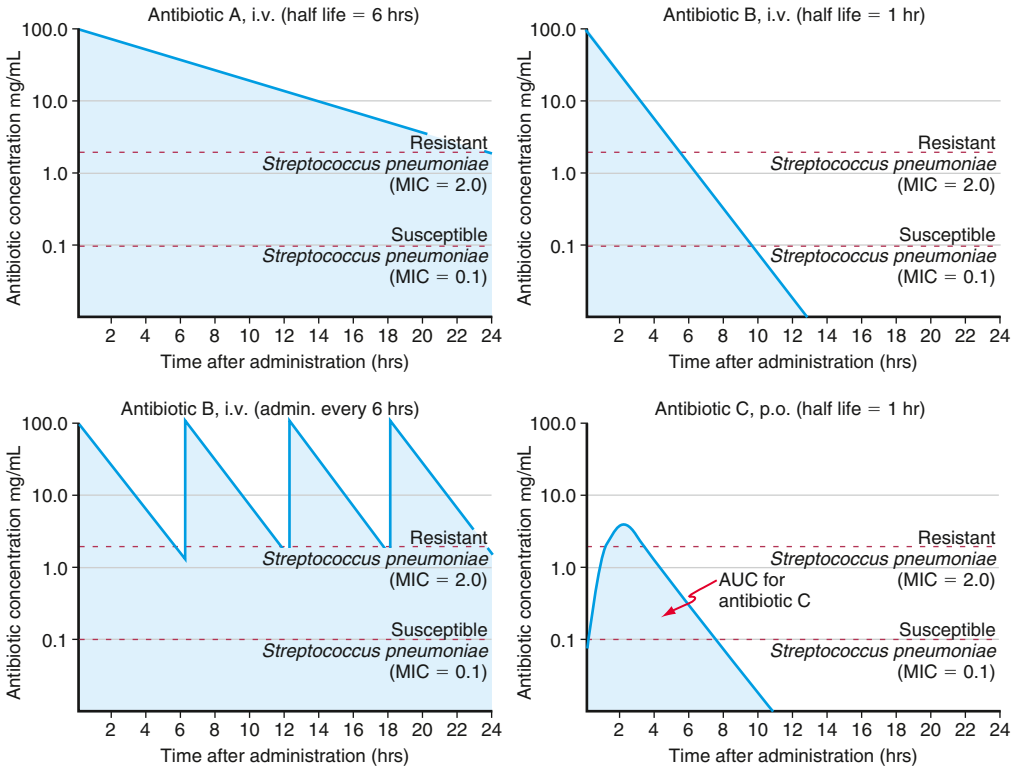

Fig. 225.1 Area under the curve (AUC; *shaded area*) for different antibiotics. The AUC provides a measure of antibiotic exposure to bacterial pathogens. The greatest exposure comes with antibiotics that have a long serum half-life and are administered parenterally (*upper left panel,* antibiotic A). The lowest exposure occurs with oral administration (*lower right panel,* antibiotic C). Dosing of antibiotic B once a day *(upper right panel)* provides far less exposure than dosing the same antibiotic every 6 hr *(lower left panel).* MIC, Minimal inhibitory concentration. *(From Pong AL, Bradley JS. Guidelines for the selection of antibacterial therapy in children. Pediatr Clin North Am. 2005;52:869–894.)*

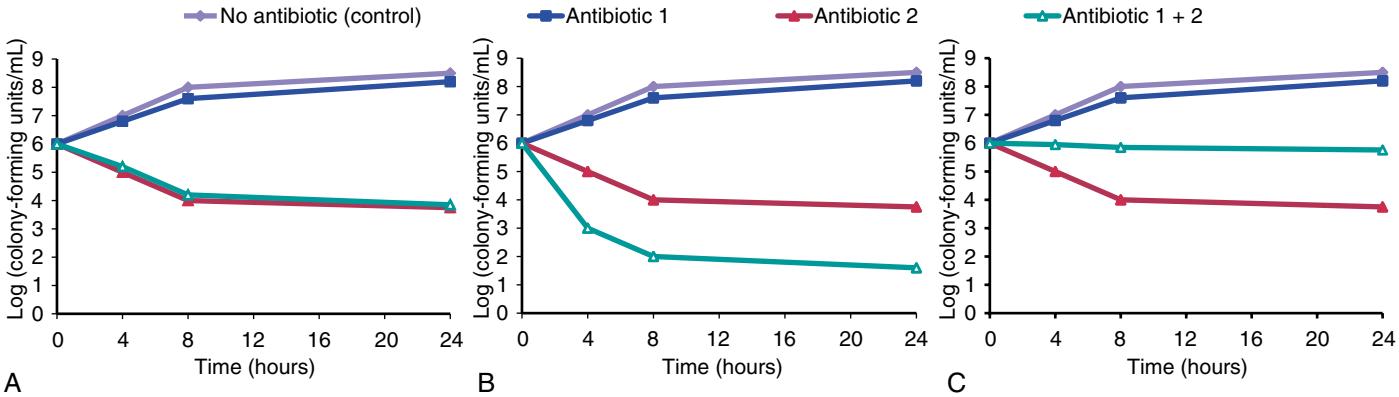

Fig. 225.2 Antibacterial effects of antibiotic combinations. **A,** Combination of antibiotics 1 and 2 is *indifferent;* killing by antibiotic 2 is unchanged when antibiotic 1 is added. **B,** Combination of antibiotics 1 and 2 results in *synergy;* killing by antibiotic 2 is significantly enhanced when antibiotic 1 is added at a subinhibitory concentration. **C,** Combination of antibiotics 1 and 2 is *antagonistic;* killing by antibiotic 2 is diminished in the presence of antibiotic 1. *(From Eliopoulos GM, Moellering RC Jr. Principles of anti-infective therapy. In: Bennett JF, Dolin R, Blaser MJ, eds. Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases, 8th ed. Philadelphia: Elsevier; 2015: Fig 17-1.)*

underscore the importance of formulation of a complete differential diagnosis in children with suspected severe bacterial infections, including an assessment of the severity of the infection in parallel with consideration of local epidemiologic disease trends. Knowledge of the antimicrobial susceptibility patterns in the community is also critically important in devising an antibiotic treatment strategy.

Immunocompromised and Hospitalized Patients

It is important to consider the risks associated with immunocompromising conditions (malignancy, solid organ or hematopoietic stem cell transplantation, immunodeficiencies) and the risks conferred by conditions leading to prolonged hospitalization (intensive care, trauma, burns). Influenza infection can also predispose to invasive bacterial infections, especially those caused by *S. aureus*. Measles infection is well-known to predispose to serious bacterial infection, particularly with *Mycobacteria*. Infection with SARS-CoV-2 can also be associated with bacterial and fungal opportunistic infections. Immunocompromised children are predisposed to develop a wide range of bacterial, viral, fungal, or parasitic infections. Prolonged hospitalization can lead to nosocomial infections, often associated with indwelling catheters and caused by highly antibiotic-resistant gram-negative enteric organisms. In addition to bacterial pathogens already discussed, *Pseudomonas aeruginosa* and enteric organisms, including *E. coli, K. pneumoniae, Enterobacter,* and *Serratia,* are important opportunistic pathogens in these settings.

The so-called *ESKAPE pathogens* are a group of six highly virulent and antibiotic-resistant organisms that are being increasingly recognized in hospitalized patients, including *Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, Acinetobacter baumannii, Pseudomonas aeruginosa,* and *Enterobacter* species. Selection of appropriate antimicrobials is challenging because of the diverse causes and scope of antimicrobial resistance exhibited by these organisms. Many strains of enteric

organisms have resistance because of ESBLs (see Table 225.1). Class B metallo-β-lactamases (also known as *New Delhi metallo-β-lactamases*) that hydrolyze all β-lactam antibiotics except aztreonam and KPCs that confer resistance to carbapenems are increasingly being described. CRE are different from other multidrug-resistant microorganisms in that they are susceptible to few (if any) antibacterial agents.

Other modes of antimicrobial resistance exist that complicate management of common hospital-acquired infections. *P. aeruginosa* encodes proteins that function as efflux pumps to eliminate multiple classes of antimicrobials from the cytoplasm or periplasmic space. In addition to these gram-negative pathogens, infections caused by *Enterococcus faecalis* and *E. faecium* are inherently difficult to treat. Isolates of *E. faecalis* are typically susceptible to ampicillin, whereas most *E. faecium* are resistant to ampicillin, with resistance mediated by alterations in either the stoichiometry or sequence of a specific penicillin binding protein (PBP). These organisms may cause urinary tract infection (UTI) or infective endocarditis in immunocompetent children and may be responsible for a variety of syndromes in immunocompromised patients, especially in the setting of prolonged intensive care. The emergence of infections caused by **vancomycin-resistant enterococcus (VRE)** has further complicated antimicrobial selection in high-risk patients and has necessitated the development of newer antimicrobials that target these highly resistant gram-positive bacteria.

Infections Associated with Medical Devices

A special situation affecting antibiotic use is the presence of an indwelling medical device, such as a venous catheter, ventriculoperitoneal shunt, stent, or other catheter (see Chapter 224). In addition to *S. aureus,* coagulase-negative staphylococci are a major consideration. Coagulase-negative staphylococci seldom cause serious disease in the absence of risk factors such as indwelling catheters. Empirical antibiotic regimens must take this risk into consideration. In addition to appropriate antibiotic therapy, removal or replacement of the colonized prosthetic material is usually required for cure.

ANTIBIOTICS, INCLUDING NEWER AGENTS AND THERAPIES COMMONLY USED IN PEDIATRIC PRACTICE

Table 225.3 lists selected antibiotic medications, including recently licensed agents. Not all agents have formal pediatric indications, but dosage considerations for infants and children are provided, as available.

Penicillins

Although there has been ever-increasing emergence of resistance to penicillins, these agents remain valuable and are commonly used for management of many pediatric infectious diseases.

Penicillins remain the drugs of choice for pediatric infections caused by group A and group B streptococci, *Treponema pallidum* (syphilis), *L. monocytogenes,* and *N. meningitidis.* The **semisynthetic penicillins** (nafcillin, cloxacillin, dicloxacillin) are useful for management of susceptible (non-MRSA) staphylococcal infections. The **aminopenicillins** (ampicillin, amoxicillin) were developed to provide broad-spectrum activity against gram-negative organisms, including *E. coli* and *H. influenzae,* but the emergence of resistance (typically mediated by a β-lactamase) has limited their utility in many clinical settings. The **carboxypenicillins** (ticarcillin) and **ureidopenicillins** (piperacillin, mezlocillin, azlocillin) also have bactericidal activity against most strains of *P. aeruginosa.*

Resistance to penicillin is mediated by a variety of mechanisms (see Table 225.1). The production of β-lactamase is a common mechanism exhibited by many organisms that may be overcome, with variable success, by including a β-lactamase inhibitor in the therapeutic formulation with the penicillin. Such combination products (ampicillin-sulbactam, amoxicillin-clavulanate, ticarcillin–clavulanic acid [no longer available in the United States], piperacillin-tazobactam) are potentially very useful for management of resistant isolates, but only if the resistance is β-lactamase mediated. Notably, MRSA and *S. pneumoniae* mediate resistance to penicillins through mechanisms other than β-lactamase production, rendering these combination agents of little value for the management of these infections. Cephalosporin (ceftazidime/avibactam, ceftolozane/tazobactam) and carbapenem (meropenem/vaborbactam, and imipenem/relebactam) antibiotics combined with β-lactamase inhibitors have also been recently licensed by the FDA (described later). In addition, the FDA has recently approved a novel β-lactam-β-lactamase inhibitor combination, sulbactam-durlobactam (SUL-DUR), designed specifically for the treatment of carbapenem-resistant *Acinetobacter baumannii* infections, in particular, those associated with hospital-acquired and ventilator-associated pneumonias.

Table 225.4 lists adverse reactions to penicillins.

Cephalosporins

Cephalosporins differ structurally from penicillins insofar as the β-lactam ring exists as a six-member ring, compared with the five-member ring structure of the penicillins. These agents are widely used in pediatric practice, both in oral and parenteral formulations (Table 225.5). The **first-generation cephalosporins** (e.g., cefazolin, a parenteral formulation, and cephalexin, an oral equivalent) are commonly used for management of skin and soft tissue infections caused by susceptible strains of *S. aureus* and group A streptococcus. The **second-generation cephalosporins** (e.g., cefuroxime, cefoxitin) have better activity against gram-negative bacterial infections than first-generation cephalosporins and are used to treat respiratory tract infections, UTIs, and skin and soft tissue infections. A variety of orally administered second-generation agents (cefaclor, cefprozil, loracarbef, cefpodoxime) are commonly used in the outpatient management of sinopulmonary infections and otitis media. The agents cefoxitin and cefotetan are also referred to as **cephamycins**, because they were originally isolated from actinomycetes (although synthetic versions also have been developed). The **third-generation cephalosporins** (cefotaxime [no longer available], ceftriaxone, and ceftazidime) are typically used for serious pediatric infections, including meningitis and sepsis. Oral third-generation cephalosporins have been developed, including cefixime, ceftibuten, cefdinir, cefpodoxime, and cefditoren. Ceftazidime is highly active against most strains of *P. aeruginosa,* making this a useful agent for febrile, neutropenic oncology patients. The FDA approved the combination of ceftazidime and the novel β-lactamase inhibitor avibactam in 2015. Current indications include complicated intraabdominal infections and UTIs. The combination may also be useful for the treatment of infection caused by KPCs. Pediatric experience is limited. Ceftriaxone should not be mixed or reconstituted with a calcium-containing product, such as Ringer or Hartmann solution or parenteral nutrition containing calcium, because particulate formation can result. Cases of fatal reactions with ceftriaxone-calcium precipitates in the lungs and kidneys in neonates have been reported.

Cefepime is a **fourth-generation cephalosporin** and has activity against *P. aeruginosa* along with good activity against methicillin-susceptible *S. aureus*. Phase 3 studies of two new formulations of cefepime (one combined with a β-lactamase inhibitor, taniborbactam, and the other with a penicillanic acid sulfone β-lactamase inhibitor, enmetazobactam) are ongoing. *Cefpirome* is a fourth-generation cephalosporin with activity against *P. aeruginosa* and methicillin-sensitive *S. aureus* (MSSA) and is licensed for complicated UTIs and ventilator-associated pneumonia in adults, but no data on pediatric use are available. *Ceftizoxime* is a fourth-generation cephalosporin that is no longer in use in the United States. *Cefiderocol* is a novel cephalosporin that is classified as a *siderophore* antibiotic and is used for treatment of resistant gram-negative organisms, particularly *P. aeruginosa,* associated with complicated UTIs. It also recently received FDA approval for the treatment of hospital-acquired bacterial pneumonia caused by resistant gram-negative organisms. Its mechanism of action involves binding to iron, followed by active transport into bacterial cells. It was the first siderophore antibiotic to be approved by the FDA. It is approved for ages 18 and older, so pediatric experience is limited. Some classification schemes have classified it as a fourth-generation cephalosporin.

Table 225.3 Selected Antibacterial Medications (Antibiotics)*

DRUG (TRADE NAMES, FORMULATIONS)	INDICATIONS (MECHANISM OF ACTION) AND DOSING	COMMENTS
Amikacin sulfate Amikin Injection: 50 mg/mL, 250 mg/mL	**Aminoglycoside antibiotic active against gram-negative bacilli, especially *Escherichia coli, Klebsiella, Proteus, Enterobacter, Serratia,* and *Pseudomonas*** Neonates: Postnatal age ≤7 days, weight 1,200-2,000 g: 7.5 mg/kg q12-18h IV or IM; weight >2,000 g: 10 mg/kg q12h IV or IM; postnatal age >7 days, weight 1,200-2,000 g: 7.5 mg/kg q8-12h IV or IM; weight >2,000 g: 10 mg/kg q8h IV or IM Children: 15-25 mg/kg/24 hr divided q8-12h IV or IM Adults: 15 mg/kg/24 hr divided q8-12h IV or IM	*Cautions:* Anaerobes, *Streptococcus* (including *S. pneumoniae*) are resistant. May cause ototoxicity and nephrotoxicity. Monitor renal function. Drug eliminated renally. Administered IV over 30-60 min. *Drug interactions:* May potentiate other ototoxic and nephrotoxic drugs. *Target serum concentrations:* Peak 25-40 mg/L; trough <10 mg/L.
Amoxicillin Amoxil, Polymox Capsule: 250, 500 mg Tablet: chewable: 125, 250 mg Suspension: 125 mg/5 mL, 250 mg/5 mL Drops: 50 mg/mL	**Penicillinase-susceptible β-lactam: gram-positive pathogens except *Staphylococcus;* susceptible gram-negatives, including *Salmonella, Shigella, Neisseria* species, *E. coli,* and *Proteus mirabilis*** Children: 20-50 mg/kg/24 hr divided q8-12h PO; higher dose of 80-90 mg/kg 24 hr PO for otitis media Adults: 250-500 mg q8-12h PO	*Cautions:* Rash, diarrhea, abdominal cramping. Drug eliminated renally. *Drug interaction:* Probenecid.
Amoxicillin-clavulanate Augmentin Oral Tablet: 250, 500, 875 mg Tablet, chewable: 125, 200, 250, 400 mg Suspension: 125 mg/5 mL, 200 mg/5 mL, 250 mg/5 mL, 400 mg/5 mL	**β-Lactam (amoxicillin) combined with β-lactamase inhibitor (clavulanate) enhances amoxicillin activity against penicillinase-producing bacteria. *S. aureus* (not methicillin-resistant organism), *Streptococcus, Haemophilus influenzae, Moraxella catarrhalis, E. coli, Klebsiella, Bacteroides fragilis*** Neonates: 30 mg/kg/24 hr divided q12h PO Children: 20-45 mg/kg 24 hr divided q8-12h PO; higher dose 80-90 mg/kg/24 hr PO for otitis media	*Cautions:* Drug dosed on amoxicillin component. May cause diarrhea, rash. Drug eliminated renally. *Drug interaction:* Probenecid. *Comment:* Higher dose may be active against penicillin-tolerant/resistant *S. pneumoniae.*
Ampicillin Polycillin, Omnipen Capsule: 250, 500 mg Suspension: 125 mg/5 mL, 250 mg/5 mL, 500 mg/5 mL Injection Oral	**β-Lactam with same spectrum of antibacterial activity as amoxicillin** Neonates: Postnatal age ≤7 days weight ≤2,000 g: 50 mg/kg/24 hr IV or IM q12h (meningitis: 100 mg/kg/24 hr divided q12h IV or IM); weight >2,000 g: 75 mg/kg/24 hr divided q8h IV or IM (meningitis: 150 mg/kg/24 hr divided q8h IV or IM). Postnatal age >7 days weight <1,200 g: 50 mg/kg/24 hr IV or IM q12h (meningitis: 100 mg/kg/24 hr divided q12h IV or IM); weight 1,200-2,000 g: 75 mg/kg/24 hr divided q8h IV or IM (meningitis: 150 mg/kg/24 hr divided q8hr IV or IM); weight >2,000 g: 100 mg/kg/24 hr divided q6h IV or IM (meningitis: 200 mg/kg/24 hr divided q6h IV or IM) Children: 100-200 mg/kg/24 hr divided q6h IV or IM (meningitis: 200-400 mg/kg/24 hr divided q4-6h IV or IM) Adults: 250-500 mg q4-8h IV or IM	*Cautions:* Less bioavailable than amoxicillin, causing greater diarrhea. *Drug interaction:* Probenecid.
Ampicillin-sulbactam Unasyn Injection	**β-Lactam (ampicillin) and β-lactamase inhibitor (sulbactam) enhances ampicillin activity against penicillinase-producing bacteria: *S. aureus, H. influenzae, M. catarrhalis, E. coli, Klebsiella, B. fragilis*** Children: 100-200 mg/kg/24 hr divided q4-8h IV or IM Adults: 1-2 g q6-8h IV or IM (max daily dose: 8 g)	*Cautions:* Drug dosed on ampicillin component. May cause diarrhea, rash. Drug eliminated renally. *Note:* Higher dose may be active against penicillin-tolerant/resistant *S. pneumoniae.* *Drug interaction:* Probenecid.
Azithromycin Zithromax Tablet: 250 mg Suspension: 100 mg/5 mL, 200 mg/5 mL	**Azalide antibiotic with activity against *S. aureus, Streptococcus, H. influenzae, Mycoplasma, Legionella, Chlamydia trachomatis, Babesia microti*** Children: 10 mg/kg PO on day 1 (max dose: 500 mg) followed by 5 mg/kg PO q24h for 4 days Group A streptococcus pharyngitis: 12 mg/kg/24 hr PO (max dose: 500 mg) for 5 days Adults: 500 mg PO on day 1, followed by 250 mg for 4 days Uncomplicated *C. trachomatis* infection: single 1 g dose PO	*Note:* Very long half-life permitting once-daily dosing. No metabolic-based drug interactions (unlike erythromycin and clarithromycin), limited GI distress. Shorter-course regimens (e.g., 1-3 days) under investigation. For a 3-day course of therapy, use dose of (10 mg/kg/24 hr × 3 days); single-dose therapy, 30 mg/kg (not for streptococcal pharyngitis).
Aztreonam Azactam Injection	**β-Lactam (monobactam) antibiotic with activity against gram-negative aerobic bacteria, Enterobacteriaceae, and *Pseudomonas aeruginosa*** Neonates: Postnatal age ≤7 days weight ≤2,000 g: 60 mg/kg/24 hr divided q12h IV or IM; weight >2,000 g: 90 mg/kg/24 hr divided q8h IV or IM; postnatal age >7 days weight <1,200 g: 60 mg/kg/24 hr divided q12h IV or IM; weight 1,200-2,000 g: 90 mg/kg/24 hr divided q8h IV or IM; weight >2,000 g: 120 mg/kg/24 hr divided q6-8h IV or IM Children: 90-120 mg/kg/24 hr divided q6-8h IV or IM. For cystic fibrosis, up to 200 mg/kg/24 hr IV Adults: 1-2 g IV or IM q8-12h (max dose: 8 g/24 hr)	*Cautions:* Rash, thrombophlebitis, eosinophilia. Renally eliminated. *Drug interaction:* Probenecid.

Table 225.3 Selected Antibacterial Medications (Antibiotics)*—cont'd

DRUG (TRADE NAMES, FORMULATIONS)	INDICATIONS (MECHANISM OF ACTION) AND DOSING	COMMENTS
Cefadroxil Generic Capsule: 500 mg Tablet: 1,000 mg Suspension: 125 mg/5 mL, 250 mg/5 mL, 500 mg/5 mL	First-generation cephalosporin active against *S. aureus, Streptococcus, E. coli, Klebsiella*, and *Proteus* Children: 30 mg/kg/24 hr divided q12h PO (max dose: 2 g) Adults: 250-500 mg q8-12h PO	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Long half-life permits q12-24h dosing. *Drug interaction:* Probenecid.
Cefazolin Ancef, Kefzol Injection	First-generation cephalosporin active against *S. aureus, Streptococcus, E. coli, Klebsiella*, and *Proteus* Neonates: Postnatal age ≤7 days 40 mg/kg/24 hr divided q12h IV or IM; >7 days 40-60 mg/kg/24 hr divided q8h IV or IM Children: 50-100 mg/kg/24 hr divided q8h IV or IM Adults: 0.5-2g q8h IV or IM (max dose: 12 g/24 hr)	*Caution:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Does not adequately penetrate CNS. *Drug interaction:* Probenecid.
Cefdinir Omnicef Capsule: 300 mg Oral suspension: 125 mg/5 mL	Extended-spectrum, semisynthetic cephalosporin Children 6 mo-12 yr: 14 mg/kg/24 hr in 1 or 2 doses PO (max dose: 600 mg/24 hr) Adults: 600 mg q24h PO	*Cautions:* Reduce dosage in renal insufficiency (creatinine clearance <60 mL/min). Avoid taking concurrently with iron-containing products and antacids because absorption is markedly decreased; take at least 2 hr apart. *Drug interaction:* Probenecid.
Cefepime Maxipime Injection	Expanded-spectrum, fourth-generation cephalosporin active against many gram-positive and gram-negative pathogens, including *P. aeruginosa* and many multidrug-resistant pathogens Children: 100-150 mg/kg/24 hr q8-12h IV or IM Adults: 2-4 g/24 hr q12h IV or IM	*Adverse events:* Diarrhea, nausea, vaginal candidiasis. Cautions: β-lactam safety profile (rash, eosinophilia). Renally eliminated. *Drug interaction:* Probenecid.
Cefiderocol Fetroja Injection 1 g vials	Expanded-spectrum, classified in some classifications as a fourth-generation cephalosporin; novel siderophore antibiotic; mechanism of action is mediated by binding to iron, followed by active transport into bacterial cells Indicated for treatment of complicated urinary tract infections, including pyelonephritis, caused by susceptible gram-negative microorganisms and for hospital-acquired and ventilator-associated pneumonia Adults: 2 g IV q8hr for 7-14 days Children: dose not established	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Not indicated for meningitis (in contrast with cefepime).
Cefixime Suprax Oral Tablet: 200, 400 mg Suspension: 100 mg/5 mL	Third-generation cephalosporin active against streptococci, *H. influenzae, M. catarrhalis, Neisseria gonorrhoeae, Serratia marcescens*, and *Proteus vulgaris* No antistaphylococcal or antipseudomonal activity Children: 8 mg/kg/24 hr divided q12-24h PO Adults: 400 mg/24 hr divided q12-24h PO	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Does not adequately penetrate CNS. *Drug interaction:* Probenecid.
Cefoperazone sodium Cefobid Injection	Third-generation cephalosporin active against many gram-positive and gram-negative pathogens Neonates: 100 mg/kg/24 hr divided q12h IV or IM Children: 100-150 mg/kg/24 hr divided q8-12h IV or IM Adults: 2-4 g/24 hr divided q8-12h IV or IM (max dose: 12 g/24 hr)	*Cautions:* Highly protein-bound cephalosporin with limited potency reflected by weak antipseudomonal activity. Variable gram-positive activity. Primarily hepatically eliminated in bile. *Drug interaction:* Disulfiram-like reaction with alcohol.
Cefotaxime sodium Claforan Injection	Third-generation cephalosporin active against gram-positive and gram-negative pathogens. No antipseudomonal activity Neonates: ≤7 days: 100 mg/kg/24 hr divided q12h IV or IM; >7 days: weight <1,200 g 100 mg/kg/24 hr divided q12h IV or IM; weight >1,200 g: 150 mg/kg/24 hr divided q8h IV or IM Children: 150 mg/kg/24 hr divided q6-8h IV or IM (meningitis: 200 mg/kg/24 hr divided q6-8h IV) Adults: 1-2 g q8-12h IV or IM (max dose: 12 g/24 hr)	
Cefotetan disodium Cefotan Injection	Second-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, E. coli, Klebsiella, Proteus*, and *Bacteroides*. Inactive against *Enterobacter* Children: 40-80 mg/kg/24 hr divided q12h IV or IM Adults: 2-4 g/24 hr divided q12h IV or IM (max dose: 6 g/24 hr)	*Cautions:* Highly protein-bound cephalosporin, poor CNS penetration; β-lactam safety profile (rash, eosinophilia), disulfiram-like reaction with alcohol. Renally eliminated (~20% in bile).

Table 225.3 Selected Antibacterial Medications (Antibiotics)*—cont'd

DRUG (TRADE NAMES, FORMULATIONS)	INDICATIONS (MECHANISM OF ACTION) AND DOSING	COMMENTS
Cefoxitin sodium Mefoxin Injection	**Second-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, E. coli, Klebsiella, Proteus*, and *Bacteroides*. Inactive against *Enterobacter*** Neonates: 70-100 mg/kg/24 hr divided q8-12h IV or IM Children: 80-160 mg/kg/24 hr divided q6-8h IV or IM Adults: 1-2 g q6-8h IV or IM (max dose: 12 g/24 hr)	*Cautions:* Poor CNS penetration; β-lactam safety profile (rash, eosinophilia). Renally eliminated. Painful given intramuscularly. *Drug interaction:* Probenecid.
Cefpirome Cefrom Keiten Broact Cefir	**Fourth-generation cephalosporin; indicated for complicated urinary tract infections, including pyelonephritis, caused by susceptible gram-negative microorganisms; indicated for hospital-acquired and ventilator-associated pneumonia** Adults: 2 g IV q 8hr for 7-14 days Children: Dose not established	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Not indicated for meningitis (in contrast with cefepime).
Cefpodoxime proxetil Vantin Tablet: 100 mg, 200 mg Suspension: 50 mg/5 mL, 100 mg/5 mL	**Third-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, M. catarrhalis, N. gonorrhoeae, E. coli, Klebsiella*, and *Proteus*** **No antipseudomonal activity** Children: 10 mg/kg/24 hr divided q12h PO Adults: 200-800 mg/24 hr divided q12h PO (max dose: 800 mg/24 hr) Uncomplicated gonorrhea: 200 mg PO as single-dose therapy	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Does not adequately penetrate CNS. Increased bioavailability when taken with food. *Drug interaction:* Probenecid; antacids and H_2 receptor antagonists may decrease absorption.
Cefprozil Cefzil Tablet: 250, 500 mg Suspension: 125 mg/5 mL, 250 mg/5 mL	**Second-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, E. coli, M. catarrhalis, Klebsiella*, and *Proteus* spp.** Children: 30 mg/kg/24 hr divided q8-12h PO Adults: 500-1,000 mg/24 hr divided q12h PO (max dose: 1.5 g/24 hr)	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Good bioavailability; food does not affect bioavailability. *Drug interaction:* Probenecid.
Ceftaroline fosamil Teflaro Injection 400 mg/vial (20 mg/mL reconstituted) 600 mg/vial (30 mg/mL reconstituted)	**Fifth-generation cephalosporin active against *S. aureus* (including MRSA when used for skin and soft tissue infection), *S. pyogenes, S. agalactiae, E. coli, K. pneumoniae, H. influenzae,* and *K. oxytoca*** Children: skin/skin structure infections *or* community-acquired pneumonia, 24 mg/kg/24 hr divided q8h IV (2-23 mo old) ×5-14 days; 36 mg/kg/24 hr divided q8h IV (weight ≤33 kg) ×5-14 days; 400 mg q8h IV (weight >33 kg) Adults: 600 mg q12h IV	*Caution:* β-Lactam safety profile (rash, eosinophilia). *Drug interaction:* Probenecid.
Ceftazidime Fortaz, Ceptaz, Tazicef, Tazidime Injection	**Third-generation cephalosporin active against gram-positive and gram-negative pathogens, including *P. aeruginosa*** Neonates: Postnatal age ≤7 days: 100 mg/kg/24 hr divided q12h IV or IM; >7 days weight ≤1,200 g: 100 mg/kg/24 hr divided q12h IV or IM; weight >1,200 g: 150 mg/kg/24 hr divided q8h IV or IM Children: 150 mg/kg/24 hr divided q8h IV or IM (meningitis: 150 mg/kg/24 hr IV divided q8h) Adults: 1-2 g q8-12h IV or IM (max dose: 8-12 g/24 hr)	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Increasing pathogen resistance developing with long-term, widespread use. *Drug interaction:* Probenecid.
Ceftazidime/avibactam Avycaz Injection (2 g/0.5 g)/vial: 2.5 g Equivalent to 2.635 g of ceftazidime and 0.551 g of avibactam sodium	**Third-generation cephalosporin active against gram-positive and gram-negative pathogens, including *P. aeruginosa;* addition of β-lactamase; inhibits *K. pneumoniae* carbapenemases and AmpC-type β-lactamases that are resistant to β-lactamases, tazobactam, and clavulanic acid** **Useful for complicated intraabdominal infections, urinary tract infections, and pneumonia** Adults: 2.5 g (2 g/0.5 g) IV q8h infused over 2 hr for 7-14 days Children: 3 mo to <2 yr: 62.5 mg/kg (ceftazidime 50 mg/kg and avibactam 12.5 mg/kg) IV q8h for 5-14 days 2 yr to <18 yr: 62.5 mg/kg (ceftazidime 50 mg/kg and avibactam 12.5 mg/kg) IV q8h for 5-14 days; not to exceed 2.5 g (ceftazidime 2 g and avibactam 0.5 g)	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Increasing pathogen resistance developing with long-term, widespread use. *Drug interaction:* Probenecid.

Continued

Table 225.3 Selected Antibacterial Medications (Antibiotics)*—cont'd

DRUG (TRADE NAMES, FORMULATIONS)	INDICATIONS (MECHANISM OF ACTION) AND DOSING	COMMENTS
Ceftolozane/tazobactam Zerbaxa Injection	**Fifth-generation cephalosporin (with β-lactamase inhibitor) indicated for complicated intraabdominal infections; acute pyelonephritis; complicated urinary tract infections; hospital-acquired and ventilator-associated bacterial pneumonia** Adults: Community-acquired pneumonia, skin and soft tissue infections 600 mg IV q12 h ×5-7 days Children: Birth to <2 mo: 6 mg/kg IV q8h ×5-14 days 2 mo to <2 yr: 8 mg/kg IV q8h ×5-14 days 2 yr to <18 yr (≤33 kg): 12 mg/kg IV q8h ×5-14 days 2 yr to <18 yr (>33 kg): 400 mg q8h OR 600 mg q12h IV ×5-14 days	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. *Drug interaction:* Probenecid.
Ceftriaxone sodium Rocephin Injection	**Third-generation cephalosporin widely active against gram-positive and gram-negative pathogens** **No antipseudomonal activity** Neonates: 50-75 mg/kg q24h IV or IM Children: 50-75 mg/kg q24h IV or IM (meningitis: 75 mg/kg dose once then 80-100 mg/kg/24 hr divided q12-24h IV or IM) Adults: 1-2 g q24h IV or IM (max dose: 4 g/24 hr) Gonorrhea: 500 mg IM, single dose	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Eliminated via kidney (33–65%) and bile; can cause sludging. Long half-life and dose-dependent protein binding favors q24h rather than q12h dosing. Can add 1% lidocaine for IM injection. *Drug interaction:* Probenecid. In neonates, co-administration with calcium-containing products can result in severe precipitation and attendant embolic complications.
Cefuroxime (cefuroxime axetil for oral administration) Ceftin, Kefurox, Zinacef Injection Suspension: 125 mg/5 mL Tablet: 125, 250, 500 mg	**Second-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, E. coli, M. catarrhalis, Klebsiella,* and *Proteus*** Neonates: 40-100 mg/kg/24 hr divided q12h IV or IM Children: 200-240 mg/kg/24 hr divided q8h IV or IM; PO administration: 20-30 mg/kg/24 hr divided q8-12h PO Adults: 750-1,500 mg q8h IV or IM (max dose: 6 g/24 hr)	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Food increases PO bioavailability. *Drug interaction:* Probenecid.
Cephalexin Keflex, Keftab Capsule: 250, 500 mg Tablet: 500 mg, 1 g Suspension: 125 mg/5 mL, 250 mg/5 mL, 100 mg/mL drops	**First-generation cephalosporin active against *S. aureus, Streptococcus, E. coli, Klebsiella,* and *Proteus*** Children: 25-100 mg/kg/24 hr divided q6-8h PO Adults: 250-500 mg q6h PO (max dose: 4 g/24 hr)	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. *Drug interaction:* Probenecid.
Cephradine Velosef Capsule: 250, 500 mg Suspension: 125 mg/5 mL, 250 mg/5 mL	**First-generation cephalosporin active against *S. aureus, Streptococcus, E. coli, Klebsiella,* and *Proteus*** Children: 50-100 mg/kg/24 hr divided q6-12h PO Adults: 250-500 mg q6-12h PO (max dose: 4 g/24 hr)	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. *Drug interaction:* Probenecid.
Ciprofloxacin Cipro Tablet: 100, 250, 500, 750 mg Injection Ophthalmic solution and ointment Otic suspension Oral suspension: 250 and 500 mg/5 mL	**Quinolone antibiotic active against *P. aeruginosa, Serratia, Enterobacter, Shigella, Salmonella, Campylobacter, N. gonorrhoeae, H. influenzae, M. catarrhalis,* some *S. aureus,* and some *Streptococcus*** Neonates: 10 mg/kg q12h PO or IV Children: 15-30 mg/kg/24 hr divided q12h PO or IV; cystic fibrosis: 20-40 mg/kg/24 hr divided q8-12h PO or IV Adults: 250-750 mg q12h; 200-400 mg IV q12h PO (max dose: 1.5 g/24 hr)	*Cautions:* Concerns of joint destruction in juvenile animals but not seen in humans; tendonitis, superinfection, dizziness, confusion, crystalluria, some photosensitivity. *Drug interactions:* Theophylline; magnesium-, aluminum-, or calcium-containing antacids; sucralfate; probenecid; warfarin; cyclosporine.
Clarithromycin Biaxin Tablet: 250, 500 mg Suspension: 125 mg/5 mL, 250 mg/5 mL	**Macrolide antibiotic with activity against *S. aureus, Streptococcus, H. influenzae, Legionella, Mycoplasma,* and *C. trachomatis*** Children: 15 mg/kg/24 hr divided q12h PO Adults: 250-500 mg q12h PO (max dose: 1 g/24 hr)	*Cautions:* Adverse events less than erythromycin; GI upset, dyspepsia, nausea, cramping. *Drug interactions:* Same as erythromycin: astemizole, carbamazepine, terfenadine, cyclosporine, theophylline, digoxin, tacrolimus.
Clindamycin Cleocin Capsule: 75, 150, 300 mg Suspension: 75 mg/5 mL Injection Topical solution, lotion, and gel Vaginal cream	**Protein synthesis inhibitor active against most gram-positive aerobic and anaerobic cocci except *Enterococcus*** Neonates: Postnatal age ≤7 days weight <2,000 g; 10 mg/kg/24 hr divided q12h IV or IM; weight >2,000 g: 15 mg/kg/24 hr divided q8h IV or IM; >7 days weight <1,200 g: 10 mg/kg/24 hr IV or IM divided q12h; weight 1,200-2,000 g: 15 mg/kg/24 hr divided q8h IV or IM; weight >2,000 g: 20 mg/kg/24 hr divided q8h IV or IM Children: 10-40 mg/kg/24 hr divided q6-8h IV, IM, or PO Adults: 150-600 mg q6-8h IV, IM, or PO (max dose: 5 g/24 hr IV or IM or 2 g/24 hr PO)	*Cautions:* Diarrhea, nausea, *Clostridium difficile*–associated colitis, rash. Administer slow IV over 30-60 min. Topically active as an acne treatment.

Table 225.3 Selected Antibacterial Medications (Antibiotics)*—cont'd

DRUG (TRADE NAMES, FORMULATIONS)	INDICATIONS (MECHANISM OF ACTION) AND DOSING	COMMENTS
Cloxacillin sodium Tegopen Capsule: 250, 500 mg Suspension: 125 mg/5 mL	**Penicillinase-resistant penicillin active against *S. aureus* and other gram-positive cocci except *Enterococcus* and coagulase-negative staphylococci** Children: 50-100 mg/kg/24 hr divided q6h PO Adults: 250-500 mg q6h PO (max dose: 4 g/24 hr)	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Primarily hepatically eliminated; requires dose reduction in renal disease. Food decreases bioavailability. *Drug interaction:* Probenecid.
Colistin (colistimethate sodium; polymyxin E) Injection Inhalation	**Treatment of multidrug-resistant gram-negative organisms (*Enterobacteriaceae* including extended-spectrum β-lactamase– and carbapenemase-producing strains)** Children: 2.5-5 mg/kg/day divided in 2-4 divided doses IV Adults: 300 mg/day in 2-4 divided doses IV	*Cautions:* Nephrotoxicity (~3% in young children; higher rates in adolescents and adults); adjust dose for renal insufficiency; neurotoxicity (headaches, paresthesia, ataxia). *Drug interactions:* Should not be administered concomitantly with polymyxins or aminoglycosides.
Co-trimoxazole (trimethoprim-sulfamethoxazole; TMP-SMX) Bactrim, Cotrim, Septra, Sulfatrim Tablet: SMX 400 mg and TMP 80 mg Tablet DS: SMX 800 mg and TMP 160 mg Suspension: SMX 200 mg and TMP 40 mg/5 mL Injection	**Antibiotic combination with sequential antagonism of bacterial folate synthesis with broad antibacterial activity: *Shigella, Legionella, Nocardia, Chlamydia, Pneumocystis jiroveci*** **Dosage based on TMP component** Children: 6-20 mg TMP/kg/24 hr or IV divided q12h PO *Pneumocystis carinii* pneumonia: 15-20 mg TMP/kg/24 hr divided q12h PO or IV *P. carinii* prophylaxis: 5 mg TMP/kg/24 hr or 3 times/wk PO Adults: 160 mg TMP q12h PO	*Cautions:* Drug dosed on TMP (trimethoprim) component. Sulfonamide skin reactions: rash, erythema multiforme, Stevens-Johnson syndrome, nausea, leukopenia. Renal and hepatic elimination; reduce dose in renal failure. *Drug interactions:* Protein displacement with warfarin, possibly phenytoin, cyclosporine.
Dalbavancin Dalvance 500 mg/vial (20 mg/mL after reconstitution) Injection	**Glycopeptide antibiotic; bacteriocidal; disrupts cell wall synthesis** Indicated for acute bacterial skin and skin structure infections caused by susceptible gram-positive bacteria; active against MRSA Adult dose: 1-dose regimen of 1,500 mg IV or 2-dose regimen of 1000 mg IV followed 1 wk later by 500 mg IV; infuse IV over 30 min Pediatric dose: Not approved for use in children	Rapid IV infusion, as with other glycopeptide antibacterial agents, can cause reactions, including upper body flushing, urticaria, pruritus, back pain, and rash; stopping or slowing infusion may result in cessation of these reactions.
Daptomycin Cubicin Injection	**Disrupts bacterial cell membrane function, causing depolarization leading to inhibition of protein, DNA, and RNA synthesis, which results in bacterial cell death** **Active against enterococci (including glycopeptide-resistant strains), staphylococci (including MRSA), streptococci, and corynebacteria. Approved for skin and soft tissue infections** **Acceptable for bacteremia and right-sided endocarditis with susceptible strains** Adults: In skin and soft tissue infections, 4 mg/kg daptomycin IV once daily. For *S. aureus* bacteremia or right-sided endocarditis, 6 mg/kg IV once daily Children: For skin/skin structure infections, 12-23 mo, 10 mg/kg IV q24h; 2-6 yr, 9 mg/kg IV q24h; 7-11 yr, 7 mg/kg q24h; 12-17 yr, 5 mg/kg q24h, all for up to 14 days. For staphylococcal bacteremia, 1-6 yr, 12 mg/kg q24h; 7-11 yr, 9 mg/kg q24h; 12-17 yr, 7 mg/kg q24h; all for up to 42 days. For staphylococcal endocarditis, 1-5 yr, 10 mg/kg IV q24h for at least 6 wk; ≥6 yr, 6 mg/kg IV q24h for at least 6 wk	*Cautions:* Should not be used for pneumonia because drug inactivated by surfactants. Associated with rash, renal failure, anemia, and headache. Is reported to cause myopathy, rhabdomyolysis, and eosinophilic pneumonia. *Drug interactions:* Should not be administered with statins.
Delafloxacin Baxdela Injection Oral Injection, lyophilized powder for reconstitution 300 mg/vial (equivalent to 433 mg delafloxacin meglumine) Tablet, 450 mg (equivalent to 649 mg delafloxacin meglumine)	**Fluoroquinolone class of drugs; active against MSSA, MRSA, CoNS, and streptococci; retains activity against fluoroquinolone-resistant *S. aureus* strains.** **Approved for skin and soft tissue infections and community-acquired pneumonia.** Adults: 300 mg IV q12h for 5-14 days OR 300 mg IV q12h, then switch to a 450-mg tablet PO q12h for 5-14 days OR 450 mg PO q12h for 5-14 days Children: No dosage established	Similar to ciprofloxacin.

Table 225.3 Selected Antibacterial Medications (Antibiotics)*—cont'd

DRUG (TRADE NAMES, FORMULATIONS)	INDICATIONS (MECHANISM OF ACTION) AND DOSING	COMMENTS
Demeclocycline Declomycin Tablet: 150, 300 mg Capsule: 150 mg	**Tetracycline active against most gram-positive cocci except *Enterococcus*, many gram-negative bacilli, anaerobes, *Borrelia burgdorferi* (Lyme disease), *Mycoplasma*, and *Chlamydia*** Children: 8-12 mg/kg/24 hr divided q6-12h PO Adults: 150 mg PO q6-8h Syndrome of inappropriate antidiuretic hormone secretion: 900-1,200 mg/24 hr or 13-15 mg/kg/24 hr divided q6-8h PO with dose reduction based on response to 600-900 mg/24 hr	*Cautions:* Teeth staining, possibly permanent (if administered <8 yr old) with prolonged use; photosensitivity, diabetes insipidus, nausea, vomiting, diarrhea, superinfections. *Drug interactions:* Aluminum-, calcium-, magnesium-, zinc- and iron-containing food, milk, dairy products may decrease absorption.
Dicloxacillin Dynapen, Pathocil Capsule: 125, 250, 500 mg Suspension: 62.5 mg/5 mL	**Penicillinase-resistant penicillin active against *S. aureus* and other gram-positive cocci except *Enterococcus* and coagulase-negative staphylococci** Children: 12.5-100 mg/kg/24 hr divided q6h PO Adults: 125-500 mg q6h PO	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Primarily renal (65%) and biliary (30%) elimination. Food may decrease bioavailability. *Drug interaction:* Probenecid.
Doripenem Doribax Injection	**Carbapenem antibiotic with broad-spectrum activity against gram-positive cocci and gram-negative bacilli, including *P. aeruginosa* and anaerobes** Children: dose unknown Adults: 500 mg q8h IV	*Cautions:* β-Lactam safety profile; does not undergo hepatic metabolism. Renal elimination (70–75%); dose adjustment for renal failure. *Drug interactions:* Valproic acid, probenecid.
Doxycycline Vibramycin, Doxy Injection Capsule: 50, 100 mg Tablet: 50, 100 mg Suspension: 25 mg/5 mL Syrup: 50 mg/5 mL	**Tetracycline antibiotic active against most gram-positive cocci except *Enterococcus*, many gram-negative bacilli, anaerobes, *B. burgdorferi* (Lyme disease), *Mycoplasma*, and *Chlamydia*** Children: 2-5 mg/kg/24 hr divided q12-24h PO or IV (max dose: 200 mg/24 hr) Adults: 100-200 mg/24 hr divided q12-24h PO or IV	*Cautions:* Teeth staining, possibly permanent (<8 yr old) with prolonged use; photosensitivity, nausea, vomiting, diarrhea, superinfections. *Drug interactions:* Aluminum-, calcium-, magnesium-, zinc-, iron-, kaolin-, and pectin-containing products, food, milk, dairy products may decrease absorption. Carbamazepine, rifampin, and barbiturates may decrease half-life.
Eravacycline Xerava 50 mg single-dose vials	**Tetracycline-class antibiotic (glycylcycline) active against Enterobacteriaceae, including extended spectrum β-lactamase producers; streptococci (including VRE); staphylococci (including MRSA); and CRE** Indicated for treatment of complicated intraabdominal infections in adults Dose: 1 mg/kg IV q12h ×4-14 days; infuse IV over ~60 min	Contraindications similar to other tetracyclines, including photosensitivity; pseudotumor cerebri; concerns for discoloration of tooth enamel in children under 8 yr of age.
Erythromycin E-Mycin, Ery-Tab, Eryc, Ilosone Estolate 125, 500 mg Tablet EES: 200 mg Tablet base: 250, 333, 500 mg Suspension: estolate 125 mg/5 mL, 250 mg/5 mL, EES 200 mg/5 mL, 400 mg/5 mL Estolate drops: 100 mg/mL; EES drops: 100 mg/2.5 mL Available in combination with sulfisoxazole (Pediazole), dosed on erythromycin content	**Bacteriostatic macrolide antibiotic most active against gram-positive organisms, *Corynebacterium diphtheriae*, and *Mycoplasma pneumoniae*** Neonates: Postnatal age ≤7 days: 20 mg/kg/24 hr divided q12h PO; >7 days weight <1,200 g: 20 mg/kg/24 hr divided q12h PO; weight >1,200 g: 30 mg/kg/24 hr divided q8h PO (give as 5 mg/kg/dose q6h to improve feeding intolerance) Children: Usual max dose: 2 g/24 hr Base: 30-50 mg/kg/24 hr divided q6-8h PO Estolate: 30-50 mg/kg/24 hr divided q8-12h PO Stearate: 20-40 mg/kg/24 hr divided q6h PO Lactobionate: 20-40 mg/kg/24 hr divided q6-8h IV Gluceptate: 20-50 mg/kg/24 hr divided q6h IV; usual max dose: 4 g/24 hr IV Adults: Base: 333 mg PO q8h; estolate/stearate/base: 250-500 mg q6h PO	*Cautions:* Motilin agonist leading to marked abdominal cramping, nausea, vomiting, and diarrhea. Associated with hypertrophic pyloric stenosis in young infants. Many different salts with questionable tempering of GI adverse events. Rare cardiac toxicity with IV use. Dose of salts differs. Topical formulation for treatment of acne. *Drug interactions:* Antagonizes hepatic CYP 3A4 activity: astemizole, carbamazepine, terfenadine, cyclosporine, theophylline, digoxin, tacrolimus.
Gentamicin Garamycin Injection Ophthalmic solution, ointment, topical cream	**Aminoglycoside antibiotic active against gram-negative bacilli, especially *E. coli, Klebsiella, Proteus, Enterobacter, Serratia,* and *Pseudomonas*** Neonates: Postnatal age ≤7 days weight 1,200-2,000 g: 2.5 mg/kg q12-18h IV or IM; weight <2,000 g: 2.5 mg/kg q12h IV or IM; postnatal age >7 days weight 1,200-2,000 g: 2.5 mg/kg q8-12h IV or IM; weight >2,000 g: 2.5 mg/kg q8h IV or IM Children: 2.5 mg/kg/24 hr divided q8-12h IV or IM; alternatively, may administer 5-7.5 mg/kg/24 hr IV once daily Intrathecal: Preservative-free preparation for intraventricular or intrathecal use: neonate: 1 mg/24 hr; children: 1-2 mg/24 hr intrathecal; adults: 4-8 mg/24 hr Adults: 3-6 mg/kg/24 hr divided q8h IV or IM	*Cautions:* Anaerobes, *S. pneumoniae,* and other *Streptococcus* are resistant. May cause ototoxicity and nephrotoxicity. Monitor renal function. Drug eliminated renally. Administered IV over 30-60 min. *Drug interactions:* May potentiate other ototoxic and nephrotoxic drugs. *Target serum concentrations:* Peak 6-12 mg/L; trough >2 mg/L with intermittent daily dose regimens only.

Table 225.3 Selected Antibacterial Medications (Antibiotics)*—cont'd

DRUG (TRADE NAMES, FORMULATIONS)	INDICATIONS (MECHANISM OF ACTION) AND DOSING	COMMENTS
Imipenem-cilastatin Primaxin Injection	**Carbapenem antibiotic with broad-spectrum activity against gram-positive cocci and gram-negative bacilli, including *P. aeruginosa* and anaerobes. No activity against *Stenotrophomonas maltophilia*** Neonates: Postnatal age ≤7 days weight <1,200 g: 20 mg/kg q18-24h IV or IM; weight >1,200 g: 40 mg/kg divided q12h IV or IM; postnatal age >7 days weight 1,200-2,000 g: 40 mg/kg q12h IV or IM; weight >2,000 g: 60 mg/kg q8h IV or IM Children: 60-100 mg/kg/24 hr divided q6-8h IV or IM Adults: 2-4 g/24 hr divided q6-8h IV or IM (max dose: 4 g/24 hr)	*Cautions:* β-Lactam safety profile (rash, eosinophilia), nausea, seizures. Cilastatin possesses no antibacterial activity; reduces renal imipenem metabolism. Primarily renally eliminated. *Drug interaction:* Possibly ganciclovir.
Imipenem/relebactam (imipenem/cilastatin/relebactam) Recarbrio 500 mg/500 mg/250 mg per vial (i.e., 1.25 g/vial)	**Carbapenem antibiotic similar to imipenem/cilastatin; addition of relebactam restores activity against *K. pneumoniae* isolates that encode KPCs; is indicated for treatment of complicated urinary tract infections and complicated intraabdominal infections and hospital-acquired/ventilator-associated bacterial pneumonia in adults 18 yr of age and older** Adults: 1.25 g IV q6h ×4-14 days Children: No dosing information available	*Cautions:* β-Lactam safety profile (rash, eosinophilia), nausea, seizures. Cilastatin possesses no antibacterial activity; reduces renal imipenem metabolism. Primarily renally eliminated.
Linezolid Zyvox Tablet: 400, 600 mg Oral suspension: 100 mg/5 mL Injection: 100 mg/5 mL	**Oxazolidinone antibiotic active against gram-positive cocci (especially drug-resistant organisms), including *Staphylococcus, Streptococcus, E. faecium,* and *Enterococcus faecalis*. Interferes with protein synthesis by binding to 50S ribosome subunit** Children: 10 mg/kg q12h IV or PO Adults: Pneumonia: 600 mg q12h IV or PO; skin infections: 400 mg q12h IV or PO	*Adverse events:* Myelosuppression, pseudomembranous colitis, nausea, diarrhea, headache, peripheral and optic neuropathy. *Drug interaction:* Probenecid.
Loracarbef Lorabid Generic Capsule: 200 mg Suspension: 100 mg/5 mL, 200 mg/5 mL	**Carbacephem very closely related to cefaclor (second-generation cephalosporin) active against *S. aureus, Streptococcus, H. influenzae, M. catarrhalis, E. coli, Klebsiella,* and *Proteus*** Children: 30 mg/kg/24 hr divided q12h PO (max dose: 2 g) Adults: 200-400 mg q12h PO (max dose: 800 mg/24 hr)	*Cautions:* β-Lactam safety profile (rash, eosinophilia). Renally eliminated. *Drug interaction:* Probenecid.
Meropenem Merrem Injection	**Carbapenem antibiotic with broad-spectrum activity against gram-positive cocci and gram-negative bacilli, including *P. aeruginosa* and anaerobes** **No activity against *S. maltophilia*** Children: 60 mg/kg/24 hr divided q8h IV; meningitis: 120 mg/kg/24 hr (max dose: 6 g/24 hr) q8h IV Adults: 1.5-3 g q8h IV	*Cautions:* β-Lactam safety profile; appears to possess less CNS excitation than imipenem; 80% renal elimination. *Drug interaction:* Probenecid.
Meropenem/vaborbactam Vabomere 1 g/1 g vials	**Carbapenem antibiotic with broad-spectrum activity against gram-positive cocci and gram-negative bacilli, including *P. aeruginosa* and anaerobes** **Vaborbactam protects meropenem from degradation by certain serine β-lactamases including *K. pneumoniae* carbapenemases (KPCs); added to enhance activity for complicated urinary tract infections, including pyelonephritis caused by *E. coli, K. pneumoniae,* and *E. cloacae* species complex in adults ≥18 yr** Adults: 4 g (meropenem [2 g]/vaborbactam [2 g]) IV q8h for up to 14 days; infuse over 3 hr.	*Cautions:* β-Lactam safety profile; appears to possess less CNS excitation than imipenem; 80% renal elimination. *Drug interaction:* Probenecid.
Metronidazole Flagyl, Metro I.V., Topical gel, vaginal gel Injection Tablet: 250, 500 mg	**Highly effective in the treatment of infections caused by anaerobes. Oral therapy of *C. difficile* colitis** Neonates: weight <1,200 g: 7.5 mg/kg/48 hr PO or IV; postnatal age ≤7 days weight 1,200-2,000 g: 7.5 mg/kg/24 hr q24h PO or IV; weight 2,000 g: 15 mg/kg/24 hr divided q12h PO or IV; postnatal age <7 days weight 1,200-2,000 g: 15 mg/kg/24 hr divided q12h PO or IV; weight >2,000 g: 30 mg/kg/24 hr divided q12 h PO or IV Children: 30 mg/kg/24 hr divided q6-8h PO or IV Adults: 30 mg/kg/24 hr divided q6h PO or IV (max dose: 4 g/24 hr)	*Cautions:* Dizziness, seizures, metallic taste, nausea, disulfiram-like reaction with alcohol. Administer IV slow over 30-60 min. Adjust dose with hepatic impairment. *Drug interactions:* Carbamazepine, rifampin, phenobarbital may enhance metabolism; may increase levels of warfarin, phenytoin, lithium.
Mezlocillin sodium Mezlin Infection	**Extended-spectrum penicillin active against *E. coli, Enterobacter, Serratia,* and *Bacteroides;* limited antipseudomonal activity** Neonates: Postnatal age ≤7 days: 150 mg/kg/24 hr divided q12h IV; >7 days: 225 mg/kg divided q8h IV Children: 200-300 mg/kg/24 hr divided q4-6h IV; cystic fibrosis 300-450 mg/kg/24 hr IV Adults: 2-4 g/dose q4-6h IV (max dose: 12 g/24 hr)	*Cautions:* β-Lactam safety profile (rash, eosinophilia); painful given intramuscularly; each gram contains 1.8 mEq sodium. Interferes with platelet aggregation with high doses; increases noted in liver function test results. Renally eliminated. Inactivated by β-lactamase enzyme. *Drug interaction:* Probenecid.

Continued

Table 225.3 Selected Antibacterial Medications (Antibiotics)*—cont'd

DRUG (TRADE NAMES, FORMULATIONS)	INDICATIONS (MECHANISM OF ACTION) AND DOSING	COMMENTS
Mupirocin Bactroban Ointment	**Topical antibiotic active against *Staphylococcus* and *Streptococcus*** Topical application: Nasal (eliminate nasal carriage) and to the skin 2-4 times daily	*Caution:* Minimal systemic absorption because drug metabolized within the skin.
Nafcillin sodium Nafcil, Unipen Injection Capsule: 250 mg Tablet: 500 mg	**Penicillinase-resistant penicillin active against *S. aureus* and other gram-positive cocci, except *Enterococcus* and coagulase-negative staphylococci** Neonates: Postnatal age ≤7 days weight 1,200-2,000 g: 50 mg/kg/24 hr divided q12h IV or IM; weight >2,000 g: 75 mg/kg/24 hr divided q8h IV or IM; postnatal age >7 days weight 1,200-2,000 g: 75 mg/kg/24 hr divided q8h; weight >2,000 g: 100 mg/kg/24 hr divided q6-8h IV (meningitis: 200 mg/kg/24 hr divided q6h IV) Children: 100-200 mg/kg/24 hr divided q4-6h IV Adults: 4-12 g/24 hr divided q4-6h IV (max dose: 12 g/24 hr)	*Cautions:* β-Lactam safety profile (rash, eosinophilia), phlebitis; painful given intramuscularly; oral absorption highly variable and erratic (not recommended). *Adverse effect:* Neutropenia.
Nalidixic acid NegGram Tablet: 250, 500, 1,000 mg Suspension: 250 mg/5 mL	**First-generation quinolone effective for short-term treatment of lower UTIs caused by *E. coli, Enterobacter, Klebsiella*, and *Proteus*** Children: 50-55 mg/kg/24 hr divided q6h PO; suppressive therapy: 25-33 mg/kg/24 hr divided q6-8h PO Adults: 1 g q6h PO; suppressive therapy: 500 mg q6h PO	*Cautions:* Vertigo, dizziness, rash. Not for use in systemic infections. *Drug interactions:* Liquid antacids.
Neomycin sulfate Mycifradin Tablet: 500 mg Topical cream, ointment Solution: 125 mg/5 mL	**Aminoglycoside antibiotic used for topical application or orally before surgery to decrease GI flora (nonabsorbable) and hyperammonemia** Infants: 50 mg/kg/24 hr divided q6h PO Children: 50-100 mg/kg/24 hr divided q6-8h PO Adults: 500-2,000 mg/dose q6-8h PO	*Cautions:* In patients with renal dysfunction because small amount absorbed may accumulate. *Adverse events:* Primarily related to topical application, abdominal cramps, diarrhea, rash. Like any aminoglycoside, ototoxicity and nephrotoxicity occur if absorbed.
Nitrofurantoin Furadantin, Furan, Macrodantin Capsule: 50, 100 mg Extended-release capsule: 100 mg Macrocrystal: 50, 100 mg Suspension: 25 mg/5 mL	**Effective in treatment of lower UTIs caused by gram-positive and gram-negative pathogens** Children: 5-7 mg/kg/24 hr divided q6h PO (max dose: 400 mg/24 hr); suppressive therapy 1-2.5 mg/kg/24 hr divided q12-24h PO (max dose: 100 mg/24 hr) Adults: 50-100 mg/24 hr divided q6h PO	*Cautions:* Vertigo, dizziness, rash, jaundice, interstitial pneumonitis. Do not use with moderate to severe renal dysfunction. *Drug interactions:* Liquid antacids.
Ofloxacin Ocuflox 0.3% ophthalmic solution: 1, 5, 10 mL Floxin 0.3% otic solution: 5, 10 mL	**Quinolone antibiotic for treatment of conjunctivitis or corneal ulcers (ophthalmic solution) and otitis externa or chronic suppurative otitis media (otic solution) caused by susceptible gram-positive, gram-negative, anaerobic bacteria, or *C. trachomatis*** *Child >1-12 yr:* Conjunctivitis: 1-2 drops in affected eye(s) q2-4h for 2 days, then 1-2 drops qid for 5 days Corneal ulcers: 1-2 drops q30min while awake and at 4-hr intervals at night for 2 days, then 1-2 drops hourly for 5 days while awake, then 1-2 drops q6h for 2 days Otitis externa (otic solution): 5 drops into affected ear bid for 10 days Chronic suppurative otitis media: treat for 14 days *Child >12 yr and adults:* Ophthalmic solution doses same as for younger children. Otitis externa (otic solution): Use 10 drops bid for 10 or 14 days as for younger children	*Adverse events:* Burning, stinging, eye redness (ophthalmic solution), dizziness with otic solution if not warmed.
Omadacycline Nuzyra Injection 100 mg/single-dose vial Oral 150 mg tablet	**New subclass of tetracyclines; active against MSSA, MRSA CoNS, streptococci, including pneumococcus, and enterococci, including VRE** Adults: 200 mg IV once OR 100 mg IV × 2 doses OR 300 mg PO × 2 doses Follow with maintenance dosing starting on day 2: Maintenance dose 100 mg IV qday OR 300 mg PO qday Treatment duration: 7-14 days Children: No dosing information available	Omadacycline has comparable adverse events to other tetracyclines such as tooth discoloration, enamel hypoplasia, and inhibition of bone growth. However, no cases of photosensitivity were observed in phase 3 studies.

Table 225.3 Selected Antibacterial Medications (Antibiotics)*—cont'd

DRUG (TRADE NAMES, FORMULATIONS)	INDICATIONS (MECHANISM OF ACTION) AND DOSING	COMMENTS
Oxacillin sodium Prostaphlin Injection Capsule: 250, 500 mg Suspension: 250 mg/5 mL	**Penicillinase-resistant penicillin active against *S. aureus* and other gram-positive cocci, except *Enterococcus* and coagulase-negative staphylococci** Neonates: Postnatal age ≤7 days weight 1,200-2,000 g: 50 mg/kg/24 hr divided q12h IV; weight >2,000 g: 75 mg/kg/24 hr IV divided q8h IV; postnatal age >7 days weight <1,200 g: 50 mg/kg/24 hr IV divided q12h IV; weight 1,200-2,000 g: 75 mg/kg/24 hr divided q8h IV; weight >2,000 g: 100 mg/kg/24 hr IV divided q6h IV Infants: 100-200 mg/kg/24 hr divided q4-6h IV Children: PO 50-100 mg/kg/24 hr divided q4-6h IV Adults: 2-12 g/24 hr divided q4-6h IV (max dose: 12 g/24 hr)	*Cautions:* β-Lactam safety profile (rash, eosinophilia) Moderate oral bioavailability (35–65%). Primarily renally eliminated *Drug interaction:* Probenecid *Adverse effect:* Neutropenia
Penicillin G Injection Tablets	**Penicillin active against most gram-positive cocci; *S. pneumoniae* (resistance is increasing), group A *Streptococcus*, and some gram-negative bacteria (e.g., *N. gonorrhoeae, N. meningitidis*)** Neonates: Postnatal age ≤7 days weight 1,200-2,000 g: 50,000 units/kg/24 hr divided q12h IV or IM (meningitis: 100,000 U/kg/24 hr divided q12h IV or IM); weight >2,000 g: 75,000 U/kg/24 hr divided q8h IV or IM (meningitis: 150,000 U/kg/24 hr divided q8h IV or IM); postnatal age >7 days weight ≤1,200 g: 50,000 U/kg/24 hr divided q12h IV (meningitis: 100,000 U/kg/24 hr divided q12h IV); weight 1,200-2,000 g: 75,000 U/kg/24 hr q8h IV (meningitis: 225,000 U/kg/24 hr divided q8h IV); weight >2,000 g: 100,000 U/kg/24 hr divided q6h IV (meningitis: 200,000 U/kg/24 hr divided q6h IV) Children: 100,000-250,000 units/kg/24 hr divided q4-6h IV or IM (max dose: 400,000 U/kg/24 hr) Adults: 2-24 million units/24 hr divided q4-6h IV or IM	*Cautions:* β-Lactam safety profile (rash, eosinophilia), allergy, seizures with excessive doses particularly in patients with marked renal disease. Substantial pathogen resistance. Primarily renally eliminated *Drug interaction:* Probenecid
Penicillin G, benzathine Bicillin Injection	**Long-acting repository form of penicillin effective in treatment of infections responsive to persistent, low penicillin concentrations (1-4 wk) (e.g., group A *Streptococcus* pharyngitis, rheumatic fever prophylaxis)** Neonates weighing >1,200 g: 50,000 units/kg IM once Children: 300,000-1.2 million units/kg q3-4wk IM (max dose: 1.2-2.4 million units/dose) Adults: 1.2 million units IM q3-4wk	*Cautions:* β-Lactam safety profile (rash, eosinophilia), allergy. Administer by IM injection only. Substantial pathogen resistance. Primarily renally eliminated. *Drug interaction:* Probenecid.
Penicillin G, procaine Crysticillin Injection	**Repository form of penicillin providing low penicillin concentrations for 12 hr** Neonates with weight >1,200 g: 50,000 units/kg/24 hr IM Children: 25,000-50,000 units/kg/24 hr IM for 10 days (max dose: 4.8 million units/dose) Gonorrhea: 100,000 units/kg (max dose: 4.8 million units/24 hr) IM once with probenecid 25 mg/kg (max dose: 1 g) Adults: 0.6-4.8 million units q12-24h IM	*Cautions:* β-Lactam safety profile (rash, eosinophilia) allergy. Administer by IM injection only. Substantial pathogen resistance. Primarily renally eliminated. *Drug interaction:* Probenecid.
Penicillin V Pen VK, V-Cillin K Tablet: 125, 250, 500 mg Suspension: 125 mg/5 mL, 250 mg/5 mL	**Preferred oral dosing form of penicillin, active against most gram-positive cocci; *S. pneumoniae* (resistance is increasing), other streptococci, and some gram-negative bacteria (e.g., *N. gonorrhoeae, N. meningitidis*)** Children: 25-50 mg/kg/24 hr divided q4-8h PO Adults: 125-500 mg q6-8h PO (max dose: 3 g/24 hr)	*Cautions:* β-Lactam safety profile (rash, eosinophilia), allergy, seizures with excessive doses particularly in patients with renal disease. Substantial pathogen resistance. Primarily renally eliminated. Inactivated by penicillinase. *Drug interaction:* Probenecid.
Piperacillin Pipracil Injection	**Extended-spectrum penicillin active against *E. coli, Enterobacter, Serratia, P. aeruginosa,* and *Bacteroides*** Neonates: Postnatal age ≤7 days 150 mg/kg/24 hr divided q8-12h IV; >7 days; 200 mg/kg divided q6-8h IV Children: 200-300 mg/kg/24 hr divided q4-6h IV; cystic fibrosis: 350-500 mg/kg/24 hr IV Adults: 2-4 g/dose q4-6h (max dose: 24 g/24 hr) IV	*Cautions:* β-Lactam safety profile (rash, eosinophilia); painful given intramuscularly; each gram contains 1.9 mEq sodium. Interferes with platelet aggregation/serum sickness–like reaction with high doses; increases in liver function test results. Renally eliminated. Inactivated by penicillinase. *Drug interaction:* Probenecid.
Piperacillin-tazobactam Zosyn Injection	**Extended-spectrum penicillin (piperacillin) combined with a β-lactamase inhibitor (tazobactam) active against *S. aureus, H. influenzae, E. coli, Enterobacter, Serratia, Acinetobacter, P. aeruginosa,* and *Bacteroides*** Children: 300-400 mg/kg/24 hr divided q6-8h IV or IM Adults: 3.375 g q6-8h IV or IM	*Cautions:* β-Lactam safety profile (rash, eosinophilia); painful given intramuscularly; each gram contains 1.9 mEq sodium. Interferes with platelet aggregation, serum sickness–like reaction with high doses, increases in liver function test results. Renally eliminated. *Drug interaction:* Probenecid.

Continued

Table 225.3 Selected Antibacterial Medications (Antibiotics)*—cont'd

DRUG (TRADE NAMES, FORMULATIONS)	INDICATIONS (MECHANISM OF ACTION) AND DOSING	COMMENTS
Plazomicin Zemdri 500 mg/10 mL (50 mg/mL) vials Each vial contains plazomicin sulfate equivalent to 500 mg plazomicin free base	**Aminoglycoside active against resistant Enterobacteriaceae, including CRE** Adults: 15 mg/kg IV q24hr infused over 30 min Duration of therapy should be guided by the severity of infection and the patient's clinical status for up to 7 days; usual duration 4-7 days Children: no pediatric dose established	May cause ototoxicity and nephrotoxicity. Monitor renal function. Drug eliminated renally. *Drug interactions:* May potentiate other ototoxic and nephrotoxic drugs.
Quinupristin/dalfopristin Synercid IV injection: powder for reconstitution, 10 mL contains 150 mg quinupristin, 350 mg dalfopristin	**Streptogramin antibiotic (quinupristin) active against vancomycin-resistant *E. faecium* (VRE) and methicillin-resistant *S. aureus* (MRSA). Not active against *E. faecalis*** Children and adults: VRE: 7.5 mg/kg q8h IV for VRE; skin infections: 7.5 mg/kg q12h IV	*Adverse events:* Pain, edema, or phlebitis at injection site; nausea; diarrhea. *Drug interactions*: Synercid is a potent inhibitor of CYP 3A4.
Sulfadiazine Tablet: 500 mg	**Sulfonamide antibiotic primarily indicated for treatment of lower UTIs caused by *E. coli, P. mirabilis,* and *Klebsiella*** Toxoplasmosis: Neonates: 100 mg/kg/24 hr divided q12h PO with pyrimethamine 1 mg/kg/24 hr PO (with folinic acid) Children: 120-200 mg/kg/24 hr divided q6h PO with pyrimethamine 2 mg/kg/24 hr divided q12h PO ≥3 days, then 1 mg/kg/24 hr (max dose: 25 mg/24 hr) with folinic acid Rheumatic fever prophylaxis: weight ≤30 kg: 500 mg/24 hr q24h PO; weight >30 kg: 1 g/24 hr q24h PO	*Cautions:* Rash, Stevens-Johnson syndrome, nausea, leukopenia, crystalluria. Renal and hepatic elimination; avoid use with renal disease. Half-life: ~10 hr. *Drug interactions:* Protein displacement with warfarin, phenytoin, methotrexate.
Sulfamethoxazole Gantanol Tablet: 500 mg Suspension: 500 mg/5 mL	**Sulfonamide antibiotic used for treatment of otitis media, chronic bronchitis, and lower UTIs caused by susceptible bacteria** Children: 50-60 mg/kg/24 hr divided q12h PO Adults: 1 g/dose q12h PO (max dose: 3 g/24 hr)	*Cautions:* Rash, Stevens-Johnson syndrome, nausea, leukopenia, crystalluria. Renal and hepatic elimination; avoid use with renal disease. Half-life: ~12 hr. Initial dose often a loading dose (doubled). *Drug interactions:* Protein displacement with warfarin, phenytoin, methotrexate.
Sulfisoxazole Gantrisin Tablet: 500 mg Suspension: 500 mg/5 mL Ophthalmic solution, ointment	**Sulfonamide antibiotic used for treatment of otitis media, chronic bronchitis, and lower UTIs caused by susceptible bacteria. Also used for *Nocardia*** ***Plasmodium falciparum* resistant to chloroquine, toxoplasmosis in combination with pyrimethamine (sulfadiazine preferred).** Children: 120-150 mg/kg/24 hr divided q4-6h PO (max dose: 6 g/24 hr) Adults: 4-8 g/24 hr divided q4-6h PO	*Cautions:* Rash, Stevens-Johnson syndrome, nausea, leukopenia, crystalluria. Renal and hepatic elimination; avoid use with renal disease. Half-life: ~7-12 hr. Initial dose often a loading dose (doubled). *Drug interactions:* Protein displacement with warfarin, phenytoin, methotrexate.
Tedizolid Sivextro 200 mg vial 200 mg tablet	**Oxazolidinone agent; indicated for skin and soft tissue/skin structure infections caused by susceptible gram-positive organisms; active against MSSA, MRSA, streptococci, enterococci** Adults: 200 mg PO/IV qday for 6 days Children: Indicated for acute bacterial skin and skin structure infections in patients age ≥12 yr <12 yr: Safety and efficacy not established 12-18 yr: 200 mg PO/IV qday for 6 days	Similar to linezolid. Adverse events may include myelosuppression, pseudomembranous colitis, nausea, diarrhea, headache, peripheral and optic neuropathy.
Tigecycline Tygacil Injection	**Tetracycline-class antibiotic (glycylcycline) active against Enterobacteriaceae, including extended spectrum β-lactamase producers; streptococci (including VRE); staphylococci (including MRSA); and anaerobes** Children: unknown Adults: 100 mg loading dose followed by 50 mg q12h IV	*Cautions:* Pregnancy; children <8 yr old; photosensitivity; hypersensitivity to tetracyclines; hepatic impairment (~60% hepatic clearance). *Drug interaction:* Warfarin; mycophenolate mofetil.
Tobramycin Nebcin, Tobrex Injection Ophthalmic solution, ointment Inhalation capsule (28 mg); inhalation solution (60 mg/mL; 75 mg/mL)	**Aminoglycoside antibiotic active against gram-negative bacilli, especially *E. coli, Klebsiella, Enterobacter, Serratia, Proteus,* and *Pseudomonas*** Can be administered by inhalational route Neonates: Postnatal age ≤7 days, weight 1,200-2,000 g: 2.5 mg/kg q12-18h IV or IM; weight >2,000 g: 2.5 mg/kg q12h IV or IM; postnatal age >7 days, weight 1,200-2,000 g: 2.5 mg/kg q8-12h IV or IM; weight >2,000 g: 2.5 mg/kg q8h IV or IM Children: 2.5 mg/kg/24 hr divided q8-12h IV or IM. Alternatively, may administer 5-7.5 mg/kg/24 hr IV. Preservative-free preparation for intraventricular or intrathecal use: neonate, 1 mg/24 hr; children, 1-2 mg/24 hr; adults, 4-8 mg/24 hr Adults: 3-6 mg/kg/24 hr divided q8h IV or IM	*Cautions: S. pneumoniae*, other streptococcus, and anaerobes are resistant. May cause ototoxicity and nephrotoxicity. Monitor renal function. Drug eliminated renally. Administered IV over 30-60 min. *Drug interactions:* May potentiate other ototoxic and nephrotoxic drugs. *Target serum concentrations:* Peak 6-12 mg/L; trough <2 mg/L.

Table 225.3 Selected Antibacterial Medications (Antibiotics)*—cont'd

DRUG (TRADE NAMES, FORMULATIONS)	INDICATIONS (MECHANISM OF ACTION) AND DOSING	COMMENTS
Trimethoprim Proloprim, Trimpex Tablet: 100, 200 mg	**Folic acid antagonist effective in prophylaxis and treatment of *E. coli, Klebsiella, P. mirabilis,* and *Enterobacter* UTIs; *P. carinii* pneumonia** Children: For UTI: 4-6 mg/kg/24 hr divided q12h PO Children >12 yr and adults: 100-200 mg q12h PO. *P. carinii* pneumonia (with dapsone): 15-20 mg/kg/24 hr divided q6h for 21 days PO	*Cautions:* Megaloblastic anemia, bone marrow suppression, nausea, epigastric distress, rash. *Drug interactions:* Possible interactions with phenytoin, cyclosporine, rifampin, warfarin.
Vancomycin Vancocin, Lyphocin Injection Capsule: 125 mg, 250 mg Suspension	**Glycopeptide antibiotic active against most gram-positive pathogens including staphylococci (including MRSA and coagulase-negative staphylococci), *S. pneumoniae* including penicillin-resistant strains, *Enterococcus* (resistance is increasing), and *C. difficile*–associated colitis** Neonates: Postnatal age ≤7 days, weight <1,200 g: 15 mg/kg/24 hr divided q24h IV; weight 1,200-2,000 g: 15 mg/kg/24 hr divided q12-18h IV; weight >2,000 g: 30 mg/kg/24 hr divided q12h IV; postnatal age >7 days, weight <1,200 g: 15 mg/kg/24 hr divided q24h IV; weight 1,200-2,000 g: 15 mg/kg/24 hr divided q8-12h IV; weight >2,000 g: 45 mg/kg/24 hr divided q8h IV Children: 45-60 mg/kg/24 hr divided q8-12h IV; *C. difficile*–associated colitis; 40-50 mg/kg/24 hr divided q6-8h PO	*Cautions:* Ototoxicity and nephrotoxicity, particularly when co-administered with other ototoxic and nephrotoxic drugs. Infuse IV over 45-60 min. Cutaneous and systemic side effects can be observed with rapid IV infusions, fever, chills, phlebitis (central line is preferred for infusions). Renally eliminated. *Target serum concentrations:* Peak (1 hr after 1 hr infusion) 30-40 mg/L; trough 5-10 mg/L.

*In the Drug column, the generic drug name is in **bold**. In the Indications column, **bold** indicates major organisms targeted and mechanisms of action.
CNS, Central nervous system; GI, gastrointestinal; IM, intramuscular/ly; IV, intravenous/ly; PO, oral/ly; UTIs, urinary tract infections.

Table 225.4 Adverse Reactions to Penicillins

TYPE OF REACTION	FREQUENCY (%)	OCCURS MOST FREQUENTLY WITH
ALLERGIC Immunoglobulin E antibody	0.04-0.015	Penicillin G
Anaphylaxis*		
Early urticaria* (<72 hr)		
Cytotoxic antibody	Rare	Penicillin G
Hemolytic anemia*		
Antigen-antibody complex disease	Rare	Penicillin G
Serum sickness*		
Delayed hypersensitivity	2-5	Ampicillin, amoxicillin
Contact dermatitis*		
IDIOPATHIC	2-5	Ampicillin
Skin rash		
Fever		
Late-onset urticaria		
GASTROINTESTINAL Diarrhea	3-11	Ampicillin
Clostridioides difficile (formerly *Clostridium difficile*)–associated colitis	Rare	Ampicillin
HEMATOLOGIC Hemolytic anemia	Rare	Penicillin G
Neutropenia	10-17	Penicillin G, nafcillin, oxacillin†
Platelet dysfunction	43-73	Piperacillin
HEPATIC Elevated serum aspartate transaminase	0.01-22	Flucloxacillin, oxacillin

Table 225.5 Classification of Parenteral and Oral Cephalosporins

CEPHALOSPORINS	FIRST GENERATION	SECOND GENERATION	CEPHAMYCINS	THIRD GENERATION	FOURTH GENERATION	FIFTH GENERATION (MRSA ACTIVE)
Parenteral	Cefazolin (Ancef, Kefzol)	Cefamandole (Mandol)*	Cefmetazole (Zefazone)*	Cefoperazone (Cefobid)*	Cefepime (Maxipime)	Ceftaroline (Teflaro)
	Cephalothin (Keflin, Seffin)*	Cefonicid (Monocid)*	Cefotetan (Cefotan)	Cefotaxime (Claforan)	Cefpirome (Cefrom)	Ceftobiprole (Zeftera)*
	Cephapirin (Cefadyl)*	Cefuroxime (Kefurox, Zinacef)	Cefoxitin (Mefoxin)	Ceftazidime (Fortaz)	Cefiderocol (Fetroja; Siderophore antibiotic)	Ceftolozane (combined with tazobactam; Zerbaxa)
	Cephradine (Velosef)*			Ceftizoxime (Cefizox)*		
				Ceftriaxone (Rocephin)		
				Moxalactam*		
				Ceftazidime-avibactam (Avycaz)		
Oral	Cefadroxil (Duricef, Ultracef) Cephalexin (Keflex, Biocef, Keftab) Cephradine (Velosef)*	Cefaclor (Ceclor)* Cefprozil (Cefzil) Cefuroxime axetil (Ceftin) Loracarbef (Lorabid)*		Cefdinir (Omnicef) Cefditoren (Spectracef) Cefixime (Suprax) Cefpodoxime (Vantin) Ceftibuten (Cedax)		

*Not currently available in the United States.
Adapted from Lepak AJ, Andes DR. Cephalosporins. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, 9th ed. Philadelphia: Elsevier; 2020: Table 21-1.

A **fifth-generation cephalosporin** called *ceftaroline* has been licensed. Ceftaroline is the active metabolite of the prodrug ceftaroline fosamil (which is the agent administered to the patient). Ceftaroline is a broad-spectrum cephalosporin with bactericidal activity against resistant gram-positive organisms, including MRSA, and common gram-negative pathogens. It has FDA approval and is licensed for use in children. Ceftaroline is indicated for MRSA in the treatment of skin and soft tissue infections. It is also licensed for treatment of community-acquired pneumonia but is not indicated for MRSA pneumonia. Ceftaroline's activity is attributed to its ability to bind to PBP 2a with higher affinity than other β-lactams. Another fifth-generation cephalosporin with a similar spectrum of activity, *ceftobiprole,* has been approved for use in Canada and the European Union. A third fifth-generation cephalosporin, *ceftolozane,* has been licensed. It is a derivative of ceftazidime with improved activity against *Pseudomonas* spp. It is not stable against most ESBLs or carbapenemases. It is marketed in combination with the β-lactam inhibitor tazobactam to improve its activity against β-lactamase–producing Enterobacteriaceae. Experience with children is limited.

Table 225.6 lists adverse reactions to cephalosporins.

Carbapenems

The carbapenem group of antibiotics includes imipenem (formulated in combination with cilastatin), meropenem, ertapenem, and doripenem. The basic structure of these agents is similar to that of β-lactam antibiotics, and these drugs have a similar mechanism of

Table 225.6 Potential Adverse Effects of Cephalosporins

TYPE	SPECIFIC	FREQUENCY
Hypersensitivity	Rash	1–3%
	Urticaria	<1%
	Serum sickness	<1%
	Anaphylaxis	0.01%
Gastrointestinal	Diarrhea	1–19%

*Ceftriaxone.
†Cephalosporins with thiomethyl tetrazole ring (MTT) side chain.
Adapted from Craig WA, Andes DR. Cephalosporins. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases,* 9th ed. Philadelphia: Elsevier; 2020: Table 21-6.

action. The carbapenems provide the broadest spectrum of antibacterial activity of any licensed class of antibiotics and are active against gram-positive, gram-negative, and anaerobic organisms. Among the carbapenems, **meropenem** is the only agent licensed for treatment of pediatric meningitis. Importantly, MRSA and *E. faecium* are *not* susceptible to carbapenems. Carbapenems also tend to be poorly active against *Stenotrophomonas maltophilia,* rendering their use for cystic fibrosis patients who are infected with this organism problematic. Ertapenem is poorly active against *P. aeruginosa* and *Acinetobacter* species and should be avoided when these pathogens are encountered. Although imipenem-cilastatin is the first carbapenem approved for clinical use and the carbapenem with the greatest clinical experience, this antibiotic unfortunately has a propensity to cause seizures in children, particularly in the setting of intercurrent meningitis. Accordingly, meropenem is typically more suitable for pediatric use, where meningitis is commonly a consideration. Carbapenems have also been combined with β-lactamase inhibitors. One example is **meropenem/vaborbactam,** where the β-lactamase inhibitor vaborbactam extends the spectrum of activity to include some ESBL- and carbapenemase-producing bacteria. No dosage recommendations exist as yet for pediatric use. Another example is **imipenem/relebactam** (imipenem/cilastatin/relebactam), which is approved for complicated urinary tract and intraabdominal infections and for ventilator-associated pneumonia.

Other carbapenems in various stages of clinical trials include benapenum, panipenem, biapenem, razupenem, and tomopenem. Tebipenem pivoxil is an orally available prodrug of tebipenem, a carbapenem with activity against multidrug-resistant gram-negative pathogens, including quinolone-resistant and ESBL-producing Enterobacteriaceae. Sulopenem/sulopenem etzadroxil/probenecid is an oral carbapenem combination. Sulopenem etzadroxil is an oral prodrug form of sulopenem, a thiopenem with broad-spectrum antibacterial activity against most gram-positive and gram-negative bacteria, not including *P. aeruginosa*. Probenecid is included to prolong half-life. Panipenem is a combination agent coformulated with betamipron, which inhibits renal uptake of panipenem (analogous to imipenem/cilastatin). Panipenem, biapenem, and tebipenem/pivoxil are licensed in Japan. There is minimal experience with pediatric dosing for all of these newer carbapenems.

Glycopeptides

Glycopeptide antibiotics include **vancomycin** and **teicoplanin**, the less commonly available analog. These agents are bactericidal and act by inhibiting cell wall biosynthesis. The antimicrobial activity of the glycopeptides is limited to gram-positive organisms, including *S. aureus,* coagulase-negative staphylococci, pneumococcus, enterococci, *Bacillus,* and *Corynebacterium.* Vancomycin is frequently employed in pediatric practice and is of particular value for serious infections, including meningitis, caused by MRSA and penicillin- and cephalosporin-resistant *S. pneumoniae.* Vancomycin is also commonly used for infections in the setting of fever and neutropenia in oncology patients, in combination with other antibiotics (see Chapter 223), and for infections associated with indwelling medical devices (see Chapter 224). Oral formulations of vancomycin are occasionally used to treat pseudomembranous colitis caused by *Clostridium difficile* infections; intrathecal therapy may also be used for selected CNS infections. Vancomycin must be administered with care because of its propensity to produce **vancomycin infusion syndrome**, which is a reversible adverse effect that is rare in young children and can typically be readily managed by slowing the rate of drug infusion.

Newer FDA-approved glycopeptide antibiotics include telavancin, dalbavancin, and oritavancin; pediatric experience is limited. **Telavancin** is indicated for skin and skin structure infections caused by *S. aureus* (including MRSA), group A streptococcus, and *E. faecalis* (vancomycin-susceptible isolates only). It is also approved for hospital-acquired (including ventilator-associated) pneumonia caused by *S. aureus*. The recommended adult dose for skin and soft tissue infections, and for nosocomial pneumonia, is 10 mg/kg intravenously (IV) every 24 hours for 7-21 days. Telavancin appears to be more nephrotoxic than vancomycin and has been associated with prolongation of the QT interval. **Dalbavancin**'s unique characteristic is its long half-life, 150-250 hours. In adults with normal renal function, the dose is 1000 mg IV, followed 1 week later by 500 mg IV. This agent can be considered when MRSA is confirmed or strongly suggested. Dalbavancin is not active against vancomycin-resistant *S. aureus*. It is FDA-approved for bacterial skin and soft tissue infections. **Oritavancin** is a vancomycin derivative with indications similar to those of dalbavancin. It has a half-life of approximately 250 hours. The dosage for adults is a single 1200-mg dose administered IV over 3 hours. The FDA has approved dalbavancin and oritavancin for the treatment of acute bacterial skin and skin structure infections caused by gram-positive bacteria, including MRSA. **Cefilavancin** is a unique agent spanning two antimicrobial classes in a single agent. It is a covalently linked glycopeptide-cephalosporin heterodimer antibiotic that is highly active against gram-positive bacteria and is in a phase 3 study.

Aminoglycosides

Aminoglycoside antibiotics include streptomycin, kanamycin, gentamicin, tobramycin, netilmicin, and amikacin. The most commonly used aminoglycosides in pediatric practice are **gentamicin** and **tobramycin**. They exert their action by inhibiting bacterial protein synthesis. Although they are most often used to treat gram-negative infections, the aminoglycosides are broad-spectrum agents, with activity against *S. aureus* and synergistic activity against GBS, *L. monocytogenes,* viridans streptococci, *Corynebacteria jeikeium*, *P. aeruginosa,* coagulase-negative staphylococci, and enterococci when co-administered with a β-lactam agent. Aminoglycoside use has decreased with the development of alternatives, but they still play a key role in pediatric practice in the management of neonatal sepsis, UTIs, gram-negative bacterial sepsis, and complicated intraabdominal infections; infections in cystic fibrosis patients (including both parenteral and aerosolized forms of therapy); and oncology patients with fever and neutropenia. Aminoglycosides, in particular streptomycin, are also important in the management of *Francisella tularensis, Mycobacterium tuberculosis,* and nontuberculous mycobacterial infections.

Toxicities of aminoglycoside therapy include nephrotoxicity and ototoxicity (cochlear and/or vestibular), and serum levels as well as renal function and hearing should be monitored in patients on long-term therapy. Toxicities of aminoglycosides may be reduced by the use of once-daily dosing regimens with appropriate monitoring of serum levels. Hypokalemia, volume depletion, hypomagnesemia, and other nephrotoxic drugs may increase the renal toxicity of aminoglycosides. A rare complication of aminoglycosides is **neuromuscular blockade**, which may occur in the presence of other neuromuscular blocking agents and in the setting of infant botulism.

A novel aminoglycoside, **plazomicin**, has recently been approved by the FDA for adult use. It was designed to evade all of the clinically relevant aminoglycoside-modifying enzymes (Table 225.2) responsible for aminoglycoside resistance. It is approved for complicated UTIs, including pyelonephritis caused by *E. coli*, *K. pneumoniae*, *Proteus mirabilis,* and *Enterobacter cloacae.* FDA approval is pending for bloodstream infections caused by multidrug-resistant *Enterobacteriaceae*, including CRE.

Tetracyclines

The tetracyclines (tetracycline hydrochloride, doxycycline, minocycline, demeclocycline, eravacycline, omadacycline, and minocycline) are bacteriostatic antibiotics that exhibit their antimicrobial effect by binding to the bacterial 30S ribosomal subunit, inhibiting protein translation. These agents have a broad spectrum of antimicrobial activity against gram-positive and gram-negative bacteria, rickettsia, and some parasites. The oral bioavailability of these agents facilitates oral dosing for many infections, including Rocky Mountain spotted fever, anaplasmosis, ehrlichiosis, Lyme disease, and malaria. Tetracyclines must be prescribed judiciously to children <9 years old, because they can cause staining of teeth, hypoplasia of dental enamel, and abnormal bone growth in this age-group.

Tigecycline, a semisynthetic derivative of minocycline, is a parenteral agent of a new antibiotic class **(glycylcyclines)** and is licensed in the United States. It has a broader spectrum of activity (bacteriostatic) than traditional tetracyclines but retains the side effect profile of tetracyclines. Tigecycline is active against tetracycline-resistant gram-positive and gram-negative pathogens, including MRSA and possibly VRE, but not *Pseudomonas.* **Demeclocycline** is an orally administered tetracycline with a similar antimicrobial spectrum as other agents in this class. A novel tetracycline derivative, **eravacycline** (a fluorocycline), has recently been approved for treatment of complicated intraabdominal infections in adults and has the broadest spectrum of any tetracycline, including MRSA and CRE. **Omadacycline** is another new tetracycline that is similar to that of other tetracyclines, functioning as an inhibitor of bacterial protein synthesis, but has activity against bacterial strains expressing the two main forms of tetracycline resistance, specifically, antibiotic efflux and ribosomal protection.

Complications of tetracyclines include eosinophilia, leukopenia and thrombocytopenia (tetracycline), pseudotumor cerebri, anorexia, emesis and nausea, hepatitis, photosensitivity, and a hypersensitivity reaction (urticaria, asthma exacerbation, facial edema, dermatitis) as well as a systemic lupus erythematosus–like syndrome (most common with minocycline). The FDA has issued a "black box" warning regarding tigecycline based on a meta-analysis of 10 studies that showed increased mortality among patients receiving this drug.

A salutary side effect of **demeclocycline** has been identified; it is occasionally used as an off-label treatment of hyponatremia resulting from the syndrome of inappropriate antidiuretic hormone (ADH). The mechanism of action appears to be inhibition of adenylyl cyclase activation after ADH binds to renal vasopressin receptors.

Sulfonamides

Trimethoprim and the sulfonamides are bacteriostatic agents that inhibit the bacterial folate synthesis pathway, in the process impairing both nucleic acid and protein synthesis. Sulfonamides interfere

with the synthesis of dihydropteroic acid from paraaminobenzoic acid, whereas trimethoprim acts at a site further downstream, interfering with synthesis of tetrahydrofolic acid from dihydrofolic acid. The sulfonamides are available in both parenteral and oral formulations. Although there have historically been a large number of sulfonamide antibiotics developed for clinical use, relatively few remain available for pediatric practice. The most important agent is the combination of **trimethoprim-sulfamethoxazole** (TMP-SMX), used for treatment of UTIs. TMP-SMX has also emerged as a commonly prescribed agent for staphylococcal skin and soft tissue infections, because this antibiotic generally retains activity against MRSA. TMP-SMX also plays a unique role in immunocompromised patients, as a prophylactic and therapeutic agent for *Pneumocystis jiroveci* infection. Other common sulfonamides include **sulfisoxazole**, which is useful in the management of UTIs, and **sulfadiazine**, which is a drug of choice in the treatment of toxoplasmosis.

Recently, a novel sulfonamide, **iclaprim**, demonstrated noninferiority to vancomycin in the treatment of complicated skin and soft tissue infections. Iclaprim is a diaminopyrimidine with a 20-fold higher affinity for the target molecule for sulfonamides, dihydrofolate reductase, than trimethoprim. It was granted orphan drug status by the FDA for treatment of *S. aureus* infection in patients with cystic fibrosis but has not been formally approved for general use.

Macrolides

The macrolide antibiotics most often used in pediatric practice include **erythromycin**, **clarithromycin**, and **azithromycin**. This class of antimicrobials exerts its antibiotic effect through binding to the 50S subunit of the bacterial ribosome, producing a block in elongation of bacterial polypeptides. Clarithromycin is metabolized to 14-hydroxy clarithromycin, and this active metabolite also has potent antimicrobial activity. The spectrum of antibiotic activity includes many gram-positive bacteria. Unfortunately, resistance to these agents among *S. aureus* and group A streptococcus is fairly widespread, limiting the usefulness of macrolides for many skin and soft tissue infections and for streptococcal pharyngitis. Azithromycin and clarithromycin have demonstrated efficacy for otitis media. All macrolide members have an important role in the management of pediatric respiratory infections, including atypical pneumonia caused by *M. pneumoniae, Chlamydophila pneumoniae,* and *Legionella pneumophila,* as well as infections caused by *Bordetella pertussis.*

Telithromycin, a ketolide antibiotic derived from erythromycin, was initially FDA-approved for the treatment in adults of mild to moderate community-acquired pneumonia, acute exacerbations of chronic bronchitis, and acute sinusitis, having good activity against the agents causing these infections (*S. pneumoniae*, *M. pneumoniae, C. pneumoniae,* and *L. pneumophila* for community-acquired pneumonia; *M. catarrhalis* and *H. influenzae* for sinusitis). Reports of liver failure and myasthenia gravis from telithromycin prompted the withdrawal of the drug from the market. **Solithromycin** is a related next-generation oral and IV fluoroketolide in phase 3 clinical development for the treatment of community-acquired pneumonia.

Drug interactions are common with erythromycin and to a lesser extent with clarithromycin. These agents can inhibit the CYP 3A4 enzyme system, resulting in increased levels of certain drugs, such as astemizole, cisapride, statins, pimozide, and theophylline. Itraconazole may increase macrolide levels, whereas rifampin, carbamazepine, and phenytoin may decrease macrolide levels. There are few reported adverse drug interactions with azithromycin. Cross-resistance may develop between a macrolide and the subsequent use of clindamycin.

Lincosamides

The prototype of the lincosamide class of antibiotics is **clindamycin**, which acts at the ribosomal level to exert its antimicrobial effect. The 50S subunit of the bacterial ribosome is the molecular target of this agent. Its spectrum of activity includes gram-positive aerobes and anaerobes. Clindamycin has no significant activity against gram-negative organisms. An important role for clindamycin has emerged in the management of MRSA infections. Because of its outstanding penetration into body fluids (excluding the CNS) and tissues and bone, clindamycin can be used for therapy of serious infections caused by MRSA. Clindamycin is also useful in the management of invasive group A streptococcus infections and in the management of many anaerobic infections, often in combination with a β-lactam. A form of **inducible clindamycin resistance** is exhibited by some strains of MRSA; therefore consultation with the clinical microbiology laboratory is necessary before treating a serious MRSA infection with clindamycin. Pseudomembranous colitis, a common complication of clindamycin therapy in adults, is seldom observed in pediatric patients. Clindamycin also plays an important role in the treatment of malaria and babesiosis (when co-administered with quinine), *P. jiroveci* pneumonia (when co-administered with primaquine), and toxoplasmosis.

Quinolones

The **fluoroquinolones** (ciprofloxacin, levofloxacin, moxifloxacin, gemifloxacin, besifloxacin [ophthalmic suspension], ofloxacin, and delafloxacin) are antimicrobials that inhibit bacterial DNA replication by binding to the topoisomerases of the target pathogen, inhibiting the bacterial enzyme DNA gyrase. This class has broad-spectrum activity against both gram-positive and gram-negative organisms. Some fluoroquinolones exhibit activity against penicillin-resistant *S. pneumoniae* as well as MRSA. These agents uniformly show excellent activity against gram-negative pathogens, including the Enterobacteriaceae and respiratory tract pathogens such as *M. catarrhalis* and *H. influenzae.* Quinolones are also highly active against pathogens associated with atypical pneumonia, particularly *M. pneumoniae* and *L. pneumophila.*

Although these agents are not approved for use in children, there is a reasonable body of evidence that the fluoroquinolones are generally safe, well tolerated, and effective against a variety of bacterial infections frequently encountered in pediatric practice. Parenteral quinolones are appropriate for critically ill patients with gram-negative infections. The use of oral quinolones in stable outpatients may also be reasonable for treatment of infections that would otherwise require parenteral antibiotics (e.g., *P. aeruginosa* soft tissue infections such as osteochondritis) or selected genitourinary tract infections. However, these agents should be reserved for situations when no other oral antibiotic alternative is feasible. In 2013 the FDA changed the warning labels for the fluoroquinolones to better describe the associated risk of permanent peripheral neuropathy. Additional risks include tendonitis, arrhythmias, and retinal detachment. Moreover, in situations of overuse (e.g., typhoid fever, gonococcal infection), organisms have been demonstrated to rapidly develop resistance. The FDA has advised against the use of quinolones for uncomplicated infections such as sinusitis and bronchitis. Thus use of fluoroquinolones in pediatric practice should still be approached with continued caution, and consultation with an expert is recommended.

Streptogramins and Oxazolidinones

The emergence of highly resistant gram-positive organisms, in particular VRE, has necessitated development of new classes of antibiotics. One such class especially useful for resistant gram-positive infections is the streptogramins. The currently licensed agent in this category is **dalfopristin-quinupristin**, which is available in a parenteral formulation. It is appropriate for treatment of MRSA, coagulase-negative staphylococci, penicillin-susceptible and penicillin-resistant *S. pneumoniae,* and vancomycin-resistant *E. faecium* but not *E. faecalis.*

Another licensed class of antibiotics for highly resistant gram-positive infections is the oxazolidinone class. The prototype in this group is **linezolid**, available in both oral and parenteral formulations and approved for use in pediatric patients. Its mechanism of action involves inhibition of ribosomal protein synthesis. It is indicated for MRSA, VRE, coagulase-negative staphylococci, and penicillin-resistant

S. pneumoniae. A related drug, **tedizolid phosphate**, is also FDA-approved for acute bacterial skin and skin structure infections. It is more potent in vitro than linezolid against MRSA and may be associated with less myelosuppression. It is available in both IV and oral formulations.

There is little information on streptogramins and oxazolidinones in the treatment of CNS infections, and neither class is approved for pediatric meningitis. Linezolid can cause significant anemia and thrombocytopenia and is a monoamine oxidase inhibitor.

A novel oxazolidinone, **contezolid acefosamil** (MRX-4), was recently approved for use in China. It is an orally active prodrug of the active antimicrobial metabolite, contezolid (MRX-I), an oxazolidinone that shows potent in vitro activity against various multidrug-resistant gram-positive bacteria, including MRSA. It also has activity against *M. tuberculosis*.

Daptomycin

Daptomycin is a novel member of the cyclic lipopeptide class of antibiotics. Its spectrum of activity includes virtually all gram-positive organisms, including *E. faecalis* and *E. faecium* (including VRE) and *S. aureus* (including MRSA). The structure of daptomycin is a 13-member amino acid peptide linked to a 10-carbon lipophilic tail, which results in a novel mechanism of action of disruption of the bacterial membrane through the formation of transmembrane channels. These channels cause leakage of intracellular ions, leading to depolarization of the cellular membrane and inhibition of macromolecular synthesis. A theoretical advantage of daptomycin for serious infections is its bactericidal activity against MRSA and enterococci. It is administered intravenously; experience in children is limited. Myopathy and elevations in creatine phosphokinase have been described. An FDA warning has been issued linking some cases of eosinophilic pneumonitis to the use of daptomycin. Daptomycin is inactivated by surfactant and should not be used to treat pneumonia.

Miscellaneous Agents

Metronidazole, which functions by disruption of DNA synthesis, has a unique role as an antianaerobic agent and also possesses antiparasitic and anthelmintic activity. In 2017 a related drug, **benznidazole**, was approved through the FDA's orphan drug Accelerated Approval Pathway. This antiprotozoal agent inhibits the synthesis of DNA, RNA, and proteins within *Trypanosoma cruzi* and is approved for adult and pediatric use for Chagas disease. **Rifampin** is a rifamycin antibiotic that inhibits bacterial RNA polymerase and has a major role in the management of tuberculosis. It is also of value in the management of other bacterial infections in pediatric patients, usually used as a second (synergistic) agent in the treatment of *S. aureus* infections or to eliminate nasopharyngeal colonization of Hib or *N. meningitidis*. **Rifabutin** is a related drug that has an off-label indication for treatment of tuberculosis, an orphan drug indication for Crohn disease, and an indication for prevention or treatment of disseminated *Mycobacterium avium* complex disease in patients with HIV or immune deficiency. **Rifaximin** is a *nonabsorbed rifamycin* that has been used as an adjunct agent to treat patients with multiple recurrences of *C. difficile* infection. **Fidaxomicin** is a first-in-class member of a new category of narrow-spectrum macrocyclic antibiotic drugs. It is an RNA polymerase inhibitor with activity against *C. difficile* infection.

The emerging crisis in antimicrobial resistance has also necessitated the rediscovery of antimicrobial agents seldom used in clinical practice in recent decades, such as **colistin** (colistimethate sodium), a member of the polymyxin family of antibiotics (polymyxin E). The general structure of polymyxins consists of a cyclic peptide with hydrophobic tails. After binding to lipopolysaccharide in the outer membrane of gram-negative bacteria, polymyxins disrupt both outer and inner membranes, leading to cell death. Colistin is broadly active against the Enterobacteriaceae family, including *P. aeruginosa*. It is also active against ESBL- and carbapenemase-producing strains. Toxicities are chiefly renal and neurologic.

Chapter 226

Antimicrobial Stewardship

Kathleen Chiotos and Jeffrey S. Gerber

Antibiotics are the most common class of medications prescribed to pediatric outpatients, and over 50% of pediatric inpatients receive antibiotics during their hospitalization. It is estimated that between 25% and 50% of antibiotic prescriptions are inappropriate in drug choice, dose, or duration or are unnecessary altogether.

THE NEED FOR ANTIMICROBIAL STEWARDSHIP: HARMS FROM OVERUSE

There are many negative consequences of antibiotic overuse, including contributing to the dramatic rise in **antibiotic resistance** observed over the past 30 years, which has led to antibiotic resistance being named by the World Health Organization (WHO) as one of the top 10 threats to human health. Antibiotics also carry with them a risk of individual patient-level harm, including development of ***Clostridioides difficile* infection** and **antibiotic adverse events**. For example, 21% of antibiotic courses among pediatric inpatients are complicated by an adverse event, and each additional day of antibiotic therapy is associated with 7% greater odds of experiencing an adverse event. Among pediatric outpatients receiving broad- versus narrow-spectrum antibiotics for acute respiratory tract infections, adverse events are significantly more common in patients treated with broad-spectrum therapy. Finally, an emerging area of research is the **deleterious impact of antibiotics on the developing microbiome** and its potential influence on future disease states, including childhood obesity, asthma, and other allergic diseases. Collectively, these data highlight the importance of judicious antibiotic prescribing, both on a societal and individual patient level.

DEFINING ANTIMICROBIAL STEWARDSHIP AND AN ANTIMICROBIAL STEWARDSHIP PROGRAM

Antimicrobial stewardship is defined as coordinated interventions designed to improve the use of antimicrobial agents, such that dose, duration of therapy, and route of administration are optimized. The goal of these actions is to achieve the best clinical outcome for the patient, while minimizing the development of antimicrobial resistance and risk of adverse events. **It is paramount to recognize that simply reducing antimicrobial use is *not* a primary goal of antimicrobial stewardship.** However, because inappropriate antibiotic use is so common, optimization often results in de-escalation from a broader to a narrower spectrum of therapy or discontinuing antibiotics altogether.

Antimicrobial stewardship programs (ASPs) are multidisciplinary teams designed to improve the safety and quality of patient care by deploying these coordinated interventions. ASPs are often led or co-led by infectious diseases trained physicians and clinical pharmacists and work in collaboration with the infection prevention and control department, the clinical microbiology laboratory, and numerous stakeholder groups, including hospital leadership, clinicians, nurses, and pharmacy. Multiple studies have demonstrated reductions in antibiotic use, decreasing rates of *C. difficile* infections, and cost avoidance after the implementation of ASPs, with variable impact on local antibiotic resistance rates. With this growing evidence base and the crisis of antimicrobial resistance, ASPs are now a Standard from The Joint Commission and a Centers for Medicare and Medicaid Services (CMS) Condition of Participation. **Several guidelines provide evidence-based recommendations for implementation of an ASP, including the joint Infectious Diseases Society of America (IDSA) and**

Society for Healthcare Epidemiology of America (SHEA) guideline, the Centers for Disease Control and Prevention (CDC) Core Elements of Hospital Antibiotic Stewardship Programs, the CDC Core Elements of Outpatient Antibiotic Stewardship, and the WHO Practical Toolkit for Antimicrobial Stewardship Programmes in Healthcare Facilities in Low- and Middle-Income Countries.

INPATIENT ANTIMICROBIAL STEWARDSHIP STRATEGIES

Core elements of inpatient antimicrobial stewardship include hospital leadership commitment; accountability through appointment of a leader or coleaders; pharmacy expertise; implementation of actions or interventions to improve antibiotic use (Table 226.1); tracking

Table 226.1 Summary of Inpatient Antimicrobial Stewardship Interventions

ACTION	DESCRIPTION
PRIORITY ACTIONS	
Preauthorization	Clinician must contact the stewardship program to obtain approval for use of the antimicrobial before prescribing (see also text and Table 226.2).
Prospective audit and feedback	Antimicrobials are reviewed by the stewardship program after 48-72 hr and recommendations for optimization are provided at that point (see also text and Table 226.2).
Facility-specific treatment guidelines	These local guidelines should establish clear recommendations for commonly encountered infections based on published data or national guidelines, local susceptibility data, formulary options, and patient mix. These guidelines should address diagnostic testing, empiric treatment, and definitive treatment and should be developed in collaboration with clinician stakeholders.
ADDITIONAL ACTIONS	
Antibiotic "time-outs"	A "time-out" occurs after a set duration of antimicrobial therapy (e.g., 48-72 hr) and involves a clinician-led reassessment of the need for and choice of antibiotics. This differs from prospective audit and feedback in that the review is led by the frontline clinician, not the stewardship program. Time-outs may augment prospective audit and feedback led by the ASP but should not be considered an equivalent substitute.
Assessing penicillin allergy	Although penicillin allergies are reported in 10–15% of hospitalized patients, less than 1% are true serious allergies. Patients with penicillin allergy labels receive broader-spectrum antibiotics than would otherwise be recommended, and penicillin allergy labels may be associated with worse clinical outcomes. Clinicians or stewardship personnel may be able to "delabel" patients through performing a history and/or administering a challenge dose of penicillin or amoxicillin.
Documentation of antibiotic indications in orders or prescriptions	Requiring documentation of an indication for antibiotics can improve antibiotic prescribing practices. In addition, this facilitates other interventions, such as audit with feedback, where knowledge of the intended indication is needed.
Intravenous to oral antibiotic therapy	Transitioning from intravenous to oral therapy when an oral antibiotic is available can reduce the duration of hospitalization, need for long-term intravenous access, and improve patient satisfaction.
Pharmacist-based interventions	Pharmacists are uniquely positioned to optimize antibiotic use through making recommendations for optimal antibiotic dosing and administration (e.g., extended infusions of β-lactam antibiotics, therapeutic drug monitoring for vancomycin and aminoglycosides, identifying duplicative therapy such as overlapping anaerobic coverage, and detection/prevention of antibiotic-related drug-drug interactions).
Time-sensitive automatic stop orders	Including a stop date in antibiotic orders, after which the antimicrobial order is removed from the patient's active medication orders, can promote timely discontinuation of antibiotics. This may be particularly valuable for antibiotics where durations are short and well-defined (e.g., surgical prophylaxis).
Selective reporting of susceptibility testing results	Microbiology labs can partner with stewardship programs to report select antibiotics that are consistent with hospital guidelines or use "cascade" reporting in which susceptibilities to broader-spectrum agents are reported only if resistance to narrower-spectrum drugs is demonstrated.
Comments in microbiology reports	Comments in microbiology reports may guide prescribers to making appropriate antibiotic decisions, for example, by indicating bacterial growth may reflect contamination or guiding providers to using specific preferred antibiotics.
Rapid diagnostic tests for bacterial diagnostics	Molecular diagnostic tests (for example, tests using PCR, microarrays, or mass spectroscopy) may allow more rapid identification of organisms or resistance determinants than traditional culture-based techniques. When implemented together with real-time stewardship program guidance, assays performed on positive blood cultures may reduce time to optimal antibiotic therapy and improve patient outcomes.
Nursing-based interventions	Key opportunities to engage bedside nurses in stewardship activities include optimizing the appropriate collection of microbiology cultures, encouraging intravenous to oral transitions, and prompting antibiotic timeouts.

PCR, Polymerase chain reaction.

Table 226.2 Comparing Preauthorization and Prospective Audit and Feedback

PREAUTHORIZATION	PROSPECTIVE AUDIT AND FEEDBACK
Allows stewardship oversight from the point of antimicrobial initiation.	Stewardship oversight focuses on antimicrobial duration, de-escalation, or discontinuation.
Requires dedicated and expert personnel for "real-time" phone calls or electronic communication through at least the majority of the day.	Resource intensive, particularly if done hospital-wide, but can be scaled to available resource (e.g., focused on a single unit).
Opportunity to counsel provider on optimal diagnostic testing before starting antimicrobials.	Culture and susceptibility testing may be available at the time the intervention is made, such that recommendations for definitive therapy can be made.
Requires a coordinated process including providers, pharmacy, and the stewardship program to ensure approved antimicrobials are dispensed promptly and that antimicrobial requests that are declined are not dispensed.	Prescribers may or may not follow the recommendations made by the stewardship program.
May be seen as a threat to autonomy and/or having the potential to delay therapy.	Generally well-received by providers, with high adherence to recommendations reported.
Only the antimicrobials that are restricted are affected and only at the point of initiation.	More flexibility for the stewardship team regarding the timing of interventions, as well as the potential to act on all antimicrobials prescribed to an individual patient during a single discussion.

antibiotic use, resistance, and *C. difficile* rates; reporting antibiotic use and resistance metrics to prescribers and hospital leaders; and education.

Prospective Audit and Feedback Versus Preauthorization

Two broad approaches to antimicrobial stewardship are supported by the IDSA/SHEA guideline and the CDC Core Elements: preauthorization and prospective audit and feedback. Preauthorization is a strategy in which the clinician must contact the ASP and secure approval for use of the antimicrobial before prescribing the drug. In contrast, prospective audit and feedback is performed by the ASP 48-72 hours after the start of antimicrobial therapy, and recommendations for antimicrobial de-escalation, discontinuation, transition from intravenous to oral therapy, change in dose, or changes in duration are made. Each of these approaches has pros and cons (Table 226.2), and ASPs generally adapt these broad strategies to the local context and availability of resources, often using a hybrid approach. "Handshake stewardship" is a specific type of audit and feedback where recommendations from the ASP are delivered face-to-face to prescribers; this approach has the advantage of developing collaborative relationships but is resource intensive and therefore may not be feasible in all settings. Regardless of which strategy is used, it is critical that ASPs view the interaction with the prescriber as an opportunity to collaboratively optimize antimicrobial therapy and that the guidance provided is evidence-based and, whenever available, aligned with local clinical practice guidelines.

Development and Implementation of Local Guidelines

Creation of evidence-based **local guidelines** containing recommendations for empiric and definitive therapy for common infectious diseases diagnoses and syndromes is a key activity of ASPs. In pediatrics, key target conditions include community-acquired pneumonia, urinary tract infections, intraabdominal infections, skin and soft tissue infections, and neonatal and pediatric sepsis. Coproduction of these guidelines with relevant stakeholders, including prescribing clinicians, offers a unique opportunity to broadly improve antimicrobial prescribing through standardization of evidence-based practices. Because the approach is agreed upon a priori, adhering to these recommendations may also be more appealing to prescribers relative to more "top-down" approaches, where the ASP is either unilaterally authorizing antimicrobial use or providing directive feedback.

Education

While educational interventions alone are insufficient to improve antimicrobial use, education is critical to the success of ASPs and should be integrated along with other strategies. Education can take place in many forms, including at the point of an individual prescriber-steward interaction during preauthorization or prospective audit and feedback; as part of the implementation of a new local treatment guideline or other specific improvement intervention; or as a stand-alone or recurring lecture focused on a topic of relevance, preferably one deemed important to the learners.

OUTPATIENT ANTIMICROBIAL STEWARDSHIP STRATEGIES

The majority of antibiotic use in children occurs in the outpatient setting. Effective outpatient antimicrobial stewardship is therefore critical and requires approaches distinct from the individual-level preauthorization and prospective audit with feedback that form the foundation of inpatient antimicrobial stewardship. Relative to hospital-based stewardship, fewer studies have been conducted in outpatient settings to inform best practices. However, the CDC provides four elements to guide outpatient stewardship efforts, which include commitment to optimizing antibiotic prescribing, including appointment of an accountable leader; actions for policy and practice; tracking and reporting antibiotic use; and education and expertise.

Commitment

In addition to commitment on the part of practice or system leadership, **a written and publicly displayed commitment poster** stating that the individual clinician will only prescribe antibiotics when they are indicated is a powerful tool to reduce unnecessary antibiotic prescribing in the ambulatory setting. This strategy is particularly appealing, as it requires minimal resources to implement and may not only influence provider behavior but also stimulate a discussion between provider and patient around the importance of judicious antibiotic use. In addition, clear communication across clinic providers and staff to ensure this message is consistent and practices are aligned is paramount.

Actions to Improve Antibiotic Prescribing

As with hospital-based stewardship programs, development and implementation of **local guidelines** to inform antibiotic prescribing for relevant conditions is a key strategy for ambulatory stewardship programs. Target conditions in this setting include acute respiratory tract infections, such as pharyngitis, sinusitis, otitis media, and community-acquired pneumonia, given that these conditions account for the vast majority of ambulatory antibiotic use and are associated with significant variation in antibiotic prescribing practices across clinics. A number of strategies have been used to optimize adherence to such guidelines, including audit with feedback at the practice or provider level, clinician education, and computerized decision support. An additional evidence-based practice that may improve antibiotic use in the outpatient setting for specific conditions is use of **delayed prescriptions**, namely, prescriptions provided to patients with mild infections likely to improve without antibiotics at the time of the clinic visit, with instructions to fill the prescription only if symptoms worsen or fail to improve. Delayed prescribing is endorsed by the American Academy of Pediatrics for acute otitis media and acute sinusitis. This type of

"contingency plan" may contribute to patient and parent acceptance of an initial recommendation against antibiotics.

Education

Education is also a fundamental element of outpatient stewardship. In contrast to education in the inpatient setting, which focuses on clinicians, education in the ambulatory setting additionally requires a focus on the patient and family, as well as teaching providers to promote optimal communication. For example, a commonly cited challenge to judicious antibiotic prescribing in the pediatric outpatient setting is a perception on the part of providers that antibiotic prescriptions are strongly desired by parents, even in situations where bacterial infections are unlikely. **However, several studies have refuted this notion and instead suggest that communication of both "positive" treatment recommendations (e.g., specific measures to take to improve symptoms) and "negative" treatment recommendations (e.g., recommendations against using antibiotics when they are not indicated, antibiotic adverse events) is a driver of parent satisfaction and desired by parents.**

TRACKING AND REPORTING ANTIMICROBIAL USE MEASURES

Quantifying antimicrobial use and reporting it to key stakeholders, including clinicians and hospital leadership, are key elements for both inpatient and outpatient stewardship efforts.

Antimicrobial Use Measures

Most antimicrobial stewardship measures are process measures. **The preferred metric for inpatient antimicrobial use is antimicrobial days of therapy (DOTs) per 1,000 patient days.** Each antimicrobial prescribed on each hospital day counts as one DOT, independent of the number of doses the patient receives in the day. For example, if a patient with an intraabdominal infection receives ceftriaxone and metronidazole on the same day, each drug contributes 1 DOT and the total DOT is 2. If instead, this patient received meropenem alone, just 1 DOT would be recorded. DOT/1,000 patient days is a metric particularly useful to track antimicrobial use over time or in response to a specific stewardship intervention and can be measured for an individual drug, a specific unit, or throughout the hospital. Limitations of the measure are that it does not measure the appropriateness of therapy or spectrum of activity, and as demonstrated in the previous example, multidrug regimens will contribute a greater number of DOTs even if the spectrum of the combination of drugs is narrower than the single drug. Finally, DOT/1,000 patient days does not account for differences in patient complexity, illness severity, or comorbid conditions, a limitation that should be considered when making comparisons across units or hospitals.

Antibiotic use measures in the outpatient setting can include individual- or facility-level tracking of antibiotic prescriptions in all visits, or in visits with a certain diagnosis or collection of diagnoses. Metrics could include the proportion of visits in which antibiotics were prescribed, the appropriateness of the antibiotic choice (e.g., broad- versus narrow-spectrum, compliance with local guidelines), and/or the correct duration of antibiotics for a given condition. **Individual-level measures are preferred**, as they facilitate audit and feedback based on individual performance, as well as peer comparisons, strategies that have been used successfully to improve adherence to evidence-based guidelines for antibiotic use in the outpatient setting.

Outcome Measures

The impact of reductions in antimicrobial use through implementation of ASPs or specific interventions should ideally be linked to clinical outcomes. In practice, however, specific outcomes can be difficult to identify, particularly in children where adverse outcomes attributable to antibiotics are uncommon (e.g., *C. difficile* infection) or resource intensive to measure (e.g., drug adverse events, patient-reported outcomes). Improvement in antibiotic resistance rates over time is an appealing hospital-level measure, but improvement occurs slowly and is influenced by multiple factors other than inpatient antibiotic use, including infection prevention and control practices and outpatient prescribing patterns. Other outcome measures that may be considered include revisits, readmissions, or hospital length of stay, though few studies have evaluated these outcomes, which may be confounded by multifactorial influences. Importantly, because antibiotic exposure has been clearly linked to development of antibiotic resistance, *C. difficile* infection, and other adverse drug events, decreases in antibiotic use process measures without a worsening of clinical outcomes are relevant and should be considered sufficient for defining success, even if the reduction in antibiotic use does not result in improved clinical outcomes.

SUMMARY

Antimicrobial stewardship is an important element of patient safety and quality that is the responsibility of all clinicians prescribing antimicrobials. Formal ASPs can guide these local efforts, and abundant evidence demonstrates the positive impact of these programs on improving antibiotic use in both the inpatient and ambulatory settings. Key needs in the field of pediatric antimicrobial stewardship include development of risk-adjusted antibiotic use measures for benchmarking across centers; development of measures to quantify antibiotic-associated harm; incorporating perspectives from nursing and patients/families; and adapting stewardship strategies and organizational structures successful in acute care hospitals to other settings.

Section 4

Gram-Positive Bacterial Infections

Chapter 227

Staphylococcus

Carol M. Kao, Patrick J. Reich, and Stephanie A. Fritz

Staphylococci are hardy, aerobic, gram-positive bacteria that grow in pairs and clusters and are ubiquitous as normal flora of humans and present on fomites and in dust. They are resistant to heat and drying and may be recovered from nonbiologic environments weeks to months after contamination. Strains are classified as *Staphylococcus aureus* if they are coagulase positive or as one of the many species of **coagulase-negative staphylococci** (e.g., *S. epidermidis, S. lugdunensis, S. saprophyticus, S. haemolyticus*). *S. aureus* has many virulence factors that mediate various serious diseases, whereas coagulase-negative staphylococci tend to be less pathogenic unless an indwelling foreign body (e.g., intravascular catheter) is present. *S. aureus* strains resistant to β-lactam antibiotics, typically referred to as **methicillin-resistant *Staphylococcus aureus* (MRSA)**, are a significant problem in both community and hospital settings.

227.1 *Staphylococcus aureus*

Carol M. Kao, Patrick J. Reich, and Stephanie A. Fritz

S. aureus is the most common cause of skin and soft tissue infections (SSTIs). **Bacteremia** (primary or secondary) is common and can be associated with, or can result in, musculoskeletal infection (osteomyelitis, pyomyositis, septic arthritis), pneumonia, endocarditis, and rarely meningitis. **Toxin-mediated diseases**, including food poisoning,

staphylococcal scarlet fever, scalded skin syndrome, and toxic shock syndrome (TSS), are caused by certain *S. aureus* strains.

ETIOLOGY

S. aureus strains produce a wide spectrum of virulence factors. These factors contribute to pathogenesis in human disease by protecting the organism from host defenses, causing local tissue damage, and affecting noninfected sites through toxin elaboration.

Most strains of *S. aureus* possess factors that protect the organism from host defenses. The microbial surface components recognizing adhesive matrix molecules **(MSCRAMMs)** are a family of cell wall–anchored proteins with a broad spectrum of virulence properties, including host tissue and cell adhesion and invasion, biofilm formation, and evasion of the host immune response. Many staphylococci produce a loose extracellular polysaccharide that promotes formation of **biofilms**, which may interfere with opsonophagocytosis. Production of clumping factor and coagulase differentiates *S. aureus* from coagulase-negative staphylococci. **Clumping factor** interacts with fibrinogen to create large clumps of organisms, interfering with effective phagocytosis. **Coagulase** causes plasma to clot by interacting with fibrinogen and may have an important role in abscess formation. **Protein A** is located on the outermost coat of the cell wall and can absorb serum immunoglobulins, preventing opsonization and thus inhibiting phagocytosis. The **chemotaxis inhibiting protein of *S. aureus* (ChIPS)** and **extracellular adherence protein (Eap)** interfere with the native host immune response by inhibiting leukocyte chemotaxis. The staphylococcal enzyme **catalase** inactivates hydrogen peroxide, promoting intracellular survival.

Many strains of *S. aureus* produce substances that cause local tissue destruction. A number of immunologically distinct **hemolysins** that act on cell membranes and cause tissue necrosis have been identified (α-toxin, β-hemolysin, δ-hemolysin). The leukocidins (LukAB, LukDE, Panton-Valentine leucocidin) are pore-forming cytotoxins resulting in increased cell membrane permeability and eventual cell death. Strains of *S. aureus* that produce **Panton-Valentine leukocidin** are associated with more severe and invasive skin disease, necrotizing pneumonia, and osteomyelitis. Many strains of *S. aureus* release one or more exotoxins. **Exfoliatins A and B** are serologically distinct proteins that produce localized (bullous impetigo) or generalized (scalded skin syndrome, staphylococcal scarlet fever) dermatologic manifestations (see Chapter 706).

S. aureus can produce >20 distinct **enterotoxins** (types A-V). Ingestion of preformed enterotoxin, particularly types A or B, can result in **food poisoning**, resulting in vomiting and diarrhea and, in some cases, profound hypotension.

Toxic shock syndrome toxin-1 (TSST-1) is associated with **toxic shock syndrome (TSS)**, related to menstruation and focal staphylococcal infection (see Chapter 227.2). TSST-1 is a superantigen that induces production of interleukin (IL)-1 and tumor necrosis factor (TNF), resulting in hypotension, fever, and multisystem involvement. Focal infections associated with enterotoxins A or B also may be associated with nonmenstrual TSS.

S. aureus also possesses intrinsic factors that can contribute to pathogenesis, including proteins that promote adhesion to fibrinogen, fibronectin, collagen, and other human proteins. Expression of proteins that mediate antibiotic resistance is also of critical importance. Although historically sensitive to penicillin, *S. aureus* isolates now almost universally produce **penicillinase** or **β-lactamase**, which inactivates many β-lactams at the molecular level and represents the major resistance mechanism against many penicillin and some cephalosporin antibiotics. Thus treatment of *S. aureus* with β-lactam antibiotics requires either a penicillinase-resistant β-lactam ring (e.g., antistaphylococcal penicillins such as oxacillin or nafcillin) or combination with a β-lactamase inhibitor (e.g., ampicillin-sulbactam). Production of altered **penicillin-binding proteins (PBPs)** in the bacterial cell wall mediates resistance to penicillinase-resistant antibiotics; an **altered PBP-2A**, encoded by the gene *mecA,* is responsible for the methicillin, cephalosporin, and carbapenem resistance of MRSA isolates.

EPIDEMIOLOGY

S. aureus is a significant cause of morbidity and mortality, particularly in pediatric healthcare-associated infections including infections of the bloodstream, surgical sites, and respiratory tract. Genetically distinct strains of MRSA are termed *community-associated MRSA* (CA-MRSA); USA300 is the predominant pulsotype circulating in the United States. These strains led to an epidemic of SSTIs, and occasionally necrotizing invasive infections, in healthy individuals without the traditional healthcare-associated risk factors for MRSA. Ambulatory visits for purulent SSTIs rose from 5 million to 11 million annually between 2000 and 2013 but have since plateaued and even declined in some populations. Additionally, the incidence of invasive nosocomial MRSA infections (e.g., bacteremia) has also declined; however, the incidence of SSTIs and bloodstream infections caused by MSSA has increased.

Approximately 20–40% of healthy individuals carry at least one strain of *S. aureus* in the anterior nares at any given time, with intermittent carriage occurring in up to 70% of individuals. In children, the oropharynx, umbilicus, inguinal folds, and rectum are also important reservoirs of *S. aureus* carriage. Many neonates are colonized within the first 2 months of life, usually by a maternal strain. The prevalence of colonization with MRSA in the general pediatric population ranges from 2% to 10%, with higher prevalence in some locales and in children with significant healthcare exposure and chronic medical conditions.

S. aureus is acquired and transmitted through close person-to-person contact and contact with contaminated objects or environmental surfaces. *S. aureus* colonization poses a risk for subsequent *S. aureus* infection. In community settings, populations traditionally at high risk for *S. aureus* infection have included athletes, military personnel, young children, veterinarians, injection drug users, and inmates in correctional facilities. However, given the high colonization prevalence in the community, *S. aureus* infections commonly occur in individuals with no identifiable risk factors. In the outpatient setting, SSTI is the most common entity caused by *S. aureus*, accounting for 8 million annual ambulatory visits.

Households are an important reservoir for *S. aureus* transmission because of close personal contact among colonized family members. Increased disease frequency occurs among household contacts of *S. aureus*–colonized or –infected individuals. Additionally, *S. aureus* can persist on environmental surfaces over time. Contamination of environmental surfaces such as hand towels, television remote controls, and bed linens can further perpetuate transmission among household members and is a risk factor for recurrent infection. Thus preventive strategies are aimed at decreasing the burden of *S. aureus* carriage in affected individuals and household members, as well as targeted household environmental surfaces.

PATHOGENESIS

Except in the case of food poisoning resulting from ingestion of preformed enterotoxins, disease associated with *S. aureus* typically begins with colonization. Subsequent disease manifestations in susceptible individuals results either directly from tissue invasion or from injury caused by various toxins and enzymes produced by the organism (Fig. 227.1).

The most significant risk factor for the development of infection is **disruption of intact skin**, including breaches from wounds, skin diseases such as eczema, epidermolysis bullosa, insect bites, burns, ventriculoperitoneal shunts, and central venous catheter placement. Additional risk factors include immunodeficiency and malnutrition, although infection can also occur in otherwise healthy children. Viral infections of the respiratory tract, especially influenza virus infection, may predispose to secondary bacterial infection with staphylococci.

Congenital defects in chemotaxis (hyper-IgE syndromes, Chédiak-Higashi, and Wiskott-Aldrich syndromes) and defective phagocytosis and killing (neutropenia, chronic granulomatous disease) increase the risk for staphylococcal infections. Patients with HIV infection have neutrophils that are defective in their ability to kill *S. aureus* in vitro. Young infants with invasive infection or individuals with *recurrent* pyogenic infection should be evaluated for immune defects, especially those involving neutrophil dysfunction. Poor mucus clearance in children with cystic fibrosis frequently leads to chronic pulmonary staphylococcal colonization and persistent inflammation in these patients.

Infants may acquire type-specific humoral immunity to staphylococci transplacentally. Older children and adults develop antibodies to staphylococci as a result of colonization or minor infections. Antibody

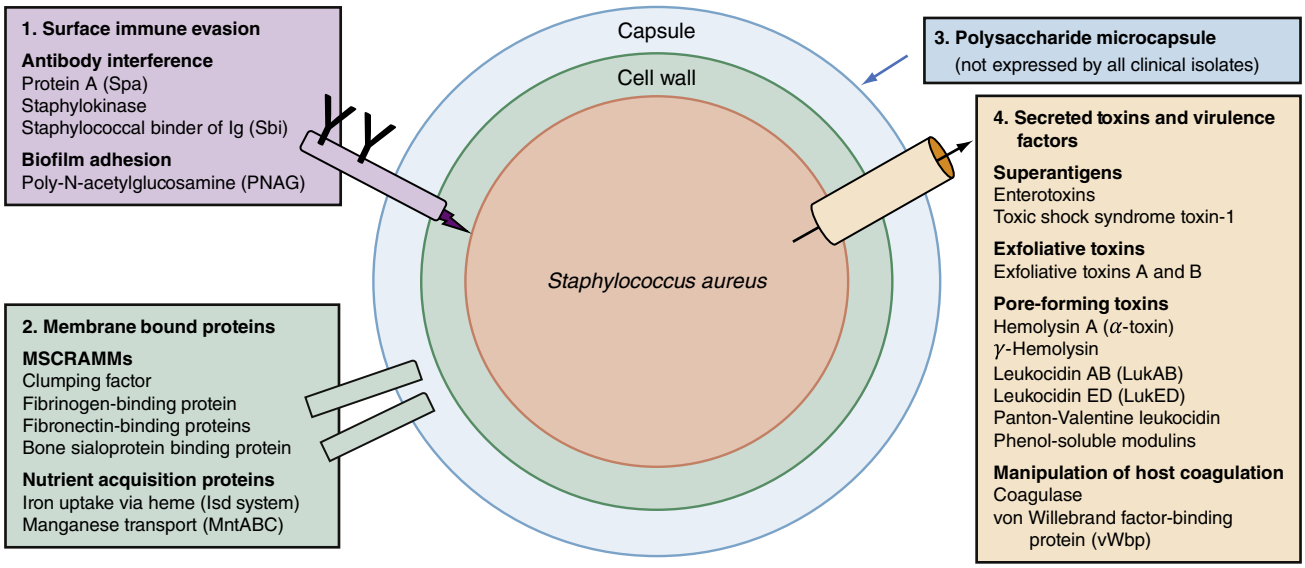

Fig. 227.1 Schematic of virulence factors and relevant surface adhesins of *Staphylococcus aureus*. YY, Immunoglobulin-binding site; MSCRAMMs, microbial surface components that recognize adhesive matrix molecules. *(From Thomsen I, Creech CB. Staphylococcus aureus. In Long SS, Prober CG, Fischer M, Kimberlin DW, eds. Principles and Practice of Pediatric Infectious Diseases, 6th ed. Philadelphia: Elsevier; 2023, Fig. 115.1, p. 711.)*

to the various *S. aureus* toxins appears to protect against those specific toxin-mediated diseases, but humoral immunity does not necessarily protect against focal or disseminated *S. aureus* infection with the same organisms.

CLINICAL MANIFESTATIONS

S. aureus has the potential to invade any tissue. Disease severity is influenced by local suppuration, systemic dissemination with metastatic infection, or systemic effects of toxin production.

Newborn

S. aureus is an important cause of neonatal infections (see Chapter 148).

Skin

S. aureus is an important cause of **pyogenic** skin infections, including impetigo contagiosa, ecthyma, bullous impetigo, folliculitis, furuncles (boils), carbuncles (multiple coalesced boils), and paronychia. **Toxigenic** infection with skin manifestations include staphylococcal scalded skin syndrome and staphylococcal scarlet fever. *S. aureus* is a frequent cause of superinfection of underlying dermatologic conditions, such as eczema, hidradenitis suppurativa, or insect bites. Skin abscesses caused by CA-MRSA commonly affect the lower extremities and buttocks. Up to 70% of individuals with SSTI will experience a recurrent infection. *S. aureus* is also an important cause of traumatic and surgical wound infections and can cause deep soft tissue involvement, including cellulitis and, rarely, necrotizing fasciitis.

Respiratory Tract

Infections of the upper respiratory tract (otitis media, sinusitis) caused by *S. aureus* are rare, in particular considering the frequency with which the anterior nares are colonized. *S. aureus* sinusitis is relatively common in children with cystic fibrosis or defects in leukocyte function and may be the only focus of infection in some children with TSS. Suppurative **parotitis** is a rare infection, but *S. aureus* is a common cause. A membranous **tracheitis** that complicates viral croup may result from infection with *S. aureus,* although other organisms may also be responsible.

Pneumonia caused by *S. aureus* is uncommon but can present with rapidly progressive respiratory failure. Children may present with recent flulike illness (see Chapter 449). Hematogenous pneumonia may be secondary to septic emboli from right-sided endocarditis or septic thrombophlebitis, with or without intravascular devices. Inhalation pneumonia is caused by alteration of mucociliary clearance, leukocyte dysfunction, or bacterial adherence initiated by a viral infection. Common symptoms and signs include high fever, abdominal pain, tachypnea, dyspnea, and localized or diffuse bronchopneumonia or lobar disease. In particular, USA300 strains of *S. aureus* often cause a **necrotizing pneumonitis** that may be associated with early development of empyema, pneumatoceles, pyopneumothorax, and bronchopleural fistulas (Fig. 227.2). Chronic pulmonary infection with *S. aureus* contributes to progressive pulmonary dysfunction in children with cystic fibrosis (see Chapter 454).

Bacteremia and Sepsis

S. aureus bacteremia and sepsis may be primary or secondary because of a localized infection such as an infected central venous catheter or thrombus, bone, or skin and soft tissue. Risk factors for *S. aureus* bacteremia include presence of a central venous catheter, immunodeficiency, malnutrition, recent MRSA STTI, and recent surgery. The onset may be acute and marked by nausea, vomiting, myalgia, fever, and chills.

Prolonged *S. aureus* bacteremia is associated with an increased risk of developing complications such as septic emboli, thrombi, and metastatic foci of infection. Methicillin resistance, musculoskeletal infection, endovascular infection, and delayed intervention for source control are risk factors for prolonged bacteremia. In general, removal of an infected central venous catheter is recommended because of the difficulty clearing *S. aureus* bacteremia in these patients.

A positive blood culture for MRSA or methicillin-sensitive *S. aureus* (MSSA) should always be considered pathogenic, and antistaphylococcus treatment should be initiated with vancomycin or daptomycin with a β-lactam until antimicrobial susceptibility is available. In the absence of an obvious source (isolated bacteremia), endocarditis must be considered. MSSA bacteremia should be treated with a β-lactam such as cefazolin or oxacillin, given poorer outcomes in children treated with vancomycin. Although vancomycin has been traditionally used as first-line treatment of MRSA bacteremia in children, daptomycin and ceftaroline, a β-lactam and fifth-generation cephalosporin, can also be considered. The duration of antibiotic therapy depends on the age and presence of associated infections. In general, 7-14 days of intravenous therapy is appropriate for uncomplicated bacteremia; however, additional studies are needed to determine the optimal duration in children. Repeat blood cultures should be obtained until negative for 2 days to document clearance of bacteremia. Prolonged positive blood cultures while on therapy suggest endocarditis, an infected thrombus, abscess formation, foreign body (central lines, bone prosthesis, or internal fixation of fractures), or other factors leading to poor source control. Whole body MRI or PET-MRI scanning may detect unrecognized metastatic foci. Infectious disease consultation has been shown to improve cure rates and outcomes in children with *S. aureus* bacteremia, including decreased mortality and decreased recurrence of bacteremia.

Muscle
Localized staphylococcal abscesses in muscle, sometimes without septicemia, have been called **pyomyositis**. This disorder is reported most frequently from tropical areas and is termed *tropical pyomyositis,* but also occurs in the United States in otherwise healthy children. Multiple abscesses occur in 30–40% of cases, most commonly affecting the pelvic and lower extremity muscles. History may include prior trauma at the site of the abscess. More commonly, pyomyositis results from seeding secondary to bacteremia, often near the site of osteomyelitis. Surgical drainage and appropriate antibiotic therapy are essential.

Bones and Joints
S. aureus is the most common cause of osteomyelitis and suppurative arthritis in children, most commonly the result of hematogenous seeding and, less often, from a contiguous focus of infection or through inoculation from trauma or a surgical procedure (see Chapters 725 and 726).

Central Nervous System
Meningitis caused by *S. aureus* is uncommon; it is associated with penetrating cranial trauma and neurosurgical procedures (craniotomy, cerebrospinal fluid [CSF] shunt placement) and, less frequently, with endocarditis, parameningeal foci (epidural or brain abscess), prematurity, complicated sinusitis, diabetes mellitus, or malignancy. The CSF profile of *S. aureus* meningitis is indistinguishable from that in other forms of bacterial meningitis (see Chapter 643.1).

Heart
S. aureus is a common cause of acute endocarditis on native valves and results in high rates of morbidity and mortality. Left-sided endocarditis is most common. The clinical presentation can be indolent with symptoms such as malaise, weight loss, or myalgias, and the typical signs of endocarditis are often not present in children (see Chapter 486).

Kidney
S. aureus is a common cause of renal and perinephric abscess, usually of hematogenous origin. Pyelonephritis and cystitis caused by *S. aureus* are unusual (see Chapter 575).

Toxic Shock Syndrome
S. aureus, more commonly MSSA than MRSA, is the principal cause of TSS, which should be suspected in anyone with fever, shock, and/or a diffuse erythroderma (see Chapter 227.2).

Intestinal Tract
Staphylococcal enterocolitis may rarely follow overgrowth of normal bowel flora by *S. aureus,* which can result from broad-spectrum oral antibiotic therapy. Diarrhea is associated with blood and mucus. Peritonitis associated with *S. aureus* in patients receiving long-term ambulatory peritoneal dialysis usually involves the catheter tunnel.

Food poisoning may be caused by ingestion of *preformed* enterotoxins produced by staphylococci in contaminated foods (see Chapter 387). The source of contamination is often colonized or infected food workers. Approximately 2-7 hours after ingestion of the toxin, sudden, severe vomiting begins. Watery diarrhea may develop, but fever is absent or low grade. Symptoms rarely persist >12-24 hours. Rarely, shock and death may occur.

DIAGNOSIS
The diagnosis of *S. aureus* infection depends on isolation of the organism in culture from the site of infection, such as cellulitis aspirates, abscess cavities, blood, bone, or joint aspirates, or other sites of infection. In patients with musculoskeletal infection, ~50% of children will have blood cultures that yield *S. aureus*. Thus surgical debridement or an aspirate or biopsy obtained by interventional radiology can maximize recovery of the organism, which is important for targeted antibiotic selection. Tissue samples or fluid aspirates in a syringe provide the best culture material. Because of the high prevalence of MRSA and the severity of *S. aureus* infections, it is important to obtain cultures before starting antibiotic treatment. The organism can be grown readily in liquid and on solid media. After isolation, identification is made on the basis of Gram stain and coagulase, clumping factor, and catalase activity. Molecular techniques and mass spectrometry are used to supplement traditional identification and antibiotic susceptibility methods. These technologies may allow for rapid species identification from positive blood cultures and simultaneously identify genetic patterns associated with methicillin resistance, such as presence of the *mecA* gene produced by MRSA. Diagnosis of *S. aureus* food poisoning is usually made on the basis of epidemiologic and clinical findings.

Differential Diagnosis
Many of the clinical entities caused by *S. aureus* can also be caused by other bacterial pathogens, and consideration of the differential diagnosis is particularly important when making empirical antibiotic choices before definitive identification of the offending pathogen. Skin lesions caused by *S. aureus* may be indistinguishable from those caused by group A streptococci, although *S. aureus* usually expands slowly and is more likely to be suppurative, whereas group A streptococci are prone to spread more rapidly and can be very aggressive. Fluctuant skin and soft tissue lesions also can be caused by other organisms, including *Mycobacterium tuberculosis,* atypical mycobacteria, *Nocardia*, *Bartonella henselae* (cat-scratch disease), *Francisella tularensis,* and various fungi. *S. aureus* pneumonia is often suspected in very ill-appearing children or after failure to improve with standard treatment that does not cover *Staphylococcus,* or on the basis of chest radiographs that reveal pneumatoceles, pyopneumothorax, or lung abscess (see Fig. 227.2). Other etiologies of cavitary pneumonias include group A streptococci, *Klebsiella pneumoniae,* and *M. tuberculosis*. In bone and joint infections, culture is the only reliable way to differentiate *S. aureus* from other etiologies, including group A streptococci and, in young children, *Kingella kingae*.

TREATMENT
Antibiotic therapy alone is rarely effective in individuals without source control of the focus of infection. Loculated collections of purulent material should be relieved by incision and drainage. Foreign bodies (e.g., orthopedic instrumentation, ventricular shunts, central venous catheters) should be removed, if possible. Therapy always should be initiated with an antibiotic consistent with the local staphylococcal susceptibility patterns, severity, and anatomic site of infection. For most patients with serious *S. aureus* infection, initial intravenous (IV) treatment is usually recommended, and transition to oral therapy can be considered based on clinical response and source of infection.

Treatment of *S. aureus* osteomyelitis (Chapter 725), meningitis (Chapter 643.1), and endocarditis (Chapter 486) is discussed in the respective chapters on these diagnoses.

Initial treatment for serious infections thought to be caused by **methicillin-susceptible *S. aureus* (MSSA)** should include a semisynthetic penicillin (e.g., nafcillin, oxacillin) or a first-generation cephalosporin (e.g., cefazolin). Penicillin and ampicillin are not appropriate, because >90% of all staphylococci isolated, regardless of source, are resistant to these agents. Addition of a β-lactamase inhibitor (clavulanic acid, sulbactam, tazobactam) to a penicillin-based drug also confers antistaphylococcal activity but has no effect on MRSA. The spectrum of these β-lactam/β-lactamase inhibitor agents (which includes gram-negative bacteria and anaerobes) can be an advantage when broad empirical coverage is needed, but narrower coverage should be selected once *S. aureus* is identified. *Antistaphylococcal penicillins and most cephalosporins do not provide activity against MRSA.*

Vancomycin is typically selected for initial treatment for penicillin-allergic individuals and those with suspected serious infections caused by MRSA. Although serum level monitoring has traditionally been used for patients receiving vancomycin, this method is no longer recommended for severe MRSA infections. Instead, calculating the ratio of area under the curve (AUC) over 24 hours to the minimum inhibitory concentration (MIC) as the primary predictor of vancomycin activity is currently recommended. Monitoring for nephrotoxicity is also important while on vancomycin therapy. Vancomycin intermediate *S. aureus* strains (VISAs), defined as having an MIC of vancomycin greater than 2 μg/mL, and, rarely, vancomycin-resistant strains of *S. aureus* (VRSA, MIC of vancomycin >16 μg/mL) have also been reported, mostly in patients being treated with vancomycin. For critically ill patients with

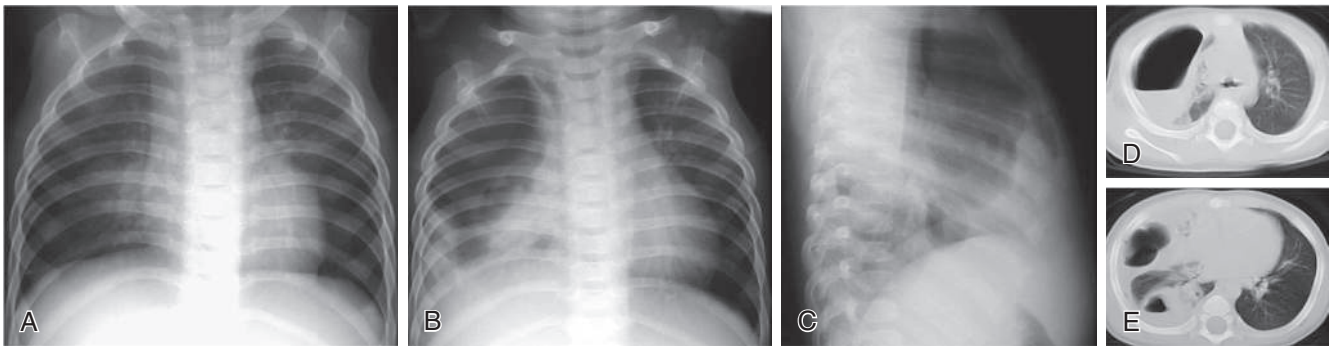

Fig. 227.2 Progressive methicillin-resistant *Staphylococcus aureus* (MRSA) pneumonia with pneumatoceles in a previously healthy 9-mo-old male. Chest radiographic findings spanning 4 days showed a perihilar right lower lobe infiltrate (**A**) progressing to a worsening infiltrate and large hydropneumothorax with mediastinal shift (**B** and **C**) despite appropriate therapy. Axial CT of the chest without contrast (lung windows) showed partial loculation of hydropneumothorax, multilobar consolidation, pneumatoceles, and atelectasis (**D** and **E**). Video-assisted thoracoscopic surgery (VATS) was performed, and a chest tube was placed for 3 days. MRSA was isolated from pleural fluid. After 2 weeks of clindamycin therapy, the chest radiograph had only minor abnormalities. *(Courtesy Dr. Sarah S. Long.)*

suspected *S. aureus* infection, empirical therapy with both vancomycin and a β-lactam (cefazolin or nafcillin) should be considered until culture results are available. Initial treatment with IV **clindamycin** followed by a transition to oral clindamycin can be considered in bone, joint, and soft tissue infection; however, not all strains of MSSA or MRSA are susceptible to clindamycin. Inducible clindamycin resistance in isolates initially reported as susceptible must be ruled out by D-test or molecular methods. Clindamycin is bacteriostatic and should not be used to treat endocarditis, persistent bacteremia, or CNS infections caused by *S. aureus*. Given that the mechanism of action of clindamycin involves inhibition or protein synthesis, many experts use clindamycin as an adjunctive agent to treat *S. aureus* toxin–mediated illnesses (e.g., TSS) to inhibit toxin production.

Although the broad-spectrum carbapenems (meropenem, ertapenem, and imipenem) have activity against MSSA, they have no activity against MRSA. As a result, carbapenems are rarely used for empirical therapy of possible staphylococcal infection and are too broad in most cases for use in identified MSSA infections. **Linezolid**, **daptomycin**, and **ceftaroline** are useful for serious *S. aureus* infections, providing excellent coverage of MRSA and MSSA (Table 227.1). A number of novel antistaphylococcal antibiotics have emerged for use in resistant or refractory MSSA and MRSA infection in adults that may be required for pediatric therapy in select patients under the guidance of a pediatric infectious disease specialist. These include the lipoglycopeptides, including **telavancin**, **oritavancin**, and **dalbavancin**, which are structurally related to vancomycin but have very long half-lives and broad activity against gram-positive organisms. **Rifampin** or **gentamicin** in addition to a β-lactam or vancomycin are recommended for prosthetic-valve endocarditis, although patients need to be monitored closely for adverse side effects; their use as combined therapy for other infections is not recommended.

In many infections, after an initial period of parenteral therapy, patients may be transitioned to oral antimicrobials to complete the course of treatment after determination of antimicrobial susceptibilities. Oral antimicrobials can be used as initial treatment in less severe infections (e.g., skin abscess). **Cephalexin** (25-100 mg/kg/24 hr divided 3-4 times daily PO) and cefadroxil (30 mg/kg/24 hr divided 2 times daily PO for noninvasive infections, 50-60 mg/kg/24 hr divided 2 times daily PO for osteoarticular infections) are absorbed well orally (PO) and are effective against MSSA. (Variable cefadroxil dosing regimens have been described, ranging from 30-150 mg/kg/day divided 2-4 times daily PO.) **Amoxicillin-clavulanate** (40-80 mg amoxicillin/kg/24 hr divided 3 times daily PO) is also effective when a broader spectrum of coverage is required. Clindamycin (30-40 mg/kg/24 hr divided 3-4 times daily PO) is highly absorbed from the intestinal tract and is frequently used for empirical coverage when both MRSA and MSSA are possible and for susceptible MRSA infections or for MSSA in penicillin/cephalosporin-allergic patients. Compliance with oral clindamycin may be limited in small children because of poor palatability of liquid formulations. **Trimethoprim-sulfamethoxazole** (TMP-SMX) may be an effective oral antibiotic for many strains of both MSSA and MRSA for SSTI. Oral linezolid is an option for severe MRSA infections that have improved but require ongoing therapy when more common options are not tolerated or are ineffective because of resistance patterns. The duration of linezolid therapy is typically limited to 2-3 weeks given toxicities such as myelosuppression and peripheral and optic neuropathy with prolonged courses. Despite in vitro susceptibility of *S. aureus* to ciprofloxacin and other quinolone antibiotics, these agents should *not* routinely be used in serious staphylococcal infections, because their use is associated with rapid development of resistance.

The **duration** of antibiotic therapy depends on the anatomic site and severity of infection and response, as determined by the clinical response and, in some cases, radiologic and laboratory findings.

PROGNOSIS

Untreated *S. aureus* septicemia is associated with a high fatality rate, which has been reduced significantly by appropriate antibiotic treatment. *S. aureus* pneumonia can be fatal at any age but is more likely to be associated with high morbidity and mortality in young infants or in patients whose therapy has been delayed. Prognosis also may be influenced by numerous host factors, including nutrition, immunologic competence, and the presence or absence of other debilitating diseases.

PREVENTION

S. aureus is transmitted primarily by direct contact. Strict attention to **hand hygiene** is the most effective measure for preventing the spread of staphylococci between individuals (see Chapter 216). Hospital surveillance programs to identify nosocomial acquisition of *S. aureus* colonization and/or infection are common, particularly in neonatal intensive care units. Clusters of nosocomial cases may be defined by molecular typing, and if associated with a singular molecular strain, investigation to identify any potential point sources (e.g., a colonized healthcare worker or contaminated environmental reservoir) should occur.

As *S. aureus* colonization often predisposes to infection, a number of protocols are aimed at **decolonization**, which is the application of topical antimicrobials to the skin and/or nares to eradicate *S. aureus* colonization. In healthcare settings, decolonization is often performed among vulnerable populations to prevent nosocomial infections. In community settings, decolonization is often recommended for patients with recurrent *S. aureus* skin infections. Decolonization regimens often involve combinations of decontaminating baths (hypochlorite, 1 tsp common bleach solution per gallon of water, or chlorhexidine 4% soap), nasal mupirocin twice daily for at least 5 days, and enhanced hygiene measures, including frequent laundering of household linens and targeted decontamination of frequently touched household surfaces. Although success is not universal, recurrent infections may be reduced, particularly when eradication is done in both the patient and household contacts, especially those with history of SSTI. Most cases of mild, recurrent disease will resolve in time without these measures.

Because of the potential severity of infections with *S. aureus* and concerns about emerging resistance, much work has focused on

Table 227.1 Parenteral Antimicrobial Agent(s) for Treatment of Serious *Staphylococcus aureus* Infections

SUSCEPTIBILITY	ANTIMICROBIALS	COMMENTS
I. INITIAL EMPIRICAL THERAPY (ORGANISM OF UNKNOWN SUSCEPTIBILITY)		
Drugs of choice	Vancomycin + nafcillin/oxacillin or cefazolin	For **life-threatening infections** (e.g., septicemia, endocarditis, CNS infection); linezolid, daptomycin, or ceftaroline could be substituted depending on the clinical scenario and site of infection
	Vancomycin	For **non–life-threatening infection** without signs of severe sepsis (e.g., skin infection, cellulitis, osteomyelitis, pyarthrosis) when prevalence of MRSA infection in the community is >20% of all *S. aureus* infections
	Cefazolin or nafcillin/oxacillin	For **non–life-threatening infection** when low likelihood of MRSA is suspected
	Clindamycin	For non–life-threatening infection without signs of severe sepsis when rates of MRSA infection in the community is substantial (>20% of all *S. aureus* infections) and prevalence of clindamycin resistance is low
II. METHICILLIN-SUSCEPTIBLE, PENICILLIN-RESISTANT *S. AUREUS*		
Drugs of choice	Cefazolin or oxacillin/nafcillin	May change to oral therapy after infection is controlled in low-risk situations
Alternatives (depending on susceptibility results)	Clindamycin	Only for patients with a serious penicillin allergy and clindamycin-susceptible strain
	Vancomycin	Only for penicillin- and cephalosporin-allergic patients
	Ampicillin + sulbactam	When broader coverage, including gram-negative organisms and/or anaerobes is required
III. METHICILLIN-RESISTANT *S. AUREUS* (MRSA)		
Drugs of choice	Vancomycin (some combine with a β-lactam) (some may begin with ceftaroline)	Linezolid, daptomycin, or ceftaroline* could be substituted or added depending on the clinical scenario, site of infection, or persistent bacteremia
Alternatives: susceptibility testing results available before alternative drugs are used	Clindamycin (if susceptible)	
	Trimethoprim-sulfamethoxazole	
	Doxycycline	

*Linezolid, daptomycin, and ceftaroline are agents with activity and efficacy against multidrug-resistant, gram-positive organisms, including *S. aureus*. Because experience with these agents in children is limited, consultation with an infectious diseases specialist should be considered before use. Daptomycin is ineffective for treatment of pneumonia, as it is inactivated by pulmonary surfactant.

developing a staphylococcal vaccine for use in high-risk patients, but to date, clinical trials have been disappointing. Because *S. aureus* is frequently a co-infection in severe influenza infections, an indirect preventive impact against staphylococcal pneumonia and tracheitis may be achieved through annual influenza vaccination.

To prevent *S. aureus* food poisoning, cooked foods should be eaten immediately or refrigerated within 2 hours of preparation to prevent multiplication of *S. aureus* that may have contaminated the food (see Chapter 387). Treatment is supportive.

227.2 Toxic Shock Syndrome

Carol M. Kao, Patrick J. Reich, and Stephanie A. Fritz

Toxic shock syndrome (TSS) is an acute and potentially severe illness characterized by fever, hypotension, diffuse erythroderma with subsequent desquamation on the hands and feet, and multisystem involvement.

ETIOLOGY

TSS is caused by TSST-1–producing and some enterotoxin-producing strains of *S. aureus,* which may colonize the skin or mucous membranes or cause focal sites of staphylococcal infection.

EPIDEMIOLOGY

TSS continues to occur in the United States in men, women, and children, with the highest rates in menstruating women 15-25 years of age.

Nonmenstrual TSS is associated with *S. aureus*–infected nasal packing and wounds, sinusitis, tracheitis, pneumonia, empyema, abscesses, burns, osteomyelitis, and primary bacteremia. The majority of strains of *S. aureus* associated with TSS are methicillin susceptible. Most strains of USA300, the predominant clone of community-associated MRSA in the United States, do not possess the genes expressing the most common TSS superantigens; however, MRSA-associated TSS can occur.

PATHOGENESIS

The primary toxin associated with TSS is TSST-1, although a significant proportion of nonmenstrual TSS is caused by one or more staphylococcal enterotoxins. These toxins act as **superantigens**, which trigger cytokine release, causing massive loss of fluid from the intravascular space and end-organ cellular injury. Epidemiologic and in vitro studies suggest that these toxins are selectively produced in a clinical environment consisting of a neutral pH, a high P_{CO_2}, and an aerobic P_{O_2}, which are the conditions found in abscesses and the vagina with tampon use during menstruation. The risk factors for symptomatic disease include a nonimmune host who is colonized with a toxin-producing organism that is exposed to focal growth conditions (menstruation plus tampon use or abscess) that in turn induce toxin production. Some hosts may have a varied cytokine response to TSST-1 exposure, helping to explain a spectrum of severity of TSS that may include staphylococcal scarlet fever. The overall mortality rate of treated patients is 3–5% when treated early.

Approximately 90% of adults have antibody to TSST-1 without a history of clinical TSS, suggesting that most individuals are colonized at some point with a toxin-producing organism at a site (e.g., anterior nares) where low-grade or inactive toxin exposure results in an immune response without disease.

CLINICAL MANIFESTATIONS

The diagnosis of TSS is based on clinical manifestations (Table 227.2). Milder cases and those with incomplete clinical characteristics may be common, particularly if the nidus of infection is addressed quickly (e.g., removal of a tampon or nasal packing). The onset of classic TSS is abrupt, with high fever, vomiting, and diarrhea, and is accompanied by sore throat, headache, and myalgias. A diffuse erythematous rash (sunburn-like or scarlatiniform) appears within 24 hours and may be associated with hyperemia of pharyngeal, conjunctival, and vaginal mucous membranes. A strawberry tongue is common. Symptoms may include alterations in the level of consciousness, oliguria, and hypotension, which in severe cases may progress to shock and disseminated intravascular coagulation. Complications, including acute respiratory distress syndrome (ARDS), myocardial dysfunction, and renal failure, are commensurate with the degree of shock. Recovery occurs within 7-10 days and is associated with desquamation, particularly of the palms and soles; hair and nail loss have also been observed after 1-2 months. Immunity to the toxins is slow to develop, so recurrences can occur, especially if there is inadequate antibiotic treatment and/or recurrent tampon use. Many cases of apparent scarlet fever without shock may be caused by TSST-1–producing *S. aureus* strains.

DIAGNOSIS

There is no specific laboratory test, and diagnosis depends on meeting certain clinical and laboratory criteria in the absence of an alternative diagnosis (see Fig. 227.2). Appropriate tests reveal involvement of multiple organ systems, including the hepatic, renal, muscular, gastrointestinal, cardiopulmonary, and central nervous systems. Bacterial cultures of the associated focus (vagina, abscess) before administration of antibiotics usually yield *S. aureus,* although this is not a required element of the definition.

Table 227.2 Toxic Shock Syndrome (Other Than Streptococcal) (TSS) 2011 Case Definition

CLINICAL CRITERIA

1. Fever: temperature ≥102.0°F (≥38.9°C)
2. Rash: diffuse macular erythroderma
3. Desquamation: 1-2 weeks after onset of rash
4. Hypotension: systolic blood pressure ≤90 mm Hg for adults or less than fifth percentile by age for children age less than 16 years
5. Multisystem involvement (three or more of the following organ systems):
   - Gastrointestinal: vomiting or diarrhea at onset of illness
   - Muscular: severe myalgia or creatine phosphokinase level at least twice the upper limit of normal
   - Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia
   - Renal: blood urea nitrogen or creatinine at least twice the upper limit of normal for laboratory or urinary sediment with pyuria (≥5 leukocytes per high-power field) in the absence of urinary tract infection
   - Hepatic: total bilirubin, alanine aminotransferase enzyme, or aspartate aminotransferase enzyme levels at least twice the upper limit of normal for laboratory
   - Hematologic: platelets less than 100,000/mm^3
   - Central nervous system: disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent

LABORATORY CRITERIA FOR DIAGNOSIS

Negative results on the following tests, if obtained:

- Blood or cerebrospinal fluid cultures (blood culture may be positive for *Staphylococcus aureus*)
- Negative serologies for Rocky Mountain spotted fever, leptospirosis, or measles

CASE CLASSIFICATION

Probable

A case that meets the laboratory criteria and in which four of the five clinical criteria described above are present

Confirmed

A case that meets the laboratory criteria and in which all five of the clinical criteria described above are present, including desquamation, unless the patient dies before desquamation occurs

From Centers for Disease Control and Prevention: https://ndc.services.cdc.gov/case-definitions/toxic-shock-syndrome-2011/

Differential Diagnosis

Group A streptococci can cause a similar TSS-like illness, termed **streptococcal TSS** (see Chapter 229), which is often associated with severe streptococcal sepsis or a focal streptococcal infection such as cellulitis, necrotizing fasciitis, or pneumonia.

Kawasaki disease closely resembles TSS clinically but is usually not as severe or rapidly progressive. Both conditions are associated with fever unresponsive to antibiotics, hyperemia of mucous membranes, and an erythematous rash with subsequent desquamation. However, many of the clinical features of TSS are rare in Kawasaki disease, including diffuse myalgia, vomiting, abdominal pain, diarrhea, azotemia, hypotension, ARDS, and shock (see Chapter 208). Kawasaki disease typically occurs in children <5 years old. Measles, scarlet fever, Rocky Mountain spotted fever, leptospirosis, toxic epidermal necrolysis, and bacterial sepsis must also be considered in the differential diagnosis.

TREATMENT

Identification and drainage/removal of any focal source of infection (e.g., abscess, tampon, nasal packing), when present, is essential. Recommended antibiotic therapy for TSS should include the combination of a β-lactamase–resistant antistaphylococcal antibiotic (nafcillin, oxacillin, or cefazolin) *plus* clindamycin to reduce toxin production. Although TSS is most often caused by MSSA, clinicians should consider use of vancomycin in addition to the β-lactam in areas where MRSA rates are very high, when hospital-acquired MRSA is suspected, and when the clinical picture overlaps with staphylococcal sepsis.

TSS often requires intensive supportive care, including aggressive fluid replacement to prevent or treat hypotension, renal failure, and cardiovascular collapse. Inotropic agents may be needed to treat shock; intravenous immunoglobulin may be helpful in severe cases.

PREVENTION

The risk for acquiring menstrual TSS is low (1-2 cases/100,000 menstruating women). Changing tampons at least every 8 hours is recommended. If a fever, rash, or dizziness develops during menstruation, any tampon should be removed immediately and medical attention sought. Avoidance of tampon use with subsequent menstrual cycles may also reduce the risk for recurrent menstrual TSS.

227.3 Coagulase-Negative Staphylococci

Carol M. Kao, Patrick J. Reich, and Stephanie A. Fritz

At present, there are approximately 50 identified species of coagulase-negative staphylococci **(CoNS)** affecting or colonizing humans. *Staphylococcus epidermidis* and, less often, *Staphylococcus hominis, S. haemolyticus,* and others are widely distributed on the skin and are significant causes of nosocomial infection, particularly in the bloodstream of neonatal and immunocompromised hosts, in surgical patients, and in those with indwelling catheters and other medical devices. *Staphylococcus saprophyticus* is a common cause of urinary tract infection (UTI). *Staphylococcus lugdunensis* and *Staphylococcus schleiferi* can cause severe infection similar to *S. aureus* and have been increasingly recognized as important pathogens since improved species identification with matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry in clinical microbiology laboratories.

EPIDEMIOLOGY

In the United States, CoNS may be the most common cause of hospital-acquired infection, particularly in neonatal intensive care units (NICUs). In many instances, growth of CoNS from clinical specimens represents contamination from skin rather than a cause of true disease, posing significant challenges for clinicians and infection prevention specialists. CoNS are normal inhabitants of the human skin, throat,

mouth, vagina, and urethra. *S. epidermidis* is the most common and persistent species, representing 65–90% of staphylococci present on the skin and mucous membranes. Colonization, sometimes with strains acquired during hospitalization, precedes infection. Alternatively, direct inoculation during surgery may initiate infection of CSF shunts, prosthetic valves, or indwelling vascular lines.

PATHOGENESIS

CoNS produce an exopolysaccharide protective biofilm, particularly on indwelling medical devices, that surrounds the organism and may enhance adhesion to foreign surfaces, resist phagocytosis, and impair penetration of antibiotics. However, the low virulence of CoNS usually requires the presence of another factor for development of clinical disease. Of these, the most significant is the presence of an indwelling catheter or other medical device, including central venous catheters (CVCs), hemodialysis shunts and grafts, CSF shunts (meningitis), peritoneal dialysis catheters (peritonitis), pacemaker wires and electrodes (local infection), prosthetic cardiac valves (endocarditis), and prosthetic joints (septic arthritis). Other risk factors for the development of infection include immature or compromised immunity and significant exposure to antibiotics.

CLINICAL MANIFESTATIONS

Bacteremia

CoNS, specifically *S. epidermidis,* are the most common cause of nosocomial bacteremia, usually in association with central vascular catheters. In neonates, CoNS bacteremia, with or without a CVC, can manifest as localized disease in the CNS, lungs, skin, heart, bones, and joints, or even as sepsis or necrotizing enterocolitis. Persistent positive blood cultures despite adequate antimicrobial therapy is common, particularly when catheters are not removed. In older children with intact immune systems, CoNS bacteremia is indolent and is not usually associated with overwhelming septic shock.

Endocarditis

Infection of native heart valves or the right atrial wall may occur secondary to an infected thrombosis at the end of a central line. *S. epidermidis* and other CoNS may rarely produce native valve subacute endocarditis in previously healthy hosts without a CVC. CoNS is a common cause of prosthetic valve endocarditis, presumably a result of inoculation at surgery. Infection of the valve sewing ring, with abscess formation and dissection, produces valve dysfunction or obstruction, dehiscence, or arrhythmias (see Chapter 486). *S. lugdunensis* has been increasingly associated with severe endocardial infection in adults but remains an uncommon cause in children.

Central Venous Catheter Infection

CVCs become infected through the exit site and subcutaneous tunnel, which provide a direct path to the bloodstream. *S. epidermidis* is the most frequent pathogen, in part because of its high rate of cutaneous colonization. Line sepsis is usually manifested as fever and leukocytosis; tenderness and erythema may be present at the exit site or along the subcutaneous tunnel. Catheter thrombosis may complicate line sepsis. Disease severity with CoNS is often less severe than other etiologies of line infection.

Cerebrospinal Fluid Shunts

CoNS, introduced at surgery, is the most common pathogen associated with CSF shunt meningitis. Most infections (70–80%) occur within 2 months of the operation and manifest as signs of meningeal irritation, fever, increased intracranial pressure (headache, vomiting), or peritonitis from the intraabdominal position of the distal end of the shunt tubing.

Urinary Tract Infection

S. saprophyticus is a common cause of primary UTIs in sexually active females. Manifestations are similar to those characteristics of UTI caused by *Escherichia coli* (see Chapter 575). CoNS also cause asymptomatic UTI in hospitalized patients with urinary catheters and after urinary tract surgery or transplantation.

DIAGNOSIS

Because *S. epidermidis* is a common skin inhabitant and may contaminate poorly collected blood cultures, differentiating bacteremia from contamination is often difficult. True bacteremia should be suspected if blood cultures grow rapidly (within 15 hours of incubation in a continuously monitored blood culture system), more than one blood culture is positive with the same CoNS strain, cultures from both the blood and another sterile site are positive, and clinical and laboratory signs and symptoms compatible with CoNS sepsis are present and subsequently resolve with appropriate therapy. Growth of CoNS from a blood culture in a neonate or patient with an intravascular catheter should be considered evidence of true bacteremia until careful review of the foregoing criteria and evaluation of the patient. Before initiating presumptive antimicrobial therapy in such patients, it is always prudent to draw two separate blood cultures to facilitate subsequent interpretation if CoNS is grown. Molecular and mass spectrometry assays similar to those used for identification of *S. aureus* allow for rapid identification of CoNS in positive blood cultures.

TREATMENT

Because most CoNS strains are resistant to methicillin (with the exception of *S. lugdunensis* and *S. saprophyticus,* which are generally methicillin susceptible), **vancomycin** is the initial drug of choice. Resistance to vancomycin has rarely been reported with *S. haemolyticus*. For patients with indwelling medical devices, the addition of rifampin to vancomycin may increase antimicrobial efficacy because of good penetration of this antibiotic into biofilms. Other antibiotics with good in vitro activity against CoNS may be considered in certain circumstances. These include linezolid, ceftaroline, and daptomycin. Removal of an infected catheter is ideal. However, this is not always possible because of the therapeutic requirements of the underlying disease (e.g., nutrition for short bowel syndrome, chemotherapy for malignancy). A trial of IV vancomycin (potentially with the addition of rifampin) with the retained catheter can be attempted to preserve the use of the central line, as long as systemic manifestations of infection are not severe. Antibiotic therapy given through an infected CVC and the use of antibiotic locks in conjunction with systemic therapy may increase the likelihood of curing CoNS line sepsis without line removal. Prosthetic heart valves and CSF shunts usually need to be removed to adequately treat the infection.

Peritonitis caused by *S. epidermidis* in patients on continuous ambulatory peritoneal dialysis is an infection that may be treated with IV or intraperitoneal antibiotics without removing the dialysis catheter. If the organism is resistant to methicillin, vancomycin adjusted for renal function is appropriate therapy. Unlike most CoNS, *S. saprophyticus* is usually methicillin susceptible, and UTIs can typically be treated with a first-generation cephalosporin (cephalexin), amoxicillin–clavulanic acid, or TMP-SMX.

PROGNOSIS

Most episodes of CoNS bacteremia respond successfully to antibiotics and removal of any foreign material that is present. Poor prognosis is associated with malignancy, neutropenia, and infected prosthetic or native heart valves. CoNS infections increase the morbidity, duration of hospitalization, and mortality among patients with underlying complicated illnesses.

PREVENTION

Iatrogenic morbidity and resource use caused by contaminated blood cultures can be reduced by following recommended strategies to prevent CVC-associated bloodstream infections during catheter insertion and maintenance. These strategies include basic techniques such as central line care "bundles," which incorporate good hand hygiene, decontamination of hubs and ports before access, minimizing frequency of access, and frequent replacement of external connections and infusion materials. Antibiotic-impregnated catheters can be considered when other preventive measures have failed.

Chapter 228

Streptococcus pneumoniae (Pneumococcus)

Kacy A. Ramirez and Timothy R. Peters

Streptococcus pneumoniae (pneumococcus) is an important pathogen that results in more than 1 million children deaths each year. Childhood invasive pneumococcal disease is prevalent and typically severe, causes numerous clinical syndromes, and is a major cause of life-threatening pneumonia, bacteremia, endocarditis, and meningitis; it may also cause sinusitis, otitis media, and bone and joint infections. Antimicrobial resistance in pneumococcus is a major public health problem, with 15–30% of isolates worldwide classified as **multidrug resistant** (**MDR**; resistant to at least three classes of antibiotics). Pneumococcal polysaccharide-protein conjugate vaccines (**PCVs**) developed for infants have been highly successful in the control of disease caused by virulent vaccine-specific serotypes. Epidemiologic surveillance reveals a dynamic pneumococcal ecology with emergence of highly virulent MDR serotypes. Ongoing vaccine development and distribution efforts remain the best approach to control this threat to childhood health.

ETIOLOGY

S. pneumoniae is a gram-positive, lancet-shaped, polysaccharide encapsulated diplococcus, occurring occasionally as individual cocci or in chains; >90 serotypes have been identified by type-specific capsular polysaccharides. Antisera to some pneumococcal polysaccharides cross-react with other pneumococcal types, defining serogroups (e.g., 6A and 6B). Encapsulated strains cause most serious disease in humans. Capsular polysaccharides impede phagocytosis. Virulence is related in part to capsule size, but pneumococcal types with capsules of the same size can vary widely in virulence.

On solid media, *S. pneumoniae* forms unpigmented, umbilicated colonies surrounded by a zone of incomplete (α) hemolysis. *S. pneumoniae* is bile soluble (i.e., 10% deoxycholate) and optochin sensitive. *S. pneumoniae* is closely related to the viridans groups of *Streptococcus mitis,* which typically overlap phenotypically with pneumococci. The conventional laboratory definition of pneumococci continues to rely on bile and optochin sensitivity, although considerable confusion occurs in distinguishing pneumococci and other α-hemolytic streptococci. Pneumococcal capsules can be microscopically visualized and typed by exposing organisms to type-specific antisera that combine with their unique capsular polysaccharide, rendering the capsule refractile (Quellung reaction). Specific antibodies to capsular polysaccharides confer protection on the host, promoting opsonization and phagocytosis. Additionally, $CD4^+$ T cells have a direct role in antibody-independent immunity to pneumococcal nasopharyngeal colonization. Conjugated PCVs promote T-cell immunity and protect against pneumococcal colonization, in contrast to the pneumococcal polysaccharide vaccine (PPSV23) that is used in adults and certain high-risk pediatric populations and that does not affect nasopharyngeal colonization.

EPIDEMIOLOGY

Most healthy individuals carry (colonized) various *S. pneumoniae* serotypes in their upper respiratory tract; >90% of children between 6 months and 5 years of age harbor *S. pneumoniae* in the nasopharynx at some time. A single serotype usually is carried by a given individual for an extended period (45 days to 6 months). Carriage does not consistently induce local or systemic immunity sufficient to prevent later reacquisition of the same serotype. Rates of pneumococcal carriage peak during the first and second year of life and decline gradually thereafter. Carriage rates are highest in institutional settings and during the winter and are lowest in summer. Nasopharyngeal carriage of pneumococci is common among young children attending out-of-home care, with rates of 21–59% in point prevalence studies.

Before the introduction of heptavalent pneumococcal conjugate vaccine **(PCV7)** in 2000, serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F caused most invasive childhood pneumococcal infections in the United States. The introduction of PCVs resulted in a marked decrease in **invasive pneumococcal infections (IPIs)** in children. By 2005, however, IPIs began to increase slightly because of an increase in non-PCV7 serotypes, particularly serotype 19A. **Serotype replacement** can result from expansion of existing nonvaccine serotypes and from vaccine-type pneumococci acquiring the polysaccharide capsule of a nonvaccine serotype **(serotype switching)**. Since the introduction of PCV13 in 2010 in the United States, there has been a decline in IPIs caused by new vaccine serotypes, including 19A. Nonetheless, 19A remains an important cause of meningitis. Indirect protection of unvaccinated persons has occurred since PCV introduction, and this *herd protection* is likely a result of decreases in nasopharyngeal carriage of virulent pneumococcal vaccine serotypes.

S. pneumoniae is the most frequent cause of bacteremia, bacterial pneumonia, and bacterial meningitis and among the most common causes of otitis media and sinusitis in children. The decreased ability in children <2 years old to produce antibody against the T-cell–independent polysaccharide antigens and the high prevalence of colonization may explain an increased susceptibility to pneumococcal infection and the decreased effectiveness of polysaccharide vaccines. Children at increased risk of pneumococcal infections include those with sickle cell disease, asplenia, deficiencies in humoral (B-cell) immunity, deficiencies in complement-mediated immunity, toll like receptor deficiencies, HIV infection, certain malignancies (e.g., leukemia, lymphoma), chronic heart, lung, or renal disease (particularly nephrotic syndrome), cerebrospinal fluid (CSF) leak, and cochlear implants. Table 228.1 lists other high-risk groups. Some American Indian, Alaska Native, and African American children may also be at increased risk. Children <5 years old in out-of-home daycare are at increased risk (approximately twofold higher) of experiencing IPIs than other children. Males are more frequently affected than females. Because immunocompetent vaccinated children have had fewer episodes of IPI, the proportion of infected children with immunologic risk factors has increased (estimated at 20%).

Pneumococcal disease usually occurs sporadically but can be spread from person to person by respiratory droplet transmission. *S. pneumoniae* is an important cause of secondary bacterial pneumonia in patients with influenza. During influenza epidemics and pandemics, most deaths result from bacterial pneumonia, and pneumococcus is the predominant bacterial pathogen isolated in this setting. Pneumococcal co-pathogenicity may be important in disease caused by other respiratory viruses as well.

PATHOGENESIS

Invasion of the host is affected by a number of factors. Nonspecific defense mechanisms, including the presence of other bacteria in the nasopharynx, may limit multiplication of pneumococci. Aspiration of secretions containing pneumococci is hindered by the epiglottic reflex and by respiratory epithelial cell cilia, which move infected mucus toward the pharynx. Similarly, normal ciliary flow of fluid from the middle ear through the eustachian tube and sinuses to the nasopharynx usually prevents infection with nasopharyngeal flora, including pneumococci. Interference with these normal clearance mechanisms by allergy, viral infection, or irritants (e.g., smoke) may allow colonization and subsequent infection with these organisms in otherwise normally sterile sites.

Virulent pneumococci are intrinsically resistant to phagocytosis by alveolar macrophages. Pneumococcal disease frequently is facilitated by viral respiratory tract infection, which may produce mucosal injury, diminish epithelial cell ciliary activity, and depress the function of

Table 228.1 Children at Increased Risk of Invasive Pneumococcal Infection

RISK GROUP	CONDITION
Immunocompetent children	Chronic heart disease* Chronic lung disease† Chronic kidney disease (excluding dialysis and nephrotic syndrome) Chronic liver disease Diabetes mellitus Cerebrospinal fluid leaks Cochlear implant
Children with immunocompromising conditions	HIV infection Maintenance dialysis or nephrotic syndrome Congenital or acquired asplenia or splenic dysfunction Congenital or acquired immunodeficiencies Sickle cell disease and other hemoglobinopathies Congenital immunodeficiency‡ Diseases and conditions treated with immunosuppressive drugs or radiation therapy, including malignant neoplasm, leukemia, lymphoma, and Hodgkin disease, or solid organ transplantation

*Particularly cyanotic congenital heart disease and cardiac failure.
†Including moderate persistent or severe persistent asthma.
‡Includes humoral or T lymphocyte deficiency; complement deficiencies, particularly C1, C2, C3 and C4 deficiency; and phagocytic disorders (excluding chronic granulomatous disease).
Adapted from Kobayashi M, Farrar JI, Gierke R, et al. Use of 15-valent pneumococcal conjugate vaccine among U.S. children: updated recommendations of the Advisory Committee on Immunization Practices -- United States, 2022. *MMWR Morb Mortal Wkly Rep*. 2022;71(4):1174-1181; and Centers for Disease Control and Prevention. ACIP updates: Recommendations for use of 20-valent pneumococcal conjugate vaccine in children—United States, 2023. *MMWR Morb Mortal Wkly Rep*. 2023;72(39):1072.

alveolar macrophages and neutrophils. Phagocytosis may be impeded by respiratory secretions and alveolar exudate. In the lungs and other tissues, the spread of infection is facilitated by the antiphagocytic properties of the pneumococcal capsule. Surface fluids of the respiratory tract contain only small amounts of immunoglobulin G (IgG) and are deficient in complement. During inflammation, there is limited influx of IgG, complement, and neutrophils. Phagocytosis of bacteria by neutrophils may occur, but normal human serum may not opsonize pneumococci and facilitate phagocytosis by alveolar macrophages. In tissues, pneumococci multiply and spread through the lymphatics or bloodstream or, less often, by direct extension from a local site of infection (e.g., sinuses). In bacteremia the severity of disease is related to the number of organisms in the bloodstream and to the integrity of specific host defenses. A poor prognosis correlates with very large numbers of pneumococci and high concentrations of capsular polysaccharide in the blood and CSF.

Invasive pneumococcal disease is 30- to 100-fold more prevalent in children with sickle cell disease and other hemoglobinopathies and in children with congenital or surgical asplenia than in the general population. This risk is greatest in infants <2 years old, the age when antibody production to most serotypes is poor. The increased frequency of pneumococcal disease in asplenic persons is related to both deficient opsonization of pneumococci and absence of clearance by the spleen of circulating bacteria. Children with sickle cell disease also have deficits in the antibody-independent properdin (alternative) pathway of complement activation in addition to functional asplenia. Both complement pathways contribute to antibody-independent and antibody-dependent **opsonophagocytosis** of pneumococci. With advancing age (e.g., >5 years), children with sickle cell disease produce anticapsular antibody, augmenting antibody-dependent opsonophagocytosis and greatly reducing, but not eliminating, the risk of severe pneumococcal disease. Deficiency of many of the complement components (e.g., C2 and C3) is associated with recurrent pyogenic infection, including *S. pneumoniae* infection. The efficacy of phagocytosis also is diminished in patients with B- and T-cell immunodeficiency syndromes (e.g., agammaglobulinemia, severe combined immunodeficiency) or loss of immunoglobulin (e.g., nephrotic syndrome) and is largely caused by a deficiency of opsonic anticapsular antibody. These observations suggest that opsonization of pneumococci depends on the alternative complement pathway in antibody-deficient persons and that recovery from pneumococcal disease depends on the development of anticapsular antibodies that act as opsonins, enhancing phagocytosis and killing of pneumococci. Children with HIV infection also have high rates of IPI similar to or greater than rates in children with sickle cell disease, although rates of invasive pneumococcal disease decreased after the introduction of highly active antiretroviral therapy (HAART).

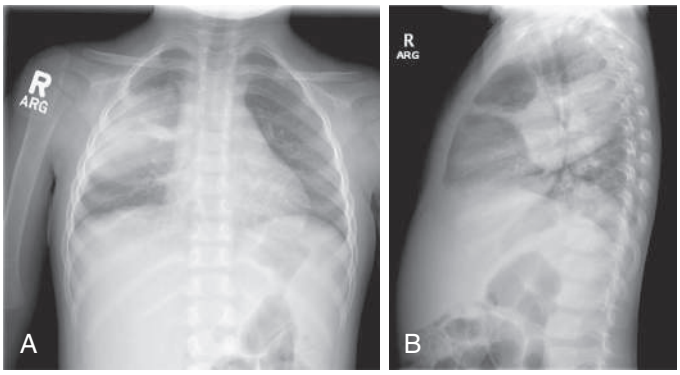

Fig. 228.1 Bacterial "round" pneumonia caused by *Streptococcus pneumoniae* in 2-yr-old child with a 2-day history of cough, high fever, leukocytosis, and back pain.

CLINICAL MANIFESTATIONS

The signs and symptoms of pneumococcal infection are related to the anatomic site of disease. Common clinical syndromes include otitis media (see Chapter 680), sinusitis (see Chapter 429), pneumonia (Fig. 228.1) (see Chapter 449), and sepsis (see Chapter 85). Before routine use of PCVs, pneumococci caused >80% of bacteremia episodes in infants 3-36 months old with fever without an identifiable source (i.e., occult bacteremia). Bacteremia may be followed by meningitis (see Chapter 643), osteomyelitis (see Chapter 725), suppurative (septic) arthritis (see Chapter 726), endocarditis (see Chapter 486), and, rarely, brain abscess (see Chapter 644). Primary peritonitis (see Chapter 419.1) may occur in children with peritoneal effusions caused by nephrotic syndrome and other ascites-producing conditions. Local complications of infection may occur, causing empyema, pericarditis, mastoiditis, epidural abscess, periorbital cellulitis, or meningitis. Hemolytic-uremic syndrome (see Chapter 533.4) and disseminated intravascular coagulation also occur as rare complications of pneumococcal infections. Epidemic conjunctivitis caused by nonencapsulated or encapsulated pneumococci occurs as well.

DIAGNOSIS

The diagnosis of pneumococcal infection is established by recovery of *S. pneumoniae* from the site of infection or the blood/sterile body fluid. Although pneumococci may be found in the nose or throat of patients with otitis media, pneumonia, septicemia, or meningitis, cultures of these locations are generally not helpful for diagnosis, because they are not indicative of causation. Blood cultures should be obtained in children with pneumonia, meningitis, endocarditis, arthritis, osteomyelitis, peritonitis, pericarditis, or gangrenous skin lesions. Because of the implementation of universal vaccination with PCVs, there has been a substantial decrease in the incidence of occult bacteremia, but blood

cultures should still be considered in febrile patients with clinical toxicity or significant leukocytosis. Leukocytosis often is pronounced, with total white blood cell (WBC) counts frequently >15,000/μL. In severe cases of pneumococcal disease, WBC count may be low.

Pneumococci can be identified in body fluids as gram-positive, lancet-shaped diplococci. Early in the course of pneumococcal meningitis, many bacteria may be seen in relatively acellular CSF. With methods of continuously monitored blood culture systems, the average time to isolation of pneumococcal organisms is 14-15 hours. Multiplex real-time polymerase chain reaction (PCR) assays are specific and more sensitive than culture of CSF and blood, particularly in patients who have recently received antimicrobial therapy. Antigen detection of C-polysaccharide in urine may be useful in adults with pneumococcal pneumonia but lacks specificity in children who may have positive results with asymptomatic colonization. Antigen immunochromatographic or PCR assays on pleural fluid are not routinely used but could be considered.

TREATMENT

Antimicrobial resistance among *S. pneumoniae* continues to be a serious healthcare concern, especially for the widely used β-lactams, macrolides, and fluoroquinolones. Serotypes 6A, 6B, 9V, 14, 19A, 19F, and 23F are the most common serotypes associated with resistance to penicillin. Consequently, the introduction of the 7- and 13-valent pneumococcal conjugate vaccines (**PCV7** and **PCV13**) has altered antimicrobial resistance patterns. By 2014, only ~5% of pneumococcal strains were penicillin nonsusceptible. However, pneumococcal serotypes 11A, 35F, and 35B have contributed to steady erosion of pneumococcal antibiotic susceptibility to penicillin, third-generation cephalosporins, fluoroquinolones, and carbapenems.

Resistance in pneumococci to penicillin and cephalosporins is defined by the minimum inhibitory concentration (MIC) and clinical syndrome. Pneumococci are considered *susceptible, intermediate,* or *resistant* to various antibacterial agents based on specific MIC breakpoints. For patients with pneumococcal meningitis, penicillin-susceptible strains have MICs ≤0.06 μg/mL, and penicillin-resistant strains have MICs ≥0.12 μg/mL. For patients with nonmeningeal pneumococcal infections, breakpoints are higher; in particular, penicillin-susceptible strains have MICs ≤2 μg/mL, and penicillin-resistant strains have MICs ≥8 μg/mL. For patients with meningitis, ceftriaxone-susceptible strains have MICs ≤0.5 μg/mL, and resistant strains have MICs ≥2.0 μg/mL. For patients with nonmeningeal pneumococcal disease, breakpoints are higher, and ceftriaxone-susceptible strains have MICs ≤1 μg/mL, and resistant strains have MICs ≥4 μg/mL. In cases when pneumococcus is resistant to erythromycin but sensitive to clindamycin, *a D-test should be performed* to determine whether clindamycin resistance can be induced; if the D-test is positive, clindamycin should not be used to complete treatment of the patient. More than 30% of pneumococcal isolates are resistant to trimethoprim-sulfamethoxazole (TMP-SMX); levofloxacin resistance is low but has also been reported. All isolates from children with severe infections should be tested for antibiotic susceptibility, given widespread pneumococcal MDR strains. Resistance to vancomycin has not been seen at this time, but vancomycin-tolerant pneumococci that are killed at a slower rate have been reported, and these tolerant pneumococci may be associated with a worse clinical outcome. Linezolid is an oxazolidinone antibacterial with activity against MDR gram-positive organisms, including pneumococcus, and has been used in the treatment of MDR pneumococcal pneumonia, meningitis, and severe otitis media. Despite early favorable studies, use of this drug is limited by myelosuppression and high cost, and linezolid resistance in pneumococcus is reported.

Children ≥1 month old with suspected pneumococcal meningitis should be treated with combination therapy using **vancomycin** (60 mg/kg/24 hr divided every 6-8 hr IV) and high-dose **ceftriaxone** (100 mg/kg/24 hr divided every 12 hr IV). Proven pneumococcal meningitis can be treated with penicillin alone or ceftriaxone alone if the isolate is penicillin susceptible. If the organism is nonsusceptible (i.e., intermediate or full resistance) to penicillin but susceptible to ceftriaxone, pneumococcal meningitis can be treated with ceftriaxone alone. However, if the organism is nonsusceptible to penicillin and to ceftriaxone, pneumococcal meningitis should be treated with combination vancomycin plus ceftriaxone, not with vancomycin alone, and consideration should be given to the addition of **rifampin**. Some experts recommend use of corticosteroids in pneumococcal meningitis early in the course of disease, but data demonstrating clear benefit in children are lacking.

The 2011 Infectious Diseases Society of America guidelines recommend **amoxicillin** as first-line therapy for previously healthy, appropriately immunized infants and preschool children with mild to moderate, uncomplicated community-acquired pneumonia. **Ampicillin** or **penicillin G** may be administered to the fully immunized infant or school-age child admitted to a hospital with uncomplicated community-acquired pneumonia when local epidemiologic data document lack of substantial high-level penicillin resistance for invasive *S. pneumoniae*. Empirical therapy with parenteral ceftriaxone should be prescribed for hospitalized infants and children who are not fully immunized, in regions where local epidemiology of invasive pneumococcal strains documents widespread penicillin resistance, or for infants and children with life-threatening infection, including those with empyema. Non–β-lactam agents, such as vancomycin, have not been shown to be more effective than ceftriaxone in the treatment of pneumococcal pneumonia, given the degree of drug resistance currently seen in the United States.

Higher doses of amoxicillin (80-90 mg/kg/24 hr) have been successful in the treatment of otitis media caused by relatively penicillin-resistant pneumococcal strains. If the patient has failed initial antibiotic therapy, alternative agents should be active against penicillin-nonsusceptible pneumococcus as well as β-lactamase–producing *Haemophilus influenzae* and *Moraxella catarrhalis*. These include high-dose oral amoxicillin-clavulanate (in the 14:1 formulation to reduce the risk of diarrhea), oral cefdinir, cefpodoxime, or cefuroxime or a 3-day course of daily intramuscular (IM) ceftriaxone if patients fail oral therapy. Empirical treatment of pneumococcal disease should be based on knowledge of susceptibility patterns in specific communities.

For individuals with a non–type I allergic reaction to penicillin, cephalosporins (standard dosing) can be used. For type I allergic reactions (immediate, anaphylactic) to β-lactam antibiotics, clindamycin and levofloxacin are preferred alternatives depending on the site of infection (e.g., clindamycin may be effective for pneumococcal infections other than meningitis). TMP-SMX may also be considered for susceptible strains but should be avoided in the absence of susceptibility results. Erythromycin and related macrolides (e.g., azithromycin, clarithromycin) should be avoided given high rates of resistance.

PROGNOSIS

Prognosis depends on the integrity of host defenses, virulence and numbers of the infecting organism, age of the host, site and extent of the infection, and adequacy of treatment. The mortality rate for pneumococcal meningitis is approximately 10% in most studies. Pneumococcal meningitis results in sensorineural hearing loss in 20–30% of patients and can cause other serious neurologic sequelae, including paralysis, epilepsy, blindness, and intellectual deficits.

Invasive pneumococcal disease is associated with various primary immunodeficiency states, leading some to suggest screening for immune defects in all or some patients with invasive diseases. In the absence of other risk factors (see Table 228.1), screening for immune defects (complement, B-cell, toll-like receptor, asplenia) may be indicated for patients with recurrent invasive disease, infection by a serotype covered by vaccination in a fully vaccinated child, children ≥2 years of age, or in some centers all patients with invasive disease.

PREVENTION

The highly successful PCVs have resulted in a marked decrease in IPIs in children. PCVs provoke protective antibody responses in 90% of infants given these vaccines at 2, 4, and 6 months of age, and greatly enhanced responses (e.g., immunologic memory) are apparent after vaccine doses given at 12-15 months of age (Table 228.2). In a large

Table 228.3 Recommended Routine Vaccination Schedule for 15- or 20-Valent Pneumococcal Conjugate Vaccine (PCV15 or 20) Among Infants and Children Who Have Not Received Previous Doses of Conjugate Vaccines, by Age at First Dose—United States, 2010

AGE AT FIRST DOSE (MO)	PRIMARY PCV15 OR PCV20 SERIES*	PCV15 OR PCV20 BOOSTER DOSE†
2-6	3 doses	1 dose at age 12-15 mo
7-11	2 doses	1 dose at age 12-15 mo
12-23	2 doses	—
24-59 (healthy children)	1 dose	—
24-71 (children with certain chronic diseases or immunocompromising conditions‡)	2 doses	—

*The minimum interval between doses is 8 wk except for children vaccinated at age <12 mo, for whom the minimum interval between doses is 4 wk. The minimum age for administration of the first dose is 6 wk.
†Given at least 8 wk after the previous dose.
‡See Table 228.1. If two doses of PCV15 are used, then 1 dose of PPSV23 vaccine is given ≥8 weeks later.
Adapted from Kobayashi M, Farrar JI, Gierke R, et al. Use of 15-valent pneumococcal conjugate vaccine among U.S. children: updated recommendations of the Advisory Committee on Immunization Practices -- United States, 2022. *MMWR Morb Mortal Wkly Rep*. 2022;71(4):1174-1181; and Centers for Disease Control and Prevention. ACIP updates: Recommendations for use of 20-valent pneumococcal conjugate vaccine in children—United States, 2023. *MMWR Morb Mortal Wkly Rep*. 2023;72(39):1072.

clinical trial, PCV7 was shown to reduce invasive disease caused by vaccine serotypes by up to 97% and to reduce invasive disease caused by all serotypes, including serotypes not in the vaccine, by 89%. Children who received PCV7 had 7% fewer episodes of acute otitis media and underwent 20% fewer tympanostomy tube placements than unvaccinated children. After PCV13, a 98% reduction in IPIs caused by vaccine serotypes has been seen, particularly in children <5 years old. The number of pneumococcal isolates and percentage of isolates with high-level penicillin resistance from cultures taken from children with otitis media or mastoiditis for clinical indications decreased, largely related to decreases in serotype 19A. Rates of hospitalization for pneumococcal pneumonia among U.S. children decreased after PCV13 introduction. The number of cases of pneumococcal meningitis in children remain unchanged, but the proportion of PCV13 serotypes has decreased significantly. In addition, pneumococcal conjugate vaccines significantly reduce nasopharyngeal carriage of vaccine serotypes. PCVs have significantly decreased rates of invasive pneumococcal disease in children with sickle cell disease, and studies suggest substantial protection for HIV-infected children and splenectomized adults. Adverse events after the administration of PCV have included local swelling and redness and slightly increased rates of fever when used in conjunction with other childhood vaccines.

Currently, the predominant non-PCV13 serotypes are 22F, 12F, 33F, 24F, 15C, 15B, 23B, 10A, 11A, 35B, 35F, and 38. Serotypes 12F and 24F have high invasive disease potential, with the latter responsible for a rebound in incidence of pneumococcal meningitis since 2015. Serotypes 11A, 35F, and 35B in nasopharyngeal and middle ear samples are increasingly resistant to antibiotics. PCV15 or PCV20, which have replaced PCV13, do not contain serotypes 24 or 35, but PCV20 includes 11A and 12F.

Immunologic responsiveness and efficacy after administration of pneumococcal polysaccharide vaccines (PPSV23) is unpredictable in children <2 years old. PPSV23 contains purified polysaccharide of 23 pneumococcal serotypes responsible for >95% of invasive disease. The clinical efficacy of PPSV23 is controversial, and studies have yielded conflicting results.

Immunization with PCV15 or PCV20 is recommended for all infants on a schedule for primary immunization, in previously unvaccinated infants, and for transition for those partially vaccinated (Table 228.3). High-risk children ≥2 years old, such as those with asplenia, sickle cell disease, some types of immune deficiency (e.g., antibody deficiencies), HIV infection, cochlear implant, CSF leak, diabetes mellitus, and chronic lung (including moderate persistent or severe persistent asthma), heart, liver, or kidney disease (including nephrotic syndrome) or immunocompromising conditions, such as asplenia, sickle cell disease, some types of immune deficiency (e.g., antibody deficiencies), HIV infection, etc., may also benefit from PPSV23 administered after 2 years of age after priming with the scheduled doses of PCV15 or 20. Thus it is recommended that children 2 years of age and older with these conditions receive supplemental vaccination with PPSV23. A second dose of PPSV23 is recommended 5 years after the first dose of PPSV23 for persons ≥2 years old who have immunocompromising conditions including sickle cell disease and functional or anatomic asplenia. Additional doses of PPSV23 are not required, however, if the patient has ever received PCV20. Additional

TABLE 228.4 CDC Advisory Committee on Immunization Practices Recommendations for Use of PCV in Children, June 2023

AGE AND RISK GROUP	RECOMMENDATIONS
Children age <24 mo	• Use of either PCV15 or PCV20 is recommended for all children age 2–23 mo according to previously recommended PCV dosing and schedules. • If only PCV13 is available when the child is scheduled to receive a PCV, PCV13 may be given as previously recommended. • If a child started the PCV series with PCV13, the child may complete the series with PCV15 or PCV20 without giving additional doses; the PCV series does not need to be restarted. • For children who have received all recommended dosing and schedules with PCV13 or PCV15, a supplemental dose of PCV20 is not indicated.
Healthy children age 24–59 mo with an incomplete PCV vaccination status*	• A single dose of either PCV15 or PCV20 is recommended. • A supplemental dose of PCV15 or PCV20 is not indicated for healthy children who have received 4 doses of PCV13 or who completed another age-appropriate PCV13 schedule.
Children age 24–71 mo with any risk condition†	• Use either PCV15 or PCV20 according to previously recommended PCV dosing and schedules. • If only PCV13 is available when the child is scheduled to receive a PCV, PCV13 may be given as previously recommended.
Children age 2–18 yr with any risk condition who completed a recommended PCV series before age 6 yr	• Completed series includes ≥1 dose of PCV20: ○ No additional doses of any pneumococcal vaccine are indicated. ○ This recommendation may be updated as additional data become available. • Completed series using PCV13 or PCV15 (no PCV20): ○ Either a single dose of PCV20 or PPSV23 using previously recommended dosing and schedules is recommended to complete the recommended vaccine series.
Children age 6–18 yr with any risk condition with no previous PCV13, PCV15, or PCV20 vaccination	• For children age 6–18 yr with any risk condition who have not received any dose of PCV (PCV13, PCV15, or PCV20) a single dose of either PCV15 or PCV20 is recommended. • If the child has previously received PCV7 and/or PPSV23, a single dose of either PCV15 or PCV20 is recommended ≥8 wk after the most recent dose of pneumococcal vaccination. ○ PCV15 should be followed by a dose of PPSV23 if not previously given. ○ PCV20 does not need to be followed by a dose of PPSV23.
Children who have received HSCT	• Children who received HSCT are recommended to receive three doses of PCV20, 4 wk apart starting 3–6 mo after HSCT. • A fourth PCV20 dose is recommended ≥6 mo after the third PCV20 dose, or ≥12 mo after HSCT, whichever is later. • HSCT recipients who have started their pneumococcal vaccine series with PCV13 or PCV15 may complete their 4-dose pneumococcal vaccine series with PCV20 without giving extra doses. • If PCV20 is not available, three doses of PCV15, 4 wk apart starting 3–6 mo after HSCT, followed by a dose of PPSV23 ≥12 mo after HSCT may be given. • For patients with chronic graft-versus-host disease who are receiving PCV15, a fourth dose of PCV15 can be given in place of PPSV23 since these children are less likely to respond to PPSV23. A patient's clinical team is best positioned to determine the appropriate timing of vaccination.

*Routine use of PCV is not recommended for healthy children age ≥5 yr.

†Risk conditions include: cerebrospinal fluid leak; chronic heart disease; chronic kidney disease (excluding maintenance dialysis and nephrotic syndrome, which are included in immunocompromising conditions); chronic liver disease; chronic lung disease (including moderate persistent or severe persistent asthma); cochlear implant; diabetes mellitus; immunocompromising conditions (on maintenance dialysis or with nephrotic syndrome; congenital or acquired asplenia or splenic dysfunction; congenital or acquired immunodeficiencies; diseases and conditions treated with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, Hodgkin disease, and solid organ transplant; HIV infection; and sickle cell disease or other with these conditions who received PCV13 or PCV15 are also recommended to receive 23-valent pneumococcal polysaccharide vaccine.

PCV, pneumococcal conjugate vaccine; PCV13, 13-valent PCV; PCV15, 15-valent PCV; PCV20, 20-valent PCV; PPSV23, 23-valent pneumococcal polysaccharide vaccine; HSCT, hematopoietic stem cell transplant.

From Centers for Disease Control and Prevention. ACIP updates: Recommendations for use of 20-valent pneumococcal conjugate vaccine in children—United States, 2023. *MMWR Morb Mortal Wkly Rep*. 2023;72(39):1072. (Table 1).

recommendations have been made for at-risk children 6-18 years old (Table 228.4).

Immunization with pneumococcal vaccines also may prevent pneumococcal disease caused by nonvaccine serotypes that are serotypically related to a vaccine strain. However, because current vaccines do not eliminate all pneumococcal invasive infections, penicillin prophylaxis is recommended for children at high risk of invasive pneumococcal disease, including children with asplenia or sickle cell disease. Oral penicillin V potassium (125 mg twice daily for children <3 years old; 250 mg twice daily for children ≥3 years old) decreases the incidence of pneumococcal sepsis in children with sickle cell disease. Once-monthly IM benzathine penicillin G (600,000 units every 3-4 weeks for children weighing <60 lb; 1,200,000 units every 3-4 weeks for children weighing ≥60 lb) may also provide prophylaxis. Erythromycin may be used in children with penicillin allergy, but its efficacy is unproven. Prophylaxis in sickle cell disease has been safely discontinued after the fifth birthday in children who have received all recommended pneumococcal vaccine doses and who had not experienced invasive pneumococcal disease. Prophylaxis is often administered for at least 2 years after splenectomy or up to 5 years of age. Efficacy in children >5 years old and adolescents is unproven. If oral antibiotic prophylaxis is used, strict compliance must be encouraged.

Given the rapid emergence of penicillin-resistant pneumococci, especially in children receiving long-term, low-dose therapy, prophylaxis cannot be relied on to prevent disease. High-risk children with fever should be promptly evaluated and treated regardless of vaccination or penicillin prophylaxis history.

Chapter 229

Group A *Streptococcus*

Stanford T. Shulman and Ami B. Patel

Group A *Streptococcus* **(GAS)**, also known as *Streptococcus pyogenes,* is a common cause of infections of the upper respiratory tract **(pharyngitis)** and the skin **(impetigo, pyoderma)** in children. Less frequently, GAS causes perianal cellulitis, vaginitis, septicemia, pneumonia, empyema, endocarditis, pericarditis, osteomyelitis, suppurative arthritis, myositis, cellulitis, omphalitis, and other infections. This organism also causes distinct clinical entities **(scarlet fever** and **erysipelas)**, as well as streptococcal **toxic shock syndrome** and monomicrobial **necrotizing fasciitis**. GAS is also the cause of at least two potentially serious nonsuppurative complications: **rheumatic fever** (see Chapters 229.1 and 487) and **acute glomerulonephritis** (see Chapter 559.4).

ETIOLOGY

Group A streptococci are gram-positive, coccoid-shaped bacteria that tend to grow in chains. Streptococci are broadly classified by their hemolytic activity on mammalian (typically sheep) red blood cells. The zone of complete hemolysis that surrounds colonies grown on blood agar distinguishes β-hemolytic (complete hemolysis) from α-hemolytic (green or partial hemolysis) and γ (nonhemolytic) species. The β-hemolytic streptococci can be divided into groups by a group-specific polysaccharide **(Lancefield C carbohydrate)** located in the bacterial cell wall. More than 20 serologic groups are identified, designated by the letters A through V, although only A through D are medically important. Serologic grouping by the Lancefield method is precise, but group A organisms can be identified more readily by any of a number of latex agglutination, coagglutination, molecular assays or enzyme immunoassays. Group A strains can also be distinguished from other groups by differences in sensitivity to bacitracin, as other groups are generally resistant to this antibiotic.

GAS can be subdivided into at least 220 serotypes on the basis of the **M protein** antigen, which is located on the cell surface and in fimbriae that project from the outer surface of the cell. Currently, a molecular approach to M-typing GAS isolates using the polymerase chain reaction (PCR) is based on sequencing the terminal portion of the *emm* gene of GAS that encodes the M protein. This *emm* typing system correlates with known serotypes and *emm* types. The *emm* types can be grouped into *emm* clusters that share structural and binding properties. It is important to note that immunity is largely based on type-specific opsonic anti-M antibody.

M/*emm* typing is valuable for epidemiologic studies; specific GAS diseases tend to be associated with certain M types. Types 1, 12, 28, 4, 3, and 2 (in that order) are the most common causes of uncomplicated streptococcal pharyngitis in the United States. M types usually associated with pharyngitis rarely cause skin infections, and the M types associated with skin infections rarely cause pharyngitis. A few **pharyngeal** GAS strains (e.g., M type 12) are associated with glomerulonephritis, but many more **skin** GAS strains (e.g., M types 49, 55, 57, and 60) are considered nephritogenic. Several pharyngeal serotypes (e.g., M types 1, 3, 5, 6, 18, and 29), but no proven skin strains, are associated with **acute rheumatic fever** in North America.

EPIDEMIOLOGY

Humans are the natural reservoir for GAS. These bacteria are highly communicable and can cause disease in normal individuals of all ages who do not have type-specific immunity against the particular serotype involved. Disease in neonates is uncommon in developed countries, probably because of maternally acquired antibody. The incidence of **pharyngitis** is highest in children 5-15 years of age, especially in young school-age children. Acute streptococcal pharyngitis is uncommon in children younger than 3 years, and testing is generally not recommended. These infections are most common in the northern regions of the United States, especially during winter and early spring. Children with untreated acute pharyngitis spread GAS by salivary droplets and nasal discharge. Transmission is favored by close proximity; therefore schools, military barracks, and homes are important environments for spread. GAS has the potential to be an important upper respiratory tract pathogen and to produce outbreaks of disease in the daycare setting. Foods contaminated by GAS occasionally cause explosive outbreaks of pharyngotonsillitis. The incubation period for pharyngitis is usually 2-5 days. Children are usually no longer infectious within 24 hours of starting appropriate antibiotic therapy. Chronic pharyngeal carriers of GAS rarely transmit this organism to others.

Streptococcal pyoderma (impetigo, pyoderma) occurs most frequently during the summer in temperate climates, or year-round in warmer climates, when the skin is exposed and abrasions and insect bites are more likely to occur (see Chapter 727). Colonization of healthy skin by GAS usually precedes the development of impetigo. Because GAS cannot penetrate intact skin, impetigo and other skin infections usually occur at the site of open lesions (insect bites, traumatic wounds, burns). Although impetigo serotypes may colonize the throat, spread is usually from skin to skin, not via the respiratory tract. Fingernails and the perianal region can harbor GAS and play a role in disseminating impetigo. Multiple cases of impetigo in the same family are common. Both impetigo and pharyngitis are more likely to occur among children living in crowded homes and in poor hygienic circumstances.

The incidence of **severe invasive** GAS infections, including bacteremia, pneumonia and empyema, osteomyelitis, septic arthritis, retropharyngeal abscess, lymphadenitis, streptococcal **toxic shock syndrome**, **scarlet fever**, and **necrotizing fasciitis**, has increased in recent decades. The incidence appears to be highest in very young and elderly persons. Before the routine use of varicella vaccine, varicella was the most commonly identified risk factor for invasive GAS infection in children. Other risk factors include diabetes mellitus, HIV infection, intravenous drug use, and chronic pulmonary or chronic cardiac disease. The portal of entry is unknown in almost 50% of cases of severe invasive GAS infection; in most cases, it is believed to be skin or, less often, mucous membranes. Severe invasive disease rarely follows clinically apparent GAS pharyngitis. Invasive GAS disease was reported in many children's hospitals in multiple countries during the COVID-19 pandemic. It is unclear why this has happened, but masking, social distancing, and school closures may have reduced exposure to common viral pathogens or colonization with GAS, resulting in more severe infection when mask and social distancing have stopped and schools have reopened. Co-infection with respiratory viruses (respiratory syncytial virus [RSV], other) may predispose to more severe infection.

PATHOGENESIS

The virulence of GAS depends primarily on the **M protein**, and strains rich in M protein resist phagocytosis in fresh human blood, whereas M-negative strains do not. M protein stimulates the production of protective opsonophagocytic antibodies that are type specific, protecting against infection with a homologous M type but much less so against other M types. Therefore multiple GAS infections attributable to various M types are common during childhood and adolescence. By adult life, individuals are probably immune to many of the common M types in the environment.

GAS produces a large variety of extracellular enzymes and toxins, including erythrogenic toxins, known as **streptococcal pyrogenic exotoxins**. Streptococcal pyrogenic exotoxins A, C, and SSA, alone or in combination, are responsible for the **rash of scarlet fever** and are elaborated by streptococci that contain a particular bacteriophage. These exotoxins stimulate the formation of specific antitoxin antibodies that provide immunity against the scarlatiniform rash but not against other streptococcal infections. Pathogenic variants in genes that are promoters of several virulence genes, including pyrogenic exotoxins, as well as several newly discovered exotoxins, appear to be involved in the

pathogenesis of invasive GAS disease, including streptococcal toxic shock syndrome.

The importance of other streptococcal toxins and enzymes in human disease is not yet established. Many of these extracellular substances are antigenic and stimulate antibody production after an infection. However, these antibodies do not confer immunity. The measurement of select toxins and antibodies is useful for establishing evidence of a recent streptococcal infection to aid in the diagnosis of postinfectious illnesses. Tests for antibodies against streptolysin O (anti–streptolysin O) and DNase B (anti–DNase B) are the most frequently used antibody determinations.

CLINICAL MANIFESTATIONS

The most common infections caused by GAS involve the respiratory tract and the skin and soft tissues.

Respiratory Tract Infections

GAS is an important cause of acute **pharyngitis** (see Chapter 430) and pneumonia, often with empyema (see Chapter 449).

Scarlet Fever

Scarlet fever is GAS pharyngitis associated with a characteristic rash, which is caused by an infection with **pyrogenic exotoxin** (erythrogenic toxin)–producing GAS in individuals who do not have antitoxin antibodies. It is now encountered less often and is less virulent than in the past, but the incidence is cyclic, depending on the prevalence of toxin-producing strains and the immune status of the population. The modes of transmission, age distribution, and other epidemiologic features are otherwise similar to those for GAS pharyngitis.

The scarlet fever rash appears within 24-48 hours after the onset of symptoms, although it may appear with the first signs of illness (Fig. 229.1A). It often begins around the neck and spreads over the trunk and extremities. The rash is a diffuse, finely papular, erythematous eruption producing bright-red discoloration of the skin, which blanches on pressure. It is often accentuated in the creases of the elbows, axillae, and groin (Pastia lines). The skin has a goose-pimple appearance and feels rough. The cheeks are often erythematous with perioral pallor. After 3-4 days, the rash begins to fade and is followed by **desquamation**, initially on the face, progressing caudally, and often resembling a mild sunburn. Occasionally, sheetlike desquamation may occur around the free margins of the fingernails, the palms, and the soles. Examination of the pharynx of a patient with scarlet fever reveals essentially the same findings as with GAS pharyngitis. In addition, the tongue is usually coated and the papillae are swollen (see Fig. 229.1B). After desquamation, the reddened papillae are prominent, giving the tongue a strawberry appearance (see Fig. 229.1C).

Typical scarlet fever is not difficult to diagnose; the milder form with equivocal pharyngeal findings can be confused with viral exanthems, Kawasaki disease, and drug eruptions. Staphylococcal infections are occasionally associated with a scarlatiniform rash. A history of recent exposure to a GAS infection is helpful. Identification of GAS in the pharynx confirms the diagnosis.

Impetigo

Impetigo (or pyoderma) has traditionally been classified into two clinical forms: bullous and nonbullous (see Chapter 706.1). **Nonbullous impetigo** is the more common form and is a superficial infection of the skin that appears first as a discrete papulovesicular lesion surrounded by a localized area of redness. The vesicles rapidly become purulent and covered with a thick, confluent, amber-colored crust that gives the appearance of having been stuck onto the skin. The lesions may occur anywhere but are most common on the face and extremities. If untreated, nonbullous impetigo is a mild but chronic illness, often spreading to other parts of the body, but occasionally self-limited. Regional **lymphadenitis** is common. Nonbullous impetigo is generally not accompanied by fever or other systemic signs or symptoms. Impetiginized excoriations around the nares are seen with active GAS infections of the nasopharynx, particularly in young children. However, impetigo is rarely associated with overt streptococcal infection of the upper respiratory tract.

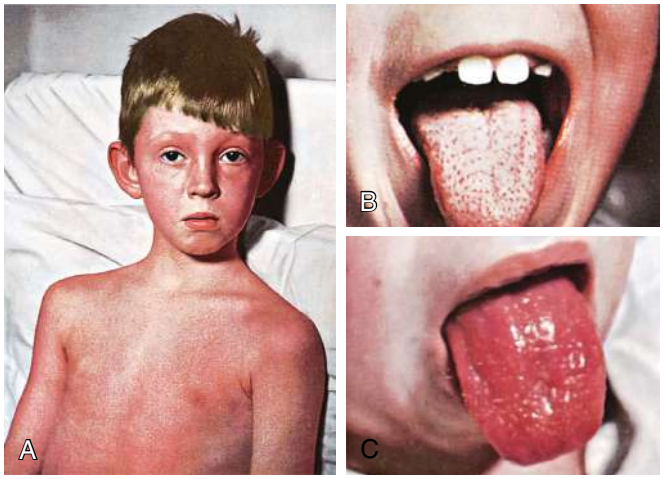

Fig. 229.1 Scarlet fever. **A,** Punctate, erythematous rash (second day). **B,** White strawberry tongue (first day). **C,** Red strawberry tongue (third day). *(Courtesy Dr. Franklin H. Top, Professor and Head of the Department of Hygiene and Preventive Medicine, State University of Iowa, College of Medicine, Iowa City, IA; and Parke, Davis & Company's Therapeutic Notes. From Gershon AA, Hotez PJ, Katz SL. Krugman's Infectious Diseases of Children, 11th ed. Philadelphia: Mosby; 2004, Plate 53.)*

Bullous impetigo is less common and occurs most often in neonates and young infants. It is characterized by flaccid, transparent bullae usually <3 cm in diameter on previously untraumatized skin. The usual distribution involves the face, buttocks, trunk, and perineum.

Although *Staphylococcus aureus* has traditionally been accepted as the sole pathogen responsible for bullous impetigo, there has been confusion about the organisms responsible for nonbullous impetigo. In most episodes of nonbullous impetigo, either GAS or *S. aureus* (or both) is isolated. Earlier investigations suggested that GAS was the causative agent in most cases of nonbullous impetigo and that *S. aureus* was only a secondary invader. However, *S. aureus* has emerged as the causative agent in most cases of nonbullous impetigo. Culture of the lesions is the only way to distinguish nonbullous impetigo caused by *S. aureus* from that caused by GAS.

Erysipelas

Erysipelas is a relatively rare acute GAS infection involving the deeper layers of the skin and the underlying connective tissue. The skin in the affected area is edematous, highly erythematous, and very tender. The erythema associated with erysipelas is very bright, which differentiates it from the dusky appearance of necrotizing fasciitis. Superficial blebs may be present. The most characteristic finding is a sharply defined, slightly elevated border. At times, reddish streaks of lymphangitis project out from the margins of the lesion. The onset is abrupt, and signs and symptoms of a systemic infection, such as high fever and sepsis, are often present. Cultures obtained by needle aspirate of the advancing margin of the inflamed area often reveal the causative agent.

Perianal Dermatitis

Perianal dermatitis, also called *perianal cellulitis* or **perianal streptococcal disease**, is a distinct clinical entity characterized by well-demarcated, perianal erythema associated with anal pruritus, painful defecation, and occasionally blood-streaked stools. Most children are 2-7 years old (range: 18 days-12 years). Physical examination reveals flat, pink to beefy-red perianal erythema with sharp margins extending

as far as 2 cm from the anus. Erythema may involve the vulva and vagina. Lesions may be very tender and, particularly when chronic, may fissure and bleed. Systemic symptoms and fever are unusual. Culture or a rapid streptococcal test of a perianal swab will yield GAS or detect antigen.

Vaginitis

GAS is a common cause of vaginitis in prepubertal girls (see Chapter 586). Patients usually have a serous discharge with marked erythema and irritation of the vulvar area, accompanied by discomfort in walking and in urination.

Severe Invasive Disease

Invasive GAS infection is defined by isolation of GAS from a normally sterile body site and includes three overlapping clinical syndromes. **GAS toxic shock syndrome (TSS)** is differentiated from other types of invasive GAS infections by the presence of shock and multiorgan system dysfunction early in the course of the infection (Table 229.1). The second syndrome is **GAS necrotizing fasciitis**, characterized by extensive local necrosis of subcutaneous soft tissues and skin. The third syndrome is the group of **focal and systemic infections** that do not meet the criteria for TSS or necrotizing fasciitis and includes bacteremia with sepsis with no identified focus, meningitis, pneumonia and empyema, peritonitis, puerperal sepsis, osteomyelitis, suppurative arthritis, myositis, and surgical wound and other infections. GAS TSS, necrotizing fasciitis, and focal and systemic infections can be present in any combination.

The pathogenic mechanisms responsible for severe, invasive GAS infections, including streptococcal TSS and necrotizing fasciitis, have yet to be defined completely, but an association with **streptococcal pyrogenic exotoxins** is strongly suspected. At least two of the three original streptococcal pyrogenic exotoxins (A and C) and potentially other as yet unidentified toxins produced by GAS act as **superantigens**, which stimulate intense activation and proliferation of T lymphocytes and macrophages, resulting in the production of large quantities of proinflammatory cytokines. These cytokines are capable of inducing shock and tissue injury and appear to mediate many of the clinical manifestations of severe, invasive GAS infections.

DIAGNOSIS OF GAS PHARYNGITIS

When deciding whether to perform a diagnostic test on a patient presenting with acute pharyngitis, the clinical and epidemiologic findings should be considered. A history of close contact with a well-documented case of GAS pharyngitis is helpful, as is an awareness of a high prevalence of GAS infections in the community. The signs and symptoms of streptococcal and nonstreptococcal pharyngitis overlap too broadly to allow the requisite diagnostic precision on clinical grounds alone. The clinical diagnosis of GAS pharyngitis cannot be made with reasonable accuracy even by the most experienced physicians, and laboratory confirmation is required, except for patients with overt viral signs and symptoms (e.g., rhinorrhea, cough, mouth ulcers, hoarseness), who generally do not need a GAS diagnostic test performed, as GAS is highly unlikely.

Culture of a throat swab on a sheep blood agar plate is effective for documenting the presence of GAS and for confirming the clinical diagnosis of acute GAS pharyngitis. When performed correctly, a single throat swab has a sensitivity of 90–95% for detecting the presence of GAS in the pharynx.

The significant disadvantage of culturing a throat swab on a blood agar plate is the delay (overnight or longer) in obtaining the culture result. **Streptococcal rapid antigen detection** tests are available for the identification of GAS directly from throat swabs. Their advantage over culture is the speed in providing results, often <10-15 minutes. Rapid identification and treatment of patients with streptococcal pharyngitis can reduce the risk for spread of GAS, allowing the patient to return to school or work sooner, and can reduce the acute morbidity of this illness.

Almost all currently available rapid antigen detection tests have excellent specificity of >95% compared with blood agar plate cultures. False-positive test results are quite unusual, and therefore therapeutic decisions can be made with confidence on the basis of a positive test result. Unfortunately, the sensitivity of most of these tests is 70–90% when compared with blood agar plate culture. Therefore a negative rapid test does not completely exclude the presence of GAS, and a confirmatory throat culture should be performed in children and adolescents, but not necessarily in adults, who are at exceptionally low risk for developing acute rheumatic fever. Definitive studies are not available to determine whether some rapid antigen detection tests are significantly more sensitive than others or whether any of these tests is sensitive enough to be used routinely in children and adolescents without throat culture confirmation of negative test results. Some experts believe that physicians who use a rapid antigen detection test without culture backup should compare the results with that specific test to those of throat cultures to confirm adequate sensitivity in their practice.

In point-of-care settings and laboratories testing for GAS pharyngitis, culture methods are being replaced by rapid antigen and molecular assays. These molecular assays include PCR methods and **nucleic acid amplification tests** using isothermal loop amplification. Some of these methods have been reported to have a sensitivity of up to 100% and specificity of >96% compared to culture or PCR. This very high sensitivity may lead to higher numbers of positive results, which in turn may contribute to identification of more patients with asymptomatic GAS colonization and unnecessary antibiotic therapy. Therefore it is important that the appropriate clinical context to perform these highly sensitive tests be considered. However, the benefit of faster results, sometimes <10 minutes, which ensures more expedited initiation of appropriate antibiotic therapy for patients with GAS pharyngitis, may be of value.

GAS infection can also be diagnosed retrospectively on the basis of an elevated or increasing streptococcal antibody titer. The **anti–streptolysin O** assay is the streptococcal antibody test most often used. The test is not specific for group A infection because streptolysin O also is produced by groups C and G streptococci. The anti–streptolysin O response can be feeble after streptococcal skin infection. In contrast, the anti–DNase B responses are generally present after either skin or throat infections. A significant antibody increase is usually defined as an increase in titer of two or more dilution increments (≥ fourfold rise) between the acute-phase and convalescent-phase specimens, regardless of the actual height of the antibody titer. Physicians frequently misinterpret streptococcal antibody titers because of a failure to appreciate that the normal levels of these antibodies are substantially higher among school-age children than adults. Both the traditional anti–streptolysin O and the anti–DNase B tests are neutralization assays. Newer tests use **latex agglutination** or nephelometric assays. Unfortunately, these newer tests often have not been well standardized against the traditional neutralization assays. Physicians should be aware of these potential problems when interpreting the results of streptococcal serologic testing.

Differential Diagnosis

Viruses are the most common cause of acute pharyngitis in children. Respiratory viruses such as influenza virus, parainfluenza virus, rhinovirus, coronavirus, adenovirus, and RSV are frequent causes of acute pharyngitis. Other viral causes of acute pharyngitis include enteroviruses and herpes simplex virus. Epstein-Barr virus is a frequent cause of acute pharyngitis that is often accompanied by other clinical findings of infectious mononucleosis (e.g., splenomegaly, generalized lymphadenopathy). Systemic infections with other viral agents, including cytomegalovirus, rubella virus, measles virus, and HIV, may be associated with acute pharyngitis.

GAS is by far the most common cause of *bacterial* pharyngitis, accounting for 15–30% of cases of acute pharyngitis in children and a lower proportion in adults. Groups C and G β-hemolytic streptococcus also cause acute pharyngitis, typically in teens and young adults (see Chapter 231). *Arcanobacterium haemolyticum* and *Fusobacterium necrophorum* are additional, less common causes. *Neisseria gonorrhoeae* can occasionally cause acute pharyngitis in sexually active adolescents and adults. Other bacteria, such as *Francisella tularensis* and *Yersinia enterocolitica,* as well as mixed infections with anaerobic bacteria (Vincent angina), are very rare causes of acute pharyngitis. *Chlamydia pneumoniae* and *Mycoplasma pneumoniae* have been implicated as causes of acute pharyngitis, particularly in adults. *Corynebacterium diphtheriae* is a serious cause of pharyngitis but is very rare in areas with universal immunization (see Chapter 233). Although other bacteria (e.g., *S. aureus, Haemophilus influenzae, Streptococcus pneumoniae*) are frequently cultured from the throats of children with acute pharyngitis, their etiologic role in pharyngitis has not been established, because they are often isolated from healthy children.

GAS pharyngitis is the only common cause of acute pharyngitis for which antibiotic therapy is definitely indicated. Therefore when confronted with a patient with acute pharyngitis, the clinical decision that usually needs to be made is whether or not the pharyngitis is attributable to GAS.

TREATMENT OF GAS PHARYNGITIS

Timely antibiotic therapy for patients with GAS pharyngitis can prevent **acute rheumatic fever** (RF), shorten the clinical course of the illness, reduce transmission of the infection to others, and prevent suppurative complications. *For the patient with classic scarlet fever, antibiotic therapy should be started immediately, but for the majority of patients, who present with much less distinctive findings, treatment should be withheld until there is laboratory confirmation by throat culture, molecular assay, or rapid antigen detection test.* Rapid antigen detection tests, because of their high degree of specificity, allow initiation of antibiotic therapy immediately for the patient with a positive test result.

GAS is exquisitely sensitive to penicillin and cephalosporins, and resistant strains have never been encountered. Penicillin or amoxicillin is therefore the drug of choice (except in patients who are allergic to penicillins) for pharyngeal infections and for suppurative complications. Oral penicillin V (250 mg/dose 2 or 3 times daily [bid-tid] for children weighing ≤60 lb and 500 mg/dose bid-tid for children >60 lb) is recommended but must be taken for a full 10 days, even though symptomatic improvement may occur within 2-3 days. Penicillin V (phenoxymethylpenicillin) is preferred over penicillin G, because it may be given without regard to mealtime. The major concern with all forms of oral therapy is the risk that the drug will be discontinued before the 10-day course has been completed. Therefore when oral treatment is prescribed, the necessity of completing a full course of therapy must be emphasized. If the parents seem unlikely to comply with oral therapy because of family disorganization, difficulties in comprehension, or other reasons, parenteral therapy with a single intramuscular (IM) injection of benzathine penicillin G (600,000 IU for children weighing ≤60 lb and 1.2 million IU for children >60 lb) is the most efficacious and often the most practical method of treatment. Disadvantages include soreness around the site of injection, which may last for several days, and potential for injection into nerves or blood vessels if not administered correctly. The local reaction is diminished when the refrigerated drug is warmed to room temperature and when benzathine penicillin G is combined in a single injection with procaine penicillin G, although it is necessary to ensure that an adequate dose of benzathine penicillin G is administered.

In several comparative clinical trials, once-daily amoxicillin (50 mg/kg, maximum: 1,000 mg) for 10 days has been demonstrated to be as effective in treating GAS pharyngitis as amoxicillin administered orally multiple times per day. This somewhat broader-spectrum agent has the advantage of once-daily dosing, which may enhance adherence. In addition, amoxicillin is relatively inexpensive and is considerably more palatable than penicillin V suspension.

A 10-day course of a narrow-spectrum oral cephalosporin is recommended for most **penicillin-allergic** individuals. It has been suggested that a 10-day course with an oral cephalosporin is superior to 10 days of oral penicillin in eradicating GAS from the pharynx. Analysis of these data suggests that the difference in eradication is mainly the result of a higher rate of eradication of GAS carriage included unintentionally in these clinical trials. Some penicillin-allergic persons (up to 10%) are also allergic to cephalosporins, and these agents should be avoided in patients with immediate (anaphylactic-type) hypersensitivity to penicillin. Most oral broad-spectrum cephalosporins are considerably more expensive than penicillin or amoxicillin and are more likely to select for antibiotic-resistant flora.

Oral clindamycin is an appropriate agent for treating penicillin-allergic patients, and resistance to clindamycin among GAS isolates in the United States is currently <6%. An oral macrolide (erythromycin or clarithromycin) or azalide (azithromycin) is also an appropriate agent for patients allergic to penicillins. Ten days of therapy is indicated except for azithromycin, which is given at 12 mg/kg on day 1 and then 6 mg/kg on days 2-5. Erythromycin is associated with substantially higher rates of gastrointestinal side effects than the other agents. In recent years, macrolide resistance rates among pharyngeal isolates of GAS in most areas of the United States have been approximately 5–10%. Sulfonamides and the tetracyclines are not recommended for treatment of GAS pharyngitis. However, studies showed that trimethoprim-sulfamethoxazole (TMP-SMX) is highly active in vitro against GAS and was comparable to IM penicillin for GAS impetigo in clinical trials.

Most oral antibiotics must be administered for the conventional 10 days to achieve maximal pharyngeal eradication rates of GAS and prevention of RF, but certain newer agents are reported to achieve comparable bacteriologic and clinical cure rates when given for ≤5 days. However, definitive results from comprehensive studies are not available to allow full evaluation of these proposed shorter courses of oral antibiotic therapy, which therefore cannot be recommended at this time. In addition, these antibiotics have a much broader spectrum than penicillin and are generally more expensive, even when administered for short courses.

The majority of patients with GAS pharyngitis respond clinically to antimicrobial therapy, and GAS is eradicated from the pharynx. Posttreatment throat cultures are indicated only in the relatively few patients who remain symptomatic, whose symptoms recur, or who have had RF or rheumatic heart disease and are therefore at unusually high risk for recurrence.

Treatment of GAS Skin Infections

Antibiotic therapy for a patient with nonbullous impetigo can prevent local extension of the lesions, spread to distant infectious foci, and transmission of the infection to others. However, the ability of antibiotic therapy to prevent poststreptococcal glomerulonephritis has not been definitively demonstrated. Patients with a few superficial, isolated lesions and no systemic signs can be treated with topical antibiotics. **Mupirocin** is a safe and effective agent that has become the topical treatment of choice. If there are widespread lesions or systemic signs, oral therapy with coverage for both GAS and *S. aureus* is needed. With the rapid emergence of methicillin-resistant *S. aureus* in many communities, one should consider using clindamycin alone or a combination

of TMP-SMX and amoxicillin as first-line therapy. Oral cefuroxime is an effective treatment of perianal streptococcal disease.

Treatment of Invasive GAS Infection

Theoretical considerations and experimental data suggest that intravenous clindamycin is a more effective agent for the treatment of severe, invasive GAS infections than IV penicillin. However, because approximately 4–6% of GAS isolates in the United States are resistant to clindamycin, clindamycin initially should be used in combination with penicillin for these infections until susceptibility to clindamycin has been established. If **necrotizing fasciitis** is suspected, immediate surgical exploration may be required to identify a deep soft tissue infection that should be debrided immediately. Patients with **streptococcal TSS** require rapid and aggressive fluid replacement, management of respiratory or cardiac failure, if present, and anticipatory management of multiorgan system failure. Limited data suggest that intravenous immune globulin (IVIG) is effective as adjunctive therapy in the management of streptococcal TSS.

COMPLICATIONS

Suppurative complications from the spread of GAS to adjacent structures were extremely common in the preantibiotic era. Cervical lymphadenitis, peritonsillar abscess, retropharyngeal abscess, otitis media, mastoiditis, and sinusitis still occur in children in whom the primary illness has gone unnoticed or in whom treatment of the pharyngitis has been inadequate. GAS pneumonia can also occur.

Acute rheumatic fever (see Chapter 229.1) and acute poststreptococcal **glomerulonephritis** (see Chapter 559.4) are both nonsuppurative sequelae of infections with GAS that occur after an asymptomatic latent period. These complications occur after the initial GAS infection resolves and involves sites distal to the initial GAS infection site. These sequelae are thought to be the result of the immune response and not of direct GAS infection. Acute RF and acute glomerulonephritis differ in their clinical manifestations, epidemiology, and potential morbidity. In addition, acute glomerulonephritis follows a GAS infection of either the upper respiratory tract or the skin, but acute RF is only proven to follow an infection of the upper respiratory tract. Some investigators have suggested that in some highly endemic areas, particularly in New Zealand and Australia, GAS skin infection may trigger acute RF, but this remains controversial.

PROGNOSIS

The prognosis for appropriately treated GAS pharyngitis is excellent, and complete recovery is the rule. When therapy is instituted within 9 days of the onset of symptoms and continued for the full course, acute RF is almost always prevented. There is no comparable evidence that acute poststreptococcal glomerulonephritis can be prevented once pharyngitis or pyoderma with a nephritogenic strain of GAS has occurred. In rare instances, particularly in neonates or in children whose response to infection is compromised, fulminant pneumonia, septicemia, and death may occur despite usually adequate therapy.

PREVENTION

The only specific indication for long-term use of an antibiotic to prevent GAS infections is for patients with a history of acute RF and/or rheumatic heart disease. Mass prophylaxis is generally not feasible except possibly to reduce the number of infections during epidemics of impetigo and to control epidemics of pharyngitis in military populations and in schools. Because the ability of antimicrobial agents to prevent GAS infections is limited, a group A streptococcal vaccine would offer the possibility of a more effective approach.

Several candidate vaccines are in development, including a 30-valent M protein–based recombinant vaccine, another recombinant vaccine that includes several conserved non–M protein epitopes that induce protective antibody, and an M-protein vaccine that includes an epitope in a highly conserved region of M protein to provide broad immunity. All these vaccines are in relatively early stages of development.

Poststreptococcal Reactive Arthritis

Poststreptococcal reactive arthritis (PSRA) describes a syndrome characterized by the onset of acute arthritis after an episode of GAS pharyngitis in a patient whose illness does not fulfill the Jones Criteria for diagnosis of acute RF. It is still unclear whether this entity represents a distinct syndrome or is a variant of acute RF. Although PSRA usually involves the large joints, similar to the arthritis of acute RF, it may also involve small peripheral joints and the axial skeleton and is typically nonmigratory, a characteristic distinct from the arthritis of acute RF. The latent period between the antecedent episode of GAS pharyngitis and PSRA may be considerably *shorter* (usually <10 days) than that typically seen with acute RF (usually 14-21 days). In contrast to the arthritis of acute RF, PSRA *does not* respond dramatically to therapy with aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs). In addition, fewer patients with PSRA than with acute RF have a temperature >38°C (100.4°F). Even though no more than half of PSRA patients with throat culture have GAS isolated, all have serologic evidence of a recent GAS infection. Because a very small proportion of patients with PSRA have been reported to develop valvular heart disease subsequently, these patients should be carefully observed for several months for clinical evidence of carditis. Some recommend that these patients receive secondary antistreptococcal prophylaxis for up to 1 year. If clinical evidence of carditis is not observed at that point, the prophylaxis can be discontinued. If valvular disease is detected, the patient should be classified as having had acute RF and should continue to receive secondary prophylaxis appropriate for RF patients.

Pediatric Autoimmune Neuropsychiatric Disorders Associated with *Streptococcus pyogenes*

Pediatric autoimmune neuropsychiatric disorders associated with *S. pyogenes* **(PANDAS)** is a term proposed for a group of neuropsychiatric disorders (originally obsessive-compulsive disorder [OCD], tic disorder, and Tourette syndrome, or only OCD or feeding abnormality) for which a possible relationship with GAS infections has been hypothesized (see Chapter 37). *This relationship has not been proved.* It has been proposed that this subset of patients with OCDs may produce autoimmune antibodies in response to a GAS infection that cross-react with brain tissue, similar to the autoimmune response believed to be responsible for the manifestations of **Sydenham chorea**. It has also been suggested that secondary prophylaxis that prevents recurrences of rheumatic fever, including Sydenham chorea, might also be effective in preventing exacerbations of OCDs in these patients, but clinical trials have not confirmed this. It has also been proposed that these patients may benefit from immunoregulatory therapy such as plasma exchange or IVIG, but these unproven modalities should only be used in a clinical research trial. That PANDAS may represent an extension of the spectrum of acute RF is intriguing, but it should be considered only as a yet-unproven hypothesis. Until carefully designed and well-controlled studies have established a causal relationship between neurobehavioral abnormalities and GAS infections, routine diagnostic laboratory testing for GAS and antistreptococcal antibodies, long-term antistreptococcal prophylaxis, or immunoregulatory therapy (e.g., IVIG, plasma exchange) to treat exacerbations of this disorder clearly are not recommended (see Chapter 37). It has also been suggested that a broad spectrum of infectious agents may have the ability to trigger exacerbations in children with these neurobehavioral disorders, which have been termed *pediatric acute-onset neuropsychiatric syndrome* (PANS), but this remains highly controversial.

229.1 Rheumatic Fever

Stanford T. Shulman and Ami B. Patel

See also Chapter 487.

Overwhelming evidence supports the link between antecedent GAS pharyngitis and **acute rheumatic fever** (RF) and **rheumatic heart disease**. As many as two thirds of patients with an acute episode of RF have a history of an upper respiratory tract infection several weeks before; the peak age and seasonal incidence of acute RF closely parallel that of GAS pharyngitis. Patients with acute RF almost always have serologic evidence of a recent GAS infection. Their antibody titers are usually *considerably higher* than those seen in patients with uncomplicated GAS infections. Outbreaks of GAS pharyngitis in closed communities, such as boarding schools or military bases, may be followed by community outbreaks of acute RF. Antimicrobial therapy that eliminates GAS from the pharynx also prevents initial episodes of acute RF, and long-term, continuous antibiotic prophylaxis that prevents GAS pharyngitis also prevents recurrences of acute RF.

Not all serotypes of GAS can cause RF. When some GAS strains (e.g., M type 4) caused acute pharyngitis in a very susceptible rheumatic population, there were no recurrences of RF. In contrast, episodes of pharyngitis caused by other serotypes in the same population led to frequent recurrences of acute RF, suggesting that the latter organisms were rheumatogenic. The concept of *rheumatogenicity* is further supported by the observation that although serotypes of GAS frequently associated with skin infection can be isolated also from the upper respiratory tract, they rarely cause recurrences of RF in individuals with a previous history of RF or first episodes of RF. In addition, certain serotypes of GAS (M types 1, 3, 5, 6, 18, and 29) are more frequently isolated from patients with acute RF than are other serotypes.

EPIDEMIOLOGY

The annual incidence of acute RF in some developing countries exceeds 50 per 100,000 children, and very high rates are also seen in ethnic minority populations within Australia and New Zealand. Worldwide, **rheumatic heart disease** remains the most common form of acquired heart disease in all age-groups, accounting for up to 50% of all cardiovascular disease and 50% of all cardiac admissions in many developing countries. Striking differences in the incidence of acute RF and rheumatic heart disease among different ethnic groups are often evident within the same country; these differences are partially related to differences in socioeconomic status, and there is a genetic basis for increased susceptibility.

In the United States at the beginning of the 20th century, acute RF was a leading cause of death among children and adolescents, with annual incidence rates of 100-200 per 100,000 population. In addition, rheumatic heart disease was a leading cause of heart disease among adults <40 years old. At that time, as many as 25% of pediatric hospital beds in the United States were occupied by patients with acute RF or its complications. By the 1940s, the annual incidence of acute RF had decreased to 50 per 100,000 population, and over the next 4 decades, the decline in incidence accelerated rapidly. By the early 1980s, the annual incidence in some areas of the United States was as low as 0.5 per 100,000 population, and rates of acute RF since the 1980s have declined substantially. This sharp decline in the incidence of acute RF has been observed in other industrialized countries as well.

The explanation for this dramatic decline in the incidence of acute RF and rheumatic heart disease in the United States and other industrialized countries is not clear but is likely related in large part to a *decline in circulating rheumatogenic strains causing acute pharyngitis*. Historically, acute RF was associated with poverty and overcrowding, particularly in urban areas. Much of the decline in the incidence of acute RF in industrialized countries during the preantibiotic era was probably the result of improved living conditions. Of the various manifestations of poverty, crowding, which facilitates the spread of GAS infections, is most closely associated with the incidence of acute RF. The decline in incidence of acute RF in industrialized countries over the past 4 decades is also attributable to the greater availability of medical care and to the widespread use of antibiotics. Antibiotic therapy of GAS pharyngitis is important in preventing initial attacks and, particularly, recurrences of the disease. In addition, the decline in the United States is attributed to a shift in the prevalent strains of GAS causing pharyngitis from mostly rheumatogenic to nonrheumatogenic.

Certain rheumatogenic serotypes (types 1, 3, 5, 6, and 18) that were isolated less often during the 1970s and early 1980s dramatically reappeared during rheumatic fever outbreaks, and their appearance in selected communities was probably a major factor. GAS that are associated with rheumatogenicity often form highly mucoid colonies on throat culture plates.

In addition to the specific characteristics of the infecting strain of GAS, the risk of developing acute RF also depends on various host factors. The incidence of both initial attacks and recurrences of acute RF peaks in children 5-15 years old, the age of greatest risk for GAS pharyngitis. Patients who have had an attack of acute RF tend to have recurrences, and the clinical features of the recurrences tend to mimic those of the initial attack. In addition, there appears to be a genetic predisposition to acute RF. Studies in twins show a higher concordance rate of acute RF in monozygotic than in dizygotic twin pairs. Preliminary studies from Oceania in a population with high rates of rheumatic heart disease have identified an allele of interest that increases one's risk of rheumatic heart disease.

PATHOGENESIS

The **cytotoxicity theory** suggests that a GAS toxin is involved in the pathogenesis of acute RF and rheumatic heart disease. GAS produces a number of enzymes that are cytotoxic for mammalian cardiac cells, such as streptolysin O, which has a direct cytotoxic effect on mammalian cells in tissue culture. A major problem with the cytotoxicity hypothesis is its inability to explain the substantial latent period (usually 10-21 days) between GAS pharyngitis and onset of acute RF.

An **immune-mediated pathogenesis** for acute RF and rheumatic heart disease has been suggested by its clinical similarity to other illnesses with an immunopathogenesis and by the latent period between the GAS infection and acute RF. The immunologic cross-reactivity of several GAS cellular and extracellular epitopes with cardiac antigenic epitopes also lends support to the hypothesis of molecular mimicry. Common epitopes are shared between certain GAS components (e.g., M protein, cell membrane, group A cell wall carbohydrate, capsular hyaluronate) and specific mammalian tissues (e.g., heart valve, sarcolemma, brain, joint).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The current **Jones Criteria**, as revised in 2015 by the American Heart Association (AHA), are intended for diagnosis of the *initial* attack of acute RF and *recurrent* attacks (Table 229.2). There are **five major and four minor criteria** and a requirement for evidence of recent GAS infection. The 2015 revision includes separate criteria for **low-risk populations** (defined as those with incidence ≤2 per 100,000 school-age children per year or all-age rheumatic heart disease prevalence of ≤1 per 1,000 population) and **moderate/high-risk populations** (defined as those with higher incidence or prevalence rates). Virtually all of the United States, Canada, and Western Europe are low-risk, whereas moderate/high-risk populations include Maoris in New Zealand, aborigines in Australia, Pacific Islanders, and most developing countries. Diagnosis of a first attack or recurrent attack of acute RF can be established when a patient fulfills **two major or one major and two minor criteria and has evidence of preceding GAS infection**. Diagnosis of recurrent acute RF can also be made only in the moderate/high-risk population by the presence of three minor criteria with evidence of preceding GAS infection. In the 2015 Jones Criteria, a major change from previous versions expands the definition of the major criterion **carditis** to include *subclinical evidence* (e.g., in the absence of a murmur, echocardiographic evidence of mitral regurgitation [MR] meeting specific criteria to distinguish physiologic from

Table 229.2 Guidelines for the Diagnosis of an Initial or Recurrent Attack of Rheumatic Fever (Jones Criteria, Updated 2015)[1–5]

MAJOR MANIFESTATIONS	MINOR MANIFESTATIONS	SUPPORTING EVIDENCE OF ANTECEDENT GROUP A STREPTOCOCCAL INFECTION
Carditis Polyarthritis Erythema marginatum Subcutaneous nodules Chorea	**Clinical features:** Arthralgia Fever **Laboratory features:** Elevated acute-phase reactants: Erythrocyte sedimentation rate C-reactive protein Prolonged P-R interval	Positive throat culture or rapid streptococcal antigen test Elevated or increasing streptococcal antibody titer

[1]**Initial attack**: Two major manifestations or one major and two minor manifestations plus evidence of recent GAS infection. **Recurrent attack**: Two major, or one major and two minor, or three minor manifestations (the latter only in the moderate/high-risk population), plus evidence of recent GAS infection (see text).
[2]**Low-risk population** is defined as acute rheumatic fever (ARF) incidence <2 per 100,000 school-age children per year or all-age rheumatic heart disease (RHD) prevalence of <1 per 1,000 population. **Moderate/high-risk population** is defined as ARF incidence >2 per 100,000 school-age children per year or all-age RHD prevalence of >1 per 1,000 population.
[3]Carditis is now defined as clinical and/or subclinical (echocardiographic valvulitis). See Table 229.3.
[4]Arthritis (major) refers only to polyarthritis in low-risk populations but also to monoarthritis or polyarthralgia in moderate/high-risk populations.
[5]Minor criteria for moderate/high-risk populations only include monoarthralgia (polyarthralgia for low-risk populations), fever of >38°C (>38.5°C in low-risk populations), and ESR >30 mm/hr (>60 mm/hr in low-risk populations).
From Gewitz MH, Baltimore RS, Tani LY, et al. Revision of the Jones Criteria for the diagnosis of acute rheumatic fever in the era of Doppler echocardiography: a scientific statement from the American Heart Association. *Circulation*. 2015;131(20):1806–1818.

pathologic MR) (see Table 487.1). Areas in which the Jones Criteria differ in low-risk from moderate/high-risk populations relate to the major criterion of **arthritis** and the minor criteria of arthralgia, definition of fever, and elevated inflammatory markers (see Table 229.2 and text that follows). These changes are designed to make it easier to fulfill the Jones Criteria in patients from moderate/high-risk populations. Even with strict application of the criteria, overdiagnosis and underdiagnosis of acute RF may occur. The diagnosis of acute RF can be made without strict adherence to the Jones Criteria in three circumstances: (1) when chorea occurs as the only major manifestation of acute RF, (2) when indolent carditis is the only manifestation in patients who first come to medical attention only months after the apparent onset of acute RF, and (3) in a limited number of patients with recurrence of acute RF in particularly high-risk populations.

The Five Major Criteria

Migratory Polyarthritis

Arthritis occurs in approximately 75% of patients with acute RF and typically involves larger joints, particularly the knees, ankles, wrists, and elbows. Involvement of the spine, small joints of the hands and feet, or hips is uncommon. Rheumatic joints are classically hot, red, swollen, and exquisitely tender, with even the friction of bedclothes being uncomfortable. The pain can precede and can appear to be disproportionate to the objective findings. The joint involvement is characteristically migratory in nature; that is, a severely inflamed joint can become normal within 1-3 days without treatment, even as one or more other large joints become involved. Severe arthritis can persist for several weeks in untreated patients. Monoarticular arthritis is unusual unless antiinflammatory therapy is initiated prematurely, aborting the progression of the migratory polyarthritis. If a child with fever and arthritis is suspected to have acute RF, it is frequently useful to withhold antiinflammatory medications like salicylates or NSAIDs and observe for migratory progression. A dramatic response to even low doses of salicylates is another characteristic feature of the arthritis, and the absence of such a response should suggest an alternative diagnosis.

Rheumatic arthritis is almost never deforming. Synovial fluid in acute RF usually has 10,000-100,000 white blood cells/μL with a predominance of neutrophils, protein level of approximately 4 g/dL, normal glucose level, and formation of a good mucin clot. Frequently, arthritis is the earliest manifestation of acute RF and may correlate temporally with peak antistreptococcal antibody titers. There is often an inverse relationship between the severity of arthritis and the severity of cardiac involvement. In moderate/high-risk populations only, monoarthritis in the absence of prior inflammatory therapies, or even polyarthralgia without frank objective signs of arthritis, can fulfill this major criterion. Before **polyarthralgia** should be considered a major criterion in the moderate/high-risk population, other potential causes should be excluded.

Carditis

A major change in the 2015 revision of the Jones Criteria is the acceptance of **subclinical carditis** (defined as without a murmur of valvulitis but with echocardiographic evidence of valvulitis) or **clinical carditis** (with a valvulitis murmur) as fulfilling the major criterion of carditis in all populations. The echocardiographic features of subclinical carditis must meet those included in Table 487.1 in Chapter 487 to distinguish pathologic from physiologic degrees of valve regurgitation. Silent or latent rheumatic heart disease describes echocardiographic evidence of rheumatic heart disease in individuals with no known history of acute RF and no clinical symptoms. In endemic regions, active surveillance via screening echocardiography has emerged as a potential strategy to detect *asymptomatic subclinical* rheumatic heart disease.

Carditis and resultant chronic rheumatic heart disease are the most serious manifestations of acute RF and account for essentially all the associated morbidity and mortality. Rheumatic carditis is characterized by **pancarditis**, with active inflammation of the myocardium, pericardium, and endocardium (see Chapter 487). Cardiac involvement during acute RF varies in severity from fulminant, potentially fatal exudative pancarditis to mild, transient cardiac involvement. **Endocarditis** (valvulitis) is a universal finding in rheumatic carditis, whereas the presence of pericarditis or myocarditis is variable. Myocarditis and/or pericarditis without clinical evidence of endocarditis almost never is rheumatic carditis; alternative etiologies (especially viral) need to be sought. Most rheumatic heart disease is isolated mitral valvular disease or combined aortic and mitral valvular disease. Isolated aortic or right-sided valvular involvement is quite uncommon. Serious and long-term illness is related entirely to the severity of valvular heart disease as a consequence of a single attack or recurrent attacks of acute RF. Valvular insufficiency is characteristic of both acute and convalescent stages of acute RF, whereas mitral and/or aortic valvular stenosis usually appears years or even decades after the acute illness. However, in developing countries, where acute RF often occurs at a younger age, mitral stenosis and aortic stenosis may develop sooner after acute RF than in developed countries and can occur in young children.

Acute rheumatic carditis usually presents as tachycardia and cardiac murmurs, with or without evidence of myocardial or pericardial

involvement. Moderate to severe rheumatic carditis can result in cardiomegaly and heart failure with hepatomegaly and peripheral and pulmonary edema. Echocardiographic findings include pericardial effusion, decreased ventricular contractility, and aortic and/or mitral regurgitation. **Mitral regurgitation** is characterized typically by a high-pitched apical holosystolic murmur radiating to the axilla. In patients with significant MR, this may be associated with an apical mid-diastolic murmur of relative mitral stenosis. Aortic insufficiency is characterized by a high-pitched decrescendo diastolic murmur at the left sternal border.

Carditis occurs in approximately 50–60% of all cases of acute RF. Recurrent attacks of acute RF in patients who had carditis with their initial attack are associated with high rates of carditis with increasing severity of cardiac disease. The major consequence of acute rheumatic carditis is chronic, progressive valvular disease, particularly valvular stenosis, which can require surgical intervention.

Chorea

Sydenham chorea occurs in approximately 10–15% of patients with acute RF and usually presents as an isolated, frequently subtle, movement disorder. Emotional lability, incoordination, poor school performance, uncontrollable movements, and facial grimacing are characteristic, all *exacerbated* by stress and *disappearing* with sleep. Chorea occasionally is unilateral (hemichorea). The latent period from acute GAS infection to chorea is usually substantially longer than for arthritis or carditis and can be months. The onset can be insidious, with symptoms being present for several months before recognition. Clinical maneuvers to elicit features of chorea include (1) demonstration of *milkmaid's grip* (irregular contractions and relaxations of the muscles of the fingers while squeezing the examiner's fingers), (2) spooning and pronation of the hands when the patient's arms are extended, (3) wormian darting movements of the tongue on protrusion, and (4) examination of handwriting to evaluate fine motor movements. Diagnosis is based on clinical findings with supportive evidence of GAS antibodies. However, in the usual patient with a long latent period from the inciting streptococcal infection to onset of chorea, antibody levels have often declined to normal. Although the acute illness is distressing, chorea rarely, if ever, leads to permanent neurologic sequelae.

Erythema Marginatum

Erythema marginatum is a rare (approximately 1% of patients with acute RF) but characteristic rash of acute RF. It consists of erythematous, serpiginous, macular lesions with pale centers that are not pruritic (Fig. 229.2). It occurs primarily on the trunk and extremities, but not on the face, and it can be accentuated by warming the skin.

Fig. 229.2 Polycyclic red borders of erythema marginatum in a febrile child with acute rheumatic fever. *(From Schachner LA, Hansen RC, eds. Pediatric Dermatology, 3rd ed. Philadelphia: Mosby; 2003:808.)*

Subcutaneous Nodules

Subcutaneous nodules are a rare (≤1% of patients with acute RF) finding and consist of firm nodules approximately 0.5-1 cm in diameter along the extensor surfaces of tendons near bony prominences. There is a correlation between the presence of these nodules and significant rheumatic heart disease.

Minor Criteria

These are more *nonspecific* than major criteria, and the 2015 revised Jones Criteria have included some changes from the previous criteria. The first of the two clinical **minor criteria** involve joint manifestations (only if arthritis is not used as a major criterion) and is defined as *polyarthralgia* in low-risk populations and *monoarthralgia* in moderate/high-risk populations. The second clinical minor manifestation is fever, defined as *at least 38.5°C* in low-risk populations and *at least 38.0°C* in moderate/high-risk populations. The two laboratory minor criteria are (1) elevated acute-phase reactants, defined as erythrocyte sedimentation rate (ESR) at least 60 mm/hr and/or C-reactive protein (CRP) at least 3.0 mg/dL (30 mg/L) in low-risk populations and ESR at least 30 mm/hr and/or CRP at least 3.0 mg/dL (30 mg/L) in moderate/high-risk populations and (2) prolonged P-R interval on ECG (unless carditis is a major criterion). However, a prolonged P-R interval alone does not constitute evidence of carditis or predict long-term cardiac sequelae.

Recent Group A *Streptococcus* Infection

An absolute requirement for the diagnosis of acute RF is supporting evidence of a recent GAS infection. Acute RF typically develops 10-21 days after an acute episode of GAS pharyngitis at a time when clinical findings of pharyngitis are no longer present and when only 10–20% of patients still harbor GAS in the throat. One third of patients with acute RF have no history of an antecedent clinically symptomatic pharyngitis. Therefore evidence of an antecedent GAS infection is usually based on elevated or rising serum antistreptococcal antibody titers. If only a single antibody is measured (usually anti–streptolysin O), only 80–85% of patients with acute RF have an elevated titer; however, 95–100% have an elevation if three different antibodies (anti–streptolysin O, anti–DNase B, anti-hyaluronidase) are measured. Therefore when acute RF is suspected clinically, multiple antibody tests should be performed. Except for chorea, the clinical findings of acute RF generally coincide with peak antistreptococcal antibody responses. Most patients with chorea have elevation of antibodies to at least one GAS antigen. However, in patients with a long latent period from the inciting GAS infection, antibody levels may have declined to within the normal range. The diagnosis of acute RF should *not* be made in those patients with elevated or increasing streptococcal antibody titers who do not fulfill the Jones Criteria.

Differential Diagnosis

The differential diagnosis of RF includes many infectious and noninfectious illnesses (Table 229.3). When children present with arthritis, a collagen vascular disease must be considered. **Juvenile idiopathic arthritis** (JIA) must be distinguished from acute RF. Children with JIA tend to be younger and usually have less joint pain relative to their other clinical findings than those with acute RF. Spiking fevers, nonmigratory arthritis, lymphadenopathy, and splenomegaly are more suggestive of JIA than acute RF. The response to salicylate therapy is also much less dramatic with JIA than with acute RF. **Systemic lupus erythematosus** (SLE) can usually be distinguished from acute RF by antinuclear antibodies in SLE. Other causes of arthritis such as pyogenic arthritis, malignancies, serum sickness, Lyme disease, sickle cell disease, and reactive arthritis related to gastrointestinal infections (e.g., *Shigella, Salmonella, Yersinia*) should also be considered. Poststreptococcal reactive arthritis is discussed earlier (see Chapter 229).

When **carditis** is the sole major manifestation of suspected acute RF, viral myocarditis, viral pericarditis, Kawasaki disease, and infective endocarditis should also be considered. Patients with infective

Table 229.3 Differential Diagnosis of Acute Rheumatic Fever

ARTHRITIS	CARDITIS	CHOREA
Juvenile idiopathic arthritis	Viral myocarditis	Huntington chorea
Reactive arthritis (e.g., *Shigella, Salmonella, Yersinia*)	Viral pericarditis	Wilson disease
Serum sickness	Infective endocarditis	Systemic lupus erythematosus
Sickle cell disease	Kawasaki disease	Tic disorder
Malignancy	Congenital heart disease	Hyperactivity
Systemic lupus erythematosus	Mitral valve prolapse	Encephalitis (infectious or autoimmune)
Lyme disease (*Borrelia burgdorferi*)	Innocent murmurs	
Pyogenic arthritis	MIS-C	
Poststreptococcal reactive arthritis	Lyme disease	

MIS-C, Multisystem inflammatory syndrome in children (COVID-19).

endocarditis may present with both joint and cardiac manifestations. These patients can usually be distinguished from patients with acute RF by blood cultures and the presence of extracardiac findings (e.g., hematuria, splenomegaly, splinter hemorrhages). When **chorea** is the sole major manifestation of suspected acute RF, Huntington chorea, Wilson disease, SLE, and various encephalitides should also be considered.

TREATMENT

All patients with acute RF should be placed on bed rest and monitored closely for evidence of **carditis**. They can be allowed to ambulate when the signs of acute inflammation have improved. However, patients with carditis require longer periods of bed rest.

Antibiotic Therapy

Once the diagnosis of acute RF has been established and regardless of the throat culture results, the patient should receive 10 days of orally administered penicillin or amoxicillin or a single IM injection of benzathine penicillin to ensure eradication of GAS from the upper respiratory tract. If penicillin allergic, 10 days of erythromycin, 5 days of azithromycin, or 10 days of clindamycin is indicated. After this initial course of antibiotic therapy, long-term antibiotic prophylaxis for secondary prevention should be instituted (see later).

Antiinflammatory Therapy

Antiinflammatory agents (e.g., salicylates, corticosteroids) should be withheld if arthralgia or atypical arthritis is the only clinical manifestation of presumed acute RF. Premature treatment with one of these agents may interfere with the development of the characteristic migratory polyarthritis and thus obscure the diagnosis of acute RF. Acetaminophen can be used to control pain and fever while the patient is being observed for more definite signs of acute RF or for evidence of another disease.

Patients with typical migratory polyarthritis and those with carditis without cardiomegaly or congestive heart failure should be treated with oral salicylates. The usual dose of aspirin is 50-70 mg/kg/day in four divided doses orally (PO) for 3-5 days, followed by 50 mg/kg/day in four divided doses PO for 2-3 weeks and half that dose for another 2-4 weeks. Determination of the serum salicylate level is not necessary unless the arthritis does not respond or signs of salicylate toxicity (tinnitus, hyperventilation) develop. There is no evidence that NSAIDs are more effective than salicylates.

Patients with carditis and more than minimal cardiomegaly and/or congestive heart failure should receive corticosteroids. The usual dose of prednisone is 2 mg/kg/day in four divided doses for 2-3 weeks, followed by half the dose for 2-3 weeks, and then tapering of the dose by 5 mg/24 hr every 2-3 days. When prednisone is being tapered, aspirin should be started at 50 mg/kg/day in four divided doses for 6 weeks to prevent rebound of inflammation. Supportive therapies for patients with moderate to severe carditis include digoxin, fluid and salt restriction, diuretics, and oxygen. The cardiac toxicity of digoxin is enhanced with myocarditis.

Termination of the antiinflammatory therapy may be followed by the reappearance of clinical manifestations or of elevation in ESR and CRP (rebound). It may be prudent to increase salicylates or corticosteroids until near-normalization of inflammatory markers is achieved.

Sydenham Chorea

Because chorea often occurs as an isolated manifestation after the resolution of the acute phase of the disease, antiinflammatory agents are usually not indicated. Sedatives may be helpful early in the course of chorea; phenobarbital (16-32 mg every 6-8 hours PO) is the drug of choice. If phenobarbital is ineffective, haloperidol (0.01-0.03 mg/kg/24 hr divided twice daily PO) or chlorpromazine (0.5 mg/kg every 4-6 hours PO) should be initiated. Some patients may benefit from a few-week course of corticosteroids.

COMPLICATIONS

The arthritis and chorea of acute RF resolve completely without sequelae. Therefore the long-term sequelae of RF are essentially limited to the heart (see Chapter 487).

The AHA has published updated recommendations regarding the use of prophylactic antibiotics to prevent infective endocarditis (see Chapter 486). The AHA recommendations no longer suggest routine endocarditis prophylaxis for patients with rheumatic heart disease who are undergoing dental or other procedures. However, the maintenance of optimal oral healthcare remains an important component of an overall healthcare program. For the relatively few patients with rheumatic heart disease in whom infective endocarditis prophylaxis remains recommended, such as those with a prosthetic valve or prosthetic material used in valve repair, the current AHA recommendations should be followed (see Chapter 486). These recommendations advise using an agent other than a penicillin to prevent infective endocarditis in those receiving penicillin prophylaxis for RF because oral α-hemolytic streptococci are likely to have developed resistance to penicillin.

PROGNOSIS

The prognosis for patients with acute RF depends on the clinical manifestations present at the initial episode, the severity of the initial episode, and the prevention of recurrences. Approximately 50–70% of patients with carditis during the initial episode of acute RF recover with no residual heart disease; the more severe the initial cardiac involvement, the greater the risk for residual heart disease. Patients without carditis during the initial episode are less likely to have carditis with recurrent attacks, but there is a stepwise increase in cardiac involvement as the number of episodes increases. In contrast, patients with carditis during the initial episode are very likely to have carditis with recurrences, and the risk for permanent heart damage increases with each recurrence. Patients who have had acute RF are susceptible to recurrent attacks after reinfection of the upper respiratory tract with GAS, with approximately 50% risk with each GAS pharyngitis. Therefore these patients require long-term continuous chemoprophylaxis.

Table 229.4 Chemoprophylaxis for Recurrences of Acute Rheumatic Fever (Secondary Prophylaxis)

DRUG	DOSE	ROUTE
Penicillin G benzathine	600,000 IU for children weighing ≤60 lb and 1.2 million IU for children >60 lb, every 4 wk*	Intramuscular
or		
Penicillin V	250 mg, twice daily	Oral
or		
Sulfadiazine or sulfisoxazole	500 mg once daily for patients weighing ≤60 lb	Oral
	1000 mg once daily for patients weighing >60 lb	
FOR PEOPLE WHO ARE ALLERGIC TO PENICILLIN AND SULFONAMIDE DRUGS		
Macrolide or azalide	Variable	Oral

*In high-risk situations, administration every 3 wk is recommended.
Adapted from Gerber MA, Baltimore RS, Eaton CB, et al. Prevention of rheumatic fever and diagnosis and treatment of acute streptococcal pharyngitis: a scientific statement from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee of the Council on Cardiovascular Disease in the Young. *Circulation*. 2009;119:1541–1551.

Before antibiotic prophylaxis was available, 75% of patients who had an initial episode of acute RF had one or more recurrences in their lifetime. These recurrences were a major source of morbidity and mortality. The risk of recurrence is highest in the first 5 years after the initial episode and decreases with time.

Approximately 20% of patients who present with isolated chorea who are not given secondary prophylaxis develop rheumatic heart disease within 20 years. Therefore patients with chorea, even in the absence of other manifestations of RF, require long-term antibiotic prophylaxis (Table 229.4).

PREVENTION

Prevention of both initial and recurrent episodes of acute RF depends on controlling GAS infections of the upper respiratory tract. Prevention of initial attacks **(primary prevention)** depends on identification and eradication of GAS causing acute pharyngitis. A New Zealand study in a population with very high rates of acute RF showed that a school-based GAS pharyngitis screening and management program using oral amoxicillin substantially decreased pharyngeal GAS prevalence and rates of acute RF. Individuals who have already suffered an attack of acute RF are particularly susceptible to recurrences of RF with any subsequent GAS upper respiratory tract infection, whether or not they are symptomatic. Therefore these patients should receive continuous antibiotic prophylaxis to prevent recurrences **(secondary prevention)**.

Primary Prevention

Appropriate antibiotic therapy instituted before the ninth day of symptoms of acute GAS pharyngitis is highly effective in preventing the first attacks of acute RF. However, approximately 30% of patients with acute RF do not recall a preceding episode of pharyngitis and did not seek therapy.

Secondary Prevention

Secondary prevention is directed at preventing acute GAS pharyngitis in patients at substantial risk of recurrent acute RF. Secondary prevention requires continuous antibiotic prophylaxis, which should begin as soon as the diagnosis of acute RF has been made and immediately after a full course of antibiotic therapy has been completed. Because patients who have had carditis with their initial episode of acute RF are at higher risk for having carditis with recurrences and for sustaining additional cardiac damage, they should receive long-term antibiotic prophylaxis well into adulthood and perhaps for life (see Table 229.4 and Table 229.5).

Patients who did not have carditis with their initial episode of acute RF have a relatively low risk for carditis with recurrences. Antibiotic prophylaxis should continue in these patients until the patient reaches 21 years of age or until 5 years have elapsed since the last RF attack, whichever is longer. The decision to discontinue prophylactic antibiotics should be made only after careful consideration of potential risks and benefits and of epidemiologic factors such as the risk for exposure to GAS infections.

Table 229.5 Duration of Prophylaxis for People Who Have Had Acute Rheumatic Fever: AHA Recommendations

CATEGORY	DURATION
Rheumatic fever without carditis	5 yr or until 21 yr of age, whichever is longer
Rheumatic fever with carditis but without residual heart disease (no valvular disease*)	10 yr or until 21 yr of age, whichever is longer
Rheumatic fever with carditis and residual heart disease (persistent valvular disease*)	10 yr or until 40 yr of age, whichever is longer; sometimes lifelong prophylaxis

*Clinical or echocardiographic evidence.
Adapted from Gerber MA, Baltimore RS, Eaton CB, et al. Prevention of rheumatic fever and diagnosis and treatment of acute streptococcal pharyngitis: a scientific statement from the American Heart Association (AHA) Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee of the Council on Cardiovascular Disease in the Young. *Circulation*. 2009;119:1541–1551.

The regimen of choice for secondary prevention is a single IM injection of benzathine penicillin G (600,000 IU for children weighing ≤60 lb and 1.2 million IU for those >60 lb) every 4 weeks (see Table 229.4). In certain high-risk patients and in certain areas of the world where the incidence of RF is particularly high, use of benzathine penicillin G every 3 weeks may be necessary because serum concentrations of penicillin may decrease to marginally effective levels after 3 weeks. In the United States, administration of benzathine penicillin G every 3 weeks is recommended only for those who have recurrent acute RF despite adherence to a 4-week regimen. In compliant patients, continuous oral antimicrobial prophylaxis can be used. Penicillin V (250 mg twice daily) and sulfadiazine or sulfisoxazole (500 mg for those weighing ≤60 lb or 1,000 mg for those >60 lb, once daily) are equally effective when used in such patients. For the exceptional patient who is allergic to both penicillin and sulfonamides, a macrolide (erythromycin or clarithromycin) or azalide (azithromycin) may be used. Table 229.5 notes the duration of secondary prophylaxis.

Chapter 230

Group B *Streptococcus*

Thomas A. Hooven

Group B *Streptococcus* **(GBS)**, or *Streptococcus agalactiae,* is a major cause of **neonatal bacterial sepsis** worldwide. Although advances in prevention strategies have led to a decline in the incidence of neonatal disease, GBS remains a dangerous pathogen for neonates, pregnant women, and nonpregnant adults.

ETIOLOGY

Group B streptococci are facultative, anaerobic, gram-positive cocci that form chains or diplococci in broth and small, gray-white or orange-tinged colonies on solid medium. GBS is definitively identified by demonstration of the Lancefield group B carbohydrate antigen, such as with latex agglutination techniques widely used in clinical laboratories. Presumptive identification can be established on the basis of a narrow zone of β-hemolysis on blood agar, resistance to bacitracin and trimethoprim-sulfamethoxazole (TMP-SMX), lack of hydrolysis of bile esculin, and elaboration of CAMP factor (named for the discoverers, Christie, Atkins, and Munch-Petersen), an extracellular protein that, in the presence of the β toxin of *Staphylococcus aureus,* produces a zone of enhanced hemolysis on sheep blood agar. Individual GBS strains are serologically classified according to the presence of one of the structurally distinct capsular polysaccharides, which are important virulence factors and stimulators of antibody-associated immunity. Ten GBS capsular types have been identified: types Ia, Ib, II, III, IV, V, VI, VII, VIII, and IX.

EPIDEMIOLOGY

GBS emerged as a prominent neonatal pathogen in the late 1960s. For the next 2 decades, the incidence of neonatal GBS disease remained fairly constant, affecting 1.0-5.4 per 1,000 liveborn infants in the United States. Two patterns of disease were seen: **early-onset disease**, which presents at <7 days of age, and **late-onset disease**, which presents at ≥7 days of age. Since the early 1990s, widespread implementation of **maternal intrapartum antibiotic prophylaxis** has led to a striking decrease in the incidence of early-onset neonatal GBS disease in the United States, from 1.7 to 0.19 per 1,000 live births in recent years. This strategy has *not* had a significant effect on the incidence of late-onset disease, which has remained stable at approximately 0.3-0.4 per 1,000 live births (Fig. 230.1). The incidence of neonatal GBS disease is higher in premature and low birthweight infants, although most cases occur in full-term infants. Rates of both early- and late-onset disease are higher in Black infants.

Colonization by GBS in healthy adults is common. Vaginal or rectal colonization occurs in up to approximately 30% of pregnant women and is the usual source for GBS transmission to newborn infants. In the absence of maternal antibiotic prophylaxis, approximately 50% of infants born to colonized women acquire GBS colonization, and 1–2% of infants born to colonized mothers develop early-onset disease. Heavy maternal colonization increases the risk for infant colonization and development of early-onset disease. Additional risk factors for early-onset disease include prolonged rupture of membranes, intrapartum fever, prematurity, maternal bacteriuria during pregnancy, and previous delivery of an infant who developed GBS disease. Risk factors for late-onset disease are less well defined. Whereas late-onset disease may follow vertical transmission, horizontal acquisition from nursery or other community sources (such as family, healthcare providers, or environmental exposure) has also been described.

GBS is also an important cause of invasive disease in adults. GBS may cause urinary tract infections, bacteremia, endometritis, chorioamnionitis, and wound infection in pregnant and parturient women. In nonpregnant adults, especially those with underlying medical conditions such as diabetes mellitus, cirrhosis, or malignancy, GBS may cause serious infections such as bacteremia, skin and soft tissue infections, bone and joint infections, endocarditis, pneumonia, and meningitis. In the era of maternal chemoprophylaxis, most invasive GBS infections occur in nonpregnant adults. Unlike neonatal disease, the incidence of invasive GBS disease in adults has increased substantially, roughly tripling between 1990 and 2016.

The serotypes most frequently associated with neonatal GBS disease are types Ia, III, and V. Strains of serotype III are the most common subtype isolated from colonized pregnant women and are also the most frequent cause of invasive disease among newborns and adults. Global epidemiologic studies have revealed regional variation in subtype prevalence, some of which may reflect local dietary and healthcare practices.

PATHOGENESIS

A major risk factor for the development of early-onset neonatal GBS infection is maternal vaginal or rectal colonization by GBS. Infants acquire GBS by ascending infection or during passage through the birth canal. Fetal aspiration of infected amniotic fluid may occur. The incidence of early-onset GBS infection increases with the duration of rupture of membranes. Infection may also occur through transcellular passage across intact membranes. In cases of late-onset infection, GBS may be vertically transmitted or acquired later from maternal or nonmaternal sources.

Several bacterial factors are implicated in the pathogenesis of invasive GBS disease, primarily the type-specific **capsular polysaccharide**. Strains that are associated with invasive disease in humans elaborate more capsular polysaccharide than do colonizing isolates. All GBS capsular polysaccharides are high molecular weight polymers composed of repeating oligosaccharide subunits that include a short side chain terminating in *N*-acetylneuraminic acid **(sialic acid)**. Studies of type III GBS show that the sialic acid component of the capsular polysaccharide prevents activation of the alternative complement pathway in the absence of type-specific antibody. Sialylated capsular polysaccharide on the GBS surface also interacts with sialic acid–binding lectins or siglecs on human leukocytes to dampen inflammatory gene activation. Thus the capsular polysaccharide appears to exert a virulence effect by protecting the organism from opsonophagocytosis in the nonimmune host and by downregulating leukocyte activation. In addition, type-specific virulence attributes are suggested by the fact that type III strains are implicated in most cases of late-onset neonatal GBS disease and meningitis. Type III strains are taken up by brain endothelial cells

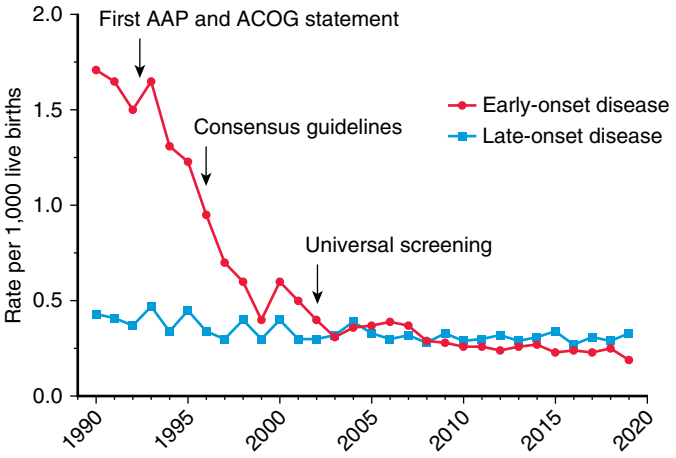

Fig. 230.1 Incidence of early- and late-onset invasive group B streptococcal (GBS) disease–active bacterial core surveillance areas, 1990-2019, and activities for prevention of GBS disease. AAP, American Academy of Pediatrics; ACOG, American College of Obstetricians and Gynecologists. *(Adapted from Jordan HT, Farley MM, Craig A, et al. Revisiting the need for vaccine prevention of late-onset neonatal group B streptococcal disease: a multistate, population-based analysis. Pediatr Infect Dis J. 2008;27:1057–1064.)*

more efficiently in vitro than are strains of other serotypes, although studies using acapsular mutant strains demonstrate that the capsule by itself does not facilitate cellular invasion. A single clade of type III GBS is highly associated with late-onset disease and meningitis. This clonal group, ST-17, produces a surface-anchored protein called *hypervirulent GBS adhesin* **(HvgA)** that is not present in other GBS isolates. HvgA contributes to GBS adherence to intestinal and endothelial cells and mediates invasion into the central nervous system (CNS) in an experimental infection model in mice. Other putative GBS virulence factors include GBS surface proteins, which may play a role in adhesion to host cells; C5a peptidase, which is postulated to inhibit the recruitment of polymorphonuclear cells to sites of infection; β-hemolysin/cytolysin, which has been associated with cell injury in vitro; and hyaluronidase, which has been postulated to act as a spreading factor in host tissues.

In a classic study of pregnant women colonized with type III GBS, those who gave birth to healthy infants had higher levels of capsular polysaccharide-specific antibody than those who gave birth to infants who developed invasive disease. In addition, there is a high correlation between antibody titer to GBS type III in the mother and titer in the paired infants. These observations indicate that transplacental transfer of maternal antibody is critically involved in neonatal immunity to GBS. Optimal immunity to GBS also requires an intact complement system. The classical complement pathway is an important component of GBS immunity in the absence of specific antibody; in addition, antibody-mediated opsonophagocytosis may proceed by the alternative complement pathway. These and other results indicate that anticapsular antibody can overcome the prevention of C3 deposition on the bacterial surface by the sialic acid component of the type III capsule.

The precise steps between GBS colonization and invasive disease remain unclear. In vitro studies showing GBS entry into alveolar epithelial cells and pulmonary vasculature endothelial cells suggest that GBS may gain access to the bloodstream by invasion from the alveolar space, perhaps after intrapartum aspiration of infected amniotic fluid. β-hemolysin/cytolysin may facilitate GBS entry into the bloodstream after inoculation into the lungs. Other studies have demonstrated intestinal GBS colonization preceding invasive disease among newborns, suggesting translocation across the intestinal wall as a pathogenic mechanism.

GBS induces the release of proinflammatory cytokines. The group B antigen and the peptidoglycan component of the GBS cell wall are potent inducers of tumor necrosis factor-α release in vitro, whereas purified type III capsular polysaccharide is not. Even though the capsule plays a central role in virulence through avoidance of immune clearance, the capsule does not directly contribute to cytokine release and the resultant inflammatory response.

The complete genome sequences of hundreds of GBS strains have been reported, facilitating a genomic approach to better understanding GBS. Analysis of these sequences shows that GBS is closely related to *Streptococcus pyogenes* and *Streptococcus pneumoniae.* Many known and putative GBS virulence genes are clustered in the genome in pathogenicity islands that also contain mobile genetic elements, suggesting that interspecies acquisition of genetic material plays an important role in genetic diversity.

CLINICAL MANIFESTATIONS

Two syndromes of neonatal GBS disease are distinguishable on the basis of age at presentation, epidemiologic characteristics, and clinical features (Table 230.1). **Early-onset neonatal GBS disease** presents within the first 6 days of life and is often associated with maternal obstetric complications, including chorioamnionitis, prolonged rupture of membranes, and premature labor. Infants may appear ill at the time of delivery, and most infants become ill within 24 hours of birth. In utero infection may result in septic abortion or immediate distress after birth. More than 80% of early-onset GBS disease presents as sepsis; pneumonia and meningitis are other common manifestations. Asymptomatic bacteremia is uncommon but can occur. In symptomatic patients, nonspecific signs such as hypothermia or fever, irritability, lethargy, apnea, and bradycardia may be present. Respiratory signs are prominent regardless of the presence of pneumonia and include cyanosis, apnea, tachypnea, grunting, flaring, and retractions. A fulminant course with hemodynamic abnormalities, including tachycardia, acidosis, and shock, may ensue. Persistent fetal circulation may develop. Clinically and radiographically, pneumonia associated with early-onset GBS disease is difficult to distinguish from **respiratory distress syndrome**. Patients with meningitis often present with nonspecific findings as described for sepsis or pneumonia, with more specific signs of CNS involvement initially absent.

Late-onset neonatal GBS disease presents at ≥7 days of life. Most cases occur within the first 3 months of life, but later presentations are also possible. Like early-onset disease, late-onset illness usually manifests as bacteremia (45–65%), often accompanied by meningitis (25–35%). Focal infections involving bone and joints, skin and soft tissue, the urinary tract, or lungs may also be seen. Cellulitis and adenitis are often localized to the submandibular or parotid regions. In contrast to early-onset disease, maternal obstetric complications are not risk factors for the development of late-onset GBS disease. Infants with late-onset disease are often less severely ill on presentation than infants with early-onset disease, and the disease is often less fulminant.

Invasive GBS disease in children beyond early infancy is uncommon. Bacteremia without a focus is the most common syndrome associated with childhood GBS disease beyond early infancy. Focal infections may include meningitis, pneumonia, endocarditis, and bone and joint infections.

DIAGNOSIS

A major challenge is distinguishing between respiratory distress syndrome and invasive neonatal GBS infection in preterm infants because the two illnesses share clinical and radiographic features. Severe apnea, early onset of shock, abnormalities in the peripheral leukocyte count, and greater lung compliance may be more likely in infants with GBS disease. Other neonatal pathogens, including *Escherichia coli* and *Listeria monocytogenes,* may cause illness that is clinically indistinguishable from that caused by GBS.

Table 230.1 Characteristics of Early- and Late-Onset Group B *Streptococcus* Disease

	EARLY-ONSET DISEASE	LATE-ONSET DISEASE
Age at onset	0-6 days	7-90 days
Increased risk after obstetric complications	Yes	No
Common clinical manifestations	Sepsis, pneumonia, meningitis	Bacteremia, meningitis, osteomyelitis, other focal infections
Common serotypes	Ia, III, V	Ia, III
Case fatality rate	4.5%	3.3%

Adapted from Seale AC, Bianchi-Jassir F, Russell NJ, et al. Estimates of the burden of Group B streptococcal disease worldwide for pregnant women, stillbirths, and children. *Clin Infect Dis.* 2017;65(Suppl 2):S200–S219.

The diagnosis of invasive GBS disease is established by isolation and identification of the organism from a normally sterile site, such as blood, urine, or cerebrospinal fluid (CSF). Isolation of GBS from gastric or tracheal aspirates or from skin or mucous membranes indicates colonization and is not diagnostic of invasive disease. CSF should be examined in all neonates suspected of having sepsis because specific CNS signs are often absent in the presence of meningitis, especially in early-onset disease. Antigen detection methods that use group B polysaccharide–specific antiserum, such as latex particle agglutination, are available for testing of urine, blood, and CSF, but these tests are less sensitive than culture. Moreover, antigen is often detected in urine samples collected by bag from otherwise healthy neonates who are colonized with GBS on the perineum or in the rectum. Commercially available methods for polymerase chain reaction (PCR) amplification of GBS-specific DNA sequences from blood or CSF samples are increasingly available, allowing earlier presumptive diagnosis than traditional culture. When possible, PCR-based diagnosis should be verified with a sterilely obtained culture; however, in certain cases the PCR result may be more accurate than the culture. A common example is a PCR performed on CSF sampled from an infant who has already received empiric antibiotic therapy, in which case the culture may remain negative despite the persistence of PCR-detectable GBS DNA. Test results must therefore be interpreted in the context of a patient's specific clinical history.

LABORATORY FINDINGS

Frequently present are abnormalities in the peripheral white blood cell count, including an increased or decreased absolute neutrophil count, elevated band count, increased ratio of bands to total neutrophils, or leukopenia. An elevated C-reactive protein level has been investigated as a potential early marker, but this test is nonspecific and cannot be used in isolation to diagnose GBS disease. Findings on chest radiograph are often indistinguishable from those of respiratory distress syndrome and may include reticulogranular patterns, patchy infiltrates, generalized opacification, pleural effusions, or increased interstitial markings. GBS meningitis is diagnosed based on a positive microbiologic test (culture or PCR), usually in combination with elevated CSF protein levels, leukocytic infiltration, and hypoglycorrhachia (decreased CSF glucose concentration).

TREATMENT

Penicillin G is the treatment of choice for confirmed GBS infection. Empirical therapy of neonatal sepsis that could be caused by GBS generally includes ampicillin and an aminoglycoside, both for the need for broad coverage pending organism identification and for synergistic bactericidal activity. Once GBS has been definitively identified and a good clinical response has occurred, therapy may be completed with penicillin alone. Especially in patients with meningitis, high doses of penicillin (450,000-500,000 units/kg/day) or ampicillin (300 mg/kg/day) are recommended because of the relatively high mean inhibitory concentration (MIC) of penicillin for GBS and the potential for a high initial CSF inoculum. The duration of therapy varies according to the site of infection and should be guided by clinical circumstances (Table 230.2). Extremely ill near-term patients with respiratory failure have been successfully treated with extracorporeal membrane oxygenation.

Although some experts recommend that, in culture-proven meningitis, additional CSF be sampled at 24-48 hours to determine whether sterility has been achieved, there is no strong evidence to support this practice. A repeat lumbar puncture, preferably paired with intracranial imaging such as MRI or CT, may be considered in patients with persistent neurologic symptoms after initiation of appropriately dosed antibiotics. The purpose in such a case is to rule out the presence of an abscess or other focal nidus of infection that may be escaping effective antibiotic exposure.

For **recurrent neonatal GBS disease**, standard intravenous antibiotic therapy recommendations for the infant should be followed. GBS recurrence can be caused by contaminated breast milk. Therefore breastfed infants with more than one episode of GBS infection should receive formula or pasteurized breast milk until expressed breast milk can be cultured for the presence of GBS. If breast milk contamination is confirmed, the mother should be counseled to consider a 5- to 7-day course of amoxicillin or rifampin to eradicate GBS carriage, followed by retesting of the milk.

Table 230.2 Recommended Duration of Therapy for Manifestations of Group B *Streptococcus* Disease

TREATMENT	DURATION
Bacteremia without a focus	10 days
Uncomplicated meningitis	14 days
Ventriculitis	At least 4 wk
Septic arthritis or osteomyelitis	3-4 wk

Data from the American Academy of Pediatrics. Group B streptococcal infections. In Kimberlin DW, Barnett ED, Lynfield R, Sawyer MH, eds. *Red Book: 2021-2024 Report of the Committee on Infectious Diseases*, 32nd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2021:707–713.

PROGNOSIS

Studies from the 1970s and 1980s showed that up to 30% of infants surviving GBS meningitis had major long-term neurologic sequelae, including developmental delay, spastic quadriplegia, microcephaly, seizure disorder, cortical blindness, or deafness. A study of infants who survived GBS meningitis diagnosed from 1998 through 2006 found that 19% had severe **neurologic impairment** and 25% had mild to moderate impairment at long-term follow-up. Periventricular leukomalacia and severe developmental delay may result from GBS disease and accompanying shock in premature infants, even in the absence of meningitis. The outcome of focal GBS infections outside the CNS is generally favorable.

In 2015, a global survey on the impact of GBS disease found the case fatality rates associated with early- and late-onset neonatal GBS disease in developed countries were 4.5% and 3.3%, respectively. Case fatality rates were higher in developing countries. Mortality is higher in premature infants; one study reported a case fatality rate of 30% in infants at gestational age <33 weeks and 2% in those ≥37 weeks. The case fatality rate in children age 3 months to 14 years was 9% and was 11.5% in nonpregnant adults.

PREVENTION

Persistent morbidity and mortality from perinatal GBS disease despite advances in neonatal care have spurred intense investigation into modes of prevention. Two basic approaches to GBS prevention have been investigated: elimination of colonization from the mother or infant (chemoprophylaxis) and induction of protective immunity (immunoprophylaxis).

Chemoprophylaxis

Administration of antibiotics to pregnant women *before* the onset of labor does not reliably eradicate maternal GBS colonization and is not an effective means of preventing neonatal GBS disease. **Interruption of neonatal colonization is achievable through administration of antibiotics to the mother during labor.** Infants born to GBS-colonized women with premature labor or prolonged rupture of membranes who were given **intrapartum chemoprophylaxis** had a substantially lower rate of GBS colonization (9% vs 51%) and early-onset disease (0% vs 6%) than did the infants born to women who were not treated. Maternal postpartum febrile illness was also decreased in the treatment group.

In the mid-1990s, guidelines for chemoprophylaxis were issued that specified administration of intrapartum antibiotics to women identified as *high risk* by either culture-based or risk factor–based criteria. These guidelines were revised in 2002 after epidemiologic data indicated the superior protective effect of the **culture-based** approach in the prevention of neonatal GBS disease, and further revised guidelines

were issued in 2010 and 2020. According to current recommendations, **vaginorectal GBS screening cultures or PCR testing (where available) should be performed for all pregnant women at 36 0/7 to 37 6/7 weeks of gestation, except for those with GBS bacteriuria during the current pregnancy or a previous infant with invasive GBS disease**. Any woman with a positive prenatal screening culture, GBS bacteriuria during pregnancy, or a previous infant with invasive GBS disease should receive intrapartum antibiotics. Women whose culture status is unknown (culture not done, incomplete, or results unknown) and present in labor with a substantial risk of preterm birth, prolonged rupture of membranes (≥18 hr), or intrapartum fever (≥38°C [100.4°F]) should also receive intrapartum chemoprophylaxis (Table 230.3). **Routine intrapartum prophylaxis is not recommended for women with GBS colonization undergoing planned cesarean delivery who have not begun labor or had rupture of membranes.**

Penicillin remains the preferred agent for **maternal chemoprophylaxis** because of its narrow spectrum and the universal penicillin susceptibility of GBS isolates associated with human infection (Fig. 230.2). Ampicillin is an acceptable alternative. If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent active against GBS should replace GBS prophylaxis. Occasional GBS isolates have demonstrated increased MICs to penicillin and other β-lactam antibiotics in association with mutations in penicillin-binding proteins. However, the clinical significance of these higher MIC values is unclear.

Table 230.3 Summary and References for GBS Prevention/Treatment Guidelines

AT-RISK POPULATION	KEY PREVENTION/ TREATMENT PRACTICES	PRACTICE GUIDELINE GOVERNING BODY
Women with history of a previous neonate with invasive GBS disease	Administer IAP during labor*	ACOG
Women with GBS bacteriuria during current pregnancy	Administer IAP during labor*	ACOG
Women with uncomplicated pregnancy	Perform prospective GBS colonization screening at 36 0/7 to 37 6/7 weeks of gestation	ACOG
	Administer IAP to colonized women during labor*	
	Women who present in term labor with unknown GBS status may qualify for IAP depending on additional clinical details	
Mothers with PROM, preterm labor, preterm intraamniotic infection, and unknown GBS colonization status	Administer IAP	ACOG
Term or late preterm (>34 wk) newborns with risk factors for GBS infection	For persistent clinical symptoms consistent with sepsis, obtain a blood culture and start empiric antibiotics with anti-GBS activity	AAP *Redbook* AAP *Pediatrics*
	In the absence of clinical symptoms, three possible approaches are available: 1. Categorical risk-based management 2. Use of an online Bayesian sepsis risk calculator to guide management 3. Serial observation of the infant	
Preterm newborns ≤34 wk with risk factors for GBS	For persistent clinical symptoms consistent with sepsis, obtain a blood culture and start empiric antibiotics with anti-GBS activity	AAP *Redbook* AAP *Pediatrics*
	If delivery followed spontaneous preterm labor, PROM, or concern for intraamniotic infection, obtain a blood culture and administer empiric antibiotics	
	If delivery followed induction of labor and there was concern for intraamniotic infection or if IAP was indicated but not provided, obtain a blood culture and administer empiric antibiotics	
Infants with signs of late-onset GBS disease	For empiric therapy of late-onset GBS disease in those who are not critically ill and in whom meningitis is not suspected, initial empiric therapy with ampicillin plus either gentamicin or cefotaxime is appropriate. If meningitis is suspected, ampicillin plus cefotaxime is recommended	AAP *Redbook*

*Infants born by cesarean section for maternal indications with no preceding labor or ROM: postnatal management should be guided by the newborn's clinical status and subsequent risk of GBS exposure.

AAP, American Academy of Pediatrics; ACOG, American College of Obstetrics and Gynecology; IAP, Intrapartum antibiotic prophylaxis; PROM, Preterm rupture of membranes

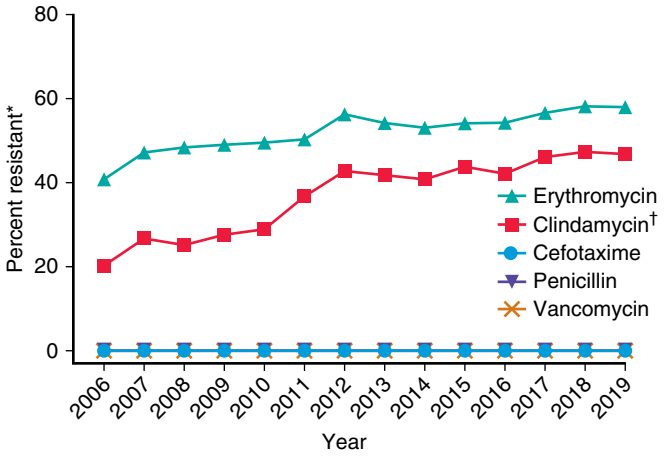

Fig. 230.2 GBS antibiotic resistance rates measured through Centers for Disease Control and Prevention active bacterial core surveillance, 2006-2019. *Resistant includes those isolates intermediate or fully resistant to antibiotics tested. †Before 2011, only constitutive resistance to clindamycin was tested. In 2011 and beyond, both constitutive and inducible resistance to clindamycin were tested. *(Courtesy Centers for Disease Control and Prevention.)*

For women who report a penicillin allergy but who have not undergone formal sensitivity testing, the American College of Obstetrics and Gynecology recommends allergy skin testing, which can be performed safely during pregnancy. Because of frequent resistance of GBS to clindamycin (up to 46%), first-generation cephalosporins (such as cefazolin) should be used for intrapartum chemoprophylaxis for penicillin-intolerant women with a low risk of anaphylaxis. For penicillin-allergic women at high risk for anaphylaxis, clindamycin should be used only if isolates are demonstrated to be susceptible. Vancomycin should be used if isolates are resistant to, or demonstrate inducible resistance to, clindamycin or if clindamycin susceptibility is unknown.

In 2019, the American Academy of Pediatrics (AAP) published updated guidelines with recommendations for prevention of early-onset GBS disease in newborns with risk factors (see Table 230.3). These replaced earlier prevention guidelines released by the AAP and Centers for Disease Control and Prevention. A key point of these revised recommendations is that **newborns with risk factors for GBS disease (such as inadequately treated maternal colonization or preterm delivery) who have persistent signs of infection after birth (beyond those attributable to transitional physiology) should undergo a laboratory evaluation that includes a blood culture and should receive empiric antibiotic therapy until infection has been ruled out**. For asymptomatic or minimally symptomatic infants born after 35 0/7 weeks of gestation, the extent of newborn evaluation and the decision to institute empiric antibiotics may be guided by one of **three systems for risk assessment**: a categorical decision chart based on the presence or absence of specific risk factors, repeated clinical evaluations, or a validated online "sepsis calculator" tool, developed from large datasets, which can estimate a newborn's risk of early-onset disease based on historical factors and clinical presentation. **For infants born before 35 0/7 weeks of gestation, the AAP recommends a blood culture and empiric antibiotics in all cases where spontaneous preterm labor, preterm rupture of the membranes, or any concern of intraamniotic infection preceded birth. Empiric treatment is also recommended in any case of a vaginal delivery before 35 0/7 weeks in which maternal chemoprophylaxis was indicated but not administered** (see Table 230.3).

Increasingly, there is recognition that decisions about whether to start empiric antibiotics for well-appearing infants with sepsis risk factors must also take into consideration the local resources available for systematic, serial examination. In medical environments where well-trained staff are available for careful, repeated observations of the newborn for 36-48 hours after birth, the threshold for initiating empiric antibiotics may be higher than sites where serial examinations are not possible. Of note, in the era of maternal chemoprophylaxis, most cases of early-onset disease are seen in infants born to women with negative prenatal screening cultures. Data from a large epidemiologic study indicate that the administration of maternal intrapartum antibiotics does not change the clinical spectrum or delay the onset of clinical signs in infants who developed GBS disease despite maternal prophylaxis.

A significant concern with maternal intrapartum chemoprophylaxis has been that large-scale antibiotic use among parturient women might lead to increased rates of antimicrobial resistance or infection in infants with organisms other than GBS, but this has not been borne out. In a population-based study of early-onset neonatal infection from 2005 to 2014, the incidence of early-onset sepsis both overall and caused by *E. coli* remained stable. At present, the substantial decline in early-onset neonatal GBS disease favors continued broad-scale intrapartum chemoprophylaxis, but continued surveillance is required.

A limitation of the maternal chemoprophylaxis strategy is that intrapartum antibiotic use is unlikely to have an impact on late-onset neonatal disease, miscarriages, or stillbirths attributed to GBS or adult GBS disease. In addition, with wider implementation of maternal chemoprophylaxis, an increasing percentage of early-onset neonatal disease has been detected in patients born to women with negative cultures, that is, false-negative screens.

Maternal Immunization

Human studies demonstrate that transplacental transfer of naturally acquired maternal antibody to the GBS capsular polysaccharide protects newborns from invasive GBS infection and that efficient transplacental passage of vaccine-induced GBS antibodies occurs. Conjugate vaccines composed of the GBS capsular polysaccharides coupled to carrier proteins have been produced for human use. In early clinical trials, conjugate GBS vaccines were well tolerated and induced levels of functional antibodies well above the range believed to be protective in >90% of recipients. A trivalent vaccine containing three subtypes of GBS capsule polysaccharide coupled to CRM_{197} was safely administered to pregnant women in a phase 2 clinical trial, eliciting functionally active type-specific antibodies that were efficiently transported to the fetus remaining detectable in the newborn. A more recent hexavalent vaccine candidate led to protective antibodies against six GBS capsular subtypes in experimental animal pregnancy models and generated robust antibody elaboration in nonpregnant adults in a phase 1/2 trial. Vaccines containing GBS surface proteins have been considered as a means to provide serotype-independent GBS protection, and availability of whole genome sequencing has enabled identification of vaccine protein candidates.

A successful GBS maternal vaccine administered before or during pregnancy should lead to transplacental passage of vaccine-induced antibody that protects the fetus and newborn against infection by several GBS serotypes. Such a vaccine would eliminate the need for cumbersome cultures during pregnancy, circumvent the various risks associated with large-scale antibiotic prophylaxis, likely have an impact on both early- and late-onset disease, and provide a prevention strategy in middle- and low-income countries, where maternal chemoprophylaxis may not be feasible. Intrapartum chemoprophylaxis will likely remain an important aspect of prevention, particularly for women in whom opportunities for GBS immunization are missed and for infants born so early that levels of transplacentally acquired antibodies may not be high enough to be protective.

Chapter 231

Non–Group A or B *Streptococci*

David B. Haslam

The genus *Streptococcus* is exceptionally diverse and includes the major human pathogens *Streptococcus pyogenes* (group A *Streptococcus Streptococcus agalactiae* (group B *Streptococcus*), and *Streptococcus pneumoniae* (Table 231.1). Other important pathogens include large-colony species bearing groups C and G Lancefield antigens and numerous small-colony variants that may or may not express Lancefield carbohydrate antigen included among the viridans streptococci (see Table 231.1). This chapter focuses on *Streptococcus dysgalactiae* subspecies *equisimilis* (SDSE), commonly known as "group C and G streptococci," while Chapter 228 discusses *S. pneumoniae* and Chapter 232 discusses enterococci.

All members of the genus *Streptococcus* are gram-positive, catalase-negative organisms. Lancefield carbohydrate antigen, hemolytic activity, and colony morphology have classically been used to further distinguish and classify streptococci. These features provide a useful framework for the clinician and are still the most commonly used classification schema. However, grouping based on these phenotypic features does not precisely correlate with genetic relatedness, and it is becoming clear that disease propensity is better correlated with sequence homology than Lancefield grouping or hemolytic activity.

In this chapter, groups C and G streptococci refer exclusively to the large colony-forming organisms, often called *S. pyogenes–like,* as their microbiologic and clinical features tend to mimic those of group A *Streptococcus*. Despite their different Lancefield antigens, the large-colony-forming C and G streptococci are grouped together as SDSE. The remaining large-colony group C streptococci, predominantly animal pathogens, are grouped as *S. dysgalactiae* subspecies *dysgalactiae*. Nonhuman group G isolates are often considered part of a single species designated *Streptococcus canis* and are genetically distinct from the SDSE group G organisms.

The groups C and G streptococci share a number of virulence factors with *S. pyogenes,* including the production of streptolysin O, M protein, streptococcal pyrogenic exotoxin B, and hyaluronidase. The M protein is similar to that of *S. pyogenes* and may account for the postinfectious glomerulonephritis that is occasionally seen after infection with these organisms. A toxic shock–like syndrome associated with groups C and G streptococcal infection has been related to M protein type and production of a pyrogenic exotoxin by SDSE.

SDSE are common habitants of the pharynx, being detected in up to 5% of asymptomatic children. Other potential sites of colonization include the skin and gastrointestinal tract. Colonization of the vagina is reported and may be the source of occasional SDSE isolated from the umbilicus of healthy neonates.

Clinical manifestations of disease caused by SDSE overlap those of *S. pyogenes*. In children, these organisms are implicated most commonly in pharyngitis. The true role of these organisms as a cause of pharyngitis is difficult to determine because asymptomatic colonization is common. Nevertheless, several epidemics of SDSE pharyngitis have been reported, including foodborne outbreaks. A large study from Sweden recently demonstrated similar rates of detection of *S. pyogenes* (15%) and SDSE (14%) in children with pharyngitis. *S. pyogenes* was most prevalent in young children, whereas SDSE predominated in older children and adolescents. The clinical presentation of SDSE is indistinguishable from *S. pyogenes*–associated pharyngitis. Isolated case reports have described SDSE pneumonia in children, which is commonly complicated by abscess formation, empyema, and bacteremia. Additional respiratory infections include rare reports of epiglottitis and sinusitis.

SDSE are a significant cause of skin and soft tissue infections. As with *S. pyogenes,* lymphangitis can complicate superficial infections caused by SDSE. Necrotizing fasciitis caused by SDSE is being described with increasing frequency. Musculoskeletal infections, particularly pyogenic arthritis, occasionally are caused by SDSE. Pediatric cases are uncommon but may be increasing in incidence.

Table 231.1 Relationship of Large-Colony Streptococci Identified by Hemolysis and Lancefield Grouping to Sites of Colonization and Disease

	GROUP A *STREPTOCOCCUS* (*S. pyogenes*)	GROUP B *STREPTOCOCCUS* (*S. agalactiae*)	OTHER β-HEMOLYTIC *STREPTOCOCCI*	*VIRIDANS STREPTOCOCCI*
Hemolysis	β	β	β	α
Lancefield group	A	B	C-H, K-V Especially C and G	
Species or strains	M types (>180)	Serotypes (Ia, Ib, II, III, IV, V, VI, VII, and VIII)	*S. dysgalactiae* subspecies *equisimilis* *S. dysgalactiae* subspecies *dysgalactiae* *S. canis*	*Streptococcus bovis* *Streptococcus mitis* *Streptococcus mutans* *Streptococcus sanguis* Many others
Normal flora	Pharynx, skin, anus	Gastrointestinal and genitourinary tract	Pharynx, skin, gastrointestinal and genitourinary tracts	Pharynx, nose, skin, genitourinary tract
Common human diseases	Pharyngitis, tonsillitis, erysipelas, impetigo, septicemia, wound infections, necrotizing fasciitis, cellulitis, meningitis, pneumonia, scarlet fever, toxic shock–like syndrome, rheumatic fever, acute glomerulonephritis	Puerperal sepsis, chorioamnionitis, endocarditis, neonatal sepsis, meningitis, osteomyelitis, pneumonia	Wound infections, cellulitis, necrotizing fasciitis, pneumonia, endocarditis, brain abscess, sepsis, nosocomial infections, opportunistic infections	Endocarditis, human bite infections

α, Partial hemolysis; β, complete hemolysis; γ, no hemolysis (nonhemolytic).

Reactive arthritis has been described after SDSE infection; however, unlike *S. pyogenes,* the association between SDSE infection and acute rheumatic fever has not clearly been defined, and antibiotic prophylaxis is not recommended after reactive arthritis with this organism.

Endocarditis, bacteremia, brain abscess, and toxic shock syndrome caused by SDSE have all been described but are uncommon in children. These infections generally occur in children with immune deficits or in adolescents after delayed recognition of sinusitis.

These organisms can cause neonatal septicemia similar to early-onset group B streptococcal disease. Risk factors include prematurity and prolonged rupture of membranes. Respiratory distress, hypotension, apnea, bradycardia, and disseminated intravascular coagulation may be seen, and associated maternal infection is common. Neonatal toxic shock syndrome associated with SDSE has also been described.

Treatment of SDSE infections is similar to that of *S. pyogenes.* These organisms retain susceptibility to penicillin and other β-lactams. Other agents with reliable activity include linezolid, daptomycin, and vancomycin, though occasional isolates demonstrate tolerance to vancomycin. Clindamycin and macrolides have poor bactericidal activity against these organisms, and resistance rates are significant. Resistance to quinolones is reported, and up to 70% of SDSE are resistant to tetracycline.

Chapter 232

Enterococcus

David B. Haslam

Enterococcus has long been recognized as a pathogen in select populations and has become a common and particularly troublesome cause of hospital-acquired infection in recent years. Enterococci were formerly classified with *Streptococcus bovis* and *Streptococcus equinus* as Lancefield group D streptococci but are now placed in a separate genus and are notorious for their propensity to cause infection in compromised hosts and frequent resistance to antibiotics.

ETIOLOGY

Enterococci are gram-positive, catalase-negative facultative anaerobes that grow in pairs or short chains. Most are nonhemolytic (also called γ-hemolytic) on sheep blood agar, although some isolates have α- or β-hemolytic activity. Enterococci are distinguished from most Lancefield groupable streptococci by their ability to grow in bile and hydrolyze esculin. They are able to grow in 6.5% NaCl and hydrolyze L-pyrrolidonyl-β-naphthylamide, features used by clinical laboratories to distinguish enterococci from group D streptococcus. Identification at the species level is enabled by differing patterns of carbohydrate fermentation.

EPIDEMIOLOGY

Enterococci are normal inhabitants of the gastrointestinal tract of humans and organisms throughout the animal kingdom, suggesting they are highly evolved to occupy this niche. Oral secretions and dental plaque, the upper respiratory tract, skin, and vagina may also be colonized by these organisms. *Enterococcus faecalis* is the predominant enterococcal species, with colonization commonly occurring in the first week of life. By the time of adulthood, *E. faecalis* colonization is nearly ubiquitous. *Enterococcus faecium* colonization is less consistent, although approximately 25% of adults harbor this organism. Disruption of the normal intestinal microbiota by antibiotic exposure or hematopoietic stem cell transplantation markedly enriches for fecal enterococcal abundance and dramatically increases the risk of subsequent bloodstream infection (BSI).

E. faecalis accounts for approximately 80% of enterococcal infections, with almost all of the remaining infections caused by *E. faecium.* Only rarely are other species, such as *Enterococcus gallinarum* and *Enterococcus casseliflavus,* associated with invasive infection, but these organisms are notable for their intrinsic low-level vancomycin resistance. Whole genome sequencing suggests that the patient's indigenous flora is the source of enterococcal infection in most cases. However, direct spread from person to person or from contaminated medical devices may occur, particularly within newborn nurseries and intensive care units, where nosocomial spread has resulted in hospital outbreaks.

PATHOGENESIS

Enterococci are not aggressively invasive organisms, usually causing disease only in children with damaged mucosal surfaces or an impaired immune system. Their dramatic emergence as a cause of nosocomial infection is predominantly a result of their resistance to antibiotics commonly used in the hospital setting. Hospital-associated enterococci generally lack CRISPR (clustered regularly interspaced short palindromic repeats) elements that defend against phage-mediated horizontal gene transfer, an important source of antimicrobial-resistance genes. Secreted and cell-surface molecules are implicated in pathogenesis. Adhesion-promoting factors such as the surface protein Eps likely account for the propensity of these organisms to cause endocarditis and urinary tract infections (UTIs). The ability to form biofilms likely facilitates the colonization of urinary and vascular catheters. Other proposed virulence factors include cytolysin, aggregation substance, gelatinase, and extracellular superoxide.

Antimicrobial Resistance

Enterococci are highly resistant to cephalosporins and semisynthetic penicillins such as nafcillin, oxacillin, and methicillin. They are moderately resistant to extended-spectrum penicillins such as ticarcillin and carbenicillin. Ampicillin and penicillin are the most active β-lactams against these organisms. Some strains of *E. faecalis* and *E. faecium* demonstrate decreased resistance to β-lactam antibiotics because of mutations in one of the penicillin-binding proteins. In addition, occasional strains of *E. faecalis* produce a plasmid-encoded β-lactamase similar to that found in *Staphylococcus aureus.* These isolates are completely resistant to penicillins, necessitating the combination of a penicillin plus a β-lactamase inhibitor or the use of imipenem or vancomycin. Any active drug may be insufficient if used alone for serious infections wherein high bactericidal activity is desired (Tables 232.1 and 232.2).

All enterococci have intrinsic low-level resistance to aminoglycosides because these antibiotics are poorly transported across the *Enterococcus* cell wall. Concomitant use of a cell wall–active agent, such as a β-lactam or glycopeptide antibiotic, improves the permeability of the cell wall for the aminoglycosides, resulting in synergistic killing. However, some isolates demonstrate high-level resistance, defined as mean inhibitory concentration (MIC) >2,000 μg/mL and a result of modification or inactivation of aminoglycoside agents. Strains demonstrating high-level resistance and even some isolates with moderate-level resistance are not affected synergistically by aminoglycosides and cell wall–active antibiotics.

Table 232.1 Intrinsic Resistance Mechanisms Among Enterococci

ANTIMICROBIAL	MECHANISM
Ampicillin, penicillin	Altered binding protein
Aminoglycoside (low level)	Decreased permeability, altered ribosomal binding
Clindamycin	Altered ribosomal binding
Erythromycin	Altered ribosomal binding
Tetracyclines	Efflux pump
Trimethoprim-sulfamethoxazole	Utilize exogenous folate

Table 232.2 Acquired Resistance Mechanisms Among Enterococci

ANTIMICROBIAL	MECHANISM
Ampicillin, penicillin (high level)	Mutation of PBP5
Aminoglycoside (high level)	Enzyme modification
Quinolones	DNA gyrase mutation
Chloramphenicol	Efflux pump
Glycopeptide	Altered cell wall binding
Quinupristin/dalfopristin	Ribosomal modification, efflux pump
Linezolid	Point mutation
Daptomycin	Unknown

Resistance to almost all other antibiotic classes, including tetracyclines, macrolides, and glycopeptides, has been described among the enterococci, necessitating individual susceptibility testing for these antibiotics when their use is considered. Despite apparent susceptibility in vitro, trimethoprim-sulfamethoxazole has poor activity in vivo and should not be used as the primary agent against enterococcal infections.

Vancomycin has traditionally been effective against *Enterococcus* isolates, but resistance to vancomycin, defined as MIC >32 μg/mL, and other glycopeptides, including teicoplanin, is increasingly common. The emergence of vancomycin-resistant *Enterococcus* (VRE) has become a major challenge in the care of hospitalized patients. In particular, mortality in patients with VRE BSIs is considerable, and treatment is complicated by frequent resistance of VRE to most other antibiotic classes. High-level vancomycin resistance (MIC ≥64 μg/mL) can be transferred by way of conjugation and usually results from plasmid-mediated transfer of the *vanA* gene. High-level resistance is most common among *E. faecium* but is increasingly seen among *E. faecalis* isolates. Moderate-level resistance (MIC 8-256 μg/mL) results from a chromosomal homolog of *vanA* known as *vanB.* Isolates that harbor the *vanB* gene are only moderately resistant to vancomycin and initially demonstrate susceptibility to teicoplanin, although resistance can emerge during therapy. Resistance to newer agents, including linezolid and daptomycin, is rare thus far. Linezolid resistance is a result of mutations in the 26S ribosomal subunit, whereas daptomycin resistance is associated with pathogenic variants in genes required for membrane synthesis and repair.

CLINICAL MANIFESTATIONS

Enterococcus infections traditionally occurred predominantly in newborn infants; infection in older children is increasingly common. Most enterococcal infections occur in patients with breakdown of normal physical barriers such as the gastrointestinal tract, skin, or urinary tract. Other risk factors for enterococcal infection include prolonged hospitalization, indwelling vascular catheters, prior use of antibiotics, and compromised immunity.

Neonatal Infections

Enterococcus accounts for up to 15% of all neonatal bacteremia and septicemia. Like group B streptococcus infections, enterococcal infections are seen in two distinct settings in neonatal patients. Early-onset infection (<7 days of age) may mimic early-onset group B streptococcus septicemia but tends to be milder. Early-onset enterococcal sepsis most often occurs in full-term infants who are otherwise healthy. Late-onset infection (≥7 days of age) is associated with risk factors such as extreme prematurity, presence of an intravascular catheter, or necrotizing enterocolitis or follows an intraabdominal surgical procedure. Symptoms in late-onset disease are more severe than those in early-onset disease and include apnea, bradycardia, and deteriorating respiratory function. Focal infections such as scalp abscess and catheter infection are commonly associated. Mortality rates range from 6% in early-onset septicemia to 15% in late-onset infections associated with necrotizing enterocolitis.

Enterococci are an occasional cause of meningitis. In neonates in particular, meningitis usually occurs as a complication of septicemia. Alternatively, the organism may gain access to the central nervous system by way of contiguous spread, such as through a neural tube defect or in association with an intraventricular shunt. Enterococcal meningitis can be associated with minimal abnormality of cerebrospinal fluid.

Infections in Older Children

Enterococcus rarely causes UTIs in healthy children but accounts for approximately 15% of cases of nosocomially acquired UTIs in both children and adults. Presence of an indwelling urinary catheter is the major risk factor for nosocomial UTIs. *Enterococcus* is frequently isolated in intraabdominal infections after intestinal perforation or surgery. The significance of enterococci in polymicrobial infections has been questioned, although reported mortality rates are higher when intraabdominal infections include enterococci. *Enterococcus* is increasingly common as a cause of nosocomial bacteremia; these organisms accounted for approximately 10% of nosocomial BSIs in children, ranking second only to coagulase-negative staphylococci. Predisposing factors for enterococcal bacteremia and endocarditis include an indwelling central venous catheter, gastrointestinal surgery, immunodeficiency, and cardiovascular abnormalities. Risk factors for vancomycin-resistant enterococcal bacteremia include prolonged mechanical ventilation, immunosuppression, and recent vancomycin exposure.

TREATMENT

Treatment of invasive enterococcal infections must recognize that these organisms are resistant to antimicrobial agents frequently used as empirical therapy. In particular, cephalosporins should not be relied upon in situations where *Enterococcus* is known or suspected to be involved. In general, in the immunocompetent host, minor localized infections caused by susceptible *Enterococcus* can be treated with ampicillin alone. Antibiotics containing β-lactamase inhibitors (clavulanate or sulbactam) provide advantage only for the very few organisms whose resistance is caused by the production of β-lactamase. In uncomplicated UTIs, nitrofurantoin is efficacious when the organism is known to be sensitive to this antibiotic.

Invasive infections such as sepsis and meningitis have traditionally been treated with a combination of penicillin or ampicillin and an aminoglycoside when the isolate is susceptible. Recent experience suggests that adjunctive aminoglycosides may increase the risk of nephrotoxicity without improving outcomes in uncomplicated BSIs. Vancomycin can be substituted for the penicillins in allergic patients but should be used with an aminoglycoside because vancomycin alone is not bactericidal. Endocarditis from strains possessing high-level aminoglycoside resistance may relapse even after prolonged therapy. Continuous-infusion penicillin or the combination of ampicillin plus ceftriaxone has been proposed for treatment of these infections in adults, yet ultimately valve replacement may be necessary. In patients with catheter-associated enterococcal bacteremia, the catheter should be removed promptly in most cases, although salvage of infected lines has occurred with the combined use of ampicillin or vancomycin with an aminoglycoside.

Treatment of Vancomycin-Resistant Enterococci

The treatment of serious infections caused by multiresistant, vancomycin-resistant strains is particularly challenging. The two most commonly used antibiotics are linezolid and daptomycin. Linezolid, an oxazolidinone antibiotic that inhibits protein synthesis, is bacteriostatic against most *E. faecium* and *E. faecalis* isolates, including vancomycin-resistant isolates. Response rates to linezolid are generally over 90%, including cases of bacteremia and sepsis, and this antibiotic is currently the only drug approved by the FDA for treatment of VRE infections. Anecdotal reports reveal the success of linezolid in treating meningitis caused by VRE. Unfortunately, as seen with other antibiotics, linezolid resistance is documented, and nosocomial spread of resistant organisms can occur. Linezolid frequently causes reversible bone marrow suppression after prolonged use and is associated with rare occurrences of lactic acidosis and irreversible peripheral neuropathy.

Serotonin syndrome may be seen in patients taking concomitant selective serotonin uptake inhibitor antidepressants. Newer oxazolidinones include tedizolid, which has better in vitro activity against enterococci and appears to have favorable pharmacokinetic and toxicity profiles when compared to linezolid.

Daptomycin is a cyclic lipopeptide that is rapidly bactericidal against a broad range of gram-positive organisms. The antibiotic inserts into the bacterial cell wall, causing membrane depolarization and cell death. It has been approved for the treatment of adults with serious skin and soft tissue infections, right-sided endocarditis, and bacteremia caused by susceptible organisms. Most strains of VRE (both *E. faecium* and *E. faecalis*) are susceptible to daptomycin in vitro, and daptomycin has become the first-line agent for VRE treatment in many centers. However, treatment failures occur when administered at the standard dose of 6 mg/kg/day, necessitating higher treatment doses in patients with severe invasive infections. Furthermore, daptomycin dosages may need to be higher in children when compared with adults because of more rapid renal clearance. The addition of a β-lactam antibiotic, such as ampicillin or ceftaroline, may enhance activity of daptomycin and provide benefit over daptomycin alone for severe VRE infections, including endocarditis. Daptomycin has unreliable activity in the lung and therefore should not be used as a sole agent to treat pneumonia. Resistance of both *S. aureus* and *Enterococcus* to daptomycin has rarely been described, sometimes arising during therapy.

Several studies and meta-analyses have suggested that clinical outcomes of invasive VRE infection are similar when linezolid and daptomycin are used. However, infection-related mortality remains significant, especially among adults, and alternative or combination therapies continue to be explored.

Ceftaroline, a fifth-generation cephalosporin with activity against methicillin-resistant *S. aureus,* has activity against many *E. faecalis* strains but is inadequate when used alone for the treatment of *E. faecium*.

Newer tetracyclines have been developed with activity against VRE, including tigecycline, omadacycline, and eravacycline. Tigecycline is approved for use in complicated intraabdominal and skin and soft tissue infections but fails to achieve high serum concentrations and may be associated with treatment failure for VRE BSIs. Gastrointestinal side effects are common with tigecycline and may be intolerable. Experience with omadacycline and eravacycline in treatment of pediatric patients with VRE infection is lacking.

Lipoglycopeptides are a newer class of antibiotics that possess a core structure similar to vancomycin with the addition of a lipid substituent. Lipoglycopeptides include telavancin, dalbavancin, and oritavancin. Only oritavancin has reliable activity against VRE, but resistance may develop, and thus far clinical experience in children is limited.

PREVENTION

Strategies for preventing enterococcal infections include timely removal of urinary and intravenous catheters and debridement of necrotic tissue. Infection control strategies, including surveillance cultures, patient and staff cohorting, and strict gown and glove isolation, are effective at decreasing colonization rates with VRE. Unfortunately, these organisms may persist on inanimate objects such as stethoscopes, complicating efforts to limit their nosocomial spread. In order to prevent the emergence and spread of vancomycin-resistant organisms, the Centers for Disease Control and Prevention has developed a series of guidelines for prudent vancomycin use. Antibiotics with broad activity against anaerobic organisms are also thought to contribute to colonization with VRE, suggesting that prudent use of such antibiotics may also help limit spread of VRE. Decolonization strategies have been attempted but are generally ineffective in eradicating skin or gastrointestinal carriage of VRE. In particular, antimicrobial therapy is not indicated for this purpose. The role of probiotic agents in eliminating VRE colonization is currently unclear but may be a useful adjunct to prudent antimicrobial usage and other infection control interventions in limiting nosocomial spread of VRE.

Chapter 233

Diphtheria (*Corynebacterium diphtheriae*)

Amruta Padhye and Stephanie A. Fritz

Diphtheria is an acute toxic infection caused by toxin-producing strains of *Corynebacterium diphtheriae* and, less often, by toxin-producing strains of *Corynebacterium ulcerans.* Non–toxin-producing *C. diphtheriae* can also cause disease, although less severe. *C. ulcerans* is more often isolated from animal sources and can cause human disease similar to *C. diphtheriae*.

Although respiratory and cutaneous presentations of diphtheria are the most common, mortality is substantially higher with respiratory diphtheria. Classic respiratory diphtheria caused by toxigenic *Corynebacterium* species is the main focus of World Health Organization (WHO) case surveillance. In the United States, the case definition was modified in 2019, and currently toxigenic cases of diphtheria, including respiratory and nonrespiratory (e.g., skin, wound, conjunctiva, ear, genital mucosa) forms, are reportable to the Centers for Disease Control and Prevention (CDC).

ETIOLOGY

Corynebacteria are aerobic, nonencapsulated, non–spore-forming, mostly nonmotile, pleomorphic, gram-positive bacilli. *C. diphtheriae* is by far the most frequently isolated agent of diphtheria. Toxigenic *C. ulcerans* can cause mastitis in cattle and respiratory infections in animals and can spread to humans through close contact with secretions. It can cause cutaneous and respiratory illnesses that are clinically indistinguishable from diphtheria in humans. Person-to-person transmission of *C. ulcerans* is possible, though not well established. A selective medium (e.g., cystine-tellurite blood agar or Tinsdale agar) that inhibits growth of competing organisms is required for isolation and, when reduced by *C. diphtheriae,* renders colonies gray-black. Differentiation of *C. diphtheriae* from *C. ulcerans* is based on urease activity; *C. ulcerans* is urease-positive. Four *C. diphtheriae* biotypes *(mitis, intermedius, belfanti, gravis)* are capable of causing diphtheria and are differentiated by colony morphology, hemolysis, and fermentation reactions. The ability of either *C. diphtheriae* or *C. ulcerans* to produce diphtheritic toxin results from acquisition of a lysogenic corynebacteriophage, which encodes the diphtheritic toxin gene and confers diphtheria-producing potential in these strains. Demonstration of diphtheritic toxin production by the modified Elek test, an agar immunoprecipitin technique, alone or in conjunction with polymerase chain reaction (PCR) testing for carriage of the toxin gene, is necessary to confirm disease. Toxigenic and nontoxigenic strains are indistinguishable by colony type, microscopic features, or biochemical test results.

EPIDEMIOLOGY

Unlike other diphtheroids (coryneform bacteria), which are ubiquitous in nature, *C. diphtheriae* is an exclusive inhabitant of human mucous membranes and skin. Spread is primarily by respiratory droplets, direct contact with respiratory secretions of symptomatic individuals, or exudate from infected skin lesions. Asymptomatic respiratory tract carriage is important in transmission. In areas where diphtheria is endemic, 3–5% of healthy individuals can carry toxigenic organisms, but carriage is exceedingly rare in nonendemic areas. Skin infection and skin carriage are silent reservoirs of *C. diphtheriae,* and organisms can remain viable in dust or on fomites for up to 6 months.

In the 1920s, >125,000 diphtheria cases and 10,000 diphtheria-related deaths were reported annually in the United States, with the highest fatality

rates among very young and elderly persons. The incidence then began to decrease and, with widespread use of diphtheria toxoid in the United States after World War II, declined steadily through the late 1970s. From 1996 to 2018, only 14 cases of respiratory diphtheria, including 1 fatal case, were reported in the United States, an average of ≤1 case annually. During this same period, five cases of culture-confirmed respiratory diphtheria-like illness caused by toxigenic *C. ulcerans* were also identified.

Despite the worldwide decrease in disease incidence, diphtheria remains endemic in many developing countries with poor immunization rates against diphtheria. Since the introduction of toxoid immunization, the disease has shifted from affecting children <15 years old to adults who lack natural exposure to toxigenic *C. diphtheriae* in the vaccine era and have low rates of booster immunization. The largest outbreak of diphtheria in the developed world since the 1960s occurred from 1990 to 1996 in the newly independent countries of the former Soviet Union, involving >150,000 cases in 14 countries. Of these, >60% of cases occurred in individuals >14 years old. Case fatality rates ranged from 3% to 23% by country. Factors contributing to the epidemic included a large population of underimmunized adults, decreased childhood immunization rates, population migration, crowding, and failure to respond aggressively during early phases of the epidemic. Cases of diphtheria among travelers from these endemic areas were transported to many countries in Europe.

WHO surveillance reports indicate that most cases of diphtheria worldwide occur in the Southeast Asia and Africa regions, reporting more than 10,000 cases worldwide in 2020. India contributes a substantial proportion to the global burden of diphtheria, with an average of over 4,000 cases annually reported to the WHO in the past decade.

Although diphtheria was reduced from a major cause of childhood death to a medical rarity in the Western Hemisphere in the early 20th century, recurring reminders of the fragility of this success, particularly in conflict areas, emphasize the need to continue vigorous promotion of those same control principles across the global community. The largest diphtheria outbreak in the refugee setting occurred when the Rohingya people were displaced from Myanmar to Bangladesh in 2017, eventually lasting over 2 years and with 7064 cases and 45 deaths reported as of November 2019. Along with outbreaks in Venezuela, Haiti, Yemen, and more recently Nigeria, these are stark reminders of the threat of re-emergence that vaccine-preventable diseases pose. Improving surveillance, vaccination coverage, and public awareness of the disease are key for control of disease during outbreaks.

When diphtheria was common, **cutaneous diphtheria** accounted for more than 50% of reported *C. diphtheriae* isolates in the United States. This indolent local infection, compared with mucosal infection, is associated with more prolonged bacterial shedding, greater contamination of the environment, and increased transmission to the pharynx and skin of close contacts. Outbreaks are associated with homelessness, crowding, poverty, alcoholism, poor hygiene, contaminated fomites, underlying dermatosis, and introduction of new strains from exogenous sources. It is no longer a tropical or subtropical disease; 1,100 *C. diphtheriae* infections were documented in a Seattle neighborhood (the site of the last major U.S. outbreak) from 1971 to 1982; 86% were cutaneous, and 40% involved toxigenic strains. The incidence of *C. diphtheriae* isolates from cutaneous infections has risen dramatically over the past decade. Cutaneous diphtheria is an important source of toxigenic *C. diphtheriae* in the United States, and its importation from endemic areas is frequently the source of subsequent sporadic cases of respiratory tract diphtheria. Between 2015 and 2018, the CDC confirmed four cases of cutaneous diphtheria from toxin-producing *C. diphtheriae* in U.S. residents returning from travel to endemic areas. Cutaneous diphtheria caused by *C. ulcerans* from travel to tropical countries or animal contact has also been increasingly reported.

In Europe, increasing reports of respiratory and systemic infections have been attributed to *C. ulcerans;* animal contact is the predominant risk factor. In the United Kingdom, from 2008 to 2017, of the 33 toxigenic cases of diphtheria, just over half of the cases were caused by *C. diphtheriae,* and the remainder were caused by *C. ulcerans*. Most of the *C. diphtheriae* cases were cutaneous, while the *C. ulcerans* cases were equally respiratory and cutaneous. Travel to an endemic area was the major risk factor for *C. diphtheriae* acquisition, while contact with a companion animal was the major factor associated with acquisition of *C. ulcerans*. Incomplete vaccination status was strongly associated with the risk of hospitalization and death.

PATHOGENESIS

Both toxigenic and nontoxigenic strains of *C. diphtheriae* cause skin and mucosal infection and can rarely cause invasive disease, including endocarditis and bacteremia. The organism usually remains in the superficial layers of skin lesions or respiratory tract mucosa, inducing a local inflammatory reaction. The major virulence of the organism lies in its ability to produce a potent polypeptide exotoxin, the diphtheritic toxin, which inhibits protein synthesis and causes local tissue necrosis and the resultant local inflammatory response. Within the first few days of respiratory tract infection (usually in the pharynx), a dense necrotic coagulum of organisms, epithelial cells, fibrin, leukocytes, and erythrocytes forms, initially white and advancing to become a gray-brown, leather-like, adherent **pseudomembrane** (*diphtheria* is Greek for leather). Removal is difficult and reveals a bleeding, edematous submucosa. Paralysis of the palate and hypopharynx is an early local effect of diphtheritic toxin. Toxin absorption can lead to systemic manifestations: kidney tubule necrosis, thrombocytopenia, cardiomyopathy, and demyelination of nerves. Because the latter two complications can occur 2-10 weeks after mucocutaneous infection, the pathophysiology in some cases is suspected to be immunologically mediated. Among infected adults in the Seattle outbreak, 3% with cutaneous infections and 21% with symptomatic nasopharyngeal infection demonstrated toxic myocarditis, neuropathy, or obstructive respiratory tract complications. All had received at least 20,000 units of equine antitoxin at the time of hospitalization.

CLINICAL MANIFESTATIONS

The manifestations of *C. diphtheriae* infection are influenced by the anatomic site of infection, the immune status of the host, and the production and systemic distribution of toxin. Although 98% of infections occur in the respiratory tract, other sites include cutaneous, conjunctival, ear, and vaginal mucosa.

New estimates of epidemiologic and clinical aspects of diphtheria from a comprehensive update by Truelove et al., with systematic reviews including recent literature, are summarized in Figure 233.1.

Respiratory Tract Diphtheria

The pharynx or tonsils is the most common location of infection in the respiratory tract (75–94%), followed by the larynx (25%). Although the incubation period has traditionally been regarded to be 2-5 days (range 1-10 days), emerging data suggest that the median time from infection to onset of prodromal symptoms is only 1.4 days. An estimated 80% of untreated symptomatic cases progress to membranous diphtheria in an average of 2-3 days after symptom onset. In tonsillar and **pharyngeal diphtheria**, sore throat is the universal early symptom. Only half of patients have fever, and fewer have dysphagia, hoarseness, malaise, or headache. Mild pharyngeal injection is followed by unilateral or bilateral tonsillar membrane formation, which can extend to involve the uvula (which may cause toxin-mediated paralysis), soft palate, posterior oropharynx, hypopharynx, or glottic areas (Fig. 233.2). Underlying soft tissue edema and enlarged lymph nodes can cause a bull-neck appearance. The degree of local extension correlates directly with profound prostration, bull-neck appearance, and fatality caused by airway compromise or toxin-mediated complications (Fig. 233.3). In infants, infection of the anterior nares is more common and causes serosanguineous, purulent, erosive rhinitis with membrane formation. Shallow ulceration of the external nares and upper lip is characteristic.

The characteristic adherent pseudomembrane, extension beyond the faucial area, dysphagia, and relative lack of fever help differentiate diphtheria from **exudative pharyngitis** caused by *Streptococcus pyogenes* or Epstein-Barr virus. Vincent angina, infective phlebitis with thrombosis of the jugular veins (Lemierre syndrome), and mucositis in patients undergoing cancer chemotherapy are usually differentiated by the clinical setting. Infection of the larynx, trachea, and bronchi

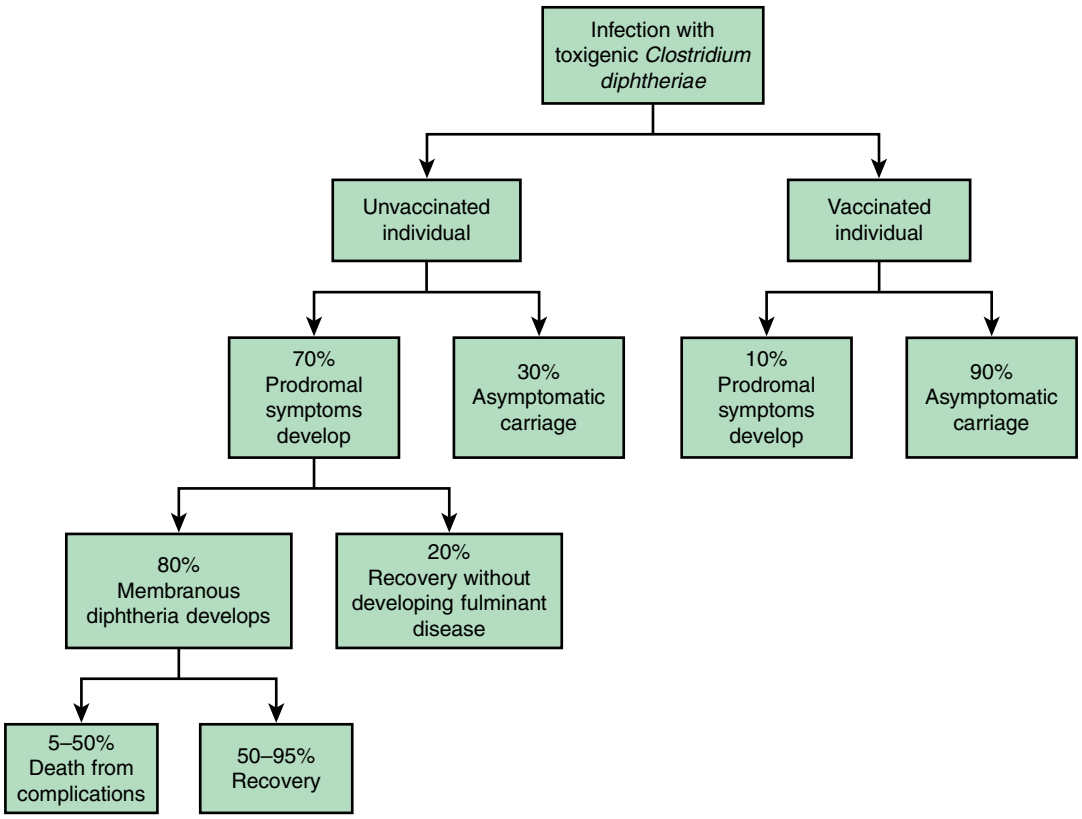

Fig. 233.1 Clinical manifestations of *Clostridium diphtheriae* infection among unvaccinated and vaccinated individuals. Among unvaccinated individuals infected with toxigenic *C. diphtheriae*, prodromal symptoms develop in ~70%, of whom 80% develop membranous diphtheria. Of those with membranous diphtheria, case fatality can be as high as 5–50%. Among vaccinated individuals infected with toxigenic *C. diphtheriae*, the toxoid vaccine provides protection from symptoms; 10% develop prodromal symptoms, whereas 90% become asymptomatic carriers. These symptomatic vaccinated individuals have a lower risk of severe disease and death and are more likely to recover. *(Adapted from Truelove SA, Keegan LT, Moss WJ, et al. Clinical and epidemiological aspects of diphtheria: a systematic review and pooled analysis. Clin Infect Dis. 2020;71[1]:89–97.)*

Fig. 233.3 Diphtheria. Bull-neck appearance of diphtheritic cervical lymphadenopathy. *(From the Centers for Disease Control and Prevention [CDC]. Public health image library [PHIL], image #5325. Available at:* https://phil.cdc.gov/Details.aspx?pid=5325.*)*

can be primary or a secondary extension from the pharyngeal infection, presenting with hoarseness, stridor, dyspnea, and croupy cough. Differentiation from bacterial epiglottitis, severe viral laryngotracheobronchitis, and staphylococcal or streptococcal tracheitis hinges partially on the relative paucity of other signs and symptoms in patients with diphtheria and primarily on visualization of the adherent pseudomembrane at laryngoscopy and intubation.

Patients with laryngeal diphtheria are at significant risk for suffocation because of local soft tissue edema and airway obstruction by the diphtheria membrane. This progression of airway obstruction in laryngeal infection within 1-2 weeks after symptom onset is responsible for 60–65% of overall deaths. Establishment of an artificial airway and resection of the pseudomembrane can be lifesaving, but further obstructive complications are common, and systemic toxic complications are inevitable.

Cutaneous Diphtheria

Classic cutaneous diphtheria is an indolent, nonprogressive infection characterized by a superficial, ecthyma-like, nonhealing ulcer with a gray-brown membrane. Diphtheria skin infections cannot always be differentiated from streptococcal or staphylococcal impetigo, and these conditions frequently coexist. In most cases, a primary process, such as dermatosis, laceration, burn, bite, or impetigo, becomes secondarily infected with *C. diphtheriae.* Extremities are more often affected than the trunk or head. Pain, tenderness, erythema, and exudate are typical. Local hyperesthesia or hypesthesia is unusual. Respiratory tract colonization or symptomatic infection with toxic complications occurs in the minority of patients with cutaneous diphtheria.

Infection at Other Sites

C. diphtheriae occasionally causes mucocutaneous infections at other sites, such as the ear (otitis externa), the eye (purulent and ulcerative conjunctivitis), and the genital tract (purulent and ulcerative vulvovaginitis). The clinical setting, ulceration, membrane formation, and submucosal bleeding help differentiate diphtheria from other bacterial and viral causes. Rare cases of septicemia are described and are universally fatal. Sporadic cases of endocarditis occur, and clusters among intravenous drug users have been reported in several countries; the skin was the probable portal of entry, and almost all strains were nontoxigenic. Sporadic cases of pyogenic arthritis, mainly from nontoxigenic strains, have been reported in adults and children. Diphtheroids isolated from sterile body sites should not be routinely dismissed as contaminants without careful consideration of the clinical setting.

DIAGNOSIS

Specimens for culture should be obtained from the nose and throat and any other mucocutaneous lesion. A portion of membrane should be removed and submitted for culture along with underlying exudate. The laboratory must be notified to use selective medium. *C. diphtheriae* survives drying. If obtained in a remote area, a dry swab specimen can be placed in a silica gel pack and sent to the laboratory. Evaluation of a direct smear using Gram stain or specific fluorescent antibody is unreliable. Culture isolates of coryneform organisms should be identified to the species level, and toxigenicity and antimicrobial susceptibility tests should be performed for *C. diphtheriae* isolates. It is recommended that all isolates be sent to a reference laboratory. In the United States, the CDC's Pertussis and Diphtheria Laboratory provides support to local and state health departments needing assistance with isolation, identification, and subtyping of *C. diphtheriae* and *C. ulcerans.*

COMPLICATIONS

Respiratory tract obstruction by pseudomembranes may require bronchoscopy or intubation and mechanical ventilation. Two other tissues usually remote from sites of *C. diphtheriae* infection can be significantly affected by **diphtheritic toxin**: the heart and the nervous system.

Toxic Cardiomyopathy

Toxic cardiomyopathy occurs in 10–25% of patients with respiratory diphtheria, resulting in death in 35–60% of cases with this complication and responsible for 20–25% of deaths overall. Subtle signs of myocarditis can be detected in most patients, especially the elderly, but the risk for significant complications correlates directly with the extent and severity of exudative local oropharyngeal disease, along with a delay in administration of antitoxin. The first evidence of cardiac toxicity characteristically occurs 7-14 days after the onset of respiratory symptoms but can appear acutely as early as the first week of illness, a poor prognostic sign, or as late as the sixth week. Tachycardia disproportionate to fever is common and may be evidence of cardiac toxicity or autonomic nervous system dysfunction. A prolonged P-R interval and changes in the ST-T wave on an electrocardiographic tracing are relatively frequent findings; dilated and hypertrophic cardiomyopathy detected by echocardiogram has been described. Single or progressive cardiac **dysrhythmias** can occur, including first-, second-, and third-degree heart block. Temporary transvenous pacing may improve outcomes. Atrioventricular dissociation and ventricular tachycardia are also described, the latter having a high associated mortality. Heart failure may appear insidiously or acutely. Elevation of the serum aspartate transaminase concentration closely parallels the severity of myonecrosis. Severe dysrhythmia portends death. Histologic postmortem findings are variable: little or diffuse myonecrosis with acute inflammatory response. Recovery from toxic myocardiopathy is usually complete, although survivors of more severe dysrhythmias can have permanent conduction defects.

Toxic Neuropathy

Neurologic complications occur in 20–25% of untreated cases, resulting in death in 50% of cases who develop them and responsible for 15% of deaths overall. They parallel the severity of primary infection and are multiphasic in onset. Acutely or 2-3 weeks after onset of oropharyngeal inflammation, hyperesthesia and local **paralysis** of the soft palate typically occur. Weakness of the posterior pharyngeal, laryngeal, and facial nerves may follow, causing a nasal quality in the voice, difficulty in swallowing, and risk for aspiration. **Cranial neuropathies** characteristically occur in the fifth week, leading to oculomotor and ciliary paralysis, which can cause strabismus, blurred vision, or difficulty with accommodation. Symmetric demyelinating **polyneuropathy** has onset 10 days to 3 months after oropharyngeal infection and causes principally motor deficits with diminished deep tendon reflexes. Nerve conduction velocity studies and cerebrospinal fluid findings in diphtheritic polyneuropathy are indistinguishable from those of Guillain-Barré syndrome. Paralysis of the diaphragm may ensue. Complete neurologic recovery is likely, but rarely vasomotor center dysfunction 2-3 weeks after onset of illness can cause hypotension or cardiac failure.

Recovery from myocarditis and neuritis is often slow but usually complete. Corticosteroids do not diminish these complications and are not recommended.

TREATMENT

Specific diphtheria **antitoxin** is the mainstay of therapy and should be administered as soon as possible, without delay on the basis of clinical diagnosis. Because it neutralizes only free toxin, antitoxin efficacy diminishes with elapsed time after the onset of mucocutaneous symptoms. Equine diphtheria antitoxin is available in the United States only from the CDC. Physicians treating a case of suspected diphtheria should contact the CDC Emergency Operations Center at 1-770-488-7100 after consulting with their state health department. Antitoxin is available from CDC under expanded access investigational new drug application protocol. Antitoxin is administered as a single empirical dose of 20,000-100,000 units based on the degree of severity, site, and duration of illness. Skin testing for hypersensitivity must be performed before administration of antitoxin. Patients with positive sensitivity testing or with a history of hypersensitivity reaction to horse equine protein should be desensitized. Antitoxin is probably of no value for local manifestations of cutaneous diphtheria, but its use is prudent because toxic sequelae can occur. Commercially available intravenous immunoglobulin preparations contain low titers of antibodies to diphtheria toxin; their use for therapy of diphtheria is not proven or approved. Antitoxin is not recommended for asymptomatic carriers.

The role of **antimicrobial therapy** is to halt toxin production, treat localized infection, and prevent transmission of the organism

to contacts. Although *C. diphtheriae* is usually susceptible to various agents in vitro, including penicillins, erythromycin, clindamycin, rifampin, and tetracycline, only erythromycin or penicillin are recommended for treatment. Erythromycin is marginally superior to penicillin for eradication of nasopharyngeal carriage. Resistance to erythromycin is common in populations where the drug has been used broadly, and resistance to penicillin has also been reported. Appropriate therapy is **erythromycin** (40-50 mg/kg/day divided every 6 hours by mouth [PO] or intravenously [IV]; maximum 2 g/day), **aqueous crystalline penicillin G** (150,000 - 250,000 units/kg/day divided every 6 hr IV or intramuscularly [IM], up to 2-3 million units/day), or **procaine penicillin** (300,000 units every 12 hr IM for those ≤10 kg in weight; 600,000 units every 12 hr IM for those >10 kg in weight) for 14 days. Once oral medications are tolerated, oral erythromycin (see dosing above) or penicillin V (50 mg/kg/day, divided every 6 hr, maximum 2 g per day) may be used for the remaining duration of therapy. *Antibiotic therapy is not a substitute for antitoxin therapy.* Some patients with cutaneous diphtheria have been treated for 7-10 days. Elimination of the organism should be documented by negative results of at least two successive cultures of specimens from the nose and throat (or skin) obtained at least 24 hours apart, collected 24 hours after completion of antimicrobial therapy. Treatment with erythromycin should be repeated if either culture yields *C. diphtheriae.*

Individuals untreated with antibiotics, including those with either symptomatic or asymptomatic infection, remain colonized with *C. diphtheriae* for an average of 18.5 days, with 5% remaining colonized longer than 48 days. With antibiotic treatment, they clear *C. diphtheriae* colonization within an average of 5.2 days, reducing the duration of infectiousness by 2 weeks.

SUPPORTIVE CARE

Droplet precautions are instituted for patients with pharyngeal diphtheria; for patients with cutaneous diphtheria, **contact precautions** are observed until the results of specimen cultures taken after cessation of therapy are negative. Cutaneous wounds are cleaned thoroughly with soap and water. Bed rest is essential during the acute phase of disease, usually for ≥2 weeks until the risk for symptomatic cardiac damage has passed, with return to physical activity guided by the degree of toxicity and cardiac involvement.

PROGNOSIS

The prognosis for patients with diphtheria depends on the virulence of the organism (subspecies *gravis* has the highest fatality rate), patient age, immunization status, site of infection, and speed of administration of the antitoxin. Mechanical obstruction from laryngeal diphtheria or bull-neck diphtheria and the complications of myocarditis account for most diphtheria-related deaths. The case fatality ratio for untreated, never-vaccinated cases is 29%, improving to 10% with antitoxin treatment. The risk of fatality increases with every day of delayed antitoxin treatment. Children age <5 years are more likely to die from symptomatic infection than adults >20 years of age, whereas children 5-19 years of age are less likely to die from infection than adults age >20 years. At recovery, administration of diphtheria toxoid is indicated to complete the primary series or booster doses of immunization, because not all patients develop antibodies to diphtheria toxin after infection.

PREVENTION

Protection against serious disease caused by imported or indigenously acquired *C. diphtheriae* depends on immunization. In the absence of a precisely determined minimum protective level for diphtheria antitoxin, the presumed minimum is 0.01-0.10 IU/mL. In outbreaks, 90% of individuals with clinical disease have had antibody values <0.01 IU/mL, and 92% of asymptomatic carriers have had values >0.1 IU/mL. In serosurveys in the United States and Western Europe, where almost universal immunization during childhood has been achieved, 25% to >60% of adults lack protective antitoxin levels, with typically very low levels in elderly persons. A serosurvey in the United States (1988–1994) indicated that 60% of the overall population had protective immunity against diphtheria; however, this level of protection declined from 80% in persons age 12-19 years to about 30% in persons age 60-69 years.

All suspected diphtheria cases should be reported to local and state health departments. Investigation is aimed at preventing secondary cases in exposed individuals and at determining the source and carriers to halt spread. The serial interval, or time between symptom onset of the infector/infectee pair, is a median of 5.9 days, with 5% of intervals <0.8 days and 5% longer than 21 days.

Asymptomatic Case Contacts

All household contacts and people who have had intimate respiratory or habitual physical contact with a patient are closely monitored for illness for 7 days. Cultures of the nose, throat, and any cutaneous lesions are performed. Antimicrobial prophylaxis is presumed effective and is administered regardless of immunization status, using a single injection of benzathine penicillin G (600,000 units IM for patients weighing <30kg, or 1,200,000 units IM for patients weighing ≥30 kg or adults,) or erythromycin (40-50 mg/kg/day divided every 6 hr PO for 7-10 days; max 1 g/day). Diphtheria toxoid vaccine, in age-appropriate form, is given to immunized individuals who have not received a booster dose within 5 years. Children who have not received their fourth dose should be vaccinated. Those who have received fewer than three doses of diphtheria toxoid or who have uncertain immunization status should be immunized with an age-appropriate preparation on a primary schedule.

Asymptomatic Carriers

When an asymptomatic carrier is identified, antimicrobial prophylaxis is given for 10-14 days, and an age-appropriate preparation of diphtheria toxoid vaccination is administered immediately if a booster has not been given within 1 year. Droplet precautions (respiratory tract colonization) or contact precautions (cutaneous colonization only) are observed until at least two subsequent cultures obtained at least 24 hours apart, collected 24 hours after cessation of therapy, have negative results.

Repeat cultures are performed about 2 weeks after completion of therapy for cases and carriers; if results are positive, an additional 10-day course of oral erythromycin should be given and follow-up cultures performed. Susceptibility testing of isolates should be performed, as erythromycin resistance is reported. Neither penicillin nor erythromycin eradicates carriage in 100% of individuals. In one report, a single course of therapy failed in 21% of carriers. Transmission of diphtheria in modern hospitals is rare. Only those who have an unusual contact with respiratory or oral secretions should be managed as contacts. Investigation of the casual contacts of patients and carriers or persons in the community without known exposure has yielded extremely low carriage rates and is not routinely recommended.

Vaccine

Universal immunization with diphtheria toxoid throughout life, designed to provide constant protective antitoxin antibody levels and to reduce severity of *C. diphtheriae* disease, is the only effective control measure. Although immunization does not preclude subsequent respiratory or cutaneous carriage of toxigenic *C. diphtheriae,* it decreases local tissue spread, prevents toxic complications, diminishes transmission of the organism, and provides herd immunity when at least 80–85% of a population is immunized.

Full vaccination is highly effective in preventing symptomatic disease (87% with three or more doses, increasing to 99% with five doses), severe disease (defined as local and systemic symptoms plus a major complication; 81%), and death (93%). Even though vaccines do not prevent colonization, they reduce transmission by 60%, likely through reduced symptomatic shedding. Asymptomatic carriers are still able to transmit infection, albeit at only 24% the rate of symptomatic cases. In an outbreak setting, both vaccination and antibiotic treatment to clear colonization are necessary to interrupt transmission. Although full vaccination coverage can interrupt transmission in only 27% of outbreak settings, this figure increases to 70% when rapid antibiotic treatment is initiated in 90% of symptomatic cases.

The COVID-19 pandemic resulted in disruptions in immunization services in 2020, leading to 3.5 million children missing their first dose of diphtheria, tetanus, and pertussis vaccine (DTP) as compared with 2019. Global annual vaccination coverage for first-dose DTP vaccine decreased from 90% in 2019 to 87% in 2020; third-dose DTP vaccine

decreased from 86% in 2019 to 83% in 2020. The impact this will have on the resurgence of vaccine-preventable infections is yet to be determined.

Diphtheria toxoid is prepared by formaldehyde treatment of toxin, standardized for potency and adsorbed to aluminum salts, enhancing immunogenicity. Two preparations of diphtheria toxoids are formulated according to the *limit of flocculation* (Lf) content, a measure of the quantity of toxoid. The pediatric (6 months to 6 years) preparations (i.e., **DTaP** [diphtheria and tetanus toxoids with acellular pertussis vaccine] and **DT** [diphtheria and tetanus toxoids vaccine]) contain 6.7-25.0 Lf units of diphtheria toxoid per 0.5 mL dose; tetanus toxoid with vaccines for ≥7 years (Td [tetanus and diphtheria toxoid vaccine] and **Tdap** [diphtheria and tetanus toxoids with acellular pertussis vaccine]) contain no more than 2-2.5 Lf units of toxoid per 0.5 mL dose. The *higher-potency* (D) formulation of toxoid is used for primary series and booster doses for children through 6 years of age, given its superior immunogenicity and minimal reactogenicity. For individuals ≥7 years old, Td or Tdap is recommended for the primary series and booster doses because the lower concentration of diphtheria toxoid is adequately immunogenic and increasing the content of diphtheria toxoid heightens reactogenicity with increasing age.

For children 6 weeks to 6 years of age, five 0.5-mL doses of diphtheria-containing (D) vaccine (DTaP preferred) are given in the primary series, including doses at 2, 4, and 6 months of age, and a fourth dose, an integral part of the primary series, at 15-18 months. Dose 4 may be administered as early as age 12 months if at least 6 months have elapsed since dose 3. A booster dose is given at 4-6 years of age (unless the fourth primary dose was administered at ≥4 years). For persons ≥7 years to 18 years not previously immunized for diphtheria, three 0.5-mL doses of *lower-level* diphtheria-containing (d) vaccine are given in a primary series of two doses at least 4 weeks apart and a third dose 6 months after the second dose. The first dose should be Tdap, and subsequent doses can be Td or Tdap.

A booster dose, consisting of Tdap, is recommended at 11-12 years of age. Tdap may be administered regardless of the interval since the last tetanus- and diphtheria-toxoid-containing vaccine. Adolescents 13-18 years old who have not received Tdap at 11-12 years should receive a single dose of Tdap, then a Td or Tdap booster every 10 years. Pregnant women should receive a single dose of Tdap during every pregnancy, preferably during gestational weeks 27-36. Adults who have never received Tdap should receive a single dose of Tdap, regardless of when they last got Td. A Td or Tdap booster should be given every 10 years.

Updated recommendations allow for use of either Td or Tdap vaccine in situations where previously only Td was recommended. This includes the decennial Td booster, tetanus prophylaxis for wound management, and for additional required doses in the catch-up immunization schedule if a person has received at least one Tdap dose.

The only contraindication to tetanus and diphtheria toxoid is a history of neurologic or severe hypersensitivity reaction after a prior dose. For children <7 years old in whom pertussis immunization is contraindicated, DT is used. Those whose immunization is begun with DTaP or DT before 1 year of age should have a total of five 0.5-mL doses of diphtheria-containing (D) vaccines by 6 years of age. For those whose immunization is begun at around 1 year old, the primary series is three 0.5-mL doses of diphtheria-containing (D) vaccine, with a booster given at 4-6 years, unless the third dose was given after the fourth birthday.

There is no association of DT or Td with seizures. Local adverse effects alone do not preclude continued use. The rare patient who experiences an Arthus-type hypersensitivity reaction or a temperature >39.4°C (103°F) after a dose of Td usually has high serum tetanus antitoxin levels and should not be given Td more frequently than every 10 years, even if the patient sustains a significant tetanus-prone injury.

The DT or Td preparation can be given concurrently with other vaccines. Meningococcal and pneumococcal conjugate vaccines containing diphtheria toxoid or a variant of diphtheria toxin, CRM197 protein, are not substitutes for diphtheria toxoid immunization and do not affect reactogenicity.

Chapter 234

Listeria monocytogenes

Ashley C. Howard and Thomas S. Murray

Listeriosis in humans is caused principally by *Listeria monocytogenes,* 1 of 17 species of the genus *Listeria* that are widely distributed in the environment and throughout the food chain. Human infections can usually be traced to an animal reservoir. Infection usually occurs at the extremes of age. In the pediatric population, perinatal infections predominate and usually occur secondary to maternal infection or colonization. Outside the newborn period, disease is most often encountered in *immunosuppressed* (usually T-cell deficiencies) children and adults and in elderly persons. For most people the major risk for infection with *Listeria* is **food-borne transmission**. In the United States, food-borne outbreaks are caused by improperly processed dairy products and contaminated vegetables and principally affect the same individuals at risk for sporadic disease.

ETIOLOGY

Members of the genus *Listeria* are facultatively anaerobic, non–spore-forming, motile, gram-positive bacilli that are catalase positive. The 17 *Listeria* species are divided into two genomically distinct groups on the basis of DNA-DNA hybridization studies. One group contains the species *L. grayi,* and 10 others discovered since 2009 are considered nonpathogenic. The second group contains six species: the nonhemolytic species *L. innocua*, *L. welshimeri,* and *L. marthii* and the hemolytic species *L. monocytogenes, L. seeligeri,* and *L. ivanovii. L. ivanovii* is pathogenic primarily in animals, and the vast majority of both human and animal disease is caused by *L. monocytogenes*.

Subtyping of *L. monocytogenes* isolates for epidemiologic purposes is now performed predominately with whole genome sequencing. This demonstrates the clonal structure of populations of *L. monocytogenes* as well as the sharing of populations between human and animal sources. **Subtyping** is an important component of determining whether cases are connected or sporadic but usually requires collaboration with a specialized laboratory.

Historically, selected biochemical tests, together with the demonstration of *tumbling motility,* an umbrella-type formation below the surface in semisolid medium, hemolysis, and a typical cyclic adenosine monophosphate test, are usually sufficient to establish a presumptive identification of *L. monocytogenes*. Once growth is present, *L. monocytogenes* can now be rapidly identified with matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry.

EPIDEMIOLOGY

L. monocytogenes is widespread in nature, has been isolated throughout the environment, and is associated with epizootic disease and asymptomatic carriage in >42 species of wild and domestic animals and 22 avian species. Epizootic disease in large animals (e.g., sheep, cattle) is associated with abortion and "circling disease," a form of basilar meningitis. *L. monocytogenes* is isolated from sewage, silage, and soil, where it survives for >295 days. Human-to-human transmission rarely occurs except in maternal-fetal transmission. The annual incidence of listeriosis decreased by 36% between 1996 and 2004 and has remained level since then, estimated between two and five cases per year per million people. However, **food-borne outbreaks** continue to occur. The rate of *Listeria* infections varies among states. Epidemic human listeriosis has been associated with food-borne transmission in several large outbreaks, especially in association with aged soft cheeses; improperly pasteurized milk and milk products; contaminated raw and ready-to-eat beef, pork, and poultry and packaged meats and

salads; and vegetables, both fresh and frozen, harvested from farms where the ground is contaminated with the feces of colonized animals. In 2017-2018, the largest *Listeria* outbreak ever recorded occurred in South Africa with >900 cases and 200 deaths related to a processed contaminated meat product, "polony." U.S. food-borne outbreaks from 2019 to 2020 included deli meats and cheeses, packaged hard boiled eggs, and enoki mushrooms. The ability of *L. monocytogenes* to grow at temperatures as low as 4°C (39.2°F) increases the risk for transmission from aged soft cheeses and stored contaminated food. Listeriosis is an uncommon but important recognized etiology of neonatal sepsis and meningitis. Small clusters of nosocomial person-to-person transmission have occurred in hospital nurseries and obstetric suites. Sporadic endemic listeriosis is less well characterized. Likely routes include food-borne infection and zoonotic spread. **Zoonotic transmission** with cutaneous infections occurs in veterinarians and farmers who handle sick animals.

Reported cases of listeriosis are clustered at the extremes of age. Some studies show higher rates in males and a seasonal predominance in the late summer and fall in the Northern Hemisphere. In the United States, there is an increased risk of infection in nonpregnant non-Hispanic Asians, non-Hispanic Blacks, and Hispanics compared with non-Hispanic Whites. Outside the newborn period and during pregnancy, disease is usually reported in patients with underlying immunosuppression, with a 100-300 times increased risk in HIV-infected persons and in the elderly population (Table 234.1). In a prospective cohort study for listeriosis, 82.5% of participants had at least one immunocompromising condition, and those with bacteremia and neurolisteriosis disease were found to have a fivefold increased risk of death if there was an underlying malignancy.

The incubation period, which is defined only for common-source food-borne disease, is 21-30 days but in some cases may be longer. Asymptomatic carriage and fecal excretion are reported in 1–5% of healthy persons and 5% of abattoir workers, but duration of excretion, when studied, is short (<1 month).

PATHOLOGY

One of the major concepts of *Listeria* pathology and pathogenesis is its ability to survive as an intracellular pathogen. *Listeria* incites a mononuclear response and elaboration of cytokines, producing multisystem disease, particularly pyogenic meningitis. Granulomatous reactions and microabscess formation develop in many organs, including the liver, lungs, adrenals, kidneys, central nervous system (CNS), and notably the placenta. Animal models demonstrate *translocation,* the transfer of intraluminal organisms across intact intestinal mucosa. Histologic examination of tissues, including the placenta, shows granulomatous inflammation and microabscess formation. Intracellular organisms can often be demonstrated with special stains.

Table 234.1 Types of *Listeria monocytogenes* Infections

Listeriosis in pregnancy
Neonatal listeriosis
Early onset
Late onset
Food-borne outbreaks/febrile gastroenteritis
Listeriosis in normal children and adults (rare)
Focal *Listeria* infections (e.g., meningitis, endocarditis, pneumonia, liver abscess, osteomyelitis, septic arthritis)
Listeriosis in immunocompromised persons
Lymphohematogenous malignancies
Collagen vascular diseases
Diabetes mellitus
HIV infection
Transplantation
Renal failure with peritoneal dialysis
Listeriosis in elderly persons

PATHOGENESIS

Listeria organisms usually enter the host through the gastrointestinal (GI) tract. Gastric acidity provides some protection, and drugs that raise gastric pH may promote infection. Studies of intracellular and intercellular spread of *L. monocytogenes* have revealed a complex pathogenesis. Four pathogenic steps are described: internalization, escape from the vacuole, nucleation of actin filaments, and cell-to-cell spread. **Listeriolysin O**, a hemolysin, mediates lysis of vacuoles and is responsible for the zone of hemolysis around colonies on blood-containing solid media. In cell-to-cell spread, locomotion proceeds via polymerization of actin filaments, which extrude the bacteria in pseudopods, which in turn are internalized by adjacent cells, necessitating escape from a double-membrane vacuole. This mechanism protects intracellular bacteria from the humoral arm of immunity and is responsible for the well-known requirement of T-cell–mediated activation of monocytes by lymphokines for clearance of infection and establishment of immunity. The significant risk for listeriosis in patients with depressed T-cell immunity speaks for the role of this arm of the immune system. The role of opsonizing antibody in protecting against infection is unclear. In addition, siderophores scavenge iron from the host, enhancing growth of the organism and likely explaining the relatively high risk of listeriosis in iron overload syndromes.

CLINICAL MANIFESTATIONS

The clinical presentation of listeriosis depends greatly on the age of the patient and the circumstances of the infection.

Listeriosis in Pregnancy

Pregnant women have increased susceptibility to *Listeria* infections (approximately 20 times higher than nonpregnant women), probably because of a relative impairment in cell-mediated immunity. *L. monocytogenes* has been grown from placental and fetal cultures of pregnancies ending in spontaneous abortion. The usual presentation in the second and third trimesters is a flulike illness that may result in seeding of the uterine contents by bacteremia. Rarely is maternal listeriosis severe, but meningitis in pregnancy has been reported. Recognition and treatment at this stage are associated with normal pregnancy outcomes, but the fetus may not be infected even if listeriosis in the mother is not treated. In other instances, placental listeriosis develops with infection of the fetus that may be associated with stillbirth or premature delivery. Delivery of an infected premature fetus is associated with very high infant mortality. Disseminated disease is apparent at birth, often with a diffuse pustular rash. Infection in the mother usually resolves without specific therapy after delivery, but postpartum fever and infected lochia may occur.

Neonatal Listeriosis

Two clinical presentations are recognized for neonatal listeriosis: early-onset neonatal disease (<5 days, usually within 1-2 days of birth), which is a predominantly **septicemic** form, and late-onset neonatal disease (>5 days, mean 14 days of life), which is a predominantly **meningitic** form (Table 234.2). The principal characteristics of the two presentations resemble the clinical syndromes described for group B *Streptococcus* (see Chapter 230).

Early-onset disease occurs with milder transplacental or ascending infections from the female genital tract. There is a strong association with recovery of *L. monocytogenes* from the maternal genital tract, obstetric complications, prematurity, and neonatal sepsis with multiorgan involvement, including rash, but without CNS localization (Fig. 234.1). The mortality rate is approximately 20–30%.

The epidemiology of **late-onset disease** is poorly understood. Onset is usually after 5 days but before 30 days of age. Affected infants frequently are full-term, and the mothers are culture negative and asymptomatic. The presenting syndrome is usually purulent meningitis with parenchymal brain involvement, which, if adequately treated, has a mortality rate of <20%.

Table 234.2 Characteristic Features of Early- and Late-Onset Neonatal Listeriosis

EARLY ONSET (<5 DAYS)	LATE ONSET (≥5 DAYS)
Positive result of maternal *Listeria* culture	Negative results of maternal *Listeria* culture
Obstetric complications	Uncomplicated pregnancy
Premature delivery	Term delivery
Low birthweight	Normal birthweight
Neonatal sepsis	Neonatal meningitis
Mean age at onset 1.5 days	Mean age at onset 14.2 days
Mortality rate <30%	Mortality rate <20% Nosocomial outbreaks

Fig. 234.1 *Listeria monocytogenes.* The generalized maculopapular rash present at birth disappeared within a few hours of life. *(From Benitez-Segura I, Fiol-Jaume M, Balliu PR, Tejedor M. Listeria monocytogenes: generalized maculopapular rash may be the clue. Arch Dis Child Fetal Neonatal Ed. 2013;98[1]:F64, Fig. 1.)*

Postneonatal Infections

Listeriosis beyond the newborn period may rarely occur in otherwise healthy children but is most often encountered in association with underlying malignancies (especially lymphomas) or immunosuppression. When associated with food-borne outbreaks, disease may cause GI symptoms or any of the *Listeria* syndromes. The clinical presentation is usually meningitis, less commonly sepsis, and rarely other CNS involvement, such as cerebritis, meningoencephalitis, brain abscess, spinal cord abscess, or a focus outside the CNS, such as suppurative arthritis, osteomyelitis, endocarditis, peritonitis (associated with peritoneal dialysis), or liver abscess. It is not known whether the frequent GI signs and symptoms result from enteric infection because the mode of acquisition is often unknown.

DIAGNOSIS

Listeriosis should be included in the differential diagnosis of infections in pregnancy, of neonatal sepsis and meningitis, and of sepsis or meningitis in older children who have underlying malignancies (lymphomas), are receiving immunosuppressive therapy, or have undergone transplantation. The diagnosis is established by culture of *L. monocytogenes* from blood or cerebrospinal fluid (CSF). Cultures from the maternal cervix, vagina, lochia, and placenta, if possible, should be obtained when intrauterine infections lead to premature delivery or early-onset neonatal sepsis. Cultures from closed-space infections may also be useful. It is helpful to alert the laboratory to suspected cases so that *Listeria* isolates are not discarded as contaminating diphtheroids.

Histologic examination of the placenta is also useful. Molecular assays are now commercially available to detect *L. monocytogenes* from CNS samples and directly from positive blood culture bottles. Serodiagnostic tests are not useful.

Differential Diagnosis

Listeriosis is indistinguishable clinically from neonatal sepsis and meningitis caused by other organisms. The presence of increased peripheral blood monocytes suggests listeriosis. Monocytosis or lymphocytosis may be modest or striking. Beyond the neonatal period, *L. monocytogenes* CNS infection is associated with fever, headache, seizures, and signs of meningeal irritation. The brainstem may be characteristically affected. The white blood cell concentration may vary from normal to slightly elevated, and the CSF laboratory findings are variable and less striking than in the more common causes of bacterial meningitis. Polymorphonuclear leukocytes or mononuclear cells may predominate, with shifts from polymorphonuclear to mononuclear cells in sequential lumbar puncture specimens. The CSF glucose concentration may be normal, but a low level mirrors the severity of disease. The CSF protein concentration is moderately elevated. *L. monocytogenes* is isolated from the blood in 40–75% of cases of meningitis caused by the organism. Deep focal infections from *L. monocytogenes,* such as endocarditis, osteomyelitis, and liver abscess, are also indistinguishable clinically from such infections from more common organisms. Cutaneous infections should be suspected in patients with a history of contact with animals, especially products of conception.

TREATMENT

The emergence of multiantibiotic resistance mandates routine susceptibility testing of all isolates. The recommended therapy is **ampicillin** (100-200 mg/kg/day divided every 6 hours intravenously [IV]; 300-400 mg/kg/day divided every 6 hours IV if meningitis is present), alone or in combination with an **aminoglycoside** (2.0-3.0 mg/kg/day IV divided every 8-24 hours depending on postnatal age). The aminoglycoside enhances the bactericidal activity and is generally recommended in cases of endocarditis and meningitis. The adult dose is ampicillin 4-6 g/day divided every 6 hours plus an aminoglycoside. The ampicillin dose is doubled if meningitis is present. Special attention to dosing is required for neonates, who require longer dosing intervals because of the longer half-lives of the antibiotics in their bodies. *L. monocytogenes* is not susceptible to the cephalosporins, including third-generation cephalosporins. If these agents are used for empirical therapy for neonatal sepsis or meningitis in a newborn, ampicillin must be added for possible *L. monocytogenes* infection. Vancomycin, vancomycin plus an aminoglycoside, and trimethoprim-sulfamethoxazole are alternatives to ampicillin. The duration of therapy is usually 2-3 weeks, with 3 weeks recommended for immunocompromised persons and patients with meningitis. A longer course is needed for endocarditis, brain abscess, and osteomyelitis. Antibiotic treatment is unnecessary for gastroenteritis without invasive disease.

PROGNOSIS

Early gestational listeriosis may be associated with abortion or stillbirth, although maternal infection with sparing of the fetus has been reported. There is no convincing evidence that *L. monocytogenes* is associated with repeated spontaneous abortions in humans. The mortality rate is >50% for premature infants infected in utero, 30% for early-onset neonatal sepsis, 15% for late-onset neonatal meningitis, and <10% in older children with prompt institution of appropriate antimicrobial therapy. Mental retardation, hydrocephalus, and other CNS sequelae are reported in survivors of *Listeria* meningitis.

Table 234.3 Prevention of Food-Borne Listeriosis

GENERAL RECOMMENDATIONS TO PREVENT *LISTERIA* INFECTION

FDA recommendations for washing and handling food:

- Rinse raw produce, such as fruits and vegetables, thoroughly under running tap water before eating, cutting, or cooking. Even if the produce will be peeled, it should still be washed first.
- Scrub firm produce, such as melons and cucumbers, with a clean produce brush.
- Dry the produce with a clean cloth or paper towel.
- Separate uncooked meats and poultry from vegetables, cooked foods, and ready-to-eat foods.

Keep your kitchen and environment cleaner and safer:

- Wash hands, knives, countertops, and cutting boards after handling and preparing uncooked foods.
- Be aware that *Listeria monocytogenes* can grow in foods in the refrigerator. Use an appliance thermometer, such as a refrigerator thermometer, to check the temperature inside your refrigerator. The refrigerator should be 4.5°C (40°F) or lower and the freezer −17.8°C (0°F) or lower.
- Clean up all spills in your refrigerator promptly, especially juices from hot dog and lunch meat packages, raw meat, and raw poultry.
- Clean the inside walls and shelves of your refrigerator with hot water and liquid soap, then rinse.

Cook meat and poultry thoroughly:

- Thoroughly cook raw food from animal sources, such as beef, pork, or poultry, to a safe internal temperature. For a list of recommended temperatures for meat and poultry, visit the safe minimum cooking temperatures chart at http://www.FoodSafety.gov.

Store foods safely:

- Use precooked or ready-to-eat food as soon as you can. Do not store the product in the refrigerator beyond the use-by date; follow USDA refrigerator storage time guidelines:
  - Hot dogs: store opened package no longer than 1 wk and unopened package no longer than 2 wk in the refrigerator.
  - Luncheon and deli meat: store factory-sealed, unopened package no longer than 2 wk. Store opened packages and meat sliced at a local deli no longer than 3-5 days in the refrigerator.
- Divide leftovers into shallow containers to promote rapid, even cooling. Cover with airtight lids or enclose in plastic wrap or aluminum foil. Use leftovers within 3-4 days.

Choose safer foods:

- Do not drink raw (unpasteurized) milk, and do not eat foods that have unpasteurized milk in them.

RECOMMENDATIONS FOR PERSONS AT HIGHER RISK*

In addition to the recommendations listed above, include:

Meats

- Do not eat hot dogs, luncheon meats, cold cuts, other deli meats (e.g., bologna) or fermented or dry sausages unless they are heated to an internal temperature of 73.9°C (165°F) or until steaming hot just before serving.
- Avoid getting fluid from hot dog and lunch meat packages on other foods, utensils, and food preparation surfaces, and wash hands after handling hot dogs, luncheon meats, and deli meats.
- Pay attention to labels. Do not eat refrigerated pâté or meat spreads from a deli or meat counter or from the refrigerated section of a store. Foods that do not need refrigeration, such as canned or shelf-stable pâté and meat spreads, are safe to eat. Refrigerate after opening.

Cheeses

- Do not eat soft cheese such as feta, queso blanco, queso fresco, brie, Camembert, blue-veined, or panela (queso panela) unless it is labeled as made with pasteurized milk. Make sure the label says "*Made With Pasteurized Milk.*"

Seafood

- Do not eat refrigerated smoked seafood, unless it is contained in a cooked dish, such as a casserole, or unless it is a canned or shelf-stable product.
- Refrigerated smoked seafood, such as salmon, trout, whitefish, cod, tuna, and mackerel, is most often labeled as "nova-style," "lox," "kippered," "smoked," or "jerky."
  - These fish are typically found in the refrigerator section or sold at seafood and deli counters of grocery stores and delicatessens.
- Canned and shelf-stable tuna, salmon, and other fish products are safe to eat.

Follow this general FDA advice for melon safety:

- Consumers and food preparers should wash their hands with warm water and soap for at least 20 sec before and after handling any whole melon, such as cantaloupe, watermelon, or honeydew.
- Scrub the surface of melons, such as cantaloupes, with a clean produce brush under running water and dry them with a clean cloth or paper towel before cutting. Be sure that your scrub brush is sanitized after each use to avoid transferring bacteria between melons.
- Promptly consume cut melon or refrigerate promptly. Keep your cut melon refrigerated ≤4.5°C (40°F) (0–1.1°C [32–34°F] is best) for no more than 7 days.
- Discard cut melons left at room temperature for >4 hours.

*Including pregnant women, persons with a weakened immune system, and older adults.
FDA, Food and Drug Administration; USDA, U.S. Department of Agriculture.
Adapted from Centers for Disease Control and Prevention: *Listeria* (listeriosis): prevention. http://www.cdc.gov/listeria/prevention.html.

PREVENTION

Listeriosis can be prevented by pasteurization and thorough cooking of foods. Irradiation of meat products may also be beneficial. Consumption of unpasteurized or improperly processed dairy products should be avoided, especially aged soft cheeses, uncooked and precooked meat products that have been stored at 4°C (39.2°F) for extended periods, and unwashed vegetables (Table 234.3). This avoidance is particularly important during pregnancy and for immunocompromised persons. Infected domestic animals should be avoided when possible. Education regarding risk reduction is aimed particularly at pregnant women and people being treated for cancer.

Careful handwashing is essential to prevent nosocomial spread within obstetric and neonatal units. Immunocompromised patients given prophylaxis with trimethoprim-sulfamethoxazole are protected from *Listeria* infections. Cases, and especially outbreaks, should be reported immediately to public health authorities so that timely investigation can be initiated in order to interrupt transmission from the contaminated source.

ACKNOWLEDGMENTS

We would like to acknowledge Robert S. Baltimore, MD, for his contribution to this chapter and Michelle R. Rychalsky, PharmD, for reviewing antibiotic dosing regimens.

Chapter 235

Actinomyces

Hamid Bassiri

TAXONOMY AND MICROBIOLOGY

Members of the phylum Actinobacteria are common soil and water gram-positive bacteria with high guanine and cytosine DNA content and play important roles in the decomposition of organic materials. A proportion of Actinobacteria form filamentous and branching structures (similar to *Nocardia* spp.) that resemble fungal mycelia; these are included in the class Actinomycetia. The genus *Actinomyces* (which translates literally to "ray fungus") belongs to the order Actinomycetales (along with *Mycobacteria* and *Nocardia*) and family Actinomycetaceae and constitutes several microaerophilic to facultatively anaerobic nonmotile species that are fastidious and slow growing.

More than 50 species of *Actinomyces* have been identified using 16S rRNA sequencing, with more than half of these species associated with human infection. ***Actinomyces israelii*** is the predominant species causing human actinomycosis. Other species associated with infection include but are not limited to *A. odontolyticus, A. meyeri, A. naeslundii, A. graevenitzii, A. neuii,* and *A. turicensis.*

PATHOGENESIS AND EPIDEMIOLOGY

Actinomyces are commensal organisms of the human oropharynx and gastrointestinal and urogenital tracts, and infections by these organisms (termed **actinomycosis**) typically emanate from these anatomic sites. The hallmark of actinomycosis is contiguous spread that fails to respect tissue or fascial planes. As such, these infections can extend to contiguous structures and form abscesses and chronically suppurative granulomatous infections and sinus tracts. Cicatricial healing can then ensue, from which the organism can further spread by burrowing along fascial planes, causing deeply communicating scarred sinus tracts. Sites of infection show dense cellular infiltrates and suppuration that form many interconnecting abscesses and sinus tracts. Bacteremia and infections of more distal sites (such as endocarditis, pericarditis, and central nervous system [CNS] infections) have also been documented. Notably, polymicrobial infections are typical, especially with copathogens such as *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans,* as well as *Fusobacterium, Clostridia, Eikenella, Enterococcus, Bacteroides,* and *Peptostreptococcus* spp.

Knowledge regarding the epidemiology of actinomycosis is limited to case reports and case series. Based on these reports, actinomycosis appears to affect people of all ages, with no racial or ethnic predilection, seasonality, or occupational associations. Actinomycosis occurs in immunocompetent and immunocompromised hosts. However, pediatric actinomycosis only represents approximately 3% of reported cases. Risk factors in children include trauma, dental caries, debilitation, and poorly controlled diabetes. Although actinomycosis is not a common opportunistic infection, disease has been associated with corticosteroid use, leukemia, renal failure, congenital immunodeficiencies, HIV infection, and solid organ or hematopoietic stem cell transplantation.

Given the sites of colonization, the most common presentations of *Actinomyces* infections include cervicofacial, abdominal/pelvic, and thoracic regions (in order of frequency). Importantly, certain medical interventions can result in mucosal barrier injuries and infection. For instance, use of intrauterine contraceptive devices can predispose to pelvic actinomycosis, and aspiration events, poor dentition, and recent dental procedures can result in involvement of the thoracic region. However, more than one third of patients do not have an identifiable antecedent event that would explain the onset of actinomycosis. Importantly, actinomyces infections are not contagious.

DIAGNOSIS

Diagnosis of actinomycosis relies on identification of the organism in tissues of affected areas via culture, molecular methods, and/or histopathology. However, growth in cultures can take up to 2-3 weeks, and up to 50% of cultures may reveal no growth because of prior antibiotic exposure, failure to maintain anaerobic conditions during sample transport, or inadequate incubation.

The presence of **sulfur granules** on macroscopic or microscopic evaluation (Fig. 235.1) of involved tissue is suggestive of actinomycosis. Despite their name, these granules are not composed of sulfur, instead deriving this designation because of their typical yellow color on macroscopic appearance; they can also be white, gray, or brown. Similar granules can be formed by *Nocardia brasiliensis, Streptomyces madurae* (which can cause mycetomas), and *Staphylococcus aureus* (which can cause botryomycosis). Microscopically, these granules appear on hematoxylin-eosin or Gomori methenamine silver stains as masses of gram-positive, branching, filamentous rods surrounded by the host immune cells (e.g., polymorphonuclear neutrophils) and a milieu of eosinophilic staining inert material, often referred to as the **Splendore-Hoeppli phenomenon**. Notably, *A. meyeri* is nonbranching and *A. odontolyticus* does not form sulfur granules.

Nocardia are indistinguishable from *Actinomyces* on Gram stain, but *Nocardia* take up the modified acid-fast stain, whereas *Actinomyces* spp. do not. Although suggestive of actinomycosis, sulfur granules are often absent, and thus additional testing such as cultures are necessary for the diagnosis. Affected tissues can be cultured on

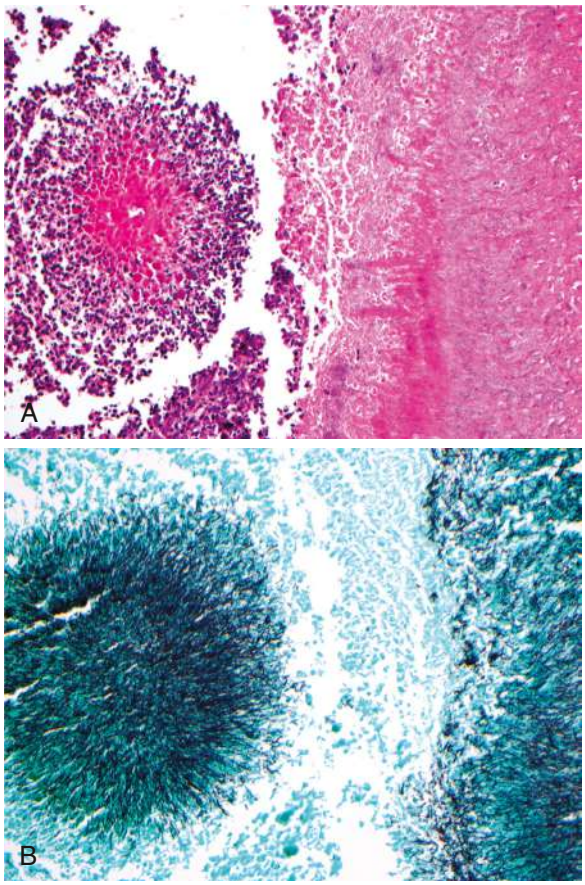

Fig. 235.1 Actinomycosis. **A,** Small cluster of *Actinomyces* on left, with sulfur granule and surrounding mixed inflammation demonstrating the Splendore-Hoeppli phenomenon (×200). **B,** Gomori methenamine silver stain of the same field, highlighting the filamentous forms (×200). *(From Johnson MM. Ear, nose, and throat infections. In: Kradin RL, ed. Diagnostic Pathology of Infectious Disease, 2nd ed. Philadelphia: Elsevier; 2018: Fig. 7.6.)*

brain-heart infusion agar incubated at 37°C anaerobically and aerobically to reveal organisms within the lines of streak at 24-48 hours. *A. israelii* colonies appear as loose masses of delicate, branching filaments with a characteristic spider-like growth. Unfortunately, even under the right conditions, it is challenging to grow *Actinomyces,* and the yield of different culturing techniques varies by species. Additionally, conventional biochemical testing for speciation is complex and may result in misclassifications. The evolution of diagnostic tools such as 16S rRNA sequence analysis and matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry has improved the accuracy of speciation of cultured organisms and highlighted the potential for detection of *Actinomyces* directly from the involved tissue without culture.

Importantly, actinomycosis is usually, if not always, **polymicrobial** in nature. In a large study of >650 cases, infection with *Actinomyces* was identified in pure culture in only 1 case. Cultures usually also identify other endogenous flora, including members of the **HACEK group**, which includes *Haemophilus* spp. (typically *H. aphrophilus, H. parainfluenzae,* or *H. paraphrophilus*), *A. actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella kingae. A. actinomycetemcomitans* is a fastidious, gram-negative bacillus that is part of the oral flora and has been implicated in periodontal disease. Other bacteria frequently isolated concomitantly in human actinomycosis include *Fusobacterium, Bacteroides, Capnocytophaga,* and aerobic and anaerobic streptococci.

CT or MRI of involved areas is often employed in the initial patient evaluation. Imaging evidence of an invasive process spreading across tissue planes and ignoring anatomic boundaries is highly suggestive of actinomycosis. Furthermore, imaging can be helpful in establishing the extent of the infection, guiding subsequent diagnostic and therapeutic interventions, and monitoring for disease resolution.

COMMON CLINICAL PRESENTATIONS

Cervicofacial Actinomycosis

Cervicofacial disease is the most common form of pediatric actinomycosis and often manifests as a neck or submandibular mass that persists for weeks to months. Less than half of patients will have associated pain, and less than one third of patients will have fever. A minority of patients will report dysphagia or have a draining sinus (Fig. 235.2). Less frequently, cervicofacial actinomycosis manifests clinically as an acute pyogenic infection with a tender, fluctuant mass with trismus, firm swelling, and fistulas with drainage containing sulfur granules. Bone is not involved early in the disease, but periostitis, mandibular osteomyelitis, or perimandibular abscess may subsequently develop. Infection may spread through sinus tracts to cranial bones, possibly leading to meningitis. The ability of *Actinomyces* to burrow through tissue planes, including the periosteum, is a key difference between actinomycosis and nocardiosis. Whereas predisposing factors for cervicofacial actinomycosis are not well defined for children, adult cases are often preceded by a history of oral trauma, oral surgery, dental procedures, or caries, facilitating entry of organisms into cervicofacial tissues.

Fig. 235.2 A 2-yr-old male with HIV infection who has cervicofacial actinomycosis and a draining fistula.

Abdominal and Pelvic Actinomycosis

Of all the forms of actinomycosis, delayed diagnosis is most typical for abdominal and pelvic infection. A disruption of the mucosa of the gastrointestinal (GI) tract (e.g., acute GI perforation, abdominal trauma, prior abdominal surgery) is often postulated as the inciting event for adult-onset abdominopelvic actinomycosis. In pediatric patients, however, medical history sometimes fails to identify prior evidence of mucosal barrier injury. In a contemporary pediatric case series of abdominal and pelvic actinomycosis, prior abdominal surgery (all appendectomies) was reported in only 21% of patients and dental caries in 11%. In two thirds to three fourths of patients, the presenting signs are abdominal pain and a palpable mass on physical exam. Fever accompanies the abdominal pain in more than half of cases, with weight loss in almost one third. As with other forms of actinomycosis, abdominopelvic infection can spread across tissue planes by contiguous extension involving any tissue or organ, including muscle, solid abdominopelvic viscera, and walls of the intestinal tract. Imaging studies may reveal a mass with invasion of tissue planes, leading to misdiagnosis of malignancies, inflammatory bowel disease with fistulae, or abdominal tuberculosis. Genitourinary actinomycosis is often associated with use of intrauterine contraceptive devices (IUDs) in adults and can mimic gynecologic tumors, but these infections are quite rare in adolescents. Because of delays in diagnosis, more than one third of pediatric cases present with draining sinus fistulae.

Thoracic Actinomycosis

Thoracic actinomycosis may present with cough, chest pain, hemoptysis, and fever. In a retrospective review of reported pediatric cases of thoracic infection, almost half presented with a chest wall mass. Additional symptoms such as cough, fever, chest pain, and weight loss were reported in <40% of patients. Radiographic imaging may reveal hilar lymphadenopathy, endobronchial infection, tumor-like lesions, diffuse pneumonia, pleural effusions, or abscesses with or without cavitation and parenchymal lung destruction. These abscesses can also form sinus tracts to the diaphragm or mediastinum, which are often pathognomonic for actinomycosis. Other complications include bony destruction of adjacent ribs, sternum, and vertebral bodies. Multiple lobe involvement of the lungs is occasionally found. Importantly, evidence of thoracic actinomycosis can be found incidentally on radiographs ordered for noninfectious concerns. The variation in presentation and indolent nature of thoracic actinomycosis often delay the diagnosis.

Other Forms of Actinomycosis

CNS actinomycosis is often the result of hematogenous spread to the brain parenchyma from a distant site but can also ensue from contiguous spread from a cervicofacial lesion. The former often results in multiple brain abscesses. **Laryngeal** actinomycosis rarely has been reported in older teenagers. Oropharyngeal colonization with *Actinomyces* may be involved in the development of obstructive tonsillar hypertrophy. Severe forms of **periodontitis**, particularly localized juvenile periodontitis, are associated with *Actinomyces,* especially in adolescents. *Actinomyces* has a propensity for infecting heart valves, a process that results in subacute endocarditis, with fever present in less than half of cases.

DIFFERENTIAL DIAGNOSIS

Actinomycosis has been referred to as a "great imitator" with presentations that mimic appendicitis, pseudoappendicitis caused by *Yersinia enterocolitica,* amebiasis, malignancy, and inflammatory bowel disease. Actinomycosis must be differentiated from other chronic infections,

including tuberculosis, nocardiosis, polymicrobial bacterial infections, and fungal infections.

TREATMENT

Most cases of actinomycosis can be managed with antibiotics, although surgery can be adjunctive and may shorten the duration of antibiotic use. Routine susceptibility testing is not typically performed, as most *Actinomyces* spp. are susceptible to penicillin. Accordingly, penicillin G is the drug of choice for parenteral therapy, and penicillin V or amoxicillin is the preferred enteral antibiotic. Because actinomycosis is often found to be polymicrobial in nature, use of combination β-lactam/β-lactamase inhibitors (e.g., ampicillin-sulbactam or amoxicillin-clavulanate) may be warranted, especially if there is an initial poor response. In particular, ***A. actinomycetemcomitans*** is a copathogen in at least 30% of cases of actinomycosis. Failure to recognize this organism and treat it adequately has resulted in clinical relapse and deterioration.

Treating actinomycosis in a patient with a penicillin allergy can be challenging, as there is variation in susceptibility by *Actinomyces* spp. to other antibiotic classes; alternatives generally include cephalosporins, carbapenems, macrolides, and tetracyclines. Despite being anaerobic, a large percentage of *Actinomyces* are not susceptible to metronidazole, and isolates are variably susceptible to clindamycin. Fluoroquinolones and aminoglycosides have little to no activity against *Actinomyces* spp. Infectious disease specialists should be consulted to guide antibiotic usage in patients with penicillin allergy or deep-seated infections such as brain abscesses, endocarditis, or osteomyelitis. Commercially available sensitivity testing methods are available and can be employed in patients with severe disease or poor response to initial therapy.

No definitive comparative effectiveness data exist to guide the optimal route and duration of therapy. For severe or extensive infections, most experts recommend initial parenteral administration of antibiotics for 4-6 weeks and then transitioning to enteral therapy upon documentation of clinical improvement. The exceptions include endocarditis and CNS disease, which generally require parenteral administration for the entire course of therapy. In cases of mild or limited disease, enteral antibiotics could be considered even at initiation. Given concern for relapses, antibiotics are often continued for several months, with total durations ranging between 2-6 months for mild/limited disease and 6-12 months for severe/extensive disease. Shorter courses of antibiotic therapy can result in relapses, especially in cases of thoracic actinomycosis without surgical debridement. Longer courses up to 18 months have also been used in invasive disease and in immunocompromised patients. At the same time, courses of antibiotic therapy <3 months have been used successfully in cases of local disease, especially after surgical resection. Close follow-up and monitoring are indicated in patients treated with short courses of antibiotics. The total duration of treatment is often ultimately dictated by the location of the infection and follow-up clinical exams and imaging.

Traditionally, an adjunctive surgical intervention was thought to be necessary for a successful outcome. However, in some case series a subset of patients have responded well to medical management alone. In the setting of significant abscesses and/or sinus tracts, a surgical approach to establish source control and, if possible, completely resect involved issue can hasten clinical improvement. The morbidity of the surgical procedure needs to be weighed against the potential benefits for each patient.

PROGNOSIS

The prognosis is excellent with early diagnosis, prompt initiation of antibiotic therapy, adherence to a prolonged course of antibiotics, and adequate surgical debridement, if necessary. Despite a good overall prognosis, permanent scarring can still develop. Although actinomycosis can present in immunocompetent children, disseminated or recalcitrant actinomycosis should raise suspicion for immunodeficiency.

Chapter 236

Nocardia

Coralee Del Valle Mojica

Various *Nocardia* species have been identified causing localized and disseminated disease in children and adults. These organisms are predominantly opportunistic pathogens infecting immunocompromised individuals, but cases in immunocompetent hosts are increasingly reported. Infection caused by these bacteria is termed *nocardiosis,* which consists of acute, subacute, or chronic suppurative manifestations.

ETIOLOGY

Nocardia spp. are a complex group of environmental, gram-positive bacteria that belong to aerobic actinomycetes. They can grow on diverse media (e.g., blood agar, brain-heart infusion agar, Lowenstein-Jensen media, buffered charcoal-yeast extract [BCYE], Sabouraud dextrose agar) and have been referred to as bacteria that masquerade as fungi, sometimes misdirected to the mycology or mycobacteriology section of clinical laboratories for identification. Colonies can appear as early as 48 hours, but typically growth of *Nocardia* is slower than in other bacteria and may take 1-2 weeks. Growth appears as waxy, folded, or heaped colonies at the edges, and yield is best achieved in conditions that include a temperature of 37°C (98.6°F) with 10% carbon dioxide. However, many isolates of *Nocardia* are thermophilic and will grow at temperatures up to 50°C (122°F). Microscopically, *Nocardia* spp. are weakly gram-positive, rod-shaped, filamentous bacteria. For some isolates, there may be alternating areas of gram-positive and gram-negative staining, giving a beaded appearance often described with *Nocardia*. These organisms are also weakly acid-fast, and the modified Kinyoun acid-fast staining technique can be helpful to identify organisms from clinical specimens such as a tissue biopsy or bronchoalveolar lavage (BAL).

To date, more than 80 species of *Nocardia* have been described and 50 species have been identified to be human pathogens. The distribution of *Nocardia* spp. causing disease varies across studies, partly because of revisions in taxonomic classification over time. A retrospective study looking at isolates in the United States from 1995 to 2004 reported *N. nova, N. brasiliensis,* and *N. farcinica* as the most common species. In contrast, a more recent study from China reported *N. otitidiscaviarum* as the most common species, and a systematic review from Iran from 1992 to 2021 reported *N. asteroides* and *N. cyriacigeorgica* as the two most common species. Species identification can be critical for optimal clinical outcomes because of variability in virulence strategies and antibiotic-resistance profiles. Traditional approaches to speciation require biochemical processing that can be laborious and inefficient. Techniques such as 16S rDNA polymerase chain reaction (PCR) or matrix-assisted laser desorption/ionization (MALDI) time of flight (TOF) mass spectrometry are now considered the gold standard.

EPIDEMIOLOGY

Once thought to be a rare human disease, nocardiosis is being recognized more frequently and has been diagnosed in people of all ages. Pediatric patients with compromised cellular immunity are at particular risk, including children receiving immune suppression after solid organ or stem cell transplantation, chemotherapy for malignancy, prolonged corticosteroid therapy, children with poorly controlled HIV infection, or those with a primary immunodeficiency, especially chronic granulomatous disease. Notably, nocardiosis has been described in patients without an identified immune defect, although in these clinical scenarios, other predisposing factors such as bronchiectasis are often present.

Due to the lack of a national reporting system for *Nocardia* infections and the molecular advances impacting the classification of this organism, measuring the incidence of the disease remains a challenge. Current knowledge of nocardiosis incidence in the United States is based on a historical survey of 171 infectious diseases physicians from 1974 and isolates received at the CDC reference laboratory, estimating 500-1000 cases annually. Prevalence estimates in high-risk populations have been reported to be less than 1%, with conflicting reports about the trends of infections in different geographic locations around the world.

PATHOGENESIS

Nocardia organisms are environmental saprophytes that are ubiquitous in soil and decaying vegetable matter and have been isolated from soil worldwide. Infection can be acquired via inhalation or direct cutaneous inoculation, including after arthropod and cat bites. From 70% to 80% of *Nocardia* infections originate in the pulmonary parenchyma, with 10–25% being primary cutaneous disease.

Nocardia can disseminate from the primary site of infection to any organ or any musculoskeletal location. Dissemination after primary lung infection is common, occurring in 15–50% of patients; those with an underlying immunocompromised condition are more likely to have disseminated disease. The central nervous system (CNS) is the most concerning and most common secondary site of infection, complicating as much as 25% of pulmonary disease. Although rare, isolated CNS disease has been described. Whereas most cases are the result of environmental exposure, *Nocardia* species diversity in the hospital environment has been reported as a reservoir for the development of nosocomial infections.

CLINICAL AND RADIOGRAPHIC MANIFESTATIONS

The clinical presentation can be nonspecific, with fever reported in approximately 60% of patients, cough in 30%, and dyspnea in 25%. Extrapulmonary signs and symptoms can correspond to the site of infection. In particular, neurologic deficit has been reported in up to 25% of all cases and in more than 50% of patients with CNS involvement. Neurologic complaints can include headache, confusion or altered mental status, weakness, and speech impairment. Renal nocardiosis can cause dysuria, hematuria, or pyuria, and gastrointestinal (GI) involvement may be associated with nausea, vomiting, diarrhea, abdominal distention, or melena. Skin infection can manifest with nodular lymphangitis (Fig. 236.1). Mycetoma is a chronic, progressive infection developing days to months after inoculation, usually on a distal location on the limbs. Musculoskeletal, endovascular, and ocular infections have also been reported.

Given the nonspecific symptoms and signs of nocardiosis (with the exception of cutaneous lesions), radiographic imaging is often necessary to define the location and extent of disease. Pulmonary infection can appear as a consolidation consistent with typical bacterial pneumonia or even as a necrotizing pneumonia with or without a pleural effusion. Single or multiple nodules and cavitary lesions have also been described. Cavitary lesions are more common in patients with an underlying immunocompromising condition. CNS disease can take the form of meningitis or focal lesions. Meningitis presents as neutrophil- or lymphocyte-predominant pleocytosis, elevated cerebrospinal fluid protein, and hypoglycorrhachia. For focal lesions, CT or MRI of the brain often reveals single- or multiple-ring enhancing lesions. Similar to the brain, when other organs or soft tissues are involved, CT or MRI also typically reveals single- or multiple-ring enhancing lesions, suggestive of an abscess or abscesses.

DIAGNOSIS

Microbiologic evidence is necessary to confirm the diagnosis of nocardiosis. In one systematic review, blood cultures were the only positive microbiologic specimen in 38% of cases, thus serving as an important noninvasive diagnostic test for nocardiosis. In the remaining patients, an invasive procedure such as bronchoscopy, tissue biopsy, or abscess aspiration is necessary to procure specimens for diagnostic testing. Histopathologic staining of such material can reveal beaded, weakly gram-positive or modified acid-fast filamentous bacteria. Histopathology can also show delicately branching bacteria with a proclivity to fragment.

Molecular methodologies, specifically gene sequencing, have become the most accurate for definitively identifying *Nocardia* to the species level. Speciation of *Nocardia* is becoming increasingly reliant on 16S rDNA PCR or MALDI-TOF technologies, with a specificity of 74% and a sensitivity of 88% in a multicenter study assessing the performance of 16S sequencing in 68 patients with proven or probable nocardiosis. Given that *Nocardia* spp. can colonize the respiratory airway, a sputum or BAL culture that yields a *Nocardia* species is not itself confirmatory of nocardiosis. However, a positive microbiologic test for a *Nocardia* species from one of these specimens in conjunction with the clinical and radiographic findings is strongly supportive of nocardiosis.

When a diagnosis of nocardiosis is made, strong consideration should be given to evaluation for disseminated disease, even in the absence of signs or symptoms, especially in the immunocompromised host. Although data are limited, most experts agree that, at a minimum, MRI of the brain should be performed in the immunocompromised host with nocardiosis.

TREATMENT

The choice, dose, and duration of antimicrobial treatment depend on the site and extent of infection, immune status of the patient, initial clinical response, and species and susceptibility testing of the *Nocardia* isolate. Several therapeutic options exist for the treatment of nocardiosis; however, there are no comparative effectiveness studies to inform the optimal therapeutic regimen. **Trimethoprim-sulfamethoxazole (TMP-SMX)** is the sulfonamide formulation that is recommended, although sulfadiazine and sulfisoxazole have been used. Increasing recognition of resistance to TMP-SMX across and within *Nocardia* spp. highlights the importance of speciation of *Nocardia* isolates and of performing sensitivity testing in a certified microbiology laboratory. TMP-SMX resistance rates as high as 42% have been reported. Administration of TMP-SMX as prophylaxis against *Pneumocystis jirovecii* pneumonia is not always protective against nocardiosis, and thus clinicians should not exclude this diagnosis from the differential in patients receiving TMP-SMX prophylaxis.

Fig. 236.1 A 9-yr-old healthy child with infected knee laceration (A) 10 days after falling onto concrete in his school playground, complicated by nodular lymphangitis (B). *(From Williams PCM, Bartlett AW, Palasanthiran P, McMullan B. A not so innocuous playground fall: lymphocutaneous nocardiosis in an immunocompetent boy. Arch Dis Child. 2022;107[3]:257–258, Figs. 1 and 2.)*

Other antibacterial agents with in vitro activity against *Nocardia* spp. include but are not limited to **amikacin, amoxicillin-clavulanate, ceftriaxone, ciprofloxacin, clarithromycin, imipenem, linezolid, and minocycline**. A recent study profiling the antimicrobial susceptibility pattern of a diverse range of *Nocardia* revealed that among 146 isolates, the susceptibilities were 100% to linezolid, 96% to amikacin, 94% to TMP-SMX, and 76% to imipenem. A similar retrospective study conducted in the United States from 1995 to 2004 revealed that 42% of the isolates were resistant to TMP-SMX. Therefore while awaiting sensitivity testing in patients with *Nocardia* isolated from a clinical specimen, it may be reasonable to administer linezolid empirically, taking into account local susceptibility data. Subsequent therapeutic decisions should be guided by final sensitivity results and consideration of the site of infection and pharmacokinetics of the available agents. It is not clear whether parenteral administration is superior to enteral formulations. However, most experts support the use of parenteral therapy for more severe disease, including endocarditis and CNS disease.

In vitro and in vivo animal models have suggested the benefit of combination regimens for the treatment of nocardiosis. There are no clinical data to confirm the need for combination therapy; however, based on the preclinical data, there is expert support for using combination therapy in CNS nocardiosis, in disseminated disease, and in children with an underlying immunocompromising condition. A variety of combination therapies have been suggested, with many experts favoring TMP-SMX, amikacin, and a carbapenem or third-generation cephalosporin. Since data on combination therapy are limited, antibiotic choices should primarily be guided by sensitivity testing of the clinical *Nocardia* isolate.

Surgical drainage of abscesses can be helpful in hastening resolution of nocardiosis. However, no comparative data have documented improvement in overall outcomes with adjunctive surgical intervention, and success has been reported with medical management alone in resolving deep-seated abscesses, even in the CNS. A literature review showed that among patients with CNS nocardiosis, 1-year overall mortality was approximately 20%, limited by cases lost to follow-up. Among patients who were treated with a combination of antibiotics and neurosurgical procedures, mortality was lower (7%). Therefore the decision to intervene surgically needs to be balanced with the potential consequences of a surgical procedure to drain an abscess. Intraventricular antibiotics have been reported.

The necessary duration of therapy for nocardiosis varies depending on the clinical presentation and the status of the patient. The optimal duration is uncertain, but long-term therapy is common because of the propensity for relapse. Historically, superficial cutaneous infection has been treated for 3 months, pulmonary or systemic nocardiosis has been treated for 6-12 months, and CNS infection has been treated for at least 12 months. These intervals should only be considered as a guide for expected therapeutic durations. The ultimate duration should be dictated by clinical and radiographic resolution of disease.

PROGNOSIS

Historically, nocardiosis has been associated with significant mortality. Fortunately, more recent reports have documented an improved rate of complete cure to approximately 80%. Predictably, attributable case fatality rates vary by disease entity. There is no attributable case fatality associated with cutaneous disease, but 10–20% attributable case fatality has been assigned to disseminated and visceral disease. CNS disease has the highest attributable case fatality rates, reaching 25%. Importantly, much of the data on case fatality rates are informed by predominantly adult cohorts, and thus there may be fewer fatal outcomes in children. Nonetheless, early diagnosis and intervention are important to reduce the morbidity and mortality of nocardiosis, especially in immunocompromised patients at increased risk for disseminated disease.

Section 5

Gram-Negative Bacterial Infections

Chapter 237

Neisseria meningitidis (Meningococcus)

Manish Sadarangani

Neisseria meningitidis (the meningococcus) is a commensal of the human nasopharynx in approximately 10% of the population and, on rare occasions, enters the bloodstream to cause devastating invasive disease such as meningitis and meningococcal septicemia (meningococcemia). Although a rare endemic disease in most countries, the epidemiology of meningococcal disease varies widely over time and in different geographic regions, with both hyperendemic and epidemic disease patterns occurring. Onset of disease in susceptible individuals may be very rapid, within hours, and the case fatality rate is high, especially among those presenting with septic shock, despite access to modern critical care. Individual susceptibility is known to involve a complex relationship among environmental, host, and bacterial factors, and prevention of meningococcal disease through behavior modification (e.g., avoiding tobacco smoke) and vaccination offers the best prospect for control.

ETIOLOGY

N. meningitidis is a gram-negative, fastidious, encapsulated, oxidase-positive, aerobic diplococcus. Differences in the chemistry of the polysaccharide capsule allow definition of 12 (previously thought to be 13) serologically distinct meningococcal capsular groups, of which 6, designated A, B, C, W (previously designated W135), X, and Y, are responsible for almost all cases of disease. Meningococcal strains may be subclassified on the basis of antigenic variation in two porin proteins found in the outer membrane, **PorB** (serotype) and **PorA** (serosubtype), and **lipopolysaccharide** (immunotype), using serology. Serologic typing is being replaced by molecular typing methods, which target genes under immune selection to provide **antigen sequence typing** (based on amino acid variation in various surface proteins, including PorA and FetA). Sequencing of antigen genes (e.g., *porA, fHbp, nadA, nhba*) is an important means of monitoring pressure on meningococcal populations by protein-based vaccines containing these antigens. Because meningococci readily exchange genetic material, typing based on a few antigens cannot provide an accurate picture of relatedness of strains, an important goal in monitoring epidemiology. **Multilocus sequence typing**, which types meningococci using variation in seven housekeeping genes, has been widely used to map the distribution of genetic lineages of meningococci (http://pubmlst.org/neisseria/) and provides a clearer picture of the genetic and epidemiologic relatedness of strains. To provide still better definition of genetic variation, in some countries, including the United Kingdom, **whole genome sequencing** is used to type meningococci and appears set to replace both antigen and multilocus sequence typing as costs continue to fall. The application of molecular approaches to epidemiology has established that (1) endemic meningococcal disease is caused by genetically heterogeneous strains, although only a small number of genetic lineages are associated with the majority of cases of invasive disease, and (2) outbreaks are usually clonal, caused by single strains.

EPIDEMIOLOGY

Meningococci are transmitted during close contact through aerosol droplets or exposure to respiratory secretions, as by kissing. The organism does not survive for long periods in the environment. Enhanced rates of mucosal colonization and increased disease risk are associated with activities that increase the likelihood of exposure to a new strain or increase proximity to a carrier, thus facilitating transmission, including kissing, bar patronage, binge drinking, attendance at nightclubs, men having sex with men, and living in freshman college dormitories. Factors that damage the nasopharyngeal mucosa, such as smoking and respiratory viral infection (notably influenza), are also associated with increased rates of carriage and disease, perhaps by driving upregulation of host adhesion molecules that are receptors for meningococci. Carriage is unusual in early childhood and peaks during adolescence and young adulthood.

Meningococcal disease is a global problem, but disease rates vary by a factor of 10- to 100-fold in different geographic locations at one point in time and in the same location at different times. Most cases of meningococcal disease are sporadic, but small outbreaks (usually in schools or colleges, representing <3% of U.S. cases), **hyperendemic** disease (increased rates of disease persisting for a decade or more as a result of a single clone), and epidemic disease are all recognized patterns. However, over the past decade, rates of meningococcal disease have declined in most industrialized countries, partly through introduction of immunization programs and possibly aided by widespread legislation against smoking in public places. The arrival of hyperinvasive lineages and their eventual decline through development of natural immunity is recognized as a major driver of changes in disease rates over time. The U.S. disease rate was 1.1 cases per 100,000 population in 1999 but had fallen to 0.11 per 100,000 by 2019 (Fig. 237.1). By contrast, the rate of disease in Ireland in 1999 was >12 per 100,000, and rates of 1,000 per 100,000 have been described during epidemic disease in sub-Saharan Africa. Disease caused by dominant hyperendemic clones has been recognized in the past 2 decades in Oregon, United States; Quebec, Canada; Normandy, France; and across New Zealand. Laboratory data underreport meningococcal disease incidence rates because up to 50% of cases are not culture confirmed, particularly where prehospital antibiotics are recommended for suspected cases. In the United Kingdom, polymerase chain reaction (PCR) methods are used routinely for diagnosis of suspected cases, doubling the number of confirmed cases.

The highest rate of meningococcal disease occurs in infants <1 year old, probably as a result of *immunologic inexperience* (antibody that recognizes meningococcal antigens is naturally acquired during later childhood), immaturity of the alternative and lectin complement pathways, and perhaps the poor responses made by infants to bacterial polysaccharides. In the absence of immunization, incidence rates decline through childhood, except for a peak of disease among adolescents and young adults, which may be related to increased opportunity for exposure from social activities. The incidence of meningococcal disease is increased among persons with HIV infection.

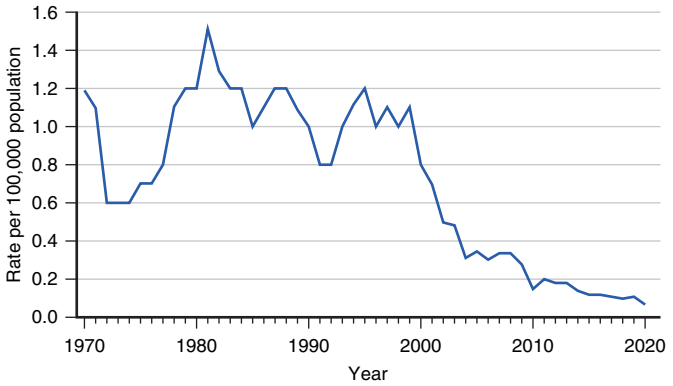

Fig. 237.1 Rate of meningococcal disease, by year—United States, 1970–2020. *(Modified from Cohn AC, MacNeil JR, Clark TA, et al; Centers for Disease Control and Prevention. Prevention and control of meningococcal disease: recommendations of the Advisory Committee on Immunization Practices. MMWR Recomm Rep 2013;62[RR-2]:1–28, updated with data from the CDC meningococcal surveillance data tables: https://www.cdc.gov/meningococcal/surveillance/surveillance-data.html#figure01.)*

In the United States, most cases of disease in the first 5 years of life are caused by capsular **group B** strains. After age 5 years, disease cases are mostly distributed among capsular groups C, W, and Y. In most other industrialized countries, capsular group B strains predominate at all ages, in part because of introduction of routine capsular **group C** meningococcal conjugate vaccine among infants and/or toddlers. For unclear reasons, disease in children caused by group Y strains was uncommon in the United States before the 1990s and then began to increase. Rates of disease caused by this capsular group have also increased in several other countries but are declining in the United States. Disease caused by capsular **group W** strains has increased in the United Kingdom and in other countries in Europe and Australia as a result of a hyperinvasive clone, which appears to have originated in Latin America.

Large outbreaks of capsular **group A** meningococcal disease occurred during and immediately after the First World War and Second World War in both Europe and the United States, but since the 1990s, almost all cases caused by capsular group A strains have occurred in Eastern Europe, Russia, and developing countries. The highest incidence of capsular group A disease has occurred in a band across sub-Saharan Africa, the *meningitis belt,* with annual endemic rates of 10-25 per 100,000 population. For more than a century, this region has experienced large capsular group A epidemics every 7-10 years, with annual rates as high as 1,000 per 100,000 population. The onset of cases in the sub-Saharan region typically begins during the dry season, possibly related to drying and damage to the nasopharyngeal mucosa; subsides with the rainy season; and may reemerge the following dry season. Rates of capsular group A meningococcal disease are currently falling across this region as a result of a mass vaccine implementation targeting strains bearing the A polysaccharide. However, both endemic and epidemic meningococcal disease in this region is also caused by capsular groups C, W, and X strains. Capsular group A and **group X** are infrequent causes of disease in other areas of the world, although both A and W strains have been associated with outbreaks among pilgrims returning from the Hajj.

PATHOGENESIS AND PATHOPHYSIOLOGY

Colonization of the nasopharynx by *N. meningitidis* is the first step in either carriage or invasive disease. Disease usually occurs 1-14 days after acquisition of the pathogen. Initial contact of meningococci with host epithelial cells is mediated by pili, which may interact with the host CD46 molecule or an integrin. Close adhesion is then mediated by Opa and Opc binding to carcinoembryonic antigen (CEA) cell adhesion molecule receptors and integrins, respectively. Subsequent internalization of meningococci by epithelial cells is followed by transcytosis through to the basolateral tissues and dissemination into the bloodstream. Immunoglobulin A_1 protease secreted by invasive bacteria degrades secretory IgA on the mucosal surface, circumventing this first-line host defense mechanism.

Once in the bloodstream, meningococci multiply rapidly to high levels to cause septicemia (**meningococcemia**). Patients with a higher bacterial load have a more rapid clinical deterioration and longer period of hospitalization, as well as a higher risk of death and permanent sequelae. Resistance to complement-mediated lysis and phagocytosis is largely mediated by the polysaccharide capsule and **lipopolysaccharide (LPS)**. Outer membrane vesicles released from the surface of the organism contain LPS, outer membrane proteins, periplasmic proteins, and phospholipid and play a major role in the inflammatory cascade that leads to severe disease.

Much of the tissue damage is caused by host immune mechanisms activated by meningococcal components, in particular LPS. During invasive disease LPS is bound to a circulating plasma protein known as *LPS-binding protein.* The host receptor complex for LPS consists of toll-like receptor (TLR)-4, CD14, and myeloid differentiation protein 2. Binding of LPS to TLR-4, which is upregulated on circulating leukocytes during septicemia, results in activation of a number of different cell types. An intense inflammatory reaction results from secretion of proinflammatory cytokines such as tumor necrosis factor (TNF)-α, interleukin

(IL)-1β, IL-6, IL-8, and granulocyte-macrophage colony-stimulating factor, levels of which are closely associated with plasma levels of LPS. The major antiinflammatory cytokines IL-1Rα, IL-2, IL-4, and IL-12 and transforming growth factor-β are present at very low levels. Both high and low levels have been observed for IL-10 and interferon-γ.

The pathophysiologic events that occur during meningococcal septicemia are largely related to microvascular injury. This injury leads to increased vascular permeability and capillary leak syndrome, pathologic vasoconstriction and vasodilation, disseminated intravascular coagulation (DIC), and profound myocardial dysfunction. Increased vascular permeability can lead to dramatic fluid loss and severe hypovolemia. **Capillary leak syndrome** with or without aggressive fluid resuscitation (which is essential in severe cases) leads to pulmonary edema and respiratory failure. Initial vasoconstriction is a compensatory mechanism in response to hypovolemia and results in the clinical features of pallor and cold extremities. After resuscitation, some patients experience **warm shock**, that is, intense vasodilation with bounding pulses and warm extremities, despite persistent hypotension and metabolic acidosis. Virtually all antithrombotic mechanisms appear to be dysfunctional during meningococcal sepsis, leading to a procoagulant state and DIC. All these factors contribute to depressed myocardial function, but there is also a direct negative cytokine effect on myocardial contractility, thought to be largely mediated by IL-6. Hypoxia, acidosis, hypoglycemia, hypokalemia, hypocalcemia, and hypophosphatemia are all common features in severe septicemia and further depress cardiac function. Some patients become unresponsive to the positive inotropic effects of catecholamines and require high levels of inotropic support during intensive care management. These processes result in impairment of microvascular blood flow throughout the body and ultimately lead to **multiorgan failure**, which is responsible for much of the mortality.

After invasion of the circulation, meningococci may also penetrate the blood-brain barrier and enter the cerebrospinal fluid (CSF), facilitated by pili and possibly Opc. Once there, bacteria continue to proliferate, and LPS and other outer membrane products can stimulate a proinflammatory cascade similar to that observed in the blood. This leads to upregulation of specific adhesion molecules and recruitment of leukocytes into the CSF. Central nervous system damage occurs directly by meningeal inflammation and indirectly by circulatory collapse and causes a high rate of neurologic sequelae in affected patients. Death can occur from cerebral edema, which leads to **increased intracranial pressure (ICP)** and cerebral or cerebellar herniation.

Immunity

There is an inverse correlation between the incidence of disease and the prevalence of complement-dependent **serum bactericidal antibody (SBA)**. The level of SBA is highest at birth and among adults and lowest in children between 6 months and 2 years of age, when the highest incidence of disease occurs. Such antibodies are naturally elicited by asymptomatic carriage of pathogenic and nonpathogenic *Neisseria,* such as *Neisseria lactamica,* and other antigenically related gram-negative bacteria. A similar relationship was described for capsular groups A, B, and C. Vaccine trials support these earlier findings. For the meningococcal capsular group C conjugate vaccine, an SBA titer ≥1:8 correlated strongly with postlicensure vaccine effectiveness. For capsular group B disease, the data are less certain, but the proportions of capsular group B vaccine recipients with more than fourfold rises in SBA after vaccination or SBA titers ≥1:4 have been correlated with clinical effectiveness in studies of outer membrane vesicle vaccines. These cutoffs are therefore currently used for regulatory approval of new meningococcal vaccines. The strong association between disease risk and genetic variation in human complement factor H further supports the importance of complement-mediated protection against disease.

There is evidence that mechanisms other than complement-dependent bactericidal antibodies may be important in determining protection against meningococcal disease. Disease in individuals with complement deficiency has a different age distribution, has less severe clinical features, and often involves unusual capsular groups. In particular, complement deficiency does not appear strongly related to an increased risk of capsular group B disease. Alternative surrogate markers of protection include the opsonophagocytic assay and antibody avidity, but no studies have attempted to link these laboratory tests with vaccine efficacy or even population protection, as has been found with SBA.

Host Factors

Host susceptibility is strongly related to age, as previously described, indicating that immunologic responsiveness and/or naïveté in infancy and early childhood are key determinants of risk. **Complement** is a key factor in protection against meningococcal disease. Individuals with inherited deficiencies of properdin, factor D, or terminal complement components have up to a 1,000-fold higher risk for development of meningococcal disease than complement-sufficient people. The risk of meningococcal disease is also increased in patients with acquired complement deficiencies associated with diseases such as nephrotic syndrome, systemic lupus erythematosus (SLE), and hepatic failure and in patients treated with eculizumab, a monoclonal antibody against complement protein C5.

Among those with complement deficiencies, meningococcal disease is more prevalent during late childhood and adolescence, when carriage rates are higher than in children <10 years old; meningococcal infections in these patients may be recurrent. Although meningococcal disease can occasionally be overwhelming in patients with late complement component deficiency, cases are more typically described as being less severe than in complement-sufficient persons (with properdin deficiency being the exception), perhaps reflecting that these cases are often caused by unusual capsular groups. In one study, one third of individuals with meningococcal disease caused by capsular groups X, Y, and W had a complement deficiency. Although protective against early infection, extensive complement activation and bacteriolysis may contribute to the pathogenesis of severe disease once bacterial invasion has occurred.

The sibling risk ratio for meningococcal disease is similar to that for other diseases where susceptibility shows polygenic inheritance, and a number of host genetic factors have now been identified to affect either susceptibility to meningococcal disease or severity of disease. The molecules implicated include proteins on epithelial surfaces, the complement cascade, pattern recognition receptors, clotting factors, and inflammatory mediators. Deficiencies in the complement pathways are consistently associated with an increased risk of meningococcal disease, with specific polymorphisms in mannose-binding lectin and factor H found to be associated with disease susceptibility. A genome-wide association study of 7,522 individuals in Europe identified single nucleotide polymorphisms (SNPs) within the *CFH* and *CFHR3* genes that were associated with host susceptibility to meningococcal disease. Complement-mediated bacteriolysis is known to be extremely important in protection against meningococcal disease, giving these associations biologic plausibility. In particular, factor H attaches to various binding proteins expressed on the bacterial surface, downregulating complement activation and allowing the organism to evade host responses.

In terms of disease severity, a meta-analysis of data from smaller studies found that SNPs in genes encoding plasminogen activator inhibitor 1 *(SERPINE1)*, IL-1 receptor antagonist *(IL1RN),* and IL-1β *(IL1B)* are associated with increased mortality from meningococcal disease, as reflected in pathophysiologic changes that occur during invasive disease.

CLINICAL MANIFESTATIONS

The most common form of meningococcal infection is asymptomatic carriage of the organism in the nasopharynx. In the rare cases where invasive disease occurs, the clinical spectrum of meningococcal disease varies widely, but the highest proportion of cases present with meningococcal meningitis (30–50%). Other recognized presentations include bacteremia without sepsis, meningococcal septicemia with or without meningitis, pneumonia, chronic meningococcemia, and occult bacteremia. Focal infections in various sites (e.g., myocardium, joints, pericardium, bone, eye, peritoneum, sinuses, middle ear) are well recognized, and all may progress to disseminated disease. Urethritis, cervicitis, vulvovaginitis, orchitis, and proctitis may also occur.

Acute meningococcal septicemia cannot be distinguished from other viral or bacterial infections early after onset of symptoms (Table 237.1). Typical nonspecific early symptoms include fever, irritability, lethargy, respiratory symptoms, refusal to drink, and vomiting. Less

Table 237.1 Prevalence of Symptoms and Signs in Children and Young People with Meningococcal Septicemia, Meningococcal Disease, and Meningococcal Meningitis

frequently, diarrhea, sore throat, and chills/shivering are reported. A maculopapular rash, which is indistinguishable from rashes seen after viral infections, is evident in approximately 10% of cases early in the course of infection (Fig. 237.2). Limb pain, myalgia, or refusal to walk may occur as the primary complaint in 7% of otherwise clinically unsuspected cases. As the disease progresses, cold hands or feet and abnormal skin color may be important signs, capillary refill time becomes prolonged, and a nonblanching or petechial rash will develop in >80% of cases. In fulminant meningococcal septicemia, the disease progresses rapidly over several hours from fever with nonspecific signs to septic shock characterized by prominent petechiae and purpura **(purpura fulminans)** with poor peripheral perfusion, tachycardia (to compensate for reduced blood volume resulting from capillary leak), increased respiratory rate (to compensate for pulmonary edema), hypotension (a late sign of shock in young children), confusion, and coma (resulting from decreased cerebral perfusion). Coagulopathy, electrolyte disturbance (especially hypokalemia), acidosis, adrenal hemorrhage, renal failure, and myocardial failure may all develop (Fig. 237.3). Meningitis may be present.

Fig. 237.4 Rash of chronic meningococcemia. *(From Persa OD, Jazmati N, Robinson N, et al. A pregnant woman with chronic meningococcaemia from Neisseria meningitidis with lpxL1-mutations. Lancet. 2014;384:1900.)*

Meningococcal meningitis is indistinguishable from meningitis caused by other bacteria. Nonspecific symptoms and signs (see Table 237.1), including fever and headache, predominate, especially in the young and early in the illness. Children <5 years old rarely report headache. More specific symptoms of photophobia, nuchal rigidity, bulging of the fontanel, and clinical signs of meningeal irritation may develop but are unusual in infants. Seizures and focal neurologic signs occur less frequently than in patients with meningitis caused by *Streptococcus pneumoniae* or *Haemophilus influenzae*. A meningoencephalitis-like picture can occur, associated with rapidly progressive cerebral edema and death from increased ICP, which may be more common with capsular group A infection.

Occult meningococcal bacteremia manifests as fever with or without associated symptoms that suggest a minor viral infection. Resolution of bacteremia may occur without antibiotics, but sustained bacteremia leads to meningitis in approximately 60% of cases and to distant infection of other tissues.

Chronic meningococcemia, which occurs rarely, is characterized by fever, nontoxic appearance, arthralgia, headache, splenomegaly, and a maculopapular or petechial rash (Fig. 237.4). Symptoms are intermittent, with a mean duration of illness of 6-8 weeks. Blood culture results are usually positive, but cultures may initially be sterile. Chronic meningococcemia may spontaneously resolve, but meningitis may develop in untreated cases. Some cases have been associated with complement deficiency and others with sulfonamide therapy. One report indicates that up to 47% of isolates from patients with chronic meningococcemia (vs <10% in acute cases) have a pathogenic variant in the *lpxl1* gene, leading to a reduced inflammatory response and a milder course of infection.

DIAGNOSIS

The initial diagnosis of meningococcal disease should be made on clinical assessment to avoid delay in implementation of appropriate therapy. Laboratory findings are variable but may include leukocytopenia or leukocytosis, often with increased percentages of neutrophils and band forms, and anemia, thrombocytopenia, proteinuria, and hematuria. Elevations of erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) may occur, but in patients with rapid onset of disease, these values may be within normal limits at presentation. Increased CRP in the presence of fever and petechiae makes the diagnosis likely. Hypoalbuminemia, hypocalcemia, hypokalemia, hypomagnesemia, hypophosphatemia, hypoglycemia, and metabolic acidosis, often with increased lactate levels, are common in patients with meningococcal septicemia. Patients with coagulopathy have decreased serum concentrations of prothrombin and fibrinogen and prolonged coagulation times.

A confirmed diagnosis of meningococcal disease is established by isolation of *N. meningitidis* from a normally sterile body fluid such as blood, CSF, or synovial fluid. Meningococci may be identified in a Gram stain preparation and/or culture of petechial or purpuric skin lesions, although this procedure is rarely undertaken, and occasionally are seen on Gram stain of the buffy coat layer of a centrifuged blood sample. Although blood culture may be positive in more than two thirds of cases before antibiotic use, culture results often are negative if the patient has been treated with antibiotics before collection of the culture specimen; data suggest that <50% are culture positive. Isolation of the organism from the nasopharynx is not diagnostic of invasive disease because the organism is a common commensal.

PCR using primers specific for meningococcal genes (e.g., *ctrA*) has high sensitivity and specificity for detection of meningococci using whole blood samples and has increased confirmation of suspected cases by >40% in the United Kingdom.

Lumbar puncture should be undertaken to establish a diagnosis of meningococcal meningitis in patients without contraindications, including presence of septic shock, coagulopathy, thrombocytopenia, respiratory distress, seizures, increased ICP, or local infection. In patients with meningococcal meningitis, the cellular and chemical characteristics of the CSF are those of acute bacterial meningitis, showing gram-negative diplococci in up to 75% of cases. CSF culture results may be positive in patients with meningococcemia in the absence of CSF pleocytosis or clinical evidence of meningitis; conversely, positive CSF specimens that are gram positive are sometimes culture negative. Overdecolorized pneumococci in Gram stain preparations can be mistaken for meningococci, and therefore empirical therapy should not be narrowed to *N. meningitidis* infection on the basis of Gram stain findings alone.

Detection of capsular polysaccharide antigens using rapid latex agglutination tests on CSF can support the diagnosis in cases clinically consistent with meningococcal disease, but the tests have not performed adequately in clinical practice (poor sensitivity and cross-reactivity of capsular group B test with *Escherichia coli* K1 antigen) and have been replaced by molecular diagnostic methods. Urine antigen testing is insensitive and should not be used. PCR-based assays for detection of meningococci in blood and CSF have been developed, and multiplex PCR assays that detect several bacterial species associated with meningitis, including the meningococcus, are used in some laboratories.

Differential Diagnosis

Meningococcal disease can appear similar to sepsis or meningitis caused by many other gram-negative bacteria, *S. pneumoniae, Staphylococcus aureus,* or group A streptococcus; to Rocky Mountain spotted fever, ehrlichiosis, or epidemic typhus; and to bacterial endocarditis. Viral and other infectious etiologies of meningoencephalitis should be considered in some cases.

Petechial **rashes** are common in viral infections (enteroviruses, influenza and other respiratory viruses, measles virus, Epstein-Barr virus, cytomegalovirus, parvovirus) and may be confused with meningococcal disease. Petechial or purpuric rashes are also associated with protein C or protein S deficiency, platelet disorders (including idiopathic thrombocytopenic purpura), Henoch-Schönlein purpura, connective tissue disorders, drug eruptions, and trauma, including nonaccidental injury. The nonpetechial, blanching maculopapular rash observed in some cases of meningococcal disease, especially early in the course, may initially be confused with a viral exanthem.

TREATMENT

Antibiotics

Empirical antimicrobial therapy should be initiated immediately after the diagnosis of invasive meningococcal infection is suspected and cultures are obtained, using a **third-generation cephalosporin** to cover the most likely bacterial pathogens until the diagnosis is confirmed. In regions with a high rate of β-lactam–resistant *S. pneumoniae,* empirical *addition* of intravenous (IV) **vancomycin** is recommended (see Chapter 643.1) while awaiting the outcome of bacterial identification and sensitivity, but this is unnecessary in other settings where cephalosporin resistance of pneumococci is very rare (in these settings a risk assessment of each case should be made). Once the diagnosis of β-lactam–sensitive meningococcal disease is confirmed in the laboratory, some authorities recommend a switch to penicillin. Even with no evidence that survival outcomes are different, however, limited evidence from one study indicates that in meningococcal purpura, necrotic skin lesions are less common among children treated with ceftriaxone than with penicillin. Furthermore, it may be cost-effective to use a once-daily dose of ceftriaxone for therapy in younger children, and this is the recommended practice in the United Kingdom (Table 237.2). No adequate studies have investigated the optimal duration of therapy for children, but the course is generally continued for 5-7 days.

Early treatment of meningococcal infections may prevent serious sequelae, but timely early diagnosis is often difficult in the absence of petechial or purpuric skin findings. Among children presenting with petechial rashes, 1–10% may have underlying meningococcal disease, and protocols have been established to ensure that these patients are identified without exposing the >90% of cases without meningococcal disease to unnecessary parenteral antibiotic therapy (Fig. 237.5).

Isolates of *N. meningitidis* with decreased susceptibility to penicillin (minimal inhibitory concentration of penicillin of 0.1-1.0 mg/mL) have been reported from Europe, Africa, Canada, and the United States (4% of isolates in 2006). Decreased susceptibility is caused at least in part by altered penicillin-binding protein 2 and does not appear to adversely affect the response to therapy. Isolates with reduced susceptibility to third-generation cephalosporins have been described in France, but the level of reduced susceptibility is not likely to affect therapeutic outcomes where these agents are used for treatment.

Supportive Care

Most children with meningococcal disease can be managed with antibiotics and simple supportive care and will improve rapidly. However, with an overall 5–10% case fatality rate, the priority in initiating management of children presenting with meningococcal disease is identification of the life-threatening features of the disease: shock and increased ICP. Delayed initiation of supportive therapy is associated with poor outcome, and protocols have therefore been established to aid clinicians in a step-by-step approach (http://www.meningitis.org). In all children presenting with meningococcal disease, assessment of the airway should be performed, because the airway could be compromised as a result of a depressed level of consciousness (elevated ICP in meningitis or poor cerebral perfusion in shock). In patients with meningococcal septicemia, supplementary oxygen should be used to treat hypoxia, which is caused by pulmonary edema (from capillary leak), and some patients will require endotracheal intubation. Hypovolemia requires both volume

Table 237.2 Treatment of *Neisseria meningitidis* Invasive Infections Beyond the Newborn Period

DRUG	ROUTE	DOSE	DOSING INTERVAL (hr)	MAXIMUM DAILY DOSE	NOTES
Penicillin G	IM or IV	300,000-400,000 units/kg/day	4-6 (4-hourly for meningitis)	12-24 million units	Does not clear carriage, and "prophylaxis" is required at the end of treatment
Ampicillin	IM or IV	200-400 mg/kg/day	4-6 (4-hourly for meningitis)	8 g	Does not clear carriage, and "prophylaxis" is required at the end of treatment
Cefotaxime‡	IM or IV	180-225 mg/kg/day	6-8 (6-hourly for meningitis)	8-12 g	Recommended in the neonate
Ceftriaxone	IM or IV	75-100 mg/kg/day	12-24	2-4 g	Preferred treatment as only once or twice daily, and may reduce skin complications
ALTERNATIVE THERAPY IN THE FACE OF LIFE-THREATENING β-LACTAM ALLERGY					
Chloramphenicol*	IV	50-100 mg/kg/day	6	2-4 g	Adjust based on target serum concentrations (15-25 mg/L)
Meropenem†	IV	60-120 mg/kg/day	8	3-6 g	

*Monitor blood levels to avoid toxicity.
†Rate of cross-reactivity in penicillin-allergic adults is 2–3%.
‡May not be available due to manufacturing issues.
IM, Intramuscular; IV, intravenous.

replacement and inotropic support to maintain cardiac output. Because ongoing fluid resuscitation may lead to pulmonary edema, endotracheal intubation and ventilation should be initiated in a patient who remains in compensated shock after 40 mL/kg of fluid resuscitation to improve oxygenation and reduce work of breathing. Aggressive fluid resuscitation with unbuffered electrolyte solutions in febrile African children led to increased mortality; similar studies in industrialized settings are required. Metabolic and hematologic abnormalities are common in meningococcal septicemia, and protocols recommend anticipation, assessment, and correction of glucose, potassium, calcium, magnesium, phosphate, clotting factors, and anemia.

Children with meningococcal meningitis should be cautiously managed with maintenance fluids (fluid restriction is not recommended and may be harmful), and those with increased ICP should be managed with close attention to maneuvers to maintain normal cerebral perfusion. If there is shock in the presence of elevated ICP, the shock should be carefully corrected to ensure that cerebral perfusion pressure is maintained.

Many adjunctive therapies have been attempted in patients with severe meningococcal septicemia, but few have been subjected to randomized controlled trials (RCTs). Data are insufficient to recommend the use of anticoagulant or fibrinolytic agents, extracorporeal membrane oxygenation, plasmapheresis, or hyperbaric oxygen. In well-designed clinical trials, an antibody directed against endotoxin (HA1A) did not confer any benefit in children with meningococcal disease, and although initially promising in adult sepsis, activated protein C was not useful in pediatric sepsis and was associated with an increased risk of bleeding. Recombinant bactericidal permeability increasing protein was studied in an underpowered (survival endpoint) trial and showed some potentially beneficial effects against secondary end-points (amputations, transfusions, functional outcome) and requires further investigation.

Although the benefits of **corticosteroids** for adjunctive therapy in pediatric *bacterial* meningitis caused by *H. influenzae* type b (Hib) are accepted, no pediatric data specifically demonstrate benefit in *meningococcal* meningitis. However, some authorities extrapolate from animal data, from experience with Hib, and from compelling data from adult meningitis and recommend corticosteroids as adjunctive therapy in pediatric meningococcal meningitis, given with or soon after the first dose of antibiotics. Therapeutic doses of corticosteroids should not be used routinely in meningococcal septicemia. Some intensivists recommend replacement doses of corticosteroids in patients with treatment-refractory septic shock, because severe sepsis caused by meningococcus is associated with adrenal insufficiency resulting from adrenal necrosis or hemorrhage (Waterhouse-Friderichsen syndrome).

COMPLICATIONS

Adrenal hemorrhage, endophthalmitis, arthritis, endocarditis, pericarditis, myocarditis, pneumonia, lung abscess, peritonitis, and renal infarcts can occur during acute infection. Renal insufficiency requiring dialysis may result from prerenal failure. Reactivation of latent herpes simplex virus infections is common during meningococcal infection.

A self-limiting immune complex vasculitis may occur, usually in the first 10 days after onset of the disease, resulting in various manifestations, including fever, rash, arthritis, and rarely, iritis, pericarditis, or carditis. The arthritis is monoarticular or oligoarticular, involves large joints, and is associated with sterile effusions that respond to nonsteroidal antiinflammatory drugs. Because most patients with meningococcal meningitis become afebrile by the seventh hospital day, persistence or recrudescence of fever after 5 days of antibiotics warrants evaluation for immune complex–mediated complications.

The most common complication of acute severe meningococcal septicemia is focal skin infarction, which typically affects the lower limbs and can lead to substantial scarring and require skin grafting. Distal tissue necrosis in purpura fulminans may require amputation (which should be delayed to allow demarcation) in approximately 2% of survivors. Avascular necrosis of epiphyses and epiphyseal-metaphyseal defects can result from the generalized DIC and may lead to growth disturbance and late skeletal deformities.

Deafness is the most frequent neurologic sequela of meningitis, occurring in 5–10% of children. Cerebral arterial or venous thrombosis with resultant cerebral infarction can occur in severe cases. Meningococcal meningitis is rarely complicated by subdural effusion or empyema or by brain abscess. Other rare neurologic sequelae include ataxia, seizures, blindness, cranial nerve palsies, hemiparesis or quadriparesis, and obstructive hydrocephalus (manifests 3-4 weeks after the onset of illness). Behavioral and psychosocial complications of the disease are frequently reported.

PROGNOSIS

The case fatality rate for invasive meningococcal disease is 5–10%, with clear differences related to age of the patient and meningococcal genotype. Most deaths occur within 48 hours of hospitalization in children with meningococcemia. Poor prognostic factors on presentation include hypothermia or extreme hyperpyrexia, hypotension or shock, purpura fulminans, seizures, leukopenia, thrombocytopenia (including DIC), acidosis, and high circulating levels of endotoxin and TNF-α. The presence of petechiae for <12 hours before admission, absence of meningitis, and low or normal ESR indicate rapid, fulminant progression and a poorer prognosis.

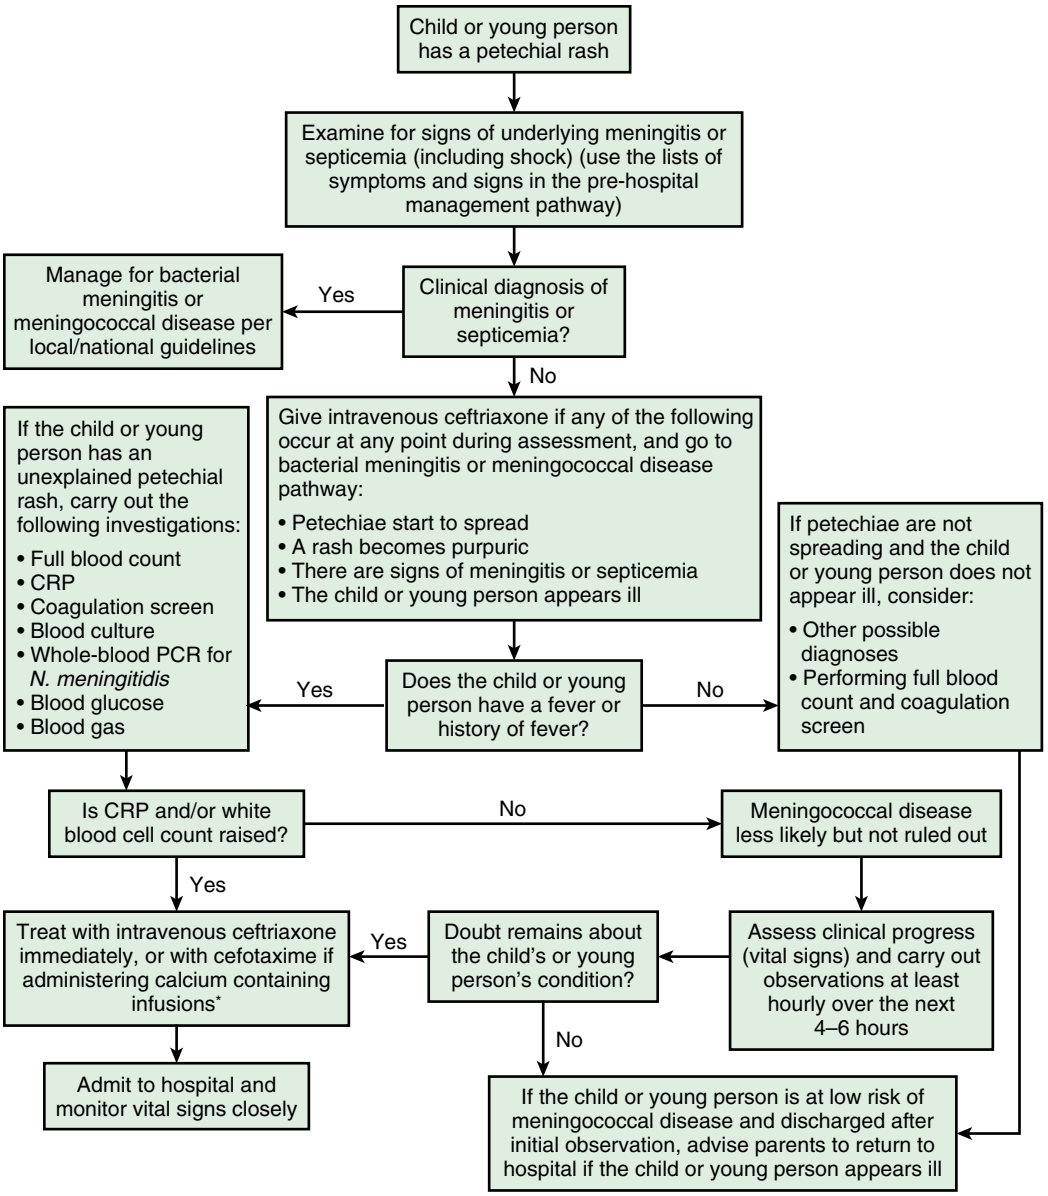

Fig. 237.5 Treatment algorithm for petechial rash. *See Medicines and Healthcare Products Regulatory Agency Drug Safety Update, 2009;3(3). Available from www.mhra.gov.uk. CRP, C-reactive protein; PCR, polymerase chain reaction. *(Data from National Collaborating Center for Women's and Children's Health (UK). Bacterial meningitis and meningococcal septicaemia: management of bacterial meningitis and meningococcal septicaemia in children and young people younger than 16 years in primary and secondary care. NICE Clinical Guidelines, No 102. London: RCOG Press; 2010.)*

Because complement deficiency is rare in patients with capsular group B infection, screening is unlikely to be useful in detecting cases caused by this group, but some authorities recommend routine screening in these cases. However, with one third or more of cases of disease caused by groups X, Y, and W apparently associated with complement deficiency, it is clearly appropriate to screen after infection with non-B capsular groups.

PREVENTION

Secondary Prevention

Close contacts of patients with meningococcal disease are at increased risk of infection because such individuals are likely to be colonized with the index case's (hyperinvasive) strain. Antibiotic prophylaxis should be offered as soon as possible to individuals who have been exposed directly to a patient's oral secretions, for whom the risk may be 1,000 times the background rate in the population. This includes household, kissing, and close family contacts of cases, as well as child-care and recent preschool contacts in the United States. Up to 30% of cases occur in the first week, but the risk persists for up to 1 year after presentation of the index case. Although prophylaxis is effective in preventing secondary cases, coprimary cases may occur in the days after presentation of the index case, and contacts should be carefully evaluated if they develop symptoms. Advice on management of nonclose contacts, such as those in daycare, nursery settings, or school and other institutions, varies in different countries because the risk of a secondary case in this situation is low and opinion on risk assessment varies. **Ceftriaxone**, **ciprofloxacin**, and **rifampin** are 90–95% effective in reducing nasopharyngeal carriage of *N. meningitidis* and are acceptable agents for prophylaxis, with ciprofloxacin the drug of choice in some countries (Table 237.3). **Azithromycin** should not be used as the first-line choice for prophylaxis but is recommended in the rare instance of ciprofloxacin resistance. Prophylaxis is not routinely recommended for medical personnel except those with exposure to aerosols of respiratory secretions, such as through mouth-to-mouth resuscitation, intubation, or suctioning before or in the 24 hours after antibiotic therapy is initiated in the index case.

Neither penicillin nor ampicillin treatment eradicates nasopharyngeal carriage and should not be routinely used for prophylaxis. Patients with meningococcal infection treated solely with penicillin or ampicillin are therefore at risk of relapse or transmission to a close contact and should receive antimicrobial prophylaxis with one of the agents listed in Table 237.3 before hospital discharge. The preference is to use ceftriaxone for *treatment* of the index case, in which case further prophylaxis is not required. Droplet infection control precautions should be observed for hospitalized patients for 24 hours after initiation of effective therapy. All confirmed or probable cases of meningococcal infection must be reported to the local public health department according to national or regional regulations.

Table 237.3 Antibiotic Prophylaxis to Prevent *Neisseria meningitidis* Infection*

AGE-GROUP	DOSE	DURATION	EFFICACY
RIFAMPIN†			
Infants <1 mo¶	5 mg/kg PO every 12 hr	2 days (4 doses)	
Children ≥1 mo and adults	15-20 mg/kg PO every 12 hr (max 600 mg)	2 days (4 doses)	90–95%
CEFTRIAXONE			
Children <15 yr	125 mg IM	1 dose	90–95%
Children ≥15 yr and adults	250 mg IM	1 dose	90–95%
CIPROFLOXACIN			
Children ≥1 mo and adults†,‡	20 mg/kg (max 500 mg) PO	1 dose	90–95%
AZITHROMYCIN (NOT RECOMMENDED ROUTINELY)			
All ages	10 mg/kg (max 500 g) PO	1 dose	90%

*Recommended for household and kissing contacts. In the United States, chemoprophylaxis is recommended for:
- Household contact, especially children <2 yr old
- Childcare or preschool contact at any time during 7 days before onset of illness
- Direct exposure to index patient's secretions through kissing, sharing toothbrushes, or eating utensils at any time during 7 days before onset of illness
- Mouth-to-mouth resuscitation, unprotected contact during endotracheal intubation during 7 days before onset of illness
- Frequently slept in same dwelling as index patient during 7 days before onset of illness
- Passengers seated directly next to the index case during airline flights lasting more than 8 hours (gate to gate), or passengers seated within one seat in any direction from an index case on a flight of any duration if the index case was coughing or vomiting during the flight
- Always check with current local public health guidance for full recommendations

†Not recommended for pregnant women (ceftriaxone is agent of choice in this setting).
‡Use only if fluoroquinolone-resistant strains of *N. meningitidis* have not been identified in the community.
¶Discussion with an expert is recommended for treatment in infants age <1 mo.
IM, Intramuscularly; PO, orally (by mouth).

Close contacts of cases could also be immunized to further reduce the risk of secondary infection, as described later.

Vaccination

Meningococcal plain *polysaccharide vaccines* containing capsular polysaccharides from capsular groups A + C or capsular groups A, C, W, and Y have been available since the 1960s and used in the control of outbreaks and epidemics and for high-risk groups. However, polysaccharide vaccines are poorly immunogenic in infants, do not induce immunologic memory, and are associated with *immunologic hyporesponsiveness* (reduced response to future doses of polysaccharide). Plain polysaccharide vaccines have been superseded by meningococcal protein-polysaccharide *conjugate vaccines,* which are generally more immunogenic than plain polysaccharides, are immunogenic from early infancy, induce immunologic memory, and are not associated with hyporesponsiveness. The conjugate vaccines contain meningococcal polysaccharides that are chemically conjugated to a carrier protein. Three carrier proteins are used in various meningococcal conjugate vaccines: tetanus toxoid, diphtheria toxoid, and the mutant diphtheria toxin CRM197. However, although plain polysaccharide vaccines should be considered redundant in most industrialized countries where the new-generation conjugates are available, they may still have a role in some regions where conjugates are not yet available.

The first meningococcal conjugate vaccine used was a monovalent capsular group C meningococcal conjugate vaccine **(MenC)**, introduced in the United Kingdom in 1999 and administered to all children and young people <19 years old in a mass catch-up campaign before establishment in the routine infant immunization schedule. The MenC vaccine has proved highly effective (>95%) in controlling disease through both direct protection of the vaccinated population and induction of herd immunity, protecting the wider population. *Herd immunity* is induced through the impact of conjugate vaccines on colonization, reducing carriage and blocking transmission of meningococci among adolescents and young adults. Monovalent MenC vaccines are used widely in the industrialized countries of Western Europe, Canada, and Australia, where disease caused by capsular group C meningococci has virtually disappeared. However, serologic surveys show that antibody levels wane, especially after infant immunization, and booster doses are now recommended during adolescence to sustain individual and population immunity.

Quadrivalent meningococcal A, C, Y, and W conjugate vaccines **(MenACWY)** have been available since 2005 and are routinely used for U.S. adolescents and as a single adolescent booster dose in some countries that had established MenC infant programs more than a decade ago. MenACWY was initially introduced as a single dose at 11 years of age in the United States, but concerns about waning immunity led to the adoption of a second dose. The initial reports on the effectiveness (>80%) of MenACWY in the U.S. program indicates that these vaccines are likely to provide control of disease caused by capsular groups C, W, and Y (capsular group A being unimportant currently), although the program has taken some time to become fully established. As the population of immunized adolescents and young adults in the United States grows, the effects of these vaccines on carriage of meningococci likely will reduce disease among other segments of the population through herd immunity, assuming the transmission dynamics of Y and W meningococci are the same as for capsular group C. Although MenACWY vaccines are not currently recommended in the United States for routine use in younger age-groups in view of the low rate of disease caused by these capsular groups in infancy, they may provide broader protection in countries that are already using MenC vaccines in infant programs. Other combination vaccines containing various conjugates, including Hib-MenC (used in the United Kingdom as a 12-month booster) and Hib-MenCY, may have a role in broadening protection beyond MenC in early life. Table 237.4 outlines the current U.S. programmatic recommendations.

Individuals of any age at high risk of meningococcal disease, such as those with complement deficiency, and travelers to regions where there is a risk of epidemic meningococcal disease caused by A or W should receive MenACWY (see Table 237.4). The risk of disease among close contacts of cases of disease caused by vaccine capsular groups may be further reduced if they are offered MenACWY in addition to antimicrobial prophylaxis. A possible association between MenACWY-diphtheria toxoid and Guillain-Barré syndrome, which caused concern early after the vaccine was first used in the United States, has not been substantiated.

A capsular group A meningococcal conjugate vaccine **(MenA)** has been developed for use in the sub-Saharan African meningitis belt, and implementation in 2010 through mass vaccination appears to have interrupted disease caused by this capsular group.

The majority of disease in infants and in most industrialized countries is caused by capsular *group B polysaccharide–bearing meningococci*. This polysaccharide capsule has chemical identity with glycosylated protein antigens in the human fetus and, as a "self" antigen, is therefore not immunogenic in humans and leads to the theoretical risk of induction of autoimmunity. Vaccine development has therefore focused on subcapsular protein antigens. Several countries (e.g., Cuba, Norway, New Zealand) successfully controlled capsular group B epidemics by immunizing with tailor-made outer membrane vesicle vaccines

Table 237.4 Recommendations for Meningococcal Vaccination (United States, 2021)

GENERAL POPULATION			
2-23 MO	**2-10 YR**	**11-23 YR**	**≥24 YR**
Not routinely recommended	Not routinely recommended	A single dose of MenACWY conjugate vaccine at age 11-12 yr with a booster dose at age 16 yr MenB series may be offered at age 16-23 yr on basis of shared clinical decision-making (2 doses of MenB-FHbp or 4CMenB)	Not routinely recommended

SPECIAL POPULATIONS AT INCREASED RISK OF MENINGOCOCCAL DISEASE			
RISK FACTOR	**2-23 MO**	**2-9 YR**	**≥10 YR**
Persistent complement deficiencies (including patients using a complement inhibitor), functional or anatomic asplenia	4 doses of MenACWY conjugate vaccine at 2, 4, 6, and 12 mo*; if commencing at age 7-23 mo, 2 doses of MenACWY conjugate vaccine, with second dose administered at age ≥12 mo and ≥12 wk after first dose	2 doses of MenACWY conjugate vaccine at least 8 wk apart*	2 doses of MenACWY conjugate vaccine at least 8 wk apart* *and* MenB vaccine (2 doses of 4CMenB or 3 doses of MenB-Hbp) †
At risk during a community outbreak with a vaccine capsular group covered by the relevant vaccine	4 doses of MenACWY conjugate vaccine at 2, 4, 6, and 12 mo*; if commencing at age 7-23 mo, 2 doses of MenACWY conjugate vaccine, with second dose administered at age ≥12 mo and ≥12 weeks after first dose	2 doses of MenACWY conjugate vaccine at least 8 wk apart*	2 doses of MenACWY conjugate vaccine at least 8 wk apart* *or* MenB vaccine (2 doses of 4CMenB or 3 doses of MenB-FHbp) † depending on the capsular group of the outbreak
Travel to or resident of countries where meningococcal disease is hyperendemic or epidemic‡	4 doses of MenACWY conjugate vaccine at 2, 4, 6, and 12 mo*; if commencing at age 7-23 mo, 2 doses of MenACWY conjugate vaccine, with second dose administered at age ≥12 mo and ≥12 weeks after first dose	2 doses of MenACWY conjugate vaccine at least 8 wk apart*	2 doses of MenACWY conjugate vaccine at least 8 wk apart*
Persons with HIV infection	4 doses of MenACWY conjugate vaccine at 2, 4, 6, and 12 mo*; if commencing at age 7-23 mo, 2 doses of MenACWY conjugate vaccine, with second dose administered at age ≥12 mo and ≥12 weeks after first dose	2 doses of MenACWY conjugate vaccine at least 8 wk apart*	2 doses of MenACWY conjugate vaccine at least 8 wk apart*

*Booster every 5 yr if ongoing risk (after 3 yr if <7 yr old).
†Boosters 1 yr after primary series and every 2-3 yr thereafter if remains at increased risk.
‡For example, visitors to the "meningitis belt" of sub-Saharan Africa. Vaccination also is required by the government of Saudi Arabia for all travelers to Mecca during the annual Hajj.
Note that different MenACWY conjugate vaccines are interchangeable, but different MenB vaccines (4CMenB and MenB-FHbp) are not interchangeable
Adapted from https://www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/mening.html

prepared from blebs of outer membrane harvested from the respective epidemic strains. The principal limitation of outer membrane vesicle vaccines is that the bactericidal antibody responses induced by immunization are limited to the vaccine strain, because the response is largely directed against the homologous PorA (serosubtype) protein, and they are therefore not considered for use in endemic settings, including the United States or most other industrialized countries.

Promising approaches for prevention of capsular group B disease have been developed over the past decade. One vaccine that was developed for adolescent immunization was licensed in the United States in 2014 and contains two variants of factor H–binding protein (**2FHbp**; Pfizer vaccines); it appears highly immunogenic in the target population, inducing bactericidal antibodies directed against a panel of strains bearing variants of fHbp. It is currently recommended for use in high-risk groups and during outbreaks (see Table 237.4). Factor H–binding protein appears to be an important virulence determinant, aiding survival of meningococci in blood, and is expressed by virtually all strains.

A four-component meningococcal vaccine, **4CMenB** (Bexsero, GSK Vaccines), is licensed in Europe and North America and available in various other regions. This vaccine contains outer membrane vesicles (derived from the New Zealand outbreak strain) and three recombinant proteins: a single variant of factor H–binding protein (FHbp), neisserial adhesin A (NadA), and neisserial heparin-binding antigen (NHBA). 4CMenB vaccine induced bactericidal antibodies against strains containing the vaccine antigens in infants, toddlers, and adolescents in clinical trials. The vaccine appears to have a generally favorable safety profile, although induction of fever in infants and pain at the injection site in other age-groups are common. This vaccine has been used to control university outbreaks of capsular group B meningococcal disease in the United States and Canada and hyperendemic disease in Quebec, Canada. Current recommendations for use in the United States are outlined in Table 237.4. It was recommended for routine use in the infant immunization program in the United Kingdom in 2014 and deployed from September 2015. Early data reported a 75% reduction in age-groups that were fully eligible for vaccination, with a high coverage rate of 95% (a nonsignificant vaccine effectiveness of 53% after two doses and 59% after a booster dose at 1 year of age). A large cluster randomized trial in Australia found no effect of 4CMenB on carriage of disease-causing meningococci, highlighting that the benefit of this vaccine is likely to be via direct protection.

Chapter 238

Neisseria gonorrhoeae (Gonococcus)

Katherine Hsu, Sanjay Ram, and Toni Darville

Neisseria gonorrhoeae is the causative agent of **gonorrhea**, an infection of the genitourinary tract mucous membranes and of the mucosa of the rectum, oropharynx, and conjunctiva. Among sexually transmissible infections, gonorrhea transmitted by sexual contact or perinatally is second only to chlamydial infections in the number of cases reported to the U.S. Centers for Disease Control and Prevention (CDC). This high prevalence and the development of antibiotic-resistant strains have led to significant morbidity.

ETIOLOGY

N. gonorrhoeae is a nonmotile, aerobic, non–spore-forming, gram-negative diplococcus with flattened adjacent surfaces. Optimal growth occurs at 35–37°C (95–98.6°F) and at pH 7.2-7.6 in an atmosphere of 3–5% carbon dioxide. The specimen should be inoculated quickly onto fresh, moist, modified Thayer-Martin or specialized transport media, because gonococci do not tolerate drying. Thayer-Martin selective medium contains antimicrobial agents that inhibit the normal flora present in clinical specimens from mucosal sites that may otherwise overgrow gonococci. Presumptive identification may be based on colony appearance, Gram stain, and production of cytochrome oxidase. Gonococci are differentiated from other *Neisseria* spp. by the fermentation of glucose but not maltose, sucrose, or lactose. Gram-negative diplococci are seen in infected material, often within polymorphonuclear leukocytes (PMNs).

As with all gram-negative bacteria, *N. gonorrhoeae* possesses a cell envelope composed of an inner cytoplasmic membrane, a middle layer of peptidoglycan, and an outer membrane. The outer membrane contains **lipooligosaccharide** (**LOS**; also called **endotoxin**), phospholipid, and a variety of proteins that contribute to cell adherence, tissue invasion, and resistance to host defenses. Systems previously used to characterize gonococcal strains included auxotyping and serotyping. **Auxotyping** is based on genetically stable requirements of strains for specific nutrients or cofactors as defined by an isolate's ability to grow on chemically defined media. **Serotyping** systems were based on specific monoclonal antibodies directed against a porin protein called **PorB** (formerly *Protein I* or *PorI*), a trimeric outer membrane protein that makes up a substantial part of the gonococcal envelope structure. Changes in the PorB protein present in a community are believed to result, at least in part, from selective immune pressure. DNA-based typing methods have now supplanted auxotyping and serotyping. Older gel-based DNA-based typing methods that included restriction fragment length polymorphism (RFLP) analysis of genomic DNA or rRNA (ribotyping) or typing of genes encoding opacity protein *(opa)* were labor intensive and sometimes lacked the ability to accurately discriminate among strains. Methods currently used include the *N. gonorrhoeae* multiantigen sequence typing **(NG-MAST)**, which examines the sequences of the variable internal fragments of two highly polymorphic *N. gonorrhoeae* genes (*porB* encoding PorB and *tbpB* encoding subunit B of transferrin-binding protein), multilocus sequence typing (**MLST**), which analyzes the sequences of seven chromosomal housekeeping genes, and whole genome sequencing.

EPIDEMIOLOGY

Since gonorrhea became a nationally notifiable disease in 1944, U.S. rates have ranged between a historic high of 467.7 cases per 100,000 population in 1975 and a historic low of 98.1 per 100,000 in 2009. However, rates of gonorrhea have increased almost every year since 2009 (with an overall increase of 118% between 2009 and 2021), with a total of 710,151 cases and a rate of 214.0/100,000 reported in 2021. Rates of reported gonorrhea are also highest in the South (242.9/100,000); among young adults age 20-24 (860.5 cases per 100,000); among males (249.7/100,000 vs 177.9/100,000 among females); and among Blacks (652.9/100,000 vs 78.9/100,000 among Whites). The higher case rate among men and the magnitude of recent increases suggest either increased transmission, increased case ascertainment (e.g., through increased extragenital screening among men who have sex with men [MSM]), or both. The concurrent increase in cases reported among women suggests parallel increases in heterosexual transmission, increased screening among women, or both.

Molecular typing methods (e.g., NG-MAST, MLST) are used to analyze the spread of individual strains of *N. gonorrhoeae* within a community. Maintenance and subsequent spread of gonococcal infections in a community are sustained through continued transmission by asymptomatically infected people and also by a **hyperendemic**, **high-risk** core group such as commercial sex workers, MSM, or adolescents with multiple sexual partners. This latter observation reflects that most persons who have symptomatic gonorrhea cease sexual activity and seek care, unless economic need or other factors (e.g., drug addiction) drive persistent sexual activity. Thus many core transmitters belong to a subset of infected persons who lack or ignore symptoms and continue to be sexually active, underscoring the importance of seeking out and treating the sexual contacts of infected persons who present for treatment. **Oral sex** has a role in sustaining gonorrhea in MSM by providing a pool of untreated asymptomatic pharyngeal infections and may account for as much as one third of symptomatic gonococcal urethritis in MSM.

Gonococcal infection of neonates usually results from peripartum exposure to infected exudate from the cervix of the mother. An acute infection begins 2-5 days after birth. The incidence of neonatal infection depends on the prevalence of gonococcal infection among pregnant women, prenatal screening for gonorrhea, and neonatal ophthalmic prophylaxis.

PATHOGENESIS AND PATHOLOGY

N. gonorrhoeae infects primarily columnar epithelium because stratified squamous epithelium is relatively resistant to invasion. Mucosal invasion by gonococci results in a local inflammatory response that produces a purulent exudate consisting of PMNs, serum, and desquamated epithelium. The gonococcal LOS (endotoxin) exhibits direct cytotoxicity, causing ciliostasis and sloughing of ciliated epithelial cells. Tumor necrosis factor (TNF) and other cytokines are thought to mediate the cytotoxicity of gonococcal infections. Complement activation also contributes to the acute inflammatory response.

Gonococci may ascend the urogenital tract, causing urethritis or epididymitis in postpubertal males and acute endometritis, salpingitis, and peritonitis (collectively termed **acute pelvic inflammatory disease** or **PID)** in postpubertal females. Dissemination from the fallopian tubes through the peritoneum to the liver capsule results in **perihepatitis** (Fitz-Hugh–Curtis syndrome). Gonococci that invade the lymphatics and blood vessels may cause inguinal lymphadenopathy; perineal, perianal, ischiorectal, and periprostatic abscesses; and **disseminated gonococcal infection** (DGI).

A number of gonococcal virulence and host immune factors are involved in the penetration of the mucosal barrier and subsequent manifestations of local and systemic infection. Selective pressure from different mucosal environments probably leads to changes in the outer membrane of the organism, including expression of variants of pili, opacity (Opa) proteins (formerly called *protein II*), and LOS. These changes may enhance gonococcal attachment, invasion, replication, and evasion of the host's immune response.

For infection to occur, the gonococcus must first attach to host cells. Gonococci adhere to the microvilli of nonciliated epithelial cells by hairlike protein structures (pili) that extend from the cell wall. Pili undergo high-frequency antigenic variation that may aid in

the organism's escape from the host immune response and may provide specific ligands for different cell receptors. Opa proteins, most of which confer an opaque appearance to colonies, function as ligands for members of the carcinoembryonic antigen–related cell adhesion molecule **(CEACAM)** family of proteins or heparin sulfate proteoglycans (HSPGs) to facilitate binding to human cells. Interactions between complement receptor 3 (CR3) on cervical epithelial cells and complement iC3b (deposited on bacteria), pili, and PorB on the gonococcal surface facilitate cellular entry of gonococci in women. In contrast, the interaction between LOS and asialoglycoprotein receptor (ASGP-R) permits gonococcal entry into male urethral epithelial cells. Gonococci that express certain Opa proteins adhere to CEACAM3 and are phagocytosed by human neutrophils in the absence of serum. The interaction of Opa with CEACAM1 on $CD4^+$ T lymphocytes may suppress their activation and proliferation and contribute to the immunosuppression associated with gonorrhea. A gonococcal IgA protease inactivates IgA1 by cleaving the molecule in the hinge region and could contribute to colonization or invasion of host mucosal surfaces.

Other phenotypic changes that occur in response to environmental stresses allow gonococci to establish infection. Examples include iron-repressible proteins such as transferrin-binding proteins (TbpA and TbpB) and lactoferrin-binding proteins (LbpA and LbpB) for binding to and extracting iron from transferrin or lactoferrin, respectively, anaerobically expressed proteins, and proteins that are synthesized in response to contact with epithelial cells. Gonococci may grow in vivo under anaerobic conditions or in an environment with a relative lack of iron.

Approximately 24 hours after attachment, the epithelial cell surface invaginates and surrounds the gonococcus in a phagocytic vacuole. This phenomenon is thought to be mediated by the insertion of the gonococcal PorB protein into the host cell, causing alterations in membrane permeability. Subsequently, phagocytic vacuoles begin releasing gonococci into the subepithelial space by means of exocytosis. Viable organisms may then cause local disease (i.e., salpingitis) or disseminate through the bloodstream or lymphatics.

Serum IgG and IgM directed against gonococcal proteins and LOS activate complement on gonococci. Gonococci have evolved several mechanisms to dampen complement activation. Scavenging cytidine monophospho-*N*-acetyl neuraminic acid (CMP-Neu5Ac, the donor molecule for sialic acid) to sialylate its LOS is one such example, which reduces binding of bactericidal antibodies and simultaneously enhances binding of a complement inhibitor called **factor H** (FH). This property is often lost on subculturing gonococci on medium that lacks CMP-Neu5Ac and is thus termed *unstable serum resistance*. In contrast, *stable serum resistance* (complement resistance independent of LOS sialylation) is often seen in gonococci that express particular porin proteins (most PorB.1As and select PorB.1Bs), which enables them to bind to complement inhibitors such as FH and C4b-binding protein (C4BP). Such strains are often associated with disseminated disease. *N. gonorrhoeae* differentially subverts the effectiveness of complement and alters the inflammatory responses elicited in human infection. Stably serum-resistant DGI isolates show less C3b deposition on their surface, inactivate C3b more rapidly, generate less C5a, and result in less inflammation at local sites. PID isolates (grown in the absence of the donor molecule for sialic acid) are serum sensitive, deposit more C3b on their surface, generate more C5a, and result in more inflammation at local sites. IgG antibody directed against gonococcal reduction-modifiable protein **(Rmp)** blocks complement-mediated killing of *N. gonorrhoeae.* Anti-Rmp blocking antibodies may harbor specificity for outer membrane protein (e.g., OmpA) sequences shared with other *Neisseria* spp. or Enterobacteriaceae, may be directed against a unique Rmp sequence upstream of the OmpA-shared region that includes a cysteine loop, or both. Preexisting antibodies directed against Rmp facilitate transmission of gonococcal infection to exposed women; Rmp is highly conserved in *N. gonorrhoeae,* and the blocking of mucosal defenses may be one of its functions. Gonococcal adaptation also appears to be important in the evasion of killing by neutrophils. Examples include sialylation of LOS, increases in catalase production, and changes in the expression of surface proteins. Neutrophil phagosomes bearing gonococci show delayed fusion with primary granules, promoting gonococcal survival within neutrophils. Other strategies gonococci employ to evade killing by neutrophils include blocking lysozyme activity (mediated by the proteins SliC and adhesin complex protein [ACP]) and degrading neutrophil extracellular traps.

Host factors may influence the incidence and manifestations of gonococcal infection. Prepubertal girls are susceptible to vulvovaginitis and rarely experience salpingitis. *N. gonorrhoeae* infects noncornified epithelium, and the thin noncornified vaginal epithelium and alkaline pH of the vaginal mucin predispose this age-group to infection of the lower genital tract. Estrogen-induced cornification of the vaginal epithelium in neonates and mature females resists infection. Postpubertal females are more susceptible to salpingitis, especially during menses, when diminished bactericidal activity of the cervical mucus and reflux of blood from the uterine cavity into the fallopian tubes facilitate passage of gonococci into the upper reproductive tract.

Populations at risk for DGI include asymptomatic carriers; neonates; menstruating, pregnant, and postpartum women; MSM; and individuals with congenital or acquired (for example, via pharmacologic inhibition) defects in complement. The asymptomatic carrier state implies failure of the host immune system to recognize the gonococcus as a pathogen, the capacity of the gonococcus to avoid being killed, or both. **Pharyngeal colonization** has been proposed as a risk factor for DGI. The high rate of asymptomatic infection in pharyngeal gonorrhea may account for this phenomenon. Women are at greater risk for development of DGI during menstruation, pregnancy, and the postpartum period, presumably because of the maximal endocervical shedding and decreased peroxidase bactericidal activity of the cervical mucus during these periods. A lack of neonatal bactericidal IgM antibody is thought to account for the increased susceptibility of neonates to DGI. Persons with terminal complement component deficiencies (C5-C9) are at considerable risk for development of recurrent episodes of DGI.

CLINICAL MANIFESTATIONS

Gonorrhea is manifested by a spectrum of clinical presentations from asymptomatic carriage, to the characteristic localized mucosal infections, to disseminated systemic infection (see Chapter 163).

Asymptomatic Gonorrhea

The incidence of asymptomatic gonorrhea in children has not been ascertained. Gonococci have been isolated from the oropharynx of young children who have been abused sexually by male contacts; oropharyngeal symptoms are usually absent. Most genital tract infections produce symptoms in children. However, as many as 80% of sexually mature females with urogenital gonorrhea infections are asymptomatic in settings in which most infections are detected through screening or other case-finding efforts. This situation is in contrast to that in men, who are asymptomatic only 10% of the time. Asymptomatic rectal carriage of *N. gonorrhoeae* has been documented in 26–68% of females with urogenital infection. Most persons with positive rectal culture results are asymptomatic. Most pharyngeal gonococcal infections are asymptomatic, although rarely **acute tonsillopharyngitis** or **cervical lymphadenopathy** can occur. Pharyngeal gonorrhea is easily acquired through fellatio and may account for a significant proportion of urethral gonorrhea in MSM. Pharyngeal gonorrhea is increasingly prevalent, particularly among adolescents and young adults, associated with overall increasing prevalence of oral sex behaviors.

Uncomplicated, Localized Gonorrhea

Genital gonorrhea has an incubation period of 2-5 days in men and 5-10 days in women. Primary infection develops in the urethra of males, the vulva and vagina of prepubertal females, and the cervix of postpubertal females. Neonatal ophthalmitis (ophthalmia neonatorum) occurs in both genders.

Urethritis is usually characterized by a purulent discharge and by dysuria without urgency or frequency. Untreated urethritis in males resolves spontaneously in several weeks or may be complicated by epididymitis, penile edema, lymphangitis, prostatitis, or seminal vesiculitis. Gram-negative intracellular diplococci are found in the discharge.

In MSM, the rectal mucosa can become infected after receptive anal intercourse. Symptoms range from painless mucopurulent discharge and scant rectal bleeding to overt proctitis with associated rectal pain and tenesmus.

In prepubertal females, **vulvovaginitis** is usually characterized by a purulent vaginal discharge with a swollen, erythematous, tender, and excoriated vulva. Dysuria may occur. Gonococcal infection should be considered in any girl with vaginal discharge, even when sexual abuse is not suspected; sexual abuse must be considered strongly when gonococcal infection is diagnosed in prepubertal children beyond the neonatal period. In postpubertal females, symptomatic gonococcal **cervicitis** and urethritis are characterized by purulent discharge, suprapubic pain, dysuria, intermenstrual bleeding, and dyspareunia. The cervix may be inflamed and tender. In urogenital gonorrhea limited to the lower genital tract, pain is not enhanced by moving the cervix and the adnexa are not tender to palpation. Purulent material may be expressed from the urethra or ducts of the Bartholin gland. Rectal gonorrhea is often asymptomatic but may cause proctitis with symptoms of anal discharge, pruritus, bleeding, pain, tenesmus, and constipation. Asymptomatic rectal gonorrhea may not be from anal intercourse but may represent translocation of infected secretions from cervicovaginal infection.

Gonococcal **ophthalmitis** may be unilateral or bilateral and may occur in any age-group after inoculation of the eye with infected secretions. **Ophthalmia neonatorum** caused by *N. gonorrhoeae* usually appears from 2-5 days after birth (see Chapter 674). Ocular infection in older patients results from inoculation or autoinoculation from a genital site. The infection begins with mild inflammation and a serosanguineous discharge. Within 24 hours, the discharge becomes thick and purulent and tense edema of the eyelids with marked chemosis occurs. If the disease is not treated promptly, corneal ulceration, rupture, and blindness may follow.

Disseminated Gonococcal Infection

Hematogenous dissemination occurs in 1–3% of all gonococcal infections, more frequently after asymptomatic primary infections than symptomatic infections. Women previously accounted for the majority of cases, with symptoms beginning 7-30 days after infection and within 7 days of menstruation in about one half of cases, but more recent case series describe more male than female cases. The most common manifestations are asymmetric arthralgia, petechial or pustular acral skin lesions, tenosynovitis, suppurative arthritis, and rarely, carditis, meningitis, and osteomyelitis. The most common initial symptom is acute onset of **polyarthralgia with fever**. Only 25% of patients complain of skin lesions. Most deny genitourinary symptoms; however, primary mucosal infection is documented by genitourinary cultures. Results of approximately 80–90% of cervical cultures are positive in women with DGI. In males, urethral culture results are positive in 50–60%, pharyngeal culture results are positive in 10–20%, and rectal culture results are positive in 15% of cases.

DGI is classified into two clinical syndromes that have some overlapping features. The more common **tenosynovitis-dermatitis syndrome** is characterized by fever, chills, skin lesions, and polyarthralgia predominantly involving the wrists, hands, and fingers. Blood culture results are positive in approximately 30–40% of cases, and results of synovial fluid cultures are almost uniformly negative. In **suppurative arthritis syndrome**, systemic symptoms and signs are less prominent and monoarticular arthritis is more common, often involving the knee. A polyarthralgia phase may precede the monoarticular infection. In cases of monoarticular involvement, synovial fluid culture results are positive in approximately 45–55%, and synovial fluid findings are consistent with septic arthritis. Blood culture results are usually negative. DGI in neonates usually occurs as a polyarticular suppurative arthritis.

Dermatologic lesions usually begin as painful, discrete, 1- to 20-mm, pink or red macules that progress to maculopapular, vesicular, bullous, pustular, or petechial lesions. The typical necrotic pustule on an erythematous base is distributed unevenly over the extremities, including the palmar and plantar surfaces, usually sparing the face and scalp. The lesions number between 5 and 40, and 20–30% may contain gonococci. Although immune complexes may be present in DGI, complement levels are normal, and the role of the immune complexes in pathogenesis is uncertain.

Acute endocarditis is an uncommon (1–3%) but often fatal manifestation of DGI that usually leads to rapid destruction of the aortic valve. **Acute pericarditis** is a rarely described entity in patients with disseminated gonorrhea. **Meningitis** with *N. gonorrhoeae* has been documented, and signs and symptoms are similar to those of any acute bacterial meningitis.

DIAGNOSIS

Laboratory confirmation of gonococcal infection is essential, given the legal implications of potential sexual abuse in children and the need to refer sex partners of adolescents and adults for treatment. Given the advent of highly sensitive and specific nucleic acid amplification tests (NAATs), the use of less sensitive, nonamplified test technologies (nucleic acid hybridization/probe tests, nucleic acid genetic transformation tests, or enzyme immunoassays) is no longer justified. Culture and susceptibility testing capability still need to be maintained, because culture is necessary to evaluate suspected cases of gonorrhea treatment failure and to monitor developing resistance to current treatment regimens.

Gram Stain and Culture

Gram stains can be useful in the initial evaluation of patients with suspected gonococcal infection. In males with symptomatic urethritis, a presumptive diagnosis of gonorrhea can be made by identification of gram-negative intracellular diplococci (within PMNs) in the urethral discharge. A similar finding in females is not sufficient because *Mima polymorpha* and *Moraxella,* which are normal vaginal flora, have a similar appearance. The sensitivity of the Gram stain for diagnosing gonococcal cervicitis and asymptomatic infections is also low. The presence of commensal *Neisseria* spp. in the oropharynx prevents the use of the Gram stain for diagnosis of pharyngeal gonorrhea.

Culture can be performed of any site, including nongenital sites. Advantages of culture include the availability of an isolate for further studies, including antibiotic susceptibility testing. Disadvantages of culture include more stringent transport and growth requirements, lower sensitivity than NAATs, and a delay in availability of results. Material for cervical cultures is obtained as follows. After the exocervix is wiped, a swab is placed in the cervical os and rotated gently for several seconds. Male urethral specimens are obtained by placement of a small swab 2-3 cm into the urethra. Rectal swabs are best obtained by passing a swab 2-4 cm into the anal canal; specimens that are heavily contaminated by feces should be discarded. For optimal culture results, specimens should be obtained with noncotton swabs, inoculated directly onto culture plates containing selective media (see later), and incubated immediately. The choice of anatomic sites to culture depends on the sites exposed and the clinical manifestations. If symptoms are present, samples from the urethra and rectum can be cultured for men, and samples from the endocervix and rectum can be cultured for all females, regardless of a history of anal intercourse. A pharyngeal culture specimen should be obtained from both men and women if symptoms of pharyngitis are present with a history of recent oral exposure or oral exposure to a person known to have genital gonorrhea. In a suspected case of **child sexual abuse**, culture or FDA approved NAAT are recommended methods of detection for *N. gonorrhoeae* in genital and extragenital specimens. Culture of the endocervix should not be attempted until after puberty.

Specimens from sites that are normally colonized by other organisms (e.g., cervix, rectum, pharynx) should be inoculated on a selective culture medium, such as modified Thayer-Martin medium (fortified with vancomycin, colistin, nystatin, and trimethoprim to inhibit growth of indigenous flora). Specimens from sites that are normally sterile or minimally contaminated (i.e., synovial fluid, blood, cerebrospinal fluid) should be inoculated on a nonselective chocolate agar medium. If DGI is suspected, blood, pharynx, rectum, urethra, cervix, and synovial fluid (if involved) should be cultured. Cultured specimens should

be incubated promptly at 35–37°C (95–98.6°F) in 3–5% carbon dioxide. When specimens must be transported to a central laboratory for culture plating, a reduced, nonnutrient holding medium (i.e., Amies [modified Stuart] transport medium) preserves specimens with minimal loss of viability for up to 6 hours. When transport may delay culture plating by >6 hours, it is preferable to inoculate the sample directly onto a culture medium and transport it at an ambient temperature in a CO_2-enriched atmosphere. The Transgrow and John E. Martin Biological Environmental Chamber (JEMBEC) systems of modified Thayer-Martin medium are alternative transport systems.

Nucleic Acid Amplification Tests

The U.S. FDA has approved NAATs for use with genital (endocervical, vaginal, male urethral, and female and male first-catch urine) and extragenital (pharyngeal and rectal) specimens. Advantages of using NAATs include less stringent transport conditions, more rapid turnaround time, flexibility in sampling source (providing additional feasibility of testing in settings where a physical exam is not done), and patient preference for less invasive sampling. However, NAATs cannot provide antimicrobial susceptibility results, so in cases of persistent gonococcal infection after treatment, clinicians should perform both culture and antimicrobial susceptibility testing. Although urine specimens are acceptable for women, the sensitivity for screening appears to be lower than with vaginal or endocervical swab samples. In contrast, the sensitivity and specificity of urine and urethral swab specimens from men are similar, so first-catch urine is the recommended sample type for urethral screening in men. Product inserts for each NAAT vendor must be carefully examined to assess current indications and allowable specimens. Some NAAT platforms are now FDA cleared for use with specimens from the rectum and pharynx, facilitating their use for clinical management of extragenital infections (gonorrhea screening of rectal and pharyngeal sites with NAATs is recommended quarterly for some sexually active MSM, e.g., those taking HIV prophylaxis). NAATs have not yet been FDA cleared for specimens from the conjunctiva, joint fluid, blood, or cerebrospinal fluid. Rapid NAATs with shortened turnaround times of 30 minutes and waivers allowing use in point-of-care settings such as physician offices, community clinics, and other outpatient settings have now also been FDA cleared.

Although data regarding NAAT for children are more limited and performance is test-dependent, there is no evidence that performance of FDA-approved NAAT for detection of *N. gonorrhoeae* among children differs from that among adults. In a multicenter study of NAATs using strand displacement amplification or transcription-mediated amplification in children being evaluated for sexual abuse, urine from prepubertal girls was a reliable alternative to vaginal culture for detection for *N. gonorrhoeae*. Consultation with an expert is necessary before using NAAT in this context, both to minimize the possibility of cross-reaction with nongonococcal *Neisseria* species and other commensals (e.g., *N. meningitidis, N. sicca, N. lactamica, N. cinerea,* or *Moraxella catarrhalis*) and to ensure correct interpretation of results. Because of the implications of a diagnosis of *N. gonorrhoeae* infection in a child, only CLIA-validated, FDA-cleared NAATs should be used, and all positive specimens should be retained for additional confirmatory testing.

TREATMENT

All patients who are presumed or proven to have gonorrhea should be evaluated for concurrent syphilis, HIV, and *Chlamydia trachomatis* infection. The incidence of *Chlamydia* co-infection is 15–25% among males and 35–50% among females. Patients beyond the neonatal period should be treated presumptively for *C. trachomatis* infection unless a negative chlamydial NAAT result is documented at the time treatment is initiated for gonorrhea. However, if chlamydial test results are not available or if a non-NAAT result is negative for *Chlamydia,* patients should be treated for both gonorrhea and *Chlamydia* infection (see Chapter 272.2). Persons who receive a diagnosis of gonorrhea should be instructed to abstain from sexual activity for 7 days after treatment and until all sex partners are adequately treated (7 days after receiving treatment and resolution of symptoms, if present). Sexual partners exposed in the preceding 60 days should be examined, specimens collected, and presumptive treatment started.

N. gonorrhoeae has progressively developed resistance to the antibiotics used to treat it. Antimicrobial resistance in *N. gonorrhoeae* occurs as plasmid-mediated resistance to penicillin and tetracycline and chromosomally mediated resistance to penicillins, tetracyclines, spectinomycin, fluoroquinolones, cephalosporins, and azithromycin. Emergence of cephalosporin resistance worldwide has prompted designation of *N. gonorrhoeae* as antibiotic-resistance threat level "Urgent" by the CDC. Surveillance data from the CDC Gonococcal Isolate Surveillance Project reveal concerning fluctuations in minimum inhibitory concentration (MIC) for the oral cephalosporin **cefixime** and the injectable third-generation cephalosporin **ceftriaxone**, leading the CDC to revise its U.S. gonorrhea treatment guidelines in 2012 to dual therapy (usually a combination of ceftriaxone and azithromycin) in an attempt to preserve the last commercially available effective treatment. However, the CDC revised its recommendations in 2020; ceftriaxone is now the only first-line recommended treatment for gonorrhea at all sites. The change from dual therapy to monotherapy was based on (1) increasing concern for antimicrobial stewardship and the potential impact of dual therapy on commensal organisms and concurrent pathogens, (2) new pharmacokinetic and pharmacodynamic data regarding optimal dosing for gonorrhea, and (3) increasing azithromycin resistance (and therefore no optimal second drug to pair with a cephalosporin if dual therapy were the goal).

Table 238.1 summarizes first-line treatment regimens for neonate, child (weight ≤45 kg), adolescent, and adult gonococcal regimens. Mucosal, localized infections are treatable with single doses; disseminated infections are treated for a minimum of 1 week.

Alternative regimens exist for adolescents and adults but are extremely limited. For patients with cephalosporin allergy, the combination of gentamicin (240 mg intramuscularly [IM]) plus azithromycin (2 g orally [PO]) cured 100% of uncomplicated urogenital cases in a trial of U.S. patients age 15-60 years; the combination of gemifloxacin (320 mg PO) (not licensed for use in those <18 years old) plus azithromycin (2 g PO) cured >99% of uncomplicated urogenital cases in the same trial but was limited by 8% of patients vomiting within 1 hour of dual oral drug administration. For patients with azithromycin allergy, doxycycline (100 mg PO twice daily for 7 days) can be used in place of azithromycin as an alternative second antimicrobial. If ceftriaxone is not available, alternative cephalosporins include oral cefixime (800 mg PO), which has limited efficacy for pharyngeal gonorrhea, and other single-dose injectable cephalosporin regimens, such as ceftizoxime (500 mg IM) or cefoxitin (2 g IM) with probenecid (1 g PO), neither of which offers any advantage over ceftriaxone for urogenital infection, and their efficacy against pharyngeal infection is less certain.

Pregnant women with gonococcal infection should be treated with standard adult therapy. If allergy precludes standard treatment, consultation with an infectious disease specialist is recommended. HIV–co-infected patients with gonococcal infection are treated the same as HIV-negative patients.

Follow-up test of cure is not recommended for persons diagnosed with uncomplicated urogenital or rectal gonorrhea receiving recommended or alternative regimens. However, any person with pharyngeal gonorrhea should return 7-14 days after treatment for a test of cure using culture, NAAT, or both, because pharyngeal gonorrhea is more difficult to eradicate. Symptoms persisting after treatment should be evaluated by culture for *N. gonorrhoeae* (with or without simultaneous NAAT), and any gonococci isolated should be tested for antimicrobial susceptibility. **Treatment failure** should be considered in (1) persons whose symptoms do not resolve within 3-5 days after appropriate treatment and who report no sexual contact during posttreatment follow-up and (2) persons with a positive test of cure (i.e., positive culture >72 hours or positive NAAT ≥7 days after receiving recommended treatment) who report no sexual contact during posttreatment follow-up.

COMPLICATIONS

Prompt diagnosis and correct therapy ensure complete recovery from uncomplicated gonococcal disease. Complications of gonorrhea result

Table 238.1 Recommended Treatment of Gonococcal Infections

AGE GROUP	INFECTION	TREATMENT REGIMEN	LENGTH OF THERAPY
Neonates	Ophthalmia neonatorum	Ceftriaxone* 25-50 mg/kg IV or IM *OR* cefotaxime 100 mg/kg IV or IM	Once
	Disseminated infection Scalp abscess Septic arthritis	Ceftriaxone 25-50 mg/kg IV or IM every day *OR* cefotaxime 25-50 mg/kg IV or IM q8–12h†	7 days
	Meningitis	Ceftriaxone 25-50 mg/kg IV or IM every day *OR* cefotaxime 25-50 mg/kg IV or IM q8-12h	10-14 days
	Endocarditis	Ceftriaxone 25-50 mg/kg IV or IM every day *OR* cefotaxime 25-50 mg/kg IV or IM q8-12h	Minimum 28 days
Children ≤45 kg	Pharyngeal infection Anorectal infection Urogenital infection	Ceftriaxone 25-50 mg/kg IV or IM (max 500 mg)	Once
	Conjunctivitis	Ceftriaxone 50 mg/kg IM (max 1 g) plus consider lavage of infected eye with saline solution	Once
	Disseminated infection Septic arthritis	Ceftriaxone 50 mg/kg IV or IM every day (max 1 g daily)	7 days
	Meningitis	Ceftriaxone 50 mg/kg IV or IM q12-24h (max 4 g daily)	10-14 days
	Endocarditis	Ceftriaxone 50 mg/kg IV or IM q12-24h (max 4 g daily)	Minimum 28 days
Adults, adolescents, and children >45 kg	Pharyngeal infection Anorectal infection Urogenital infection	Ceftriaxone 500 mg IM (or 1 g IM for persons ≥150 kg)	Once
	Conjunctivitis	Ceftriaxone 1 g IM plus consider lavage of infected eye with saline solution	Once
	Disseminated infection Septic arthritis	Ceftriaxone 1 g IV or IM every day	7 days
	Meningitis	Ceftriaxone 1-2 g IV q12-24h	10-14 days
	Endocarditis	Ceftriaxone 1-2 g IV q12-24h	Minimum 28 days

*Ceftriaxone should be administered cautiously to neonates with hyperbilirubinemia, especially those born prematurely. Cefotaxime can be administered for those neonates unable to receive ceftriaxone because of simultaneous administration of IV calcium. Consult neonatal dosing references.
†Dose or dosing frequency changes after postnatal age >7 days of life: consult neonatal dosing references.

From Wangu Z, Hsu KK. *Neisseria gonorrhoeae.* In Long SS, Prober CG, Fischer M, Kimberlin D, eds. *Principles and Practice of Pediatric Infectious Diseases,* 6th ed. Philadelphia: Elsevier; 2023: Table 126.1.

from the spread of gonococci from a local site of invasion. Complications and permanent sequelae may be associated with delayed treatment, recurrent infection, metastatic sites of infection (meninges, aortic valve), and delayed or topical therapy of gonococcal ophthalmia.

The interval between primary infection and development of a complication is usually days to weeks. In postpubertal females, endometritis may occur, especially during menses, and may progress to salpingitis, tuboovarian abscess, and peritonitis (PID). Manifestations of PID include signs of lower genital tract infection (e.g., vaginal discharge, suprapubic pain, cervical tenderness) and upper genital tract infection (e.g., fever, leukocytosis, elevated erythrocyte sedimentation rate, and adnexal tenderness or mass). The differential diagnosis includes gynecologic diseases (ovarian cyst, ovarian tumor, ectopic pregnancy) and intraabdominal disorders (appendicitis, urinary tract infection, inflammatory bowel disease). Although *N. gonorrhoeae* and *C. trachomatis* are implicated in many cases of PID, this syndrome encompasses a spectrum of infectious diseases of the upper genital tract caused by *N. gonorrhoeae, C. trachomatis,* and endogenous flora (streptococci, anaerobes, gram-negative bacilli). Treatment must therefore be broad. For women with more severe symptoms (inability to exclude surgical emergency, presence of tuboovarian abscess, severe illness, nausea, vomiting, or high fever), pregnancy, or lack of response to outpatient therapy within 72 hours, parenteral therapy should be initiated in the hospital. The decision to hospitalize adolescents with acute PID should be based on the same criteria used for older women, because the clinical response to outpatient treatment is similar among younger and older women.

Recommended parenteral regimens are ceftriaxone (1 g intravenously [IV] every 24 hours [q24h]) and metronidazole (500 mg PO or IV q12h); or cefotetan (2 g IV q12h); or cefoxitin (2 g IV q6h). Each of these regimens (ceftriaxone and metronidazole; cefotetan; or cefoxitin) should be combined with doxycycline (100 mg PO or IV q12h). An alternative parenteral regimen is ampicillin-sulbactam (3 g IV q6h) plus doxycycline (100 mg PO or IV q12h) or clindamycin (900 mg IV q8h) plus a loading dose of gentamicin (2 mg/kg IV or IM) followed by maintenance gentamicin (1.5 mg/kg q8h). Clinical experience should guide the transition to oral therapy, which usually can be initiated within 24 hours of improvement. Thereafter doxycycline (100 mg PO twice daily [bid]) to complete 14 days of total therapy, with oral clindamycin (450 mg PO 4 times daily [qid]) or metronidazole (500 mg PO bid) added for more effective anaerobic coverage, is provided. Parenteral therapy and IM/PO therapy appear to be similar in terms of clinical efficacy for younger and older women with PID of mild to moderate severity. Recommended IM/PO therapy regimens are as follows: a single dose of ceftriaxone (500 mg IM); single doses of cefoxitin (2 g IM) and probenecid (1 g PO) plus doxycycline (100 mg PO bid); or another parenteral third-generation cephalosporin (e.g., ceftizoxime). Each of these regimens (ceftriaxone; cefoxitin and probenecid; other

parenteral third-generation cephalosporin) should be combined with doxycycline (100 mg PO bid) and metronidazole (500 mg PO bid) for 14 days.

Once inside the peritoneum, gonococci may seed the liver capsule, causing a perihepatitis with right upper quadrant pain **(Fitz-Hugh–Curtis syndrome)**, with or without signs of salpingitis. Perihepatitis may also be caused by *C. trachomatis*. Progression to PID occurs in approximately 20% of cases of gonococcal cervicitis, and *N. gonorrhoeae* is isolated in approximately 40% of cases of PID in the United States. Untreated cases may lead to hydrosalpinx, pyosalpinx, tubo-ovarian abscess, and eventual sterility. Even with adequate treatment of PID, the risk for sterility from bilateral tubal occlusion approaches 20% after one episode of salpingitis and exceeds 60% after three or more episodes. The risk for ectopic pregnancy is increased approximately sevenfold after one or more episodes of salpingitis. Additional sequelae of PID include chronic pain, dyspareunia, and increased risk for recurrent PID.

Urogenital gonococcal infection acquired during the first trimester of pregnancy carries a high risk for septic abortion. After 16 weeks of pregnancy, infection leads to **chorioamnionitis**, a major cause of premature rupture of the membranes and premature delivery.

In males, without treatment, gonococcal urethritis usually resolves spontaneously over several weeks to months. Epididymitis and acute or chronic prostatitis are uncommon complications; most men with gonococcal epididymitis also have overt urethritis. Even more unusual complications include penile edema associated with penile dorsal lymphangitis or thrombophlebitis, periurethral abscess or fistulas, seminal vesiculitis, and balanitis in uncircumcised men.

PREVENTION

Efforts to develop gonococcal vaccines that confer broad cross-protection have been unsuccessful thus far. A pilus vaccine elicited an antibody response and conferred protection against challenge with the homologous strain but did not protect against disease in a trial involving 3,250 volunteers. The high degree of interstrain and intrastrain antigenic variability of pili poses a formidable barrier to the development of a single effective pilus vaccine. An outer membrane vaccine that was enriched in PorB also elicited an antibody response but failed to protect male volunteers against challenge with the homologous strain, likely because small amounts of Rmp present in the vaccine preparation elicited subversive antibodies. A formalin-killed whole cell vaccine trial in 62 volunteers in an Inuvik population in Canada also failed to provide any protection. Gonococcal surface structures, such as the porin protein (isolated without contaminating Rmp), proteins expressed under various stress conditions that may be encountered in vivo and have been identified by proteomic and transcriptomic approaches, and lipooligosaccharides, may prove more promising as vaccine candidates.

A retrospective epidemiologic analysis showed that a meningococcal outer membrane vesicle vaccine (MeNZB) that was used to curb an epidemic of group B meningococcal disease in New Zealand was associated with a clinical efficacy of 31% against gonorrhea, which lends optimism for development of a gonococcal vaccine. However, efficacy was only 14% in persons co-infected with gonorrhea and chlamydia. Cross-reactive antigens shared by *N. gonorrhoeae* and *N. meningitidis* may have contributed to the efficacy of the group B outer membrane vesicle vaccine against gonorrhea.

In the absence of a vaccine, prevention of gonorrhea in adolescents and adults can be achieved through **education**, use of **barrier protection** (especially condoms), **frequent screening** of high-risk populations as recommended by the U.S. Preventive Services Task Force (PSTF) and CDC (e.g., sexually active women ≤24 years old, MSM, individuals previously infected with gonorrhea), and **early identification and treatment** of contacts—all sex partners within the 60 days preceding symptom onset or gonorrhea diagnosis or, if none, the most recent sex partner should be examined and treated presumptively. For heterosexual patients, expedited partner therapy (EPT) with cefixime (800 mg) can be delivered to partners by the patient, a public health worker, or a collaborating pharmacy, as permitted by law (https://www.cdc.gov/std/ept/legal/). EPT has been shown to be safe and effective in the prevention of reinfection with gonorrhea and is endorsed by the American Academy of Pediatrics, American Academy of Family Physicians, and Society of Adolescent Health and Medicine, along with other clinical organizations, for use when in-person evaluation and treatment of the partner is impractical or unsuccessful. (Because of limited data regarding the effectiveness of EPT in reducing persistent or recurrent gonorrhea among MSM and the high risk for coexisting undiagnosed sexually transmitted infections such as HIV, shared clinical decision-making regarding EPT for MSM is recommended.)

An infant born to a woman with cervical gonococcal infection has an approximately 30% risk of acquiring ophthalmic infection compared with a <5% risk if ocular prophylaxis is given. **Gonococcal ophthalmia neonatorum** can be prevented by instilling erythromycin (0.5%) ophthalmic ointment into each eye in a single application at birth (see Chapter 674). If erythromycin ointment is unavailable, infants at risk for *N. gonorrhoeae* (especially those born to a mother with untreated gonococcal infection or with no prenatal care) can be administered ceftriaxone 25-50 mg/kg IV or IM, not to exceed 500 mg, in a single dose.

Chapter 239
Kingella kingae

Pablo Yagupsky

Kingella kingae is being increasingly recognized as the most common etiology of skeletal system infections in young children.

ETIOLOGY

K. kingae is a fastidious, facultative anaerobic, β-hemolytic member of the Neisseriaceae family that appears as pairs or short chains of gram-negative coccobacilli with tapered ends (Fig. 239.1).

EPIDEMIOLOGY

K. kingae is asymptomatically carried in the posterior pharynx, and the colonized mucosa is the source of bloodstream invasion of the bacterium and its dissemination to the skeletal system or the endocardium, sites for which the organism has a particular tropism. **Colonization** usually starts after 6 months of age, suggesting that maternally derived immunity, coupled with limited socialization, prevents the early acquisition of the bacterium. Colonization reaches a prevalence of 10% between 12 and 24 months and decreases in older children. Carried strains are replaced after weeks or months, suggesting that carriage induces a strain-specific immune response that eradicates the colonizing strain but does not prevent the acquisition of an antigenically different organism. The vast majority of colonized children remain healthy, and the annual risk of a carrier to develop an invasive infection is <1%.

Pharyngeal colonization plays a crucial role in the **transmission** of the organism through intimate contact between siblings and playmates. Daycare attendance increases the risk for colonization and transmission, and clusters of invasive infection have been reported in childcare facilities.

The species elaborates four different polysaccharide capsules (a-d), which appear to represent important virulence factors. Whereas capsules a and b characterize 95% of all invasive strains, capsules c and d are especially found in mere pharyngeal colonizers. Colonizing *K. kingae* strains differ in their invasive potential. Whereas certain clones are commonly found as respiratory colonizers but are seldom isolated from disease sites, other clones are responsible for most of the morbidity burden worldwide.

Invasive *K. kingae* disease is most frequently diagnosed in otherwise healthy children between the ages 6 months and 4 years, coinciding

with the peak prevalence of **pharyngeal carriage** (Fig. 239.2). In contrast, older children and adults with *K. kingae* infections often have underlying chronic diseases, immunosuppressing conditions, malignancy, or cardiac valve pathology. Because of the highly fastidious nature of the organism, *K. kingae* is rarely recovered using traditional culture methods. An annual incidence of 9.4 per 100,000 culture-proven invasive infections among Israeli children <5 years old has been calculated, but this figure can be considered only a minimal estimate because of the suboptimal culture detection of the organism. When sensitive species-specific nucleic acid amplification test (NAAT) methods are consistently used, *K. kingae* appears as the most frequent etiology of skeletal system infections in children 6 months to 4 years old. In a Swiss study in which sensitive NAATs were routinely employed, the organisms caused 88% of all joint and bone infections in this age-group.

PATHOGENESIS

The pathogenesis of *K. kingae* disease begins with adherence of the organism to the pharyngeal epithelium, mediated by pili and a non-pilus adhesin. *K. kingae* secretes a potent repeats-in-toxin (RTX) toxin that is cytotoxic to respiratory epithelial cells, macrophages, and synoviocytes, suggesting that it may play a role in disrupting the respiratory mucosa, promoting survival of the bacterium in the bloodstream, and facilitating invasion of skeletal system tissues. Children with *K. kingae* disease frequently present with symptoms of an upper respiratory infection, hand-foot-and-mouth disease, herpangina, herpetic stomatitis, or buccal aphthous ulcers, suggesting that viral-induced damage to the colonized mucosal surface facilitates invasion of the bloodstream.

CLINICAL DISEASE

Septic arthritis is the most common invasive *K. kingae* infection in children, followed by bacteremia, osteomyelitis, and endocarditis (Table 239.1). Except for patients with endocarditis, the presentation of invasive *K. kingae* infections is frequently mild, and a normal body temperature <38°C (100.4°F), a normal C-reactive protein (CRP) level, and a normal white blood cell (WBC) count are common, requiring a high index of clinical suspicion. Mild to moderate thrombocytosis has been described in more than one third of patients.

Septic Arthritis

K. kingae septic arthritis primarily affects the large, weight-bearing joints and the upper extremity joints. However, *K. kingae* infections of the small metacarpophalangeal, sternoclavicular, sacroiliac, and tarsal joints and the vertebral facets are also relatively common, in contrast to traditional bacterial pathogens associated with septic arthritis (see Chapter 726). The disease has an acute presentation, and children are brought to medical attention after a median of 3 days. The leukocyte count in the synovial fluid shows <50,000 WBCs/μL in almost 25% of the patients, and the Gram stain of synovial fluid is positive in only a small percentage of cases. Involvement of the hip joint resembles toxic synovitis, and the possibility of a *K. kingae* infection should always be suspected in children <4 years old presenting with hip pain or a limp.

Osteomyelitis

K. kingae osteomyelitis usually involves the long bones of the extremities (see Chapter 725). The calcaneus, talus, sternum, and clavicle are also frequently affected (and are rarely infected by other bacterial pathogens). In contrast to *K. kingae* arthritis, the onset of *K. kingae* bone infections is insidious, and the disease follows a subacute and indolent clinical course (Fig. 239.3). In >70% of patients *K. kingae* osteomyelitis is diagnosed after ≥1 week. MRI may show a distinct involvement of cartilages that are not yet ossified, which is only accompanied by a minor soft tissue reaction. Dissemination to the apophysis or epiphysis and contiguous joints is frequent. Despite the frequent diagnostic delay, chronic osteomyelitis and functional orthopedic disabilities are unusual.

SPONDYLODISCITIS

In industrialized countries, *K. kingae* is the most common bacterium detected in children <4 years old with spondylodiscitis. The organism presumably penetrates the rich network of blood vessels that traverse the cartilaginous vertebral end plates and enters the annulus in young children during a bacteremic episode. *K. kingae* spondylodiscitis usually involves the lumbar intervertebral spaces and, with decreasing frequency, thoracolumbar, thoracic, lumbosacral, and cervical disks. Involvement of multiple disks is uncommon. Patients present with limping, lumbar pain, back stiffness, refusal to sit or walk, neurologic symptoms, or abdominal complaints. Radiography or MRI studies demonstrate narrowing of the intervertebral space. Patients respond well to appropriate antibiotic treatment and recover without complications, although residual thinning of the intervertebral space may occur. Drainage of paraspinal abscesses is necessary when signs of cord compression appear.

Tenosynovitis

K. kingae is the etiology of most cases of hematogenous invasion of the tendon sheaths in children <4 years of age. The disease usually affects the extensor tendons of the hands and wrists and, more rarely, the ankles and the feet.

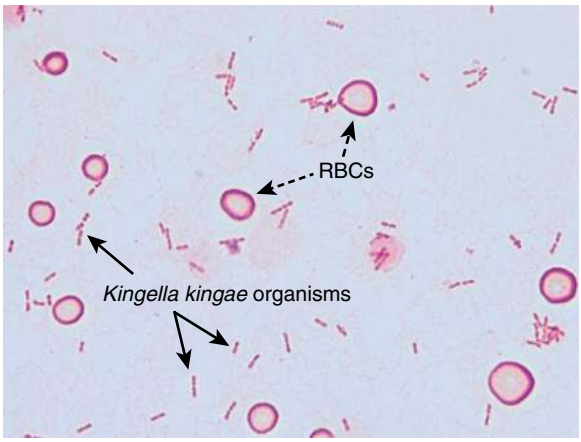

Fig. 239.1 Typical Gram stain of a positive blood culture vial from a child with *K. kingae* bacteremia showing pairs and short chains of plump gram-negative coccobacilli. RBCs, Red blood cells.

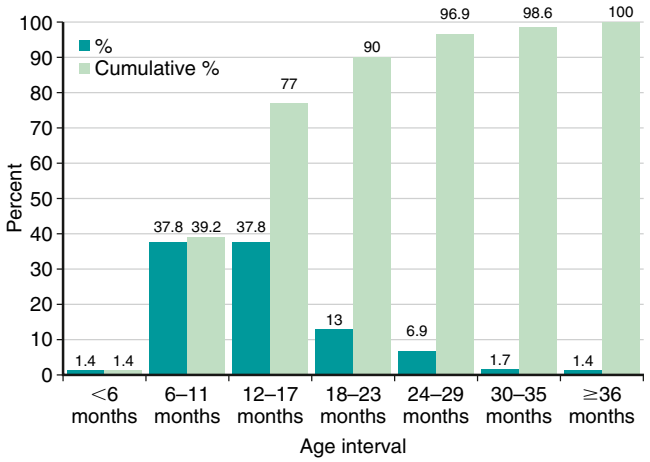

Fig. 239.2 Age distribution of 291 previously healthy children with invasive *K. kingae* infection. *(Data from Dubnov-Raz G, Ephros M, Garty BZ, et al. Invasive pediatric Kingella kingae infections: a nationwide collaborative study. Pediatr Infect Dis J. 2010;29:639–643.)*

He was afebrile and had a leukocyte count of 9.8 × 10^9 cells/L, a C-reactive protein level of 12 mg/L, and an erythrocyte sedimentation rate of 42 mm/hr. *(Courtesy Prof. Dimitri Ceroni, Hôpitaux Universitaires de Genève.)*

Occult Bacteremia

Patients with *K. kingae* bacteremia and no focal infection (occult bacteremia) usually present with mild to moderate fever, symptoms suggestive of a viral upper respiratory infection, a mean CRP level of 2.2 mg/dL, and a mean WBC count of 12,700/μL. Children with *K. kingae* bacteremia respond favorably to a short course of antibiotics.

Endocarditis

In contrast to other *K. kingae* infections, *K. kingae* endocarditis is also diagnosed in school-age children, adolescents, and adult patients. The disease may affect native and prosthetic valves. Predisposing factors include congenital cardiac malformations or rheumatic valvular disease, but some patients have previously normal hearts. Typically, the left side of the heart is involved, usually the mitral valve. Fever and acute-phase reactants are elevated more in patients with endocarditis than in those with uncomplicated bacteremia; no particular cutoff value accurately distinguishes between the two conditions. Despite the exquisite susceptibility of *K. kingae* to antibiotics, cardiac failure, septic shock, cerebrovascular accident (stroke), and other life-threatening complications are common; the mortality rate is high (>10%); and many surviving patients later require valvular repair or replacement. Because of the potential severity of *K. kingae* endocarditis, routine echocardiographic evaluation of bacteremic children is recommended by some experts.

DIAGNOSIS

The diagnosis of *K. kingae* disease can be established by isolation of the bacterium from a normally sterile site such as blood, synovial fluid, or bone tissue. Although *K. kingae* grows on routine bacteriologic media, its recovery from exudates is frequently unsuccessful. Detection is enhanced by inoculating synovial fluid specimens into blood culture vials, suggesting that diluting samples in a large volume of nutrient broth reduces the concentration of detrimental factors. The bacteriologic diagnosis is significantly improved by the use of NAATs (polymerase chain reaction). The initial approach consisted of amplifying the 16S ribosomal RNA (rRNA) gene, which is present in all bacteria followed by sequencing the species-specific amplicon to identify the pathogen. The original molecular assays are being replaced by real-time polymerase chain reaction tests that target *K. kingae*–specific genes that can be completed in a few hours. Routine use of these assays results in a fourfold improvement in the detection of the organism compared with the blood culture vial method and reduces the fraction of culture-negative septic arthritis in young children. The three *K. kingae*–specific genes that are targeted by the current tests are the *rtx* operon that encodes the RtxA toxin; the *cpn*60 (chaperonin 60 gene), also known as *gro*EL; and the malate dehydrogenase *(mdh)* gene that combines excellent sensitivity and specificity and should be the preferred method.

Because the bacterium frequently invades joints and bones that are small or difficult to reach or intervertebral disks, exudate samples or tissues are often unavailable for analysis. An alternative noninvasive diagnostic approach has been proposed consisting of obtaining an oropharyngeal specimen and subjecting it to a sensitive *K. kingae*–specific NAAT. A compatible clinical picture, coupled with a positive test result, supports *K. kingae* as the probable cause of the disease. This strategy has the obvious limitation that the background carriage rate of the organism is around 10% in children of the relevant age and twice as high in those attending daycare centers, reducing the predictive value of a positive result. On the other hand, because the colonized oropharynx is the source of the bloodborne dissemination of the bacterium, the negative predictive value of the assay is high. For practical purposes, failure to detect *K. kingae* DNA sequences when using a sensitive molecular test virtually rules out the organism as the etiology of the infection.

Novel commercially available plasma metagenomic next-generation sequencing assays appear to be a promising tool for detecting the organism, especially in patients with endocarditis receiving antibiotics.

TREATMENT

K. kingae is usually highly susceptible to penicillin and cephalosporins but exhibits decreased susceptibility to oxacillin, precluding the use of isoxazolyl penicillins for confirmed *K. kingae* infections. Although β-lactamase production is frequently detected in colonizing *K. kingae* strains, its prevalence among invasive organisms is low and shows wide geographic variation. Testing for β-lactamase production should be routinely performed in all isolates derived from normally sterile body sites.

Because of the lack of specific guidelines for treating *K. kingae* disease, patients have been administered a variety of antibiotic regimens according to protocols developed for infections caused by traditional bacterial pathogens. The first-line therapy for skeletal infections in young children usually consists of intravenous (IV) administration of a second- or third-generation **cephalosporin**, pending culture or NAAT results. *K. kingae* is always *resistant* to glycopeptide antibiotics and clindamycin, a serious concern in areas where skeletal infections caused by community-associated methicillin-resistant *Staphylococcus aureus* are common, and **vancomycin** or **clindamycin** are initially

administered to children with presumptive septic arthritis or osteomyelitis. The initial antibiotic regimen is frequently changed to a cephalosporin (e.g., ceftriaxone) once *K. kingae* is identified or to ampicillin after β-lactamase production is excluded. A favorable clinical response and decreasing CRP levels to ≤20 μg/mL are used to guide switching to oral antibiotics and defining the duration of therapy. Antibiotic treatment has ranged from 2 to 3 weeks for *K. kingae* arthritis, from 3 to 6 weeks for *K. kingae* osteomyelitis, and from 3 to 12 weeks for *K. kingae* spondylodiscitis. Although some children with septic arthritis have been managed with repeat joint aspirations and lavage, most patients respond promptly to conservative treatment with appropriate antibiotics and do not require invasive surgical procedures.

Children with *K. kingae* bacteremia without focal infection are initially treated with an IV β-lactam antibiotic and are subsequently switched to an oral drug once the clinical condition has improved. In most cases, therapy is administered for 1-2 weeks.

Patients with *K. kingae* endocarditis are usually treated with an IV β-lactam antibiotic alone or in combination with an aminoglycoside for 4-7 weeks. Early surgical intervention is necessary for life-threatening complications unresponsive to medical therapy.

PREVENTION

Because the risk of asymptomatic pharyngeal carriers for developing an invasive *K. kingae* infection is low, in the absence of clinical disease, there is no indication to eradicate the organism from the colonized mucosal surfaces. Nonetheless, in 25 reported outbreaks of *K. kingae* infections in child daycare centers, 68 of 402 (17%) classmates developed a proven or presumptive infection, including fatal endocarditis, within 1 month, indicating that the causative strains combined unusual transmissibility and virulence. Under these circumstances, prophylactic antibiotic therapy to eradicate colonization in contacts and prevent further cases of the disease has been employed, consisting of either rifampin alone 10 mg/kg or 20 mg/kg twice daily for 2 days or rifampin in combination with amoxicillin (80 mg/kg/day) for 2 days or 4 days. The effectiveness of these regimens has ranged between 47% and 80%, indicating that eradication of *K. kingae* from colonized mucosae is difficult to achieve. However, after antibiotic prophylaxis administration, no further cases of the disease have been detected, suggesting that reduction of the bacterial density by antibiotics, extinction of the precipitating viral infection, and/or induction of an effective immune response by prolonged carriage is enough to decrease transmissibility and prevent additional cases.

Chapter 240

Haemophilus influenzae

Nadia A. Kadry and Joseph W. St. Geme III

Effective vaccines to prevent ***Haemophilus influenzae* type b (Hib)** disease, introduced in the United States and most other countries, have resulted in a dramatic decrease in the incidence of infections caused by this organism. However, mortality and morbidity from Hib infection remain a problem worldwide, primarily in resource poor countries. Occasional cases of invasive disease caused by non–type b strains continue to occur but are infrequent. Nontypeable isolates of *H. influenzae* are an important cause of otitis media, sinusitis, and chronic bronchitis.

ETIOLOGY

H. influenzae is a fastidious, gram-negative, pleomorphic coccobacillus that requires factor X (hematin) and factor V (phosphopyridine nucleotide) for growth. Some *H. influenzae* isolates are surrounded by a polysaccharide capsule and can be segregated into one of six antigenically and biochemically distinct serotypes designated types a, b, c, d, e, and f. Isolates without a polysaccharide capsule are considered nontypeable. Isolates can also be categorized based on the production of indole and the presence of ornithine decarboxylase and urease and are sorted into biotypes I-VIII.

EPIDEMIOLOGY

Before the advent of an effective Hib conjugate vaccine in 1988, Hib was a major cause of serious disease among children. There was a striking age distribution of cases, with >90% in children <5 years old and the majority in children <2 years old. The annual attack rate of invasive disease was 64-129 cases per 100,000 children <5 years old. Invasive disease caused by strains producing a non–type b capsule has been much less frequent but continues to occur. The incidence of invasive disease caused by type b and non–type b serotypes has been estimated at approximately 0.08 and 1.02 cases, respectively, per 100,000 children <5 years old per year in the United States. Nontypeable (nonencapsulated) *H. influenzae* strains also occasionally cause invasive disease, especially in neonates, immunocompromised children, and children in resource poor countries. The estimated rate of invasive disease caused by nontypeable *H. influenzae* in the United States is 1.88 per 100,000 children <5 years old per year. Nontypeable isolates are common etiologic agents in otitis media, sinusitis, and chronic bronchitis. More recent evidence also implicates nasopharyngeal colonization with nontypeable *H. influenzae* in the development of asthma and allergic airway disease.

Humans are the only natural hosts for *H. influenzae,* which is part of the normal respiratory flora in 60–90% of healthy children. Most isolates are nontypeable. Before the advent of Hib conjugate vaccines, *H. influenzae* type b could be isolated from the pharynx of 2–5% of healthy preschool and school-age children, with lower rates among infants and adults. Asymptomatic colonization with Hib occurs at a much lower rate in immunized populations.

The continued circulation of type b strains despite current vaccine coverage levels suggests that elimination of Hib disease may be a formidable task. The few cases of Hib invasive disease in the United States now occur in both unvaccinated and fully vaccinated children. Approximately 50% of cases occur in infants who are too young to have received a complete primary vaccine series. Among the cases in patients who are old enough to have received a complete vaccine series, the majority are underimmunized. To highlight this point, during a shortage of Hib vaccine, invasive disease developed in five children in Minnesota, all of whom were incompletely immunized. Continued efforts are necessary to provide currently available Hib conjugate vaccines to children in resource poor countries, where affordability remains an important issue.

In the prevaccine era, certain groups and individuals had an increased incidence of invasive Hib disease, including Alaskan Natives, American Indians (Apache, Navajo), and African Americans. Persons with certain chronic medical conditions were also known to be at increased risk for invasive disease, including individuals with sickle cell disease, asplenia, congenital and acquired immunodeficiencies, and malignancies. Unvaccinated infants with invasive Hib infection are also at increased risk for recurrence, reflecting that they typically do not develop a protective immune response to *H. influenzae.*

Socioeconomic risk factors for invasive Hib disease include childcare outside the home, the presence of siblings of elementary school age or younger, short duration of breastfeeding, and parental smoking. A history of otitis media is associated with an increased risk for invasive disease. Much less is known about the epidemiology of invasive disease caused by non–type b strains, and it is not clear whether the epidemiologic features of Hib disease apply to disease caused by non-Hib strains.

Among age-susceptible household contacts who have been exposed to a case of invasive Hib disease, there is increased risk for secondary cases of invasive disease in the first 30 days after exposure, especially in susceptible children <24 months old. Whether a similar increased risk exists for contacts of individuals with non-Hib disease is unknown.

The mode of transmission is usually direct contact or inhalation of respiratory tract droplets containing *H. influenzae.* The incubation period for invasive disease is variable, and the exact period of communicability is unknown. Most children with invasive Hib disease are colonized in the nasopharynx before initiation of antimicrobial therapy; 25–40% may remain colonized during the first 24 hours of therapy.

With the decline of disease caused by type b organisms, disease caused by other serotypes (a, c-f) and by nontypeable strains has been recognized more clearly. There is no evidence that non–type b infections have increased in frequency. However, clusters of type a and, less often, type e and type f infections have occurred. Data from Israel suggest that nontypeable *H. influenzae* is the most common cause of invasive *H. influenzae* disease in that country.

PATHOGENESIS

The pathogenesis of Hib disease begins with adherence to respiratory epithelium and colonization of the nasopharynx, which is mediated by pilus and nonpilus adherence factors. The mechanism of entry into the intravascular compartment is unclear but appears to be influenced by cytotoxic factors. Once in the bloodstream, Hib, and perhaps other encapsulated strains, resist intravascular clearance mechanisms at least in part because of the polysaccharide capsule. In the case of Hib, the magnitude and duration of bacteremia influence the likelihood of dissemination of bacteria to sites such as the meninges and joints.

Noninvasive *H. influenzae* infections such as otitis media, sinusitis, and bronchitis are usually caused by nontypeable strains. These organisms gain access to sites such as the middle ear and sinus cavities by direct extension from the nasopharynx. Factors facilitating spread from the nasopharynx include eustachian tube dysfunction and antecedent viral infections of the upper respiratory tract.

Antibiotic Resistance

Ampicillin resistance is increasingly common among *H. influenzae* isolates. Resistance is typically driven by plasmid-mediated production of a β-lactamase. β-lactamase–negative ampicillin-resistant isolates have been identified and manifest resistance by production of a β-lactam–insensitive cell wall synthesis enzyme called *penicillin binding protein 3* (PBP 3).

Amoxicillin-clavulanate is uniformly active against *H. influenzae* clinical isolates except for the rare β-lactamase–negative ampicillin-resistant isolates. Among macrolides, azithromycin has in vitro activity against a high percentage of *H. influenzae* isolates; in contrast, the activity of erythromycin and clarithromycin against *H. influenzae* clinical isolates is poor. *H. influenzae* resistance to third-generation cephalosporins has not been documented. Resistance to quinolones is rare, and resistance to trimethoprim-sulfamethoxazole (TMP-SMX) is present in approximately 10% of isolates.

Immunity

In the prevaccine era, the most important known element of host defense was antibody directed against the type b capsular polysaccharide polyribosylribitol phosphate **(PRP)**. Anti-PRP antibody is acquired in an age-related fashion and facilitates clearance of Hib from blood, in part related to opsonic activity. Antibodies directed against antigens such as outer membrane proteins or lipopolysaccharide (LPS) may also have a role in opsonization. Both the classical and alternative complement pathways are important in defense against Hib.

Before the introduction of vaccination, protection from Hib infection was presumed to correlate with the concentration of circulating anti-PRP antibody at the time of exposure. A serum antibody concentration of >0.15 μg/mL was considered protective against invasive infection. Unimmunized infants >6 months old and young children usually lacked an anti-PRP antibody concentration of this magnitude and were susceptible to disease after encountering Hib. This lack of antibody in infants and young children may have reflected a maturational delay in the immunologic response to thymus-independent type 2 antigens such as unconjugated PRP, presumably explaining the high incidence of type b infections in infants and young children in the prevaccine era.

The conjugate vaccines act as thymus-dependent antigens and elicit serum antibody responses in infants and young children (Table 240.1). These vaccines are believed to prime memory antibody responses on subsequent encounters with PRP. The concentration of circulating anti-PRP antibody in a child primed by a conjugate vaccine may not correlate precisely with protection, presumably because a memory response may occur rapidly on exposure to PRP and provide protection. Conjugate vaccines have been shown to be highly effective against Hib disease and have been shown to reduce nasopharyngeal carriage rates.

Much less is known about immunity to other *H. influenzae* serotypes or to nontypeable isolates. For nontypeable isolates, evidence suggests that antibodies directed against one or more outer membrane proteins are bactericidal and protect against experimental challenge. A variety of antigens have been evaluated in an attempt to identify vaccine candidates for nontypeable *H. influenzae,* including outer membrane proteins (P1, P2, P4, P5, P6, D15, and Tbp A/B), LPS, various adhesins (e.g., Hap, HMW1, and HMW2), and lipoprotein D.

DIAGNOSIS

Presumptive identification of *H. influenzae* is established by direct examination of a clinical specimen after staining with Gram reagents. Because of its small size, pleomorphism, and occasional poor uptake of stain, as well as the tendency for proteinaceous fluids to have a red background, *H. influenzae* is sometimes difficult to visualize. Furthermore, given that identification of *H. influenzae* by microscopy requires at least 10^5 bacteria/mL in a clinical specimen (e.g., cerebrospinal fluid [CSF]), failure to visualize organisms does not preclude their presence.

Culture of *H. influenzae* requires prompt transport and processing of specimens because the organism is fastidious. Specimens should not be exposed to drying or temperature extremes. Primary isolation of *H. influenzae* can be accomplished on chocolate agar.

Serotyping of *H. influenzae* is accomplished by slide agglutination with type-specific antisera or through polymerase chain reaction (PCR) amplification of the capsule locus *(cap)*. Importantly, antigen-based detection methods are prone to false positives because of antigen cross-reactivity with other encapsulated organisms and are therefore not recommended as the primary diagnostic approach. Real-time PCR and nucleic acid amplification tests (NAATs) can be used to specifically detect *H. influenzae*. Accurate serotyping is essential to monitor progress toward elimination of type b invasive disease. Timely reporting of cases to public health authorities should be ensured.

CLINICAL MANIFESTATIONS AND TREATMENT

The initial antibiotic therapy for invasive infections possibly caused by *H. influenzae* should be a parenterally administered antibiotic effective

Table 240.1 *Haemophilus influenzae* Type b (Hib) Conjugate Vaccines Available in the United States

VACCINE	TRADE NAME	COMPONENTS	MANUFACTURER
PRP-T	ActHib	PRP conjugated to tetanus toxoid	Sanofi
PRP-T	Hibrix	PRP conjugated to tetanus toxoid	GlaxoSmithKline Biologicals
PRP-OMP	PedvaxHIB	PRP conjugated to OMP	Merck
PRP-T/DTaP-IPV	Pentacel	PRP-T + DTaP-IPV vaccines	Sanofi Pasteur
PRP-OMP/DTaP-IPV-HepB	Vaxelis	PRP-OMP + DTaP-IPV + HepB vaccines	Merck

DTaP, Diphtheria and tetanus toxoids and acellular pertussis vaccine; HepB, hepatitis B vaccine; IPV, trivalent inactivated polio vaccine; OMP, outer membrane protein complex from *Neisseria meningitidis*; PRP, polyribosylribitol phosphate.

in sterilizing all foci of infection and effective against ampicillin-resistant strains, usually an **extended-spectrum cephalosporin** such as ceftriaxone. After the antimicrobial susceptibility of the isolate has been determined, an appropriate agent can be selected to complete the therapy. **Ampicillin** remains the drug of choice for the therapy of infections caused by susceptible isolates. If the isolate is resistant to ampicillin, in selected circumstances **ceftriaxone** can be administered once daily for outpatient therapy.

Oral antimicrobial agents are sometimes used to complete a course of therapy initiated by the parenteral route and are typically initial therapy for noninvasive infections such as otitis media and sinusitis. If the organism is susceptible, **amoxicillin** is the drug of choice. An oral second- or third-generation cephalosporin or amoxicillin-clavulanate may be used when the isolate is resistant to ampicillin.

Meningitis

In the prevaccine era, meningitis accounted for more than half of all cases of invasive *H. influenzae* disease. Clinically, meningitis caused by Hib cannot be differentiated from meningitis caused by *Neisseria meningitidis* or *Streptococcus pneumoniae* (see Chapter 643.1). It may be complicated by other foci of infection such as the lungs, joints, bones, and pericardium.

Antimicrobial therapy should be administered intravenously for 7-14 days for uncomplicated cases. Ceftriaxone and ampicillin cross the blood-brain barrier during acute inflammation in concentrations adequate to treat *H. influenzae* meningitis. Intramuscular therapy with ceftriaxone may be an alternative in patients with normal organ perfusion.

The prognosis of Hib meningitis depends on the age at presentation, duration of illness before appropriate antimicrobial therapy, CSF capsular polysaccharide concentration, and rapidity with which organisms are cleared from CSF, blood, and urine. Clinically manifested inappropriate secretion of antidiuretic hormone and evidence of focal neurologic deficits at presentation are poor prognostic features. Approximately 6% of patients with Hib meningitis are left with some hearing impairment, probably because of inflammation of the cochlea and the labyrinth. **Dexamethasone** (0.6 mg/kg/day divided every 6 hours for 2 days), particularly when given shortly before or concurrent with the initiation of antimicrobial therapy, decreases the incidence of hearing loss. Major neurologic sequelae of Hib meningitis include behavior problems, language disorders, impaired vision, mental retardation, motor abnormalities, ataxia, seizures, and hydrocephalus.

Cellulitis

Children with Hib cellulitis often have an antecedent upper respiratory tract infection. They usually have no prior history of trauma, and the infection is thought to represent seeding of the organism to the involved soft tissues during bacteremia. The head and neck, particularly the cheek and preseptal region of the eye, are the most common sites of involvement. The involved region generally has indistinct margins and is tender and indurated. **Buccal cellulitis** is classically erythematous with a violaceous hue, although this sign may be absent. *H. influenzae* may often be recovered directly from an aspirate of the leading edge, although this procedure is seldom performed. A blood culture may also reveal the causative organism. Other foci of infection may be present concomitantly, particularly in children <18 months old. A diagnostic lumbar puncture should be considered at diagnosis in these children.

Parenteral antimicrobial therapy is indicated until patients become afebrile, after which an appropriate oral antimicrobial agent may be substituted. A 7- to 10-day course is customary.

Preseptal Cellulitis

Infection involving the superficial tissue layers anterior to the orbital septum is termed *preseptal cellulitis,* which may be caused by *H. influenzae.* Uncomplicated preseptal cellulitis does not imply a risk for visual impairment or direct central nervous system (CNS) extension. However, concurrent bacteremia may be associated with the development of meningitis. *H. influenzae* preseptal cellulitis is characterized by fever, edema, tenderness, warmth of the lid, and, occasionally, purple discoloration. Evidence of interruption of the integument is usually absent. Conjunctival drainage may be associated. *S. pneumoniae, Staphylococcus aureus,* and group A *Streptococcus* cause clinically indistinguishable preseptal cellulitis. The latter two pathogens are more likely when fever is absent and the integument is interrupted (e.g., because of an insect bite or trauma).

Children with preseptal cellulitis in whom *H. influenzae* and *S. pneumoniae* are etiologic considerations (young age, high fever, intact integument) should have a blood culture obtained. In addition, a diagnostic lumbar puncture should be considered.

Parenteral antibiotics are indicated for preseptal cellulitis. Because methicillin-susceptible and methicillin-resistant *S. aureus, S. pneumoniae,* and group A β-hemolytic streptococci are other causes, empirical therapy should include agents active against these pathogens. Patients with preseptal cellulitis without concurrent meningitis should receive **parenteral therapy for about 5 days, until fever and erythema have abated**. In uncomplicated cases, antimicrobial therapy should be given for 10 days.

Orbital Cellulitis

Infections of the orbit are infrequent and usually develop as complications of acute ethmoid or sphenoid sinusitis. Orbital cellulitis may manifest as lid edema but is distinguished by the presence of proptosis, chemosis, impaired vision, limitation of the extraocular movements, decreased mobility of the globe, or pain on movement of the globe. The distinction between preseptal and orbital cellulitis may be difficult and is best determined by CT scan.

Orbital infections are treated with **parenteral therapy for at least 14 days**. Underlying sinusitis or orbital abscess may require surgical drainage and more prolonged antimicrobial therapy.

Supraglottitis or Acute Epiglottitis

Supraglottitis is a cellulitis of the tissues of the laryngeal inlet (see Chapter 433). It has become exceedingly rare since the introduction of conjugate Hib vaccines. Direct bacterial invasion of the involved tissues is probably the initiating pathophysiologic event. This dramatic, potentially lethal condition can occur at any age. Because of the risk of sudden, unpredictable airway obstruction, supraglottitis is a medical emergency. Other foci of infection, such as meningitis, are rare. Antimicrobial therapy directed against *H. influenzae* and other etiologic agents should be administered parenterally, but only after the airway is secured, and therapy should be continued until patients are able to take fluids by mouth. The duration of antimicrobial therapy is typically 7 days.

Pneumonia

The true incidence of *H. influenzae* pneumonia in children is unknown because invasive procedures required to obtain culture specimens are seldom performed (see Chapter 449). In the prevaccine era, type b strains were believed to be the usual cause. The signs and symptoms of pneumonia caused by *H. influenzae* cannot be differentiated from those of pneumonia caused by many other microorganisms. Other foci of infection may be present concomitantly.

Children <12 months old in whom *H. influenzae* pneumonia is suspected should receive parenteral antimicrobial therapy initially because of their increased risk for bacteremia and its complications. Older children who do not appear severely ill may be managed with an oral antimicrobial. Therapy is continued for 7-10 days. Uncomplicated pleural effusion associated with *H. influenzae* pneumonia requires no special intervention. However, if empyema develops, chest tube or **surgical drainage** is generally indicated.

Suppurative Arthritis

Large joints, such as the knee, hip, ankle, and elbow, are affected most often (see Chapter 726). Other foci of infection may be present concomitantly. Although single-joint involvement is the rule, multijoint involvement occurs in approximately 6% of cases. The signs and symptoms of septic arthritis caused by *H. influenzae* are indistinguishable from those in arthritis caused by other bacteria.

Uncomplicated septic arthritis should generally be treated with an appropriate **parenteral antimicrobial for at least a few days**. If the clinical response is satisfactory, the remainder of the course of

antimicrobial treatment may be given orally. Therapy is typically given for 3 weeks for uncomplicated septic arthritis, but may be continued beyond 3 weeks, until the C-reactive protein concentration is normal and clinical symptoms are resolved.

Pericarditis

H. influenzae is a rare cause of pericarditis (see Chapter 489). Affected children often have had an antecedent upper respiratory tract infection. Fever, respiratory distress, and tachycardia are consistent findings. Other foci of infection may be present concomitantly.

The diagnosis may be established by recovery of the organism from blood or pericardial fluid. Gram stain or detection of PRP in pericardial fluid, blood, or urine (when type b organisms are the cause) may aid the diagnosis**.** Antimicrobials should be provided parenterally in a regimen similar to that used for meningitis (see Chapter 643.1). Pericardiectomy is useful for draining the purulent material effectively and preventing tamponade and constrictive pericarditis.

Bacteremia Without an Associated Focus

Bacteremia caused by *H. influenzae* may be associated with fever without any apparent focus of infection (see Chapter 220). In this situation, risk factors for occult bacteremia include the magnitude of fever (≥39°C [102.2°F]) and the presence of leukocytosis (≥15,000 cells/μL). In the prevaccine era, meningitis developed in approximately 25% of children with occult Hib bacteremia if left untreated. In the vaccine era, this *H. influenzae* infection has become exceedingly rare. When it does occur, the child should be reevaluated for a focus of infection and a second blood culture should be performed. The child should be hospitalized and given parenteral antimicrobial therapy after a diagnostic lumbar puncture and chest radiograph are obtained.

Miscellaneous Infections

Rarely, *H. influenzae* causes urinary tract infection, epididymoorchitis, cervical adenitis, acute glossitis, infected thyroglossal duct cysts, uvulitis, endocarditis, endophthalmitis, primary peritonitis, osteomyelitis, and periappendiceal abscess.

Invasive Disease in Neonates

Neonates occasionally have invasive *H. influenzae* infection. In the infant with illness within the first 24 hours of life, especially in association with maternal chorioamnionitis or prolonged rupture of membranes, transmission of the organism to the infant is likely to have occurred through the maternal genital tract (which is colonized with nontypeable *H. influenzae* in <1% of pregnant women). Manifestations of neonatal invasive infection include bacteremia with sepsis, pneumonia, respiratory distress syndrome with shock, conjunctivitis, scalp abscess or cellulitis, and meningitis. Less frequently, mastoiditis, septic arthritis, and congenital vesicular eruption may occur.

Otitis Media

Acute otitis media is one of the most common infectious diseases of childhood (see Chapter 680). It results from the spread of bacteria from the nasopharynx through the eustachian tube into the middle ear cavity. Usually, because of a preceding viral upper respiratory tract infection, the mucosa in the area becomes hyperemic and swollen, resulting in obstruction and an opportunity for bacterial multiplication in the middle ear.

The most common bacterial pathogens are *H. influenzae, S. pneumoniae,* and *Moraxella catarrhalis.* Most *H. influenzae* isolates causing otitis media are nontypeable. Ipsilateral conjunctivitis may also be present. **Amoxicillin (80-90 mg/kg/day)** is a suitable first-line oral antimicrobial agent, because the probability that the causative isolate is resistant to amoxicillin and the risk for invasive potential are sufficiently low to justify this approach. Alternatively, in certain cases, a single dose of ceftriaxone constitutes adequate therapy.

In the case of treatment failure or if a β-lactamase–producing isolate is obtained by tympanocentesis or from drainage fluid, amoxicillin-clavulanate (Augmentin) is a suitable alternative.

Conjunctivitis

Acute infection of the conjunctivae is common in childhood (see Chapter 666). In neonates, *H. influenzae* is an infrequent cause. However, it is an important pathogen in older children. Most *H. influenzae* isolates associated with conjunctivitis are nontypeable, although type b isolates and other serotypes are occasionally found. Empirical treatment of conjunctivitis beyond the neonatal period usually consists of topical antimicrobial therapy with **sulfacetamide**. Topical fluoroquinolone therapy is to be avoided because of its broad spectrum, high cost, and high rate of emerging resistance among many bacterial species. Ipsilateral otitis media caused by the same organism may be present and requires oral antibiotic therapy.

Sinusitis

H. influenzae is an important cause of acute sinusitis in children, likely the most common etiology since implementation of routine vaccination against *S. pneumoniae* (see Chapter 429). Chronic sinusitis lasting >1 year or severe sinusitis requiring hospitalization is often caused by *S. aureus* or anaerobes such as *Peptococcus, Peptostreptococcus,* and *Bacteroides.* Nontypeable *H. influenzae* and viridans group streptococci are also frequently recovered.

For uncomplicated sinusitis, **amoxicillin** is acceptable initial therapy. However, if clinical improvement does not occur, a broader-spectrum agent, such as amoxicillin-clavulanate, may be appropriate. A 10-day course is sufficient for uncomplicated sinusitis. Hospitalization for parenteral therapy is rarely required; the usual reason is suspicion of progression to orbital cellulitis.

PREVENTION

Immunization with a Hib conjugate vaccine is recommended for all infants. Prophylaxis is indicated if close contacts of an index patient with type b disease are unvaccinated. The contagiousness of non-Hib infections is not known, and prophylaxis is not recommended.

Vaccine

Several Hib conjugate vaccines are currently marketed in the United States, containing either PRP–outer membrane protein **(PRP-OMP)** or PRP–tetanus toxoid **(PRP-T)**, which differ in the carrier protein used and the method of conjugating the polysaccharide to the protein (see Table 240.1 and Chapter 215). Available combination vaccines include Pentacel (Sanofi Pasteur), which consists of PRP-T combined with DTaP vaccine (diphtheria and tetanus toxoids and acellular pertussis) and IPV vaccine (trivalent, inactivated polio vaccine), and Vaxelis (Merck), which consists of PRP-OMP combined with DTaP, IPV, and hepatitis B vaccine.

The Hib conjugate vaccines stimulate circulating anticapsular antibody and provide long-term immunity through B-cell memory.

Prophylaxis

Unvaccinated children <48 months old who are in close contact with an index case of invasive Hib infection are at increased risk for invasive infection. The risk for secondary disease for children >3 months old is inversely related to age. About half the secondary cases among susceptible household contacts occur in the first week after hospitalization of the index case. Because many children are now protected against Hib by prior immunization, the need for prophylaxis has greatly decreased. When prophylaxis is used, **rifampin** is indicated for all members of the household or close-contact group, including the index patient, if the group includes one or more children <48 months old who are not fully immunized.

Parents of children hospitalized for invasive Hib disease should be informed of the increased risk for secondary infection in other young children in the same household if they are not fully immunized. Parents of children exposed to a single case of invasive Hib disease in a childcare center or nursery school should be similarly informed, although there is disagreement about the need for rifampin prophylaxis for these children.

For prophylaxis, children should be given rifampin orally (0-1 months old, 10 mg/kg/dose; >1 month old, 20 mg/kg/dose, not to exceed 600 mg/dose) once daily for 4 consecutive days. The adult dose is 600 mg once daily. Rifampin prophylaxis is not recommended for pregnant women.

Chapter 241

Chancroid *(Haemophilus ducreyi)*

H. Dele Davies and Shirley Delair

Chancroid is a sexually transmitted disease characterized by painful genital ulceration and inguinal lymphadenopathy.

ETIOLOGY AND EPIDEMIOLOGY

Chancroid is caused by *Haemophilus ducreyi,* a fastidious gram-negative bacillus. It is most common in many low- and middle-income countries but also occurs sporadically in high-income countries. Most cases in high-income countries occur in returning travelers (90% are male) from endemic areas or occasionally in localized urban outbreaks associated with commercial sex workers. Chancroid is a risk factor for transmission of HIV. Diagnosis of chancroid in infants and children is strong evidence of sexual abuse. Male circumcision lowers the risk for chancroid. The incidence of chancroid has declined significantly since 1981 and remains low in the United States.

CLINICAL MANIFESTATIONS

The incubation period is 4-7 days, with a small, inflammatory papule on the preputial orifice or frenulum in men and on the labia, fourchette, or perineal region in women. The lesion becomes pustular, eroded, and ulcerative within 2-3 days. The ulcer edge is classically ragged and undermined. Without treatment, the ulcers may persist for weeks to months. Painful, tender inguinal lymphadenitis occurs in >50% of cases, more often among men. The lymphadenopathy can become fluctuant to form **buboes**, which can spontaneously rupture.

DIAGNOSIS

Diagnosis is usually established by the clinical presentation and the exclusion of both syphilis *(Treponema pallidum)* and herpes simplex virus infections. The ulcer of chancroid is accompanied by concurrent **lymphadenopathy** that is usually unilateral, unlike lymphogranuloma venereum (see Chapter 272.4). Genital herpes is characterized by vesicular lesions with a history of recurrence (see Chapter 299). Gram stain of ulcer secretions may show gram-negative coccobacilli in parallel clusters ("school of fish"). Culture requires expensive, special media and has a sensitivity of only 80%. There are currently no U.S. Food and Drug Administration (FDA)–approved polymerase chain reaction (PCR) tests for *H. ducreyi*. PCR and indirect immunofluorescence using monoclonal antibodies are available as research tools and are performed by some clinical laboratories using their own in-house Clinical Laboratory Improvement Amendments (CLIA)–verified kits.

TREATMENT

Most *H. ducreyi* organisms are resistant to penicillin and ampicillin because of plasmid-mediated β-lactamase production. Spread of plasmid-mediated resistance among *H. ducreyi* has resulted in lack of efficacy of previously useful drugs such as sulfonamides and tetracyclines. Chancroid is easy to treat if recognized early. The current treatment recommendation is for **azithromycin** (1 g as a single dose orally [PO]) or **ceftriaxone** (250 mg as a single dose intramuscularly) or **ciprofloxacin** (500 mg twice daily PO for 3 days) or **erythromycin** (500 mg 3 times daily PO for 7 days), the latter most often used in low- and middle-income countries, Fluctuant nodes may require drainage. Symptoms usually resolve within 3-7 days. Relapses can usually be treated successfully with the original treatment regimen. Patients with HIV infection may require a longer duration of treatment. Persistence of the ulcer and the organism after therapy should raise suspicion of resistance to the prescribed antibiotic.

Patients with chancroid should be evaluated for other sexually transmitted infections, including syphilis, genital herpes, hepatitis B virus, HIV, chlamydia, and gonorrhea; an estimated 10% have concomitant syphilis or genital herpes. If initial HIV or syphilis testing is negative, patients should be tested again in 3 months because of the high rates of co-infections. In low- and middle-income countries, patients with a compatible genital ulcer are treated for both chancroid and syphilis. All sexual contacts of patients with chancroid should be evaluated and treated.

COMPLICATIONS

Complications include **phimosis** in men and secondary bacterial infection. **Bubo** formation may occur in untreated cases. Genital ulceration as a syndrome increases the risk for transmission of HIV.

Chapter 242

Moraxella catarrhalis

Timothy F. Murphy and Oscar G. Gómez-Duarte

Moraxella catarrhalis is an unencapsulated, gram-negative diplococcus and is a **human-specific pathogen** that colonizes the respiratory tract beginning in infancy. Patterns of colonization and infection with *M. catarrhalis* are changing in countries where pneumococcal conjugate vaccines are used widely. The most important clinical manifestation of *M. catarrhalis* infection in children is **otitis media**.

ETIOLOGY

M. catarrhalis has long been considered to be an upper respiratory tract commensal. Substantial genetic heterogeneity exists among strains of *M. catarrhalis*. Several outer membrane proteins demonstrate sequence differences among strains, particularly in regions of the proteins that are exposed on the bacterial surface. *M. catarrhalis* endotoxin lacks repeating polysaccharide side chains and is thus a lipooligosaccharide (LOS). In contrast to other gram-negative respiratory pathogens, such as *Haemophilus influenzae* and *Neisseria meningitidis,* the LOS of *M. catarrhalis* is relatively conserved among strains; only three serotypes (A, B, and C), based on oligosaccharide structure, have been identified. Genetic and antigenic differences among strains account for the observation that resolving an infection by one strain does not induce protective immunity to other strains. *M. catarrhalis* causes recurrent infections, which generally represent reinfection by new strains.

EPIDEMIOLOGY

The ecologic niche of *M. catarrhalis* is the human respiratory tract. The bacterium has not been recovered from animals or environmental sources. **Age** is the most important determinant of the prevalence of upper respiratory tract colonization. Common throughout infancy, nasopharyngeal colonization is a dynamic process with active turnover as a result of acquisition and clearance of strains of *M. catarrhalis*. Some geographic variation in rates of colonization is observed. On the basis of monthly or bimonthly cultures, colonization during the first year of life may range from 33% to 100%. Several factors likely account for this variability among studies, including living conditions, daycare attendance, hygiene, environmental factors (e.g., household smoking), and genetics of the population. The prevalence of colonization steadily decreases with age. Understanding nasopharyngeal colonization patterns is important, because the pathogenesis of otitis media involves migration of the bacterium from the nasopharynx to the middle ear via the eustachian tube.

The widespread use of pneumococcal polysaccharide vaccines in many countries has resulted in alteration of patterns of nasopharyngeal colonization in the population. A relative decrease in colonization by vaccine pneumococcal serotypes and *M. catarrhalis* has resulted in a decreased number of new upper respiratory infection episodes **associated with** *Streptococcus pneumoniae* and *M. catarrhalis*.

PATHOGENESIS OF INFECTION

Strains of *M. catarrhalis* differ in their virulence properties. The species is composed of complement-resistant and complement-sensitive genetic lineages, with the **complement-resistant** strains being more strongly associated with virulence. Strains that cause infection in children differ in several phenotypic characteristics from strains that cause infection in adults, in whom the most common clinical manifestation is lower respiratory tract infection in the setting of chronic obstructive pulmonary disease.

The presence of several **adhesin** molecules with differing specificities for various host cell receptors reflects the importance of adherence to the human respiratory epithelial surface in the pathogenesis of infection. *M. catarrhalis* has long been viewed as an exclusively extracellular pathogen. However, the bacterium is now known to invade multiple cell types, including bronchial epithelial cells, small airway cells, and type 2 alveolar cells. In addition, *M. catarrhalis* resides intracellularly in lymphoid tissue, providing a reservoir for persistence in the human respiratory tract. As with many gram-negative bacteria, *M. catarrhalis* sheds vesicles from its surface during growth. These vesicles are internalized by respiratory epithelial cells and mediate several virulence mechanisms, including B-cell activation, induction of inflammation, and delivery of β-lactamases. Analysis of genomes reveals modest genetic heterogeneity among strains.

M. catarrhalis forms biofilms in vitro and in the middle ears of children with chronic and recurrent otitis media. It also promotes stable polymicrobial biofilms by enhancing the survival of other bacterial colonizing otopathogens. **Biofilms** are communities of bacteria encased in a matrix attached to a surface. Bacteria in biofilms are more resistant to antibiotics and to host immune responses than bacteria growing individually in planktonic form.

CLINICAL MANIFESTATIONS

M. catarrhalis causes predominantly mucosal infections in children. The mechanism of infection is **migration** of the infecting strains from the nasopharynx to the middle ear in the case of otitis media or to the sinuses in the case of sinusitis. The inciting event for both otitis media and sinusitis is often a preceding viral infection.

Acute Otitis Media

Approximately 80% of children have one or more episodes of otitis media by age 3 years. Otitis media is the most common reason that children receive antibiotics. On the basis of culture of middle ear fluid obtained by tympanocentesis, the predominant causes of acute otitis media are *S. pneumoniae, H. influenzae,* and *M. catarrhalis*. *M. catarrhalis* is cultured from the middle ear fluid in 15–20% of patients with acute otitis media. When more sensitive methods (e.g., polymerase chain reaction [PCR]) are used, the number of middle ear fluid samples from children with otitis media in which *M. catarrhalis* is detected is substantially greater than by culture alone. The distribution of the causative agents of otitis media is changing as a result of widespread administration of pneumococcal conjugate vaccines, with *M. catarrhalis* and *H. influenzae* proportionally more common than *S. pneumoniae*.

Acute otitis media caused by *M. catarrhalis* is clinically milder than otitis media caused by *H. influenzae* or *S. pneumoniae,* with less fever and lower prevalence of a red, bulging tympanic membrane. However, substantial overlap in symptoms is seen, making it impossible to predict etiology in an individual child on the basis of clinical features. Tympanocentesis is required to make an etiologic diagnosis but is not performed routinely, and thus treatment of otitis media is generally empirical.

Recurrent Otitis Media and Otitis Media with Effusion

Otitis media with effusion refers to the presence of fluid in the middle ear in the absence of signs and symptoms of acute infection. Children who experience four or more episodes of acute otitis media in a year or who have at least 8 months of middle ear effusion in a year are defined as **otitis prone**. These children have conductive hearing loss, which places them at risk for speech delays and altered language development. Analysis of middle ear fluid from children with otitis media with effusion using sensitive molecular techniques (e.g., PCR) indicates that bacterial DNA is present in up to 80% of samples from such children. Indeed, *M. catarrhalis* DNA is present, both alone and as a copathogen, in a larger proportion of cases of otitis media with effusion than of acute otitis media. Biofilms may account for these observations, although definitive evidence is lacking.

Sinusitis

A small proportion of viral upper respiratory tract infections are complicated by bacterial sinusitis. According to findings of studies that use sinus puncture, *M. catarrhalis* accounts for approximately 20% of cases of acute bacterial sinusitis in children and a smaller proportion in adults. Sinusitis caused by *M. catarrhalis* is clinically indistinguishable from that caused by *S. pneumoniae* or *H. influenzae*.

Bacteremia

M. catarrhalis rarely causes bacteremia or invasive infections in children. When bacteremia occurs, the usual source is the respiratory tract. Some children have underlying immunocompromising conditions, but no particular immunodeficiency is associated with invasive *M. catarrhalis* infections.

Pneumonia

M. catarrhalis is an uncommon cause of community-acquired pneumonia in children. Among older patients with chronic obstructive pulmonary disease, *M. catarrhalis* is associated with acute exacerbations.

DIAGNOSIS

The clinical diagnosis of otitis media is made by demonstration of erythema and bulging of the tympanic membrane and/or fluid in the middle ear by pneumatic otoscopy. A tympanocentesis is required to establish an etiologic diagnosis, but this procedure is not performed routinely. Thus the choice of antibiotic for otitis media is empirical and generally based on guidelines. Management of bacterial sinusitis is also empirical, because determining the etiology of sinusitis requires a **sinus puncture**, also a procedure that is not performed routinely.

The key to making a microbiologic diagnosis is distinguishing *M. catarrhalis* from commensal *Neisseria* organisms that are part of the normal upper respiratory tract flora. Indeed, the difficulty in distinguishing colonies of *M. catarrhalis* from *Neisseria* spp. explains in part why *M. catarrhalis* has been overlooked in the past as a respiratory tract pathogen. *M. catarrhalis* produces round, opaque colonies that can be slid across the agar surface without disruption—the "hockey puck sign." In addition, after 48 hours, *M. catarrhalis* colonies tend to be larger than *Neisseria* and take on a pink color. A variety of biochemical tests distinguish *M. catarrhalis* from *Neisseria* spp., and commercially available kits based on these tests are available.

Sensitive tests that employ PCR to detect respiratory tract bacterial pathogens in human respiratory tract secretions are in development. In addition, metagenomics next-generation sequencing is a noninvasive option to make a diagnosis of upper or lower respiratory infections associated with *M. catarrhalis* through evaluation of bacterial-derived DNA in blood samples. Their application will likely contribute new information about the epidemiology and disease patterns of *M. catarrhalis*.

TREATMENT

A high proportion of cases of *M. catarrhalis* otitis media resolve spontaneously. Treatment of otitis media is empirical, and clinicians are advised to follow guidelines of the American Academy of Pediatrics (see Chapter 680).

Strains of *M. catarrhalis* rapidly acquired β-lactamase worldwide in the 1970s and 1980s, rendering essentially all strains resistant to amoxicillin. When *M. catarrhalis* is present as a copathogen in otitis media, its β-lactamase reduces the susceptibility of nontypeable *H. influenzae* and *S. pneumoniae* to amoxicillin. Antimicrobial susceptibility patterns have remained relatively stable for decades. However, strains of *M. catarrhalis* that are resistant to macrolides and fluoroquinolones have been isolated in several centers in Asia. Careful surveillance will be important to track the potential emergence of resistant strains more widely. Most strains of *M. catarrhalis* are susceptible to amoxicillin/clavulanic acid, extended-spectrum cephalosporins, macrolides (azithromycin, clarithromycin), trimethoprim-sulfamethoxazole, and fluoroquinolones.

PREVENTION

Vaccines to prevent otitis media and other infections caused by *M. catarrhalis* are under development, but none is yet available.

Chapter 243

Pertussis (*Bordetella pertussis* and *Bordetella parapertussis*)

Emily E. Souder and Sarah S. Long

Pertussis is an acute respiratory tract infection; the term *pertussis* means "intense cough" and is preferable to *whooping cough,* because most infected individuals do not "whoop."

ETIOLOGY

Bordetella pertussis is the cause of epidemic pertussis and the usual cause of sporadic pertussis. *Bordetella parapertussis* is an occasional cause of sporadic pertussis that contributes significantly to total cases of pertussis in Eastern and Western Europe and has been detected during occasional regional pertussis outbreaks in the United States. *B. pertussis* and *B. parapertussis* are exclusive pathogens of humans and some primates. *Bordetella holmesii,* first identified as a cause of bacteremia in immunocompromised hosts without cough illness, is increasingly reported to cause pertussis-like cough illness in small outbreaks in healthy persons. *Bordetella bronchiseptica* is a common animal pathogen. Occasional reports in humans describe a variety of body sites involved, and cases typically occur in immunocompromised persons or young children with intense exposure to animals. *Bordetella petrii,* frequently found in soil, has been reported in cases of osteomyelitis, mastoiditis, and chronic respiratory infection in patients with cystic fibrosis. *Bordetella hinzii* has been isolated from the respiratory tract of poultry and rodents and has rarely been associated with human disease, including endocarditis, bacteremia, and urinary tract infection. Protracted coughing (which in some cases can be paroxysmal) is attributable sporadically to *Mycoplasma,* parainfluenza viruses, influenza viruses, enteroviruses, respiratory syncytial virus (RSV), or adenoviruses.

EPIDEMIOLOGY

A recent modeling study estimated that in 2014, 24.1 million cases of pertussis and 160,700 deaths caused by pertussis occurred worldwide in children <5 years, reflecting significantly higher numbers than actual case counts. Before vaccination was available, pertussis was the leading cause of death from communicable disease among U.S. children <14 years, with 10,000 deaths annually. Widespread use of whole cell pertussis vaccine (DTP) led to a >99% decline in cases. After the low U.S. number of 1,010 cases reported in 1976, there was an increase in annual pertussis incidence to 1.2 cases per 100,000 population from 1980 through 1989, with epidemic pertussis in many states in 1989–1990, 1993, and 1996. Since then, pertussis has become increasingly endemic, with shifting burden of disease to young infants, adolescents, and adults. By 2004, the incidence of reported pertussis in the United States was 8.9 cases per 100,000 in the general population and approximately 150 per 100,000 in infants <2 months, with 25,827 total cases reported, the highest since 1959. A total of 40 pertussis-related deaths were reported in 2005, and 16 pertussis-related deaths were reported in 2006; >90% of these cases occurred in infants.

Prospective and serologic studies show that pertussis is underrecognized, especially among adolescents and adults, in whom the actual number of U.S. cases is estimated to be 600,000 annually. A number of studies have documented pertussis in 13–32% of adolescents and adults with cough illness for >7 days. Responding to these changes in epidemiology, vaccination containing tetanus toxoid, reduced-content diphtheria toxoid, and acellular pertussis antigens **(Tdap)** was recommended in 2006 for 11- to 12-year-olds and was aimed to enhance control. With >70% uptake of Tdap in adolescents, the burden of disease in young adolescents fell commensurately, but without evidence of protection of the community (herd) of young infants, older adolescents, and adults. An epidemiologic shift has occurred as a result of substantial and rapid waning of protection after both DTaP and Tdap in the aging cohort of children and adolescents who were not primed with DTP (whole cell) vaccine, which was no longer used in the United States after 1997. The >42,000 cases of pertussis and 20 deaths reported in 2012 were the highest numbers in >50 years. A shift in disease burden was observed among 7- to 10-year-olds in 2010, 13- to 14-year-olds in 2012, and 14- to 16-year-olds in 2014 as the cohort of solely DTaP-vaccinated persons aged.

Neither natural disease nor vaccination provides complete or lifelong immunity against pertussis reinfection or disease. Subclinical reinfection undoubtedly contributed significantly to immunity against disease ascribed previously to both vaccine and prior infection. The resurgence of pertussis can be attributed to a variety of factors, including partial control of pertussis leading to less continuous exposure and increased awareness and improved diagnostics. Rapidly waning vaccine-induced immunity and pathogen adaptation are the most important factors currently. Although the DTaP series is protective short-term, vaccine effectiveness wanes rapidly, with estimates of only 10% protection 8.5 years after the fifth dose. Tdap protection also is short-lived, with efficacy falling from >70% initially to 34% within 2-4 years. A retrospective cohort study of children born between 1999 and 2016 found that the risk of pertussis among immunized children was 5 times higher ≥3 years after vaccination compared with <1 year after vaccination. Divergence of circulating strains from vaccine strains began with the introduction of DTP, but with the exclusive use of acellular pertussis vaccines, **pertactin-deficient strains** emerged and have become dominant in countries where these vaccines are used. Pertactin-deficient *B. pertussis* was first reported in the United States from a Philadelphia infant case collection from 2008 to 2011. The Centers for Disease Control and Prevention (CDC) subsequently reported the earliest U.S. isolate from 1994 and rapid dominance of pertactin-deficient strains in the United States since 2010. Despite the role of pertactin as a bacterial virulence factor, illness severity in infants with pertactin-deficient *B. pertussis* is similar to that of pertactin-producing strains. Pending introduction of novel pertussis vaccine(s) that reduce colonization and transmission, pertussis will continue to be endemic, with cycling epidemics.

PATHOGENESIS

Bordetella organisms are small, fastidious, gram-negative coccobacilli that colonize only ciliated epithelium. The exact mechanism of disease symptomatology remains unknown. *Bordetella* species share a high degree of DNA homology among virulence genes. Only *B. pertussis* expresses **pertussis toxin (PT),** the major virulence protein. PT has numerous proven biologic activities (e.g., histamine sensitivity, insulin secretion, leukocyte dysfunction). Although injection of PT in experimental animals causes lymphocytosis immediately by rerouting lymphocytes to remain in the circulating blood pool, PT

does not cause cough. PT appears to have a central, but not a singular, role in pathogenesis. *B. pertussis* produces an array of other biologically active substances, many of which are postulated to have a role in disease and immunity. After aerosol acquisition, **filamentous hemagglutinin (FHA)**, some **agglutinogens** (especially fimbriae [Fim] types 2 and 3), and the 69-kDa **pertactin (Prn)** protein are important for attachment to ciliated respiratory epithelial cells. **Tracheal cytotoxin**, **adenylate cyclase**, and PT appear to inhibit clearance of organisms. Tracheal cytotoxin, **dermonecrotic factor**, and adenylate cyclase are postulated to be predominantly responsible for the local epithelial damage that produces respiratory symptoms and facilitates absorption of PT. Both antibody and cellular immune responses follow infection and immunization. Antibody to PT neutralizes toxin, and antibody to Prn enhances opsonophagocytosis. Both disease and DTP appear to drive a mixed cellular and antibody (Th1) immunologic response, whereas both DTaP and Tdap drive a narrow, antibody-dominant (Th2) response.

Pertussis is extremely contagious, with attack rates as high as 100% in susceptible individuals exposed to aerosol droplets at close range. High airborne transmission rates were shown in a baboon model of pertussis despite vaccination with the acellular vaccine. *B. pertussis* does not survive for prolonged periods in the environment. Chronic carriage by humans is not documented. After intense exposure, as in households, the rate of subclinical infection is as high as 80% in fully immunized or previously infected individuals. When carefully sought, a symptomatic source case can be found for most patients—usually a sibling or related adult.

CLINICAL MANIFESTATIONS

Classically, pertussis is a prolonged disease, divided into catarrhal, paroxysmal, and convalescent stages. The **catarrhal stage** (1-2 weeks) begins insidiously after an incubation period ranging from 3 to 12 days with nondistinctive symptoms of congestion and rhinorrhea variably accompanied by low-grade fever, sneezing, lacrimation, and conjunctival suffusion. As initial symptoms wane, coughing marks the onset of the **paroxysmal stage** (2-6 weeks). The cough begins as a dry, intermittent, irritative hack and evolves into the inexorable paroxysms that are the hallmark of pertussis. A well-appearing, playful toddler with insignificant provocation suddenly expresses an anxious aura and may clutch a parent or comforting adult before beginning a machine-gun burst of uninterrupted cough on a single exhalation, chin and chest held forward, tongue protruding maximally, eyes bulging and watering, face purple, until coughing ceases and a loud whoop follows as inspired air traverses the still partially closed airway. **Posttussive emesis** is common, and exhaustion is universal. The number and severity of paroxysms escalate over days to a week and remain at that plateau for days to weeks. At the peak of the paroxysmal stage, patients may have one or more episodes hourly. As the paroxysmal stage fades into the **convalescent stage** (≥2 weeks), the number, severity, and duration of episodes diminish.

Infants <3 months old do not display the classic stages. The catarrhal phase lasts only a few days or is unnoticed, and then, after the most insignificant startle from a draft, light, sound, sucking, or stretching, a well-appearing young infant begins to choke, gasp, gag, and flail the extremities, with face reddened. Cough may not be prominent, especially in the early phase, and whoop is infrequent. Apnea and cyanosis can follow a coughing paroxysm, or apnea can occur as the only symptom (without cough). Both are more common with pertussis than with neonatal viral infections. The paroxysmal and convalescent stages in young infants are lengthy. Paradoxically, in infants, cough and whooping may become louder and more classic in convalescence. "Exacerbations" of paroxysmal coughing can occur throughout the first year of life with subsequent respiratory illnesses; these are not a result of recurrent infection or reactivation of *B. pertussis*.

Adolescents and previously immunized children have foreshortening of all stages of pertussis. **Adults** have no distinct stages. Classically, adolescents and adults describe a sudden feeling of strangulation followed by uninterrupted coughs, feeling of suffocation, bursting headache, diminished awareness, and then a gasping breath, usually without a whoop. Posttussive emesis and intermittency of paroxysms separated by hours of well-being are specific clues to the diagnosis. At least 30% of adolescents and adults with pertussis have nonspecific cough illness, distinguished only by duration, which usually is >21 days.

Findings on physical examination generally are uninformative. Signs of lower respiratory tract disease are not expected unless complicating secondary bacterial pneumonia is present. Conjunctival hemorrhages and petechiae on the upper body are common.

DIAGNOSIS

Pertussis should be suspected in any individual who has a pure or predominant complaint of cough, especially if the following features are *absent*: fever, malaise or myalgia, exanthem or enanthem, sore throat, hoarseness, tachypnea, wheezes, and rales. For sporadic cases, a clinical case definition of cough of ≥14 days' duration with at least one associated symptom of paroxysms, whoop, or posttussive vomiting has a sensitivity of 81% and specificity of 58% for confirmation of pertussis. Pertussis should be suspected in older children whose cough illness is *escalating* at 7-10 days and whose coughing *is not* continuous, but rather comes in bursts. Pertussis should be suspected in infants <3 months old with gagging, gasping, apnea, cyanosis, or a brief resolved unexplained event (BRUE). Sudden infant death occasionally is caused by *B. pertussis*.

Adenoviral infections usually are distinguishable by associated features, such as fever, sore throat, and conjunctivitis. *Mycoplasma* causes protracted episodic coughing, but patients usually have a history of fever, headache, and systemic symptoms at the onset of disease as well as more continuous cough and the frequent finding of rales on auscultation of the chest. Epidemics of *Mycoplasma* and *B. pertussis* in young adults can be difficult to distinguish on clinical grounds. Although pertussis often is included in the differential diagnosis of young infants with afebrile pneumonia, *B. pertussis* is not associated with staccato cough (breath with every cough), purulent conjunctivitis, tachypnea, rales, or wheezes that typify infection by *Chlamydia trachomatis* or predominant lower respiratory tract signs that typify infection by RSV. Unless an infant with pertussis has secondary pneumonia and then appears ill, the findings on examination between paroxysms, including respiratory rate, are entirely normal. Foreign body aspiration should be considered in the differential diagnosis.

Leukocytosis (15,000-100,000 cells/μL) caused by *absolute lymphocytosis* is characteristic in the catarrhal stage. Lymphocytes are normal small cells, rather than the large, atypical lymphocytes seen with viral infections. Adults, partially immune children, and occasionally infants may have less impressive lymphocytosis. Absolute increase in neutrophils suggests a different diagnosis or secondary bacterial infection. Eosinophilia is not a manifestation of pertussis. A severe course and death are correlated with rapid-rise and extreme leukocytosis (median peak white blood cell count in fatal vs nonfatal cases: 94,000 vs 18,000/μL, respectively) and thrombocytosis (median peak platelet count in fatal vs nonfatal cases: 782,000 vs 556,000/μL, respectively). Chest radiographic findings are only mildly abnormal in the majority of hospitalized infants, showing perihilar infiltrate or edema (sometimes with a butterfly appearance) and variable atelectasis. Parenchymal consolidation suggests secondary bacterial infection. Pneumothorax, pneumomediastinum, and subcutaneous emphysema can be seen occasionally.

Methods for confirmation of infection by *B. pertussis* (culture, polymerase chain reaction [PCR], serology) have limitations in sensitivity, specificity, or practicality, and the relative value of tests depends on the setting, phase of disease, and purpose of use (e.g., as clinical diagnostic vs epidemiologic tools). **PCR** testing on nasopharyngeal wash specimens is the laboratory test of choice for *B. pertussis* identification. Both stand-alone and multiplex assays are U.S. Food and Drug Administration (FDA) cleared and available commercially. PCR assays using only single primers (IS*481*) cannot differentiate between some *Bordetella* spp. and do not detect *B. parapertussis*. Multiplex assays using multiple targets can distinguish species. All assays detect pertactin-deficient strains. For **culture**, a specimen is obtained by deep nasopharyngeal aspiration or with the use of a flexible swab

(Dacron or calcium alginate–tipped) held in the posterior nasopharynx for 15-30 seconds (or until the cough occurs). A 1% casamino acid liquid is acceptable for holding a specimen up to 2 hours; Stainer-Scholte broth or Regan-Lowe semisolid transport medium is used for longer transport periods, up to 4 days. The preferred isolation media are Regan-Lowe charcoal agar with 10% horse blood and 5-40 μg/mL cephalexin and Stainer-Scholte media with cyclodextrin resins. Cultures are incubated at 35–37°C in a humid environment and examined daily for 7 days for slow-growing, tiny, glistening colonies. Results of culture and PCR are expected to be positive in unimmunized, untreated children during the catarrhal and early paroxysmal stages of disease. *However, less than 20% of culture or PCR tests have positive results in partially or remotely immunized individuals tested in the paroxysmal stage.*

Serologic tests for detection of change in antibodies to *B. pertussis* antigens between acute and convalescent samples are the most sensitive diagnostic tests in immunized individuals and are useful epidemiologically. A single serum sample showing IgG antibody to PT >90 IU/mL (>2 standard deviations [SD] above the mean of the immunized population) indicates recent symptomatic infection and usually is positive in the mid-paroxysmal phase. Tests for IgA and IgM pertussis antibody, or antibody to antigens other than PT, are not reliable methods for serologic diagnosis of pertussis.

TREATMENT

Infants <3 months old with suspected pertussis usually are hospitalized, as are many 3- to 6-month-old patients (i.e., unless witnessed paroxysms are not severe) and patients of any age if significant complications occur. Prematurely born young infants have a high risk for severe, potentially fatal disease, and children with underlying cardiac, pulmonary, muscular, or neurologic disorders have increased risk of poor outcome beyond infancy. Table 243.1 lists caveats in the assessment and care of infants with pertussis. The specific, limited goals of hospitalization are to (1) assess progression of disease and likelihood of life-threatening events at peak of disease, (2) maximize nutrition, (3) prevent or treat complications, and (4) educate parents in the natural history of the disease and in care that will be given at home. Heart rate, respiratory rate, and pulse oximetry are monitored continuously with alarm settings so that paroxysms can be witnessed and recorded by healthcare personnel. Detailed cough records and documentation of feeding, vomiting, and weight change provide data to assess severity. Features of typical paroxysms that are not life threatening are duration <45 seconds; red, but not blue, color change; tachycardia or bradycardia (but not <60 beats/min in infants); oxygen desaturation that spontaneously resolves rapidly at the end of the paroxysm; whooping or strength for brisk self-rescue at the end of the paroxysm; self-expectorated mucus plug; and posttussive exhaustion but not unresponsiveness. Assessing the need to provide oxygen, stimulation, or suctioning requires skilled personnel who can watchfully observe an infant's ability for self-rescue but who will intervene rapidly and expertly when necessary. The benefit of a quiet, dimly lighted, undisturbed, comforting environment cannot be overestimated or forfeited in a desire to monitor and intervene. Feeding children with pertussis is challenging. The risk of precipitating cough by nipple feeding does not warrant nasogastric, nasojejunal, or parenteral alimentation in most infants. The composition or thickness of formula does not affect the quality of secretions, cough, or retention. Large-volume feedings are avoided.

Table 243.1 Considerations in the Assessment and Care of Infants with Pertussis

- Infants with potentially fatal pertussis may appear well between episodes.
- A paroxysm must be witnessed before a decision is made between hospital and home care.
- Only analysis of carefully compiled cough record permits assessment of severity and progression of illness.
- Suctioning of the nose, oropharynx, or trachea should not be performed on a "preventive" schedule.
- Feeding in the period after a paroxysm may be more successful than after napping.
- Family support begins at the time of hospitalization with empathy for the child's and family's experience to date, transfer of the burden of responsibility for the child's safety to the healthcare team, and delineation of assessments and treatments to be performed.
- Family education, recruitment as part of the team, and continued support after discharge are essential.

Within 48-72 hours, the direction and severity of disease are obvious from an analysis of the recorded information. Hospital discharge is appropriate if, over 48 hours, disease severity is unchanged or diminished, intervention is not required during paroxysms, nutrition is adequate, no complication has occurred, and parents are adequately prepared for care at home. Apnea and seizures occur in the incremental phase of illness and in patients with complicated disease. Portable oxygen, monitoring, or a suction apparatus should not be needed at home.

Infants who have apnea, paroxysms that lead to life-threatening events, or respiratory failure require escalating respiratory support and frequently require intubation and pharmaceutically induced paralysis.

Antibiotics

An antimicrobial agent always is given when pertussis is suspected or confirmed to decrease contagiousness and to afford possible clinical benefit. ***Azithromycin*** *is the drug of choice in all age-groups, either for treatment or postexposure prophylaxis* (Table 243.2). Macrolide resistance has been reported rarely in the United States, and recent isolates have retained susceptibility despite genetic strain adaptations. *Infantile hypertrophic pyloric stenosis (IHPS)* is associated with macrolide use in young infants, especially in those <14 days old, with higher risk in those receiving erythromycin vs azithromycin. The benefits of postexposure prophylaxis or treatment of infants far outweigh the risk of IHPS. Young infants should be managed expectantly if projectile vomiting occurs. The FDA also warns of the risk of fatal heart rhythms with the use of azithromycin in patients already at risk for cardiovascular events, especially those with prolongation of the QT interval. Trimethoprim-sulfamethoxazole (TMP-SMX) is an alternative to azithromycin for infants >2 months old and children unable to receive azithromycin. Because of its limited effectiveness, treatment of *B. parapertussis* is based on clinical judgment and is considered in high-risk populations. Agents are the same as for *B. pertussis*. Treatment of infections caused by other *Bordetella* spp. should be undertaken with consultation of a subspecialist.

Adjunct Therapies

No rigorous clinical trial has demonstrated a beneficial effect of β_2-adrenergic stimulants such as salbutamol and albuterol. Fussing associated with aerosol treatment triggers paroxysms. No randomized, blinded clinical trial of sufficient size has been performed to evaluate the usefulness of corticosteroids in the management of pertussis; their clinical use is not warranted. A randomized, double-blind, placebo-controlled trial of pertussis immunoglobulin (IGIV) was halted prematurely because of expiration/lack of additional supply of the study product; there was no indication of clinical benefit. Standard immunoglobulin has not been studied and should not be used for treatment or prophylaxis.

Isolation

Patients with suspected pertussis are placed in isolation with **droplet precautions** to reduce close respiratory or mucous membrane contact with respiratory secretions. All healthcare personnel should wear a mask on entering the room. Screening for cough should be performed on entrance of patients to emergency departments, offices, and clinics to begin isolation immediately and until 5 days after initiation of azithromycin therapy. Children and staff with pertussis in childcare facilities or schools should be excluded until therapy has been taken for 5 days.

Care of Household and Other Close Contacts

Azithromycin should be given promptly to all household contacts and other close contacts, such as those in daycare, regardless of age, history

Table 243.2 Recommended Antimicrobial Treatment and Postexposure Prophylaxis for Pertussis

	PRIMARY AGENTS		ALTERNATIVE AGENT*	
AGE GROUP	**AZITHROMYCIN**	**ERYTHROMYCIN**	**CLARITHROMYCIN**	**TMP-SMX**
<1 mo	Recommended agent 10 mg/kg/day in a single dose for 5 days	Not preferred Erythromycin is substantially associated with infantile hypertrophic pyloric stenosis Use if azithromycin is unavailable; 40-50 mg/kg/day in 4 divided doses for 14 days	Not recommended (safety data unavailable)	Contraindicated for infants <2 mo of age (risk for kernicterus)
1-5 mo	10 mg/kg/day in a single dose for 5 days	40-50 mg/kg/day in 4 divided doses for 14 days	15 mg/kg/day in 2 divided doses for 7 days	Contraindicated at age <2 mo For infants age ≥2 mo: TMP 8 mg/kg/day plus SMX 40 mg/kg/day in 2 divided doses for 14 days
Infants age ≥6 mo and children	10 mg/kg in a single dose on day 1 (max 500 mg), then 5 mg/kg/day (max 250 mg) on days 2-5	40-50 mg/kg/day (max 2 g/day) in 4 divided doses for 14 days	15 mg/kg/day in 2 divided doses (max 1 g/day) for 7 days	TMP 8 mg/kg/day plus SMX 40 mg/kg/day in 2 divided doses (max TMP: 320 mg/day) for 14 days
Adults	500 mg in a single dose on day 1, then 250 mg/day on days 2-5	2 g/day in 4 divided doses for 14 days	1 g/day in 2 divided doses for 7 days	TMP 320 mg/day to SMX 1600 mg/day in 2 divided doses for 14 days

*Trimethoprim-sulfamethoxazole (TMP-SMX) can be used as an alternative agent to macrolides in patients ≥2 mo old who are allergic to macrolides, who cannot tolerate macrolides, or who are infected with a rare macrolide-resistant strain of *Bordetella pertussis*.

Adapted from Centers for Disease Control and Prevention (CDC). Recommended antimicrobial agents for treatment and postexposure prophylaxis of pertussis: 2005 CDC guidelines. *MMWR*. 2005;54:1–16.

of immunization, or symptoms (see Table 243.2). The same drugs and age-related doses used for treatment are used for prophylaxis. Visitation and movement of coughing family members in the hospital must be assiduously controlled until therapy has been taken for 5 days. In close contacts <7 years old who have received fewer than four doses of DTaP, DTaP should be given to complete the recommended series. Children <7 years old who received a third DTaP dose >6 months before exposure, or a fourth dose ≥3 years before exposure, should be given a booster dose. Individuals ≥9 years old should be given Tdap. Unmasked healthcare personnel exposed to untreated cases should be evaluated for postexposure prophylaxis and follow-up. Coughing healthcare personnel with or without known exposure to pertussis should be evaluated promptly for pertussis.

COMPLICATIONS

Infants <2 months old have the highest reported rates of pertussis-associated hospitalization (82%), pneumonia (25%), seizures (4%), encephalopathy (1%), and death (1%). Infants <4 months old account for 90% of cases of fatal pertussis. Preterm birth and young maternal age are significantly associated with fatal pertussis. Neonates with pertussis have substantially longer hospitalizations, greater need for oxygen, and greater need for mechanical ventilation than neonates with viral respiratory tract infection. The strategy of preventing pertussis in newborns through the vaccination of women with Tdap during pregnancy from 27 through 36 weeks of gestation is 80–91% effective. One study found that among infants with pertussis, disease severity was reduced in those whose mothers were vaccinated during pregnancy, with maternal vaccination being 58% effective in preventing hospitalization.

The principal complications of pertussis are **apnea**, **secondary infections** (e.g., otitis media, pneumonia), and **physical sequelae** of forceful coughing. Fever, tachypnea or respiratory distress between paroxysms, and absolute neutrophilia are clues to pneumonia. Expected pathogens include *Staphylococcus aureus, Streptococcus pneumoniae,* and bacteria of oropharyngeal flora. Increased intrathoracic and intraabdominal pressure during coughing can result in conjunctival and scleral hemorrhage, petechiae on the upper body, epistaxis, pneumothorax and subcutaneous emphysema, umbilical or inguinal hernia, and rarely, hemorrhage in the central nervous system or retina. Laceration of the lingual frenulum occurs occasionally.

The need for intensive care and mechanical ventilation usually is limited to infants <3 months old and children with underlying conditions. Respiratory failure from apnea may mandate intubation and ventilation through the days when disease peaks; the prognosis is good. Progressive **pulmonary hypertension** in very young infants and secondary **bacterial pneumonia** are severe complications of pertussis and are the usual causes of death. Pulmonary hypertension and cardiogenic shock with fatal outcome are associated with extreme elevation of lymphocyte and platelet counts. Autopsies in fatal cases show luminal aggregates of leukocytes in the pulmonary vasculature. Extracorporeal membrane oxygenation of infants with pertussis in whom mechanical ventilation failed has been associated with >80% fatality (questioning the advisability of this procedure). Exchange transfusion or leukapheresis is associated with marked reduction in lymphocyte and platelet counts. Although recovery has been reported in several cases, the benefit is unproven. Echocardiography should be performed in critically ill infants with pertussis to detect the presence of pulmonary hypertension and to intervene expeditiously.

Acute neurologic events during pertussis almost always are the result of **hypoxemia** or **hemorrhage** associated with coughing or apnea in young infants. Apnea or bradycardia or both may result from apparent laryngospasm or vagal stimulation just before a coughing episode, from obstruction during an episode, or from hypoxemia after an episode. Seizures usually are a result of hypoxemia, but hyponatremia from excessive secretion of antidiuretic hormone during pneumonia can occur. The only neuropathology documented in pertussis is parenchymal hemorrhage and ischemic necrosis.

Bronchiectasis has been reported rarely after pertussis. Children who have pertussis before age 2 years may have abnormal pulmonary function into adulthood.

PREVENTION

Universal immunization of children with pertussis vaccine, beginning in infancy with reinforcing dose(s) through adolescence and adulthood, is central to the *control* of pertussis. *Prevention* of pertussis mortality in young infants depends on universal maternal immunization during each pregnancy and focused full immunization of contacts, both children and adults of all ages.

DTaP Vaccines

Several diphtheria and tetanus toxoids combined with acellular pertussis vaccines **(DTaP)** or combination products currently are licensed in the United States for children <7 years old. Acellular pertussis vaccines all contain inactivated PT and two or more additional antigens (FHA, Prn, and Fim 2 and 3). Clinical effectiveness immediately at completion of the five-dose series is approximately 80% for illness defined as "paroxysmal cough" for >21 days. Mild local and systemic adverse events are not uncommon, but more serious events (i.e., persistent crying for ≥3 hours or a hypotonic hyporesponsive episode) are rare after DTaP, are not specific to pertussis vaccine or associated with serious sequelae, and are not contraindications to subsequent doses.

Four doses of DTaP should be administered during the first 2 years of life, generally at ages 2, 4, 6, and 15-18 months. In high-risk settings, infants may be given DTaP as early as 6 weeks of age, with monthly doses through the third dose. The fourth dose may be administered as early as 12 months of age, provided that 6 months have elapsed since the third dose. When feasible, the same DTaP product is recommended for all doses of the primary vaccination series. The fifth dose of DTaP is recommended for children at 4-6 years of age; a fifth dose is not necessary if the fourth dose in the series is administered on or after the fourth birthday.

Local reactions increase modestly in rate and severity with successive doses of DTaP. Swelling of the entire thigh or upper arm, sometimes accompanied by pain, erythema, and fever, has been reported in 2–3% of vaccinees after the fourth or fifth dose of a variety of DTaP products. Limitation of activity is less than might be expected. Swelling subsides spontaneously without sequelae. The pathogenesis is unknown. Extensive limb swelling after the fourth dose of DTaP usually is not associated with a similar reaction to the fifth dose and is not a contraindication to subsequent dose(s) of pertussis vaccines.

Exempting children from pertussis immunization should be considered only within the narrow limits as recommended. Exemptors have significantly increased the risk for pertussis and play a role in outbreaks of pertussis among immunized populations. Although well-documented pertussis confers short-term protection, the duration of protection is unknown; immunization should be completed on schedule in children diagnosed with pertussis. Pertussis vaccine (DTaP or Tdap) can be administered concurrently with any vaccine on the immunization schedule.

Tdap Vaccines

Two tetanus toxoid, reduced-diphtheria toxoid, and acellular pertussis antigen vaccine (Tdap) products were licensed in 2005 and recommended universally in 2006 for adolescents. The preferred age for Tdap vaccination is 11-12 years. All adolescents and adults of any age (including ≥65 years) who have not received Tdap should receive a single dose of Tdap promptly, regardless of interval since Td, or at least in place of one Td booster at the 10-year interval, or when indicated during wound management.

Pregnant women should be given Tdap during *every* pregnancy to provide passive antibody protection to the infant until administration of DTaP. Although Tdap can be given at any time during pregnancy, optimal administration is early in the period between 27 through 36 weeks of gestation to maximize antibody concentration at birth. The safety of Tdap during pregnancy and effectiveness in reducing fatal pertussis in infants are proven. Special effort should be made to ensure that contacts of infants have received DTaP or Tdap as recommended.

Clinical trials support the safety and immunogenicity of a second dose of Tdap; however, antipertussis antibodies decline rapidly after the first year. The CDC performed a decision analysis model of repeating Tdap at either a 5- or 10-year interval for the general population and concluded that "booster(s)" would have limited impact on pertussis disease burden. There is not a recommendation for a routine second dose of Tdap in the general population. A single dose of Tdap should be given to children 7-10 years of age who lack DTaP dose(s). Since 2019, the updated CDC recommendations allow use of either Tdap or Td when Td alone is indicated for catch-up dose(s), or for decennial immunization, or for wound management in individuals who have received Tdap.

Vaccines Under Development

Several strategies are being tested to create pertussis vaccines that elicit a Th1 response, dampen the density of mucosal infection and transmission, provide sustained protection against disease, and have tolerable reactogenicity. These include use of live attenuated *B. pertussis,* a genetically (rather than a chemically) inactivated PT component, novel antigens, and adjuvants.

Chapter 244

Salmonella

Jeffrey S. McKinney

Salmonellosis is one of the most widely distributed and common food-borne and fecal-oral diseases in humans, and ***Salmonellae*** live in the intestinal tracts of multiple species. *Salmonella* infections are a major public health problem, with disproportionate morbidity and mortality among infants and children and in certain immunocompromised individuals.

Clinically, *Salmonellae* have been most broadly classified as being either nontyphoidal or typhoidal, with the latter causing typhoid (also known as *enteric*) fever. The differences in the disease manifestations from these two groups of pathogens, one predominantly causing intestinal inflammation and the other leading to systemic disease, are increasingly understood to be related to specific genes and pathogenicity islands in the genomes of the respective organisms.

Most nontyphoidal serovars of *Salmonella* (widely distributed across multiple host species) are rarely able to overcome defense mechanisms in humans that limit bacterial dissemination from the intestine. Thus in immunocompetent humans, nontyphoidal serovars usually produce a self-limiting gastroenteritis. By contrast, *S.* Typhi and *S.* Paratyphi (i.e., the typhoidal strains of *Salmonella,* notably host-restricted to only humans) possess virulence traits that more readily allow them to overcome mucosal barrier functions and then cause severe systemic illness, even in immunocompetent patients.

However, a purely binary classification of *Salmonellae* as nontyphoidal vs typhoidal can be a problematic oversimplification. For example, reports from Africa have identified strains of nontyphoidal *Salmonellae* that are highly invasive and increasingly common. Like many gram-negative bacteria, mobile or differentially expressed genetic elements can radically alter phenotypes in *Salmonellae,* sometimes in direct response to selective pressures like antimicrobial exposures given to individual patients and/or in broader settings like agricultural antimicrobial use.

Although DNA hybridization studies result in enough similarities for all *Salmonellae* to currently be classified in the single species *Salmonella enterica,* serologic studies can resolve more than 2,000 serotypes. Serotype and DNA sequencing identification has helped clinical laboratories better trace disease outbreaks, and the Centers for Disease Control and Prevention (CDC) has published recent guidelines for a more consistent terminology to help both laboratory and clinical teams confront complex classification nomenclature.

Host differences are also profoundly relevant to the outcomes of *Salmonella* exposures, infections, and disease. Infants and children, patients with certain immunologic vulnerabilities, and the extent to which a given *Salmonella* infection can evade host defenses and/or antibacterial drugs can help predict, or at least better understand, the ultimate impact of *Salmonella* on both individual and public health.

244.1 Nontyphoidal Salmonellosis

Jeffrey S. McKinney

ETIOLOGY

Salmonellae are motile, nonsporulating, gram-negative rods that grow in aerobic and facultative anaerobic conditions. They remain viable at ambient or reduced temperatures for days and may survive for weeks in sewage, foods, pharmaceutical agents, and fecal material. They are resistant to many physical agents but can be killed by heat to 54.4°C (130°F) for 1 hour or 60°C (140°F) for 15 minutes.

Most serotypes of nontyphoidal *Salmonella* have a broad host spectrum, including both warm-blooded and cold-blooded vertebrates, and even insects like flies and cockroaches. Some serotypes have more limited host ranges, such as *S. dublin* in cattle (recovered in human infections associated with unpasteurized milk) and *S. choleraesuis* in pigs. In human infections, these two serotypes also have a notable propensity to cause more bacteremia and fewer gastrointestinal symptoms as compared with many other nontyphoidal *Salmonellae*. In sub-Saharan Africa, nontyphoidal *Salmonella* has become a leading cause of **bacteremia**. Up to 95% of the serovars associated with invasive *Salmonella* disease among children in this geographic region are *Salmonella* serovar Typhimurium (mostly of an unusual variant designated **multilocus sequence type 313**), a variant of sequence type 313 that does not express phase 2 flagella, or *Salmonella* serovar Enteritidis. This information represents a deviation from the historical assumption that nontyphoidal *Salmonella* is, by definition, relatively noninvasive.

In the United States, nontyphoidal *Salmonella* infections still generally cause **gastroenteritis** that is localized and self-limiting. In these uncomplicated cases, nontyphoidal *Salmonella* infection does not justify treatment with antibiotics. However, nontyphoidal infections can be severe in the young, the elderly, and patients with vulnerabilities in their immunity.

EPIDEMIOLOGY

Salmonellosis has a significant cost to society. Globally, estimates suggest there are more than 90 million cases of *Salmonella* gastroenteritis annually, causing more than 150,000 deaths. In the United States, CDC estimates suggest an annual burden of more than 1.3 million *Salmonella* infections, causing more than 26,000 hospitalizations, 420 deaths, and $400 million in direct medical costs, with approximately 30 people with unreported *Salmonella* illness for every one case confirmed by a laboratory test. Nearly half of culture-proven nontyphoidal *Salmonella* infections occur in children, with the highest incidence among infants. With the burden of HIV infections and malnutrition in Africa, nontyphoidal *Salmonella* bacteremia has emerged as a major cause of morbidity and mortality among both children and adults in Africa.

Nontyphoidal *Salmonella* has a worldwide distribution, with the incidence influenced by local standards of hygiene, sanitation, and availability of safe water and food. Modern practices of mass food production and distribution increase the potential for epidemics, which may be scattered so broadly as to only be fully appreciated via **robust national monitoring systems**, such as the CDC's **FoodNet** (https://www.cdc.gov/foodnet/foodnet-fast.html). FoodNet also helps build capacity for food-borne disease surveillance through close collaborations with PulseNet, EHS-Net, Global SalmSurv, and other partners.

Poultry meat and eggs are traditionally known to be a common source of salmonellosis, and even riding in a shopping cart next to poultry meat is a risk factor for infection of infants. However, consumption of a wide variety of foods has now been associated with outbreaks, including fruits, vegetables, and multiple factory-processed foods such as peanut butter, cookies, and infant formula.

Salmonella infections in many parts of the world may be related to **animal husbandry practices**, including drug-resistant strains that emerge in response to the widespread use of agricultural antimicrobials. Subtherapeutic antimicrobials are often added to animal feeds to promote animal growth. There is now strong evidence linking resistance to quinolones to the use of this group of antimicrobials in animal feeds. Resistance to ciprofloxacin approached 10% of all nontyphoidal *Salmonella* isolates assessed by the CDC in 2017.

In addition to the effect of antibiotic use in animal feeds, the relationship of *Salmonella* infections to prior antibiotic use in children in the month before the infection is well recognized. This association may be related to alterations in gut microbial ecology, which predisposes to colonization and infection with antibiotic-resistant *Salmonella* isolates. The CDC reports that nontyphoidal *Salmonella* isolates during the period 2015–2017 continue to manifest increasing rates of resistance, with 16% of isolates being resistant to at least one essential antibiotic (including ciprofloxacin, azithromycin, ceftriaxone, ampicillin, and trimethoprim-sulfamethoxazole). *Variation in resistance among different strains makes Salmonella culture and antibiotic susceptibility testing very important.*

It appears that some **multidrug-resistant (MDR)** strains of *Salmonella* are also more virulent than susceptible strains. Poor clinical outcomes with these infections do not relate solely to the initial empiric choice of ineffective antibiotics. Over the past 3 decades, ***S.* Typhimurium phage type DT104** has emerged as a globally disseminated MDR strain. Typically resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline, DT104 also has the capacity to acquire resistance to other antibiotics. Many of the resistance genes in DT104 are harbored on genomic islands. Integrons can also encode and disseminate virulence genes.

Several risk factors are associated with outbreaks of *Salmonella* infection. Animals constitute the principal source of human disease from nontyphoidal *Salmonella*. **High-risk pets** include reptiles, amphibians, poultry and other birds, rodents, and other small mammals. The risk of *Salmonella* from turtles was so high that the U.S. Food and Drug Administration (FDA) banned the interstate sale and distribution of turtles with shell length of less than 4 inches. Exposures can also occur from contact with cages or tanks with pets, from touching some pet foods and treats, and even at zoos *without* direct contact with an infected animal.

Animals that carry *Salmonella* still appear healthy and clean and can readily transmit nontyphoidal *Salmonella,* including in **childcare centers and schools**. When nontyphoidal serovars are identified in a childcare attendee or staff member, adherence to hygiene practices is used to control infection. Return to school is allowed as long as stools are contained in a young child's diaper, toilet-trained children do not have accidents using the toilet, and stool frequency becomes no more than two stools above the child's normal stooling frequency per day. In notable contrast to infections with typhoidal strains, demonstration of clearance of nontyphoidal *Salmonella* from stool cultures is neither sought nor required.

Given the ubiquitous nature of the organism, **nosocomial infections** with nontyphoidal *Salmonella* strains can also occur via contaminated equipment and diagnostic or pharmacologic preparations. Patient-to-patient spread can also occur in hospital settings, particularly among vulnerable hosts like neonates. Nursery nosocomial infections from *Salmonella* can be very difficult to control, sometimes taking months to stop and/or serving as a source for further spread through a hospital.

PATHOGENESIS

The estimated number of bacteria that must be ingested to cause symptomatic disease in healthy adults is 10^6-10^8 *Salmonella* organisms. Normal gastric acidity inhibits *Salmonella* multiplication, with most organisms rapidly killed at gastric pH <2.0. Achlorhydria, buffering medications, and rapid gastric emptying after gastroenterostomy allow more viable organisms to reach the small intestine and thus lower the infectious dose. Neonates and infants have hypochlorhydria and rapid gastric emptying, which contribute to their increased vulnerability to infection, even at lower inoculum exposures.

The typical intestinal response to nontyphoidal *Salmonella* infection is **enterocolitis**, with diffuse mucosal inflammation and edema, sometimes with erosions and microabscesses. Intestinal inflammation with neutrophils and macrophages usually involves the lamina propria. Underlying intestinal lymphoid tissue and mesenteric lymph

nodes enlarge and may demonstrate small areas of necrosis. Lymphoid hypertrophy may interfere with blood supply to the gut mucosa and/or serve as a leading edge for intussusception. Hyperplasia of the reticuloendothelial system can also be found in the liver and spleen. If bacteremia develops, it may lead to localized infection and suppuration in almost any organ.

Central to *S.* Typhimurium pathogenesis are two **type III secretion systems**. These systems secrete and translocate bacterial proteins termed **effectors** into host cells. These effectors manipulate the host cell to allow bacterial invasion and assembly of an intracellular niche conducive to bacterial survival and replication. Two **genomic pathogenicity islands** encode these type III systems.

The *Salmonella* pathogenicity island 1 (SPI-1) is involved with epithelial cell adherence and invasion (Fig. 244.1), which involves host cell membrane ruffling caused by organized actin rearrangement (Fig. 244.2). This adherent and invasive phenotype of *Salmonella* is activated under conditions like those found in the human small intestine (high osmolarity, low oxygen).

The *Salmonella* pathogenicity island 2 (SPI-2) is involved with formation of the *Salmonella*-containing vacuole (Fig. 244.3), creating a replication-permissive intracellular space (Fig. 244.4). Intracellular *S.* Typhimurium is found within special vacuoles that have diverged from the normal endocytic pathway. An ability to survive within monocytes/macrophages is a key process for *S.* Typhimurium to establish a systemic infection. Survival within host cells also shields *Salmonella* from antimicrobials. For example, gentamicin is not considered effective in vivo against *Salmonella,* even for strains found susceptible to this drug in vitro, because gentamicin does not effectively reach intracellular bacteria.

Bacteremia and systemic disease are possible with any *Salmonella* serotype, especially in individuals with reduced host defenses. Inflammatory bowel disease or gut ischemia can cause intestinal mucosal barrier defects. Malnutrition, corticosteroid therapy, interleukin (IL)-12/interferon gamma axis defects, and posttransplant immunosuppressant agents can significantly compromise cell-mediated immunity. The reticuloendothelial system can be overloaded with hemoglobin or iron or have impaired function from lymphoma or leukemia. In addition, other underlying systemic conditions can predispose to serious *Salmonella* infections, including sickle cell disease, collagen vascular diseases, HIV/AIDS, defects in T_H1 or T_H17 immunity, and chronic granulomatous disease.

As stated earlier, neonates and infants less than 3 months of age are also at higher risk of bacteremia from nontyphoidal *Salmonella*. This risk influences empiric treatment with appropriate antibiotics, even in otherwise healthy patients in this young age-group.

Patients with sickle cell disease are at very high risk for *Salmonella* septicemia and osteomyelitis. This risk may be related to the presence of numerous infarcted areas in the gastrointestinal tract, bones, and reticuloendothelial organs, along with reduced phagocytic and opsonizing capacity of patients with sickle cell disease.

CLINICAL MANIFESTATIONS

Acute Enteritis

The most common clinical presentation of salmonellosis is acute enteritis. After an incubation period of 6-72 hours (mean 24 hours), there is often abrupt-onset nausea, vomiting, and crampy abdominal pain, located predominantly in the periumbilical area and the lower abdominal quadrants. These symptoms are usually followed by mild to severe watery diarrhea, sometimes containing blood, neutrophils, and mucus. Although fever is a classic feature, younger infants may exhibit a normal or subnormal temperature. Symptoms usually subside within 2-7 days in otherwise healthy children. However, some children experience a septicemia-like picture, with symptoms including high fever, drowsiness, confusion, abdominal distention, meningismus, and/or seizures.

Bacteremia

After *Salmonella* gastroenteritis, it is estimated that 1–5% of otherwise healthy children are thought to experience transient bacteremia after nontyphoidal *Salmonella* in U.S. settings. Bacteremia is usually accompanied by fever in older children but is often not associated with fever in infants. As described earlier, specific vulnerable hosts are far more likely to have systemic infection. Children with HIV can have recurrent nontyphoidal *Salmonella* septicemia, despite antibiotic therapy, even without positive stool cultures or any clear nidus of infection. Some nontyphoidal strains are more likely to result in bacteremia, even without obvious gastrointestinal symptoms, including *S. dublin* and *S. choleraesuis*. In Africa, nontyphoidal *Salmonella* is a much more common cause of pediatric bacteremia (see next).

Nontyphoidal *Salmonella* Bacteremia as Emerging Disease in Africa

In Africa, particularly sub-Saharan Africa, nontyphoidal *Salmonella* has been increasingly recognized among the most common causes of *all* bacteremia in febrile children. Children age 6-36 months are at greatest risk, and case fatality rates can reach 25%.

Clinical features among children with invasive nontyphoidal *Salmonella* infections can be confusing, as diarrhea is often *not* a prominent feature. Furthermore, 60% of these children have an apparent lower respiratory tract infection (perhaps from co-infection or comorbidity). Fever is present in 95% but may have no apparent focus. Figure 244.5 summarizes other clinical features. The lack of specificity of these features severely compromises the ability of current clinical algorithms to identify invasive nontyphoidal *Salmonella* infections. Accordingly, blood culture and clinical microbiology systems for bacterial growth, isolation, speciation, and antibiotic susceptibility testing are required for diagnosis and well-informed treatment decision-making.

It remains unclear exactly why invasive infections by nontyphoidal *Salmonella* seem so much more frequent in Africa compared with the dominance of typhoid *Salmonellae* in Asia. HIV is one identified host risk factor for nontyphoidal *Salmonella* infection. Indeed, recurrent nontyphoidal *Salmonella* infection was part of early CDC case definitions for AIDS. However, only 20% of African children with invasive nontyphoidal *Salmonella* disease are HIV positive. Other risks for invasive nontyphoidal *Salmonella* may include recent or severe malaria infections, anemia, and malnutrition.

The epidemic patterns thus far appreciated for invasive infections by nontyphoidal *Salmonella* in Africa suggest that epidemics may occur over several years, peaking in the rainy season. However, it remains unclear how relevant human diarrheal disease or gastrointestinal carriage, or even food or zoonotic sources are, for invasive nontyphoidal *Salmonella* infection in this setting. Thus optimal strategies for interrupting transmission are also not known. This is particularly problematic, given the emergence of extensive antibiotic resistance among nontyphoidal *Salmonella* isolates, including the lineage referred to as *sequence type 313* (ST313).

Recent studies have attempted to better understand the geographic spread and genetic features of ST313 lineage variants isolated internationally over time. Intriguingly, the antibiotic-resistance patterns of these lineages seem to correlate with some large-scale or sequential changes in empiric (e.g., chloramphenicol, third-generation cephalosporins, ciprofloxacin, and azithromycin) antibiotic use. ST313 lineage genomic analysis also reveals the accumulation of **pseudogenes**, in what may be crucial ***loss*-of-function genetic events** involved in ST313 stepwise evolution, perhaps as part of adaptation to a more restricted (human) host range and from an intestinal to a systemic lifestyle.

For invasive nontyphoidal *Salmonella* infections in Africa, evolving resistance patterns seem likely to force increasing reliance on more expensive treatment options. Local resistance patterns may help empirically, but given the rapid spread of various ST313 lineages, susceptibility testing of individual patient isolates will be needed to ensure appropriate antibiotic choices. Targeted resistance gene sequencing, especially for gyrase mutations related to quinolone resistance, may also be warranted as that drug class becomes more widely used.

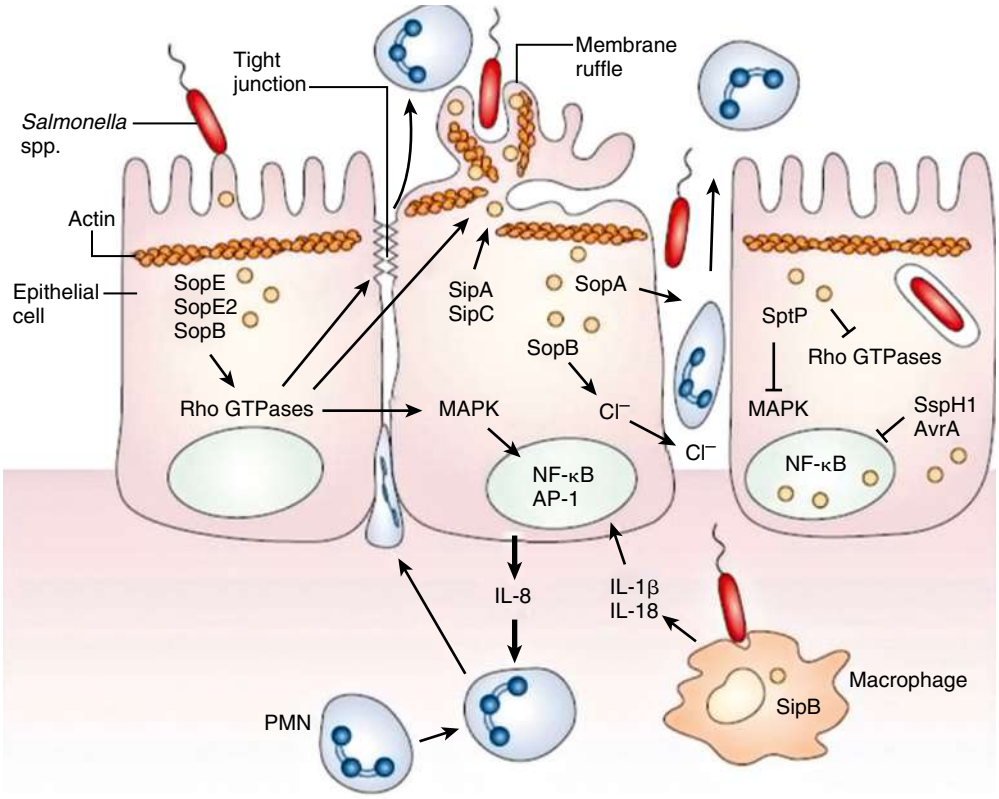

Fig. 244.1 On contact with the epithelial cell, *Salmonellae* assemble the *Salmonella* pathogenicity island 1–encoded type III secretion system (TTSS-1) and translocate effectors *(yellow spheres)* into the eukaryotic cytoplasm. Effectors such as SopE, SopE2, and SopB then activate host Rho guanosine triphosphatase (GTPase), resulting in the rearrangement of the actin cytoskeleton into membrane ruffles, induction of mitogen-activated protein kinase (MAPK) pathways, and destabilization of tight junctions. Changes in the actin cytoskeleton, which are further modulated by the actin-binding proteins SipA and SipC, lead to bacterial uptake. MAPK signaling activates the transcription factors activator protein-1 (AP-1) and nuclear factor-κB (NF-κB), which turn on production of the proinflammatory polymorphonuclear leukocyte (PMN) chemokine interleukin (IL)-8. SipB induces caspase-1 activation in macrophages, with the release of IL-1β and IL-18, augmenting the inflammatory response. In addition, SopB stimulates Cl^- secretion by its inositol phosphatase activity. The destabilization of tight junctions allows the transmigration of PMNs from the basolateral to the apical surface, paracellular fluid leakage, and access of bacteria to the basolateral surface. However, the transmigration of PMNs also occurs in the absence of tight-junction disruption and is further promoted by SopA. The actin cytoskeleton is restored, and MAPK signaling is turned off by the enzymatic activities of SptP. This also results in the downmodulation of inflammatory responses, to which SspH1 and AvrA also contribute by inhibiting activation of NF-κB. *(From Haraga A, Ohlson MB, Miller SI. Salmonellae interplay with host cells. Nat Rev Microbiol. 2008;6:53–66.)*

Nontyphoidal *Salmonella* Bacteremia in Other Geographic Regions

The emergence of invasive, high-mortality nontyphoidal *Salmonella* infections in Africa underscores that the traditional binary division of *Salmonella* infections into typhoidal vs nontyphoidal may be a problematic oversimplification. However, in settings outside of Africa, nontyphoidal *Salmonella* infections still tend to be self-limiting and noninvasive and are low-mortality events for most children who are immunocompetent.

Risk factors for systemic spread of nontyphoidal *Salmonella* include underlying sickle cell disease, HIV/AIDS, intestinal mucosal barrier defects, malnutrition, IL-12/interferon gamma axis defects, defects in T_H1 or T_H17 immunity, corticosteroid therapy or posttransplant immunosuppressants, reticuloendothelial system dysfunction (e.g., from overload with hemoglobin or iron), lymphoma or leukemia, collagen vascular diseases, and chronic granulomatous disease. Neonates and infants less than 3 months of age are also at higher risk of bacteremia from nontyphoidal *Salmonella*.

Extraintestinal Focal Infection

After bacteremia, *Salmonellae* have the propensity to cause focal suppurative infection of many organs. The most common focal infections involve the skeletal system, meninges, and intravascular sites. The peak incidence of *Salmonella* meningitis is in infancy, and the infection may be associated with a florid clinical course, high mortality, and neurologic sequelae in survivors.

Chronic *Salmonella* Carriage

Although traditionally considered a complication among *adults* with *Salmonella* infection, chronic *Salmonella* carriage has important medical and epidemiologic implications and may occasionally occur in children. Colonization of the gallbladder by *S.* Typhi and persistent shedding from the gallbladder have long been appreciated. Reports suggest some nontyphoidal *Salmonellae* (e.g., invasive nontyphoidal *Salmonella* currently in Africa) can also establish long-term carriage states.

Antibiotic treatments of *Salmonella* infections are paradoxical in that the prospect of becoming a chronic carrier is believed to be increased by exposure to antibiotics. Yet clearance of established chronic carrier status requires prolonged medical treatment using antibiotics to which the *Salmonella* is susceptible and sometimes requires gallstone or gallbladder removal.

DIAGNOSIS

Few clinical features are specific enough to *Salmonella* to allow differentiation from other infectious causes of gastroenteritis or diarrhea. Serologic tests also do not have diagnostic value. Definitive diagnosis requires identification of *Salmonella* via stool **nucleic acid amplification test** (NAAT) or **bacterial cultures**. Stool cultures have higher yields

than rectal swabs. Blood cultures are suggested for patients at higher risk of bacteremia or endovascular focus and when enteric fever is a concern. Additionally, cultures of bone marrow (particularly valuable if antimicrobial agents have been administered or if stringent criteria are met for **fever of unknown origin**), duodenal fluid, and urine may be beneficial to detect enteric fever. In patients with sites of local suppuration, aspirated specimens should be Gram-stained and cultured.

Salmonella organisms grow well on nonselective or enriched media, such as blood agar, chocolate agar, and nutrient broth, but stool specimens containing mixed bacterial flora require a selective medium, such as McConkey, xylose-lysine-deoxycholate, bismuth sulfate, or Salmonella-Shigella (SS) agar for isolation of *Salmonella*. Given *Salmonella* variation and evolution, it is important to pursue bacterial isolation, species identification, and ***antibiotic susceptibility testing*** *to best inform the choice of effective therapeutic agents.* State public health laboratories require *Salmonella* isolates as part of outbreak detection and investigation, increasingly via genomic characterization of strains.

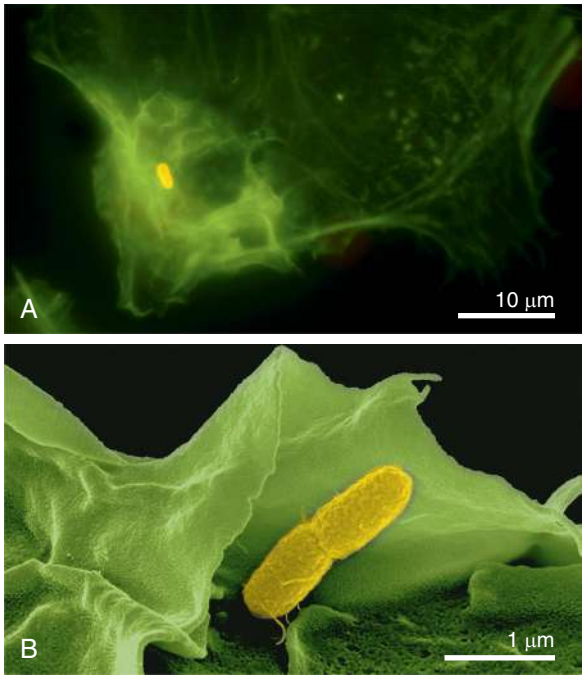

Fig. 244.2 *Salmonella* SPI-1–mediated effects include host cell actin cytoskeletal rearrangements and host cell membrane ruffling as part of *Salmonella* invasion. **A,** HeLa cell infected with *Salmonella* fixed and stained for the actin cytoskeleton with phalloidin *(green)* and for *Salmonella (yellow).* **B,** Cos cell infected with *Salmonella* and prepared for scanning electron microscopy. Cell surface extensions in the process of enveloping the bacterium are pseudocolored green, and the microbe is in yellow. *(From Rottner K, Stradal TEB, Wehland J. Bacteria-host-cell interactions at the plasma membrane: stories on actin cytoskeleton subversion. Dev Cell. 2005;9:3–17.)*

TREATMENT

Appropriate therapy depends on the specific clinical presentation of *Salmonella* infection. In children with gastroenteritis, rapid clinical assessment, correction of dehydration and electrolyte disturbances, and supportive care are key. Antimotility drugs (e.g., loperamide) should not be given to children less than 18 years of age with acute diarrhea, but antiemetic drugs (e.g., ondansetron) can be given to facilitate oral rehydration in children older than 4 years.

Antibiotics are generally *not* recommended for the treatment of isolated uncomplicated *Salmonella* gastroenteritis because they can disrupt normal intestinal flora and potentially prolong the fecal excretion of *Salmonella*.

However, empiric antibiotics are started for young infants (<3 months old) and for children with increased possibility of disseminated infection (e.g., children with HIV, malignancies, sickle cell disease, immunodeficiencies, or immunosuppression, as detailed earlier). In the United States, this empiric therapy includes a third-generation cephalosporin, with a blood culture obtained just before the initial dose. If a patient does not appear ill and does not have any evidence of disseminated infection, oral azithromycin can be started, pending blood culture results. Ampicillin, trimethoprim-sulfamethoxazole, or a fluoroquinolone may be considered as treatment options for susceptible strains.

In cases of bacteremia, blood cultures need to be repeated to confirm clearance of infection. Transition from parenteral third-generation

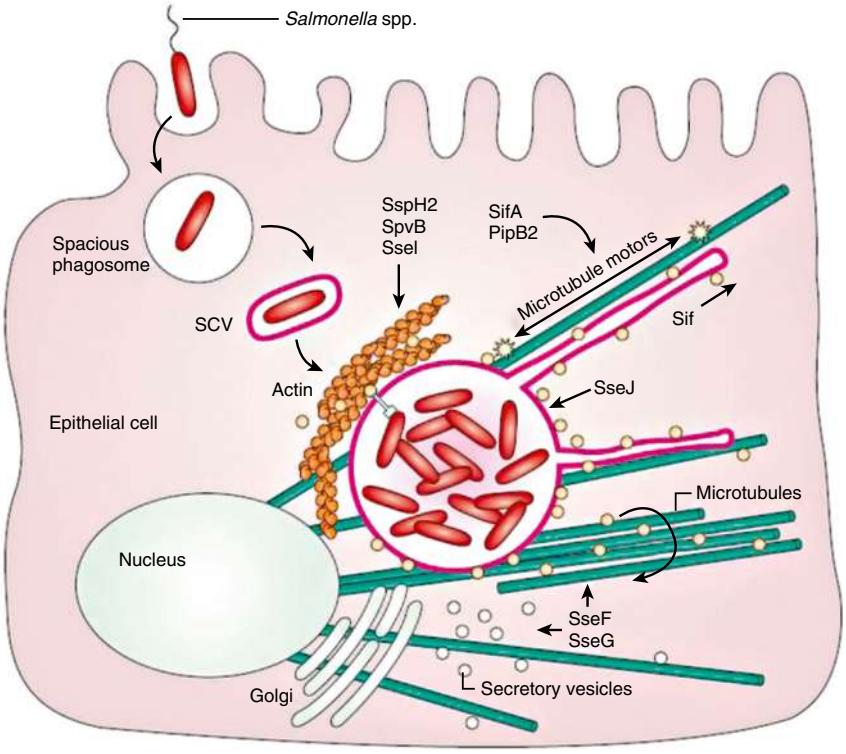

Fig. 244.3 Formation of the *Salmonella*-containing vacuole (SCV) and induction of the *Salmonella* pathogenicity island 2 (SPI-2) type III secretion system (TTSS) within the host cell. Shortly after internalization by macropinocytosis, *Salmonellae* are enclosed in a spacious phagosome that is formed by membrane ruffles. Later, the phagosome fuses with lysosomes, acidifies, and shrinks to become adherent around the bacterium and is called the SCV. It contains the endocytic marker lysosomal-associated membrane protein 1 (LAMP-1; *purple*). The *Salmonella* SPI-2 is induced within the SCV and translocates effector proteins *(yellow spheres)* across the phagosomal membrane several hours after phagocytosis. The SPI-2 effectors SifA and PipB2 contribute to formation of *Salmonella*-induced filament along microtubules *(green)* and regulate microtubule motor *(yellow star shape)* accumulation on the Sif and the SCV. SseJ is a deacylase that is active on the phagosome membrane. SseF and SseG cause microtubule bundling adjacent to the SCV and direct Golgi-derived vesicle traffic toward the SCV. Actin accumulates around the SCV in an SPI-2–dependent manner, in which SspH2, SpvB, and SseI are thought to have a role. *(From Haraga A, Ohlson MB, Miller SI. Salmonellae interplay with host cells. Nat Rev Microbiol. 2008;6:53–66.)*

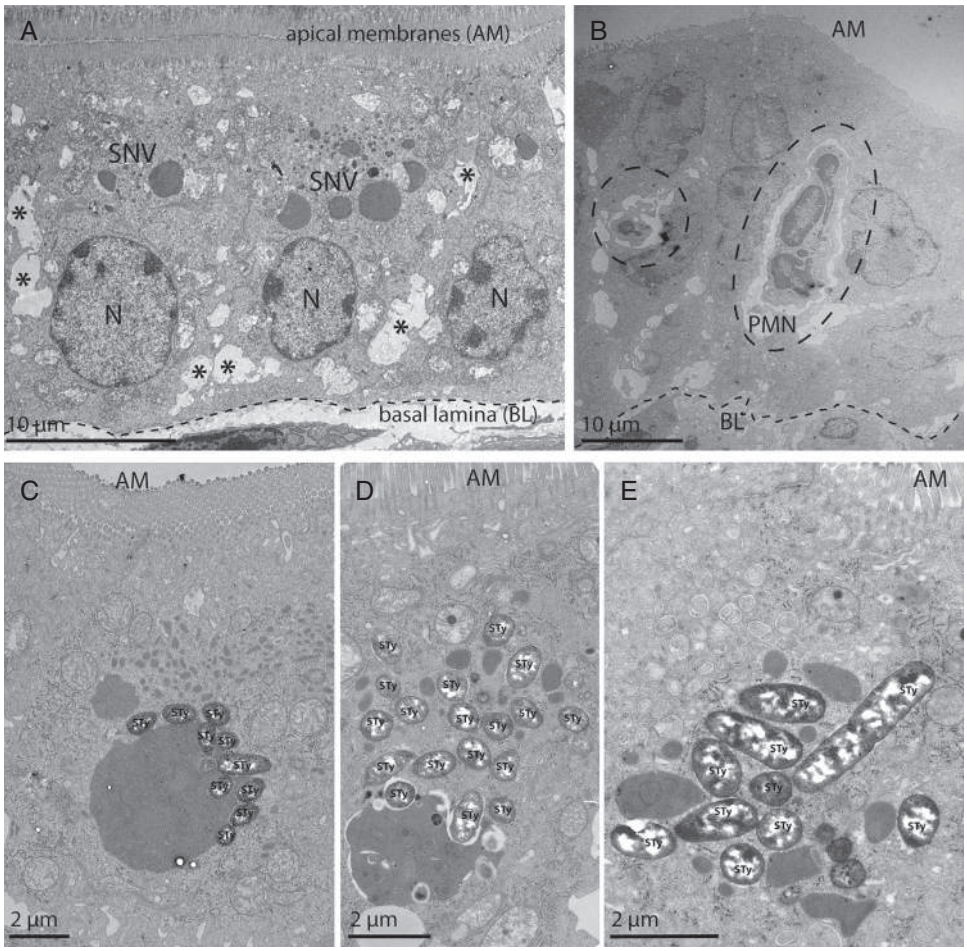

Fig. 244.4 Ultrastructural analysis of the distal small intestine with transmission electron microscopy. Distal small intestinal tissue was fixed with 1% glutaraldehyde. Short segments were cut open, post fixed with osmium tetroxide, contrasted with uranyl acetate, and dehydrated with a graded ethanol series before been embedded in epoxy resin. Thin sections were contrasted with lead citrate and analyzed in a JEM-1400 transmission electron microscope (JEOL). Images were taken with TemCam-F216 camera using EM MENU software (both TVIPS). **A,** Enterocytes in the distal intestine of healthy 5-day old neonates exhibit large supranuclear vacuoles (SNV) in their apical cytoplasm; the nuclei are situated at the basolateral site (N). SNV contain internalized milk proteins. Asterisks indicate intercellular spaces between enterocytes. **B,** 4 days after infection of 1-day-old mice with S. Typhimurium, the epithelium is infiltrated by polymorphonuclear cells (PMN). **C-E,** Intraepithelial Salmonella microcolonies are observed. Some bacteria reside in spherical vacuoles, which contain electron-dense material resembling the content of SNVs. Other bacteria appear to be localized in tight membrane-bound vesicles with few visible connections between them, or with vesicles filled with electron dense material. *(From Zhang K, Griffiths G, Repnik U, Hornef M. Seeing is understanding: Salmonella's way to penetrate the intestinal epithelium. Int J Med Microbiol. 2018 Jan;308:97-106. Fig. 2.)*

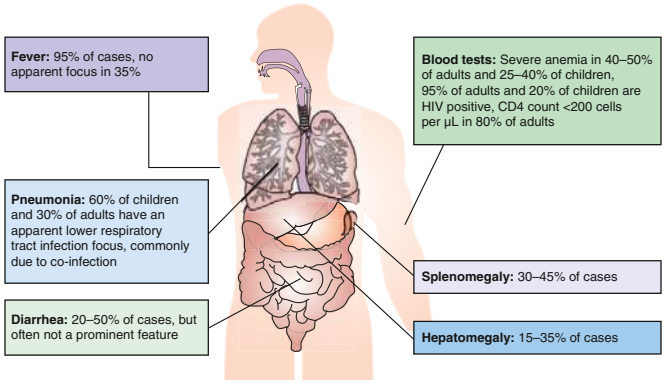

Fig. 244.5 Clinical features of invasive nontyphoidal Salmonella (NTS) disease in adults and children in Africa. *(From Feasey NA, Dougan G, Kingsley RA, et al. Invasive non-typhoidal Salmonella disease: an emerging and neglected tropical disease in Africa. Lancet. 2012;379: 2489–2499.)*

cephalosporin to oral azithromycin or a fluoroquinolone can be considered after documented clearance of blood cultures and exclusion of secondary sites, for a total 7- to 10-day course. Disseminated disease needs to be rigorously excluded, as therapy is more prolonged for meningitis (4 weeks) and osteomyelitis or other focal metastatic infections (4-6 weeks).

Given the heterogeneity, evolution, and rapid geographic spread of *Salmonella,* it is important to maintain awareness of resistance trends as related to local and national community isolate patterns, any relevant interstate outbreaks, and global patterns of emerging *Salmonella* resistance. Serially updated resources with this information include local microbiology laboratory data and open-access reporting systems like the U.S. National Antimicrobial Resistance Monitoring System for Enteric Bacteria (NARMS). In NARMS reports from 2018, the majority (81%) of nontyphoidal *Salmonella* from humans were still *not* resistant to any of the antimicrobials tested. However, approximately 3%, 10%, and 0.3% of nontyphoidal *Salmonella* isolated from humans were intrinsically resistant to ceftriaxone, ciprofloxacin, and azithromycin, respectively.

Some contemporary nontyphoidal *Salmonellae* are of particular interest, given their resistance to antimicrobials. *S.* Typhimurium DT104 spread globally in the 1990s, when it was resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. DT104 now sometimes also has reduced susceptibility to fluoroquinolones. Nontyphoidal *Salmonella* ST313 lineages (described earlier) continue

to show resistance pattern evolution in Africa. In the United States, *S.* Infantis has now supplanted other leading serotypes in poultry and not only exhibits deceased susceptibility to fluoroquinolones because of a gyrA pathogenic variant but also contains an MDR plasmid that carries up to 10 resistance genes, conferring resistance to cephalosporins, tetracycline, chloramphenicol, and sulfonamides. This MDR strain of serovar Infantis has been reported to account for up to 35% of the nontyphoidal Salmonella infections in Israel.

PROGNOSIS

Most otherwise healthy children with *Salmonella* gastroenteritis recover fully without antimicrobial treatment. Malnourished children and those who do not receive adequate supportive care can be at risk for prolonged diarrhea and complications. Young infants and immunocompromised patients often have systemic involvement, and children with HIV can have a florid and recurring course.

After infection, nontyphoidal *Salmonella* are excreted in feces for a median of 5 weeks, during which time the recovering patient can infect others via fecal-oral routes or by contaminating foods. A prolonged carrier state is rare in children but is more common among those with biliary tract disease and/or cholelithiasis.

PREVENTION

Control of transmission of *Salmonella* infections to humans requires control of the infection in animal reservoirs, judicious use of agricultural antimicrobials, prevention of contamination of foodstuffs, and appropriate standards of food processing and inspection. Parents should be advised about the risk of various pets (especially reptiles, amphibians, and rodents).

Large outbreaks are often related to mass food production, presenting among widely geographically distributed patients. In the United States, CDC outbreak investigations are reported, via this site: https://www.cdc.gov/Salmonella/outbreaks.html, which includes maps and epidemiologic, traceback, and laboratory data, including outbreaks linked to specific foods, animals, and other sources. Awareness of these events can potentially blunt the extent of a given outbreak and/or alert caregivers of vulnerable hosts.

244.2 Enteric Fever (Typhoid and Paratyphoid Fever)

Jeffrey S. McKinney

Enteric fever *(typhoid or paratyphoid fever)* remains endemic in many developing countries. Given the ease of modern travel, cases regularly occur in developed countries as well, usually among returning travelers or from secondary transmission from an asymptomatic carrier.

ETIOLOGY

Typhoid fever is caused by *S. enterica* serovar Typhi (*S.* Typhi). A similar but often less severe disease is caused by *Salmonella* Paratyphi A, B, and C. All are classically referred to as typhoidal *Salmonellae*. Typhoidal *Salmonellae* share more than 90% of their genes with the classic nontyphoidal strain, *S.* Typhimurium, but several genetic clusters known as *pathogenicity islands* and other genes have been acquired during evolution. The inactivation of single genes and the acquisition or loss of genes may have contributed to host adaptation and restriction of typhoidal strains. Importantly, whereas nontyphoidal *Salmonella* are found in many hosts and can be transmitted among them, typhoidal *Salmonella* only infects humans.

In contrast to the diarrheal symptoms classically encountered in gastroenteritis caused by nontyphoidal *Salmonellae,* enteric fever caused by typhoid or paratyphoid *Salmonellae* may present as abdominal pain without diarrhea, a fever without focus, and/or with extraintestinal foci of infection. Indeed, although enteric fever clearly starts in the gastrointestinal tract, the systemic nature of its presentation and symptomatology (and even its initial hard-to-detect primary bacteremia) can delay diagnosis, in particular among patients returning from or living in endemic areas, where the differential diagnosis for fevers is broad.

EPIDEMIOLOGY

Recent large-scale data and modeling efforts estimate that 14.3 million cases of typhoid and paratyphoid fevers occurred globally in 2017, a decline from 25.9 million cases in 1990. Incidence rates peak in the 5- to 9-year-old age-group, with roughly 13% of cases occurring in children younger than 5 years and roughly 56% of cases among children younger than 15 years of age. South and Southeast Asia have notably high incidence rates, whereas moderate incidence rates are reported from Central and South America, Africa, Central and East Asia, and Oceania (Fig. 244.6).

Typhoid fever is notable for the ongoing emergence of heterogeneous new patterns of drug resistance. After early outbreaks of chloramphenicol-resistant *S.* Typhi infections, *S.* Typhi strains emerged that were **multidrug resistant (MDR)**, fully resistant to all *three* of the traditional primary treatment antimicrobials: ampicillin, trimethoprim-sulfamethoxazole, and chloramphenicol. There is also a considerable increase in fluoroquinolone-resistant and even ceftriaxone-resistant isolates of *S.* Typhi. In the United States, most travel-associated cases of typhoid fever are now fluoroquinolone resistant.

There are now *S.* Typhi strains that are **extensively drug resistant (XDR)** not only to ampicillin, trimethoprim-sulfamethoxazole, and chloramphenicol but also to ceftriaxone and with full or intermediate resistance to ciprofloxacin. It appears that the new XDR *S.* Typhi strains came from a large outbreak in 2016 linked to contaminated water in Pakistan's Sindh province. XDR Typhi infections were then reported globally among travelers to or from Pakistan. In 2019 U.S. residents with *no* history of international travel were also diagnosed with XDR typhoid fever. The optimal therapy for these XDR isolates is still being determined, with preliminary recommendations suggesting the empiric use of a carbapenem (e.g., meropenem), azithromycin, or both.

S. Typhi is highly adapted to infections of humans, and the discovery of a large number of **pseudogenes** in *S.* Typhi suggests that its genome may have undergone degeneration as part of a specialized association with the human host. *S.* Typhi has no apparent ability to cause transmissible disease in other animals. Thus direct or indirect contact with an infected human (either sick or a chronic carrier) is a prerequisite for infection. Ingestion of foods or water contaminated with human feces is the most common mode of transmission. So-called street vendor foods outside the home are one risk factor noted in one case control study from Pakistan; such risks are included in practical guidance for travelers about food and water precautions from the CDC Yellow Book (Health Information for International Travel). However, more general water-borne outbreaks related to poor sanitation or water system contamination have also been described. Other causes of infection include consuming oysters and other shellfish cultivated in water contaminated by human sewage and the use of night soil as fertilizer.

PATHOGENESIS

Human volunteer experiments have established an infecting dose of about 10^5–10^9 organisms, with an incubation period ranging from 4 to 14 days. After ingestion, *S.* Typhi invades the gut mucosa of the terminal ileum via specialized antigen sampling cells known as *M cells* that overlie gut-associated lymphatic tissues, through enterocytes, or via a paracellular route. In contrast to nontyphoidal *Salmonella, S.* Typhi expresses factors that notably downregulate the pathogen receptor–mediated host inflammatory response. It assembles type III secretion systems to inject bacterial effectors that modulate host cell biology in elegant ways, including but not limited to rearrangements of host cell actin, facilitating invasion across the outer cell membrane and a host cell membrane ruffling process that forms a phagosome containing the bacteria. This phagosome fuses with lysosomes, acidifies, and shrinks to become adherent around the bacterium, forming the *Salmonella*-containing vacuole (SCV). This intracellular niche offers *Salmonella* a physical barrier to some

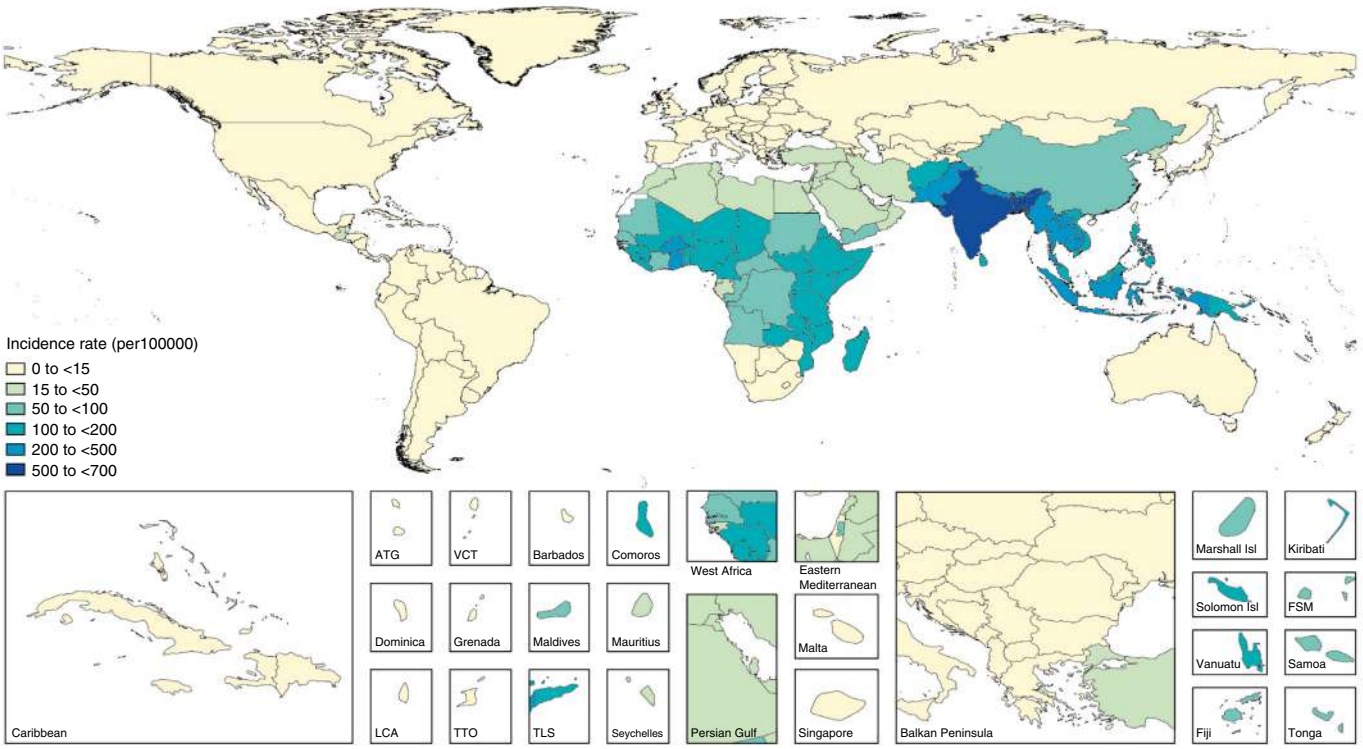

Fig. 244.6 Incidence rates (per 100,000) of typhoid and paratyphoid fevers, by country, in 2017. Inset maps detail smaller locations. ATG, Antigua and Barbuda; FSM, Federated States of Micronesia; Isl, Islands; LCA, Saint Lucia; TLS, Timor-Leste; TTO, Trinidad and Tobago; VCT, Saint Vincent and the Grenadines. *(From GBD 2017 Typhoid and Paratyphoid Collaborators. The global burden of typhoid and paratyphoid fevers: a systematic analysis for the Global Burden of Disease Study 2017. Lancet Infect Dis. 2019;19[4]:369–381.)*

drugs (e.g., gentamicin, which has very poor intracellular penetration) and an intracellular replication site and means of host cell–mediated systemic spread.

After passing through the intestinal mucosa, *S.* Typhi organisms enter the mesenteric lymphoid system and then pass into the bloodstream via the lymphatics. This primary bacteremia is usually asymptomatic, and blood culture results are frequently negative at this early stage. The blood-borne bacteria are disseminated through the body and are thought to colonize the organs of the reticuloendothelial system, where they replicate within macrophages. After a period of bacterial replication, *S.* Typhi organisms are shed back into the blood, causing a secondary bacteremia that coincides with the onset of clinical symptoms and marks the end of the incubation period (Fig. 244.7). During this secondary bacteremia, classically with fever, blood cultures are far more frequently positive, although culture of bone marrow can be even more sensitive.

Both typhoidal and nontyphoidal *Salmonellae* are members of the same species and share substantive commonalities, including more than 90% of their DNA sequences. Yet a deeper appreciation of how and why typhoidal and nontyphoidal species differ offers insights at multiple levels, ranging from genetics and ecology, to pathobiology, to more nuanced clinical recognition and care.

Despite typhoidal (and paratyphoidal, used interchangeably in this section, unless specified otherwise) fevers being synonymous with the clinical diagnosis of **enteric fever**, the initial enteric inflammation from *S.* Typhi is notably less than that caused from most nontyphoidal *Salmonellae*. Clinically, presenting symptoms of typhoid tend to include less diarrhea and far less gut mucosal inflammation. In host cell cultures, *S.* Typhi induces lower levels of IL-8 neutrophil chemoattractant and less of a toll-like receptor 5 (TLR5)–driven proinflammatory response than seen with nontyphoidal *Salmonella*. One potential implication of this is that nontyphoidal *Salmonella* may use inflammation-derived luminal substances such as electron acceptors like nitrate and tetrathionate, perhaps in competition with other fermenting gut microbes. Intriguingly, *S.* Typhi has genomic *decay* in a network of nontyphoidal *Salmonella* genes that are involved in anerobic metabolic pathways.

This is not to say that *S.* Typhi never results in intestinal lesions. In advanced stages of typhoid fever, life-threatening intestinal perforation can occur. However, the histopathology of typhoid perforation is distinct from the inflammation seen with nontyphoidal *Salmonella* gastroenteritis. With *S.* Typhi, inflammation that can finally penetrate the intestinal muscularis and serosa to cause perforation seems to originate from *deeper* sites, including underlying lymphoid tissue. In other tissues, including liver, spleen, lymph nodes, and bone marrow, **typhoid nodules** composed of macrophage aggregates can also form.

Gallbladder colonization is also a notable feature of *S.* Typhi and can result in years-long *Salmonella* carriage and shedding, with profound public health implications. The primary bacteremia of *S.* Typhi can seed the gallbladder, where exposure to bile upregulates *S.* Typhi (but seemingly *not* nontyphoidal *Salmonella*) type 3 secretion system genes that result in increased epithelial cell invasion.

S. Typhi expresses a surface **Vi (virulence) capsular polysaccharide** that is *not* present in nontyphoidal *Salmonella* or in *S.* Paratyphi A or B (which is relevant to the community-level impact of current Vi-based vaccines). Encoded as part of the *S.* Typhi pathogenicity island 7 (SPI-7), the Vi capsular polysaccharide interferes with the surface exposure of *S.* Typhi lipopolysaccharide and flagellin in ways that dampen host TLR-4 and -5 mediated **innate immune responses**. Vi also blocks complement C3 binding to the *S.* Typhi surface, interfering with **phagocytosis**.

Characterization of the **typhoid toxin** represents a major advance in understanding typhoid fever. Furthermore, in contrast to the Vi capsular polysaccharide, the typhoid toxin is expressed in both typhoidal *and* paratyphoidal *Salmonellae*. This toxin may prove important for new therapeutic or diagnostic innovations based on antitoxin

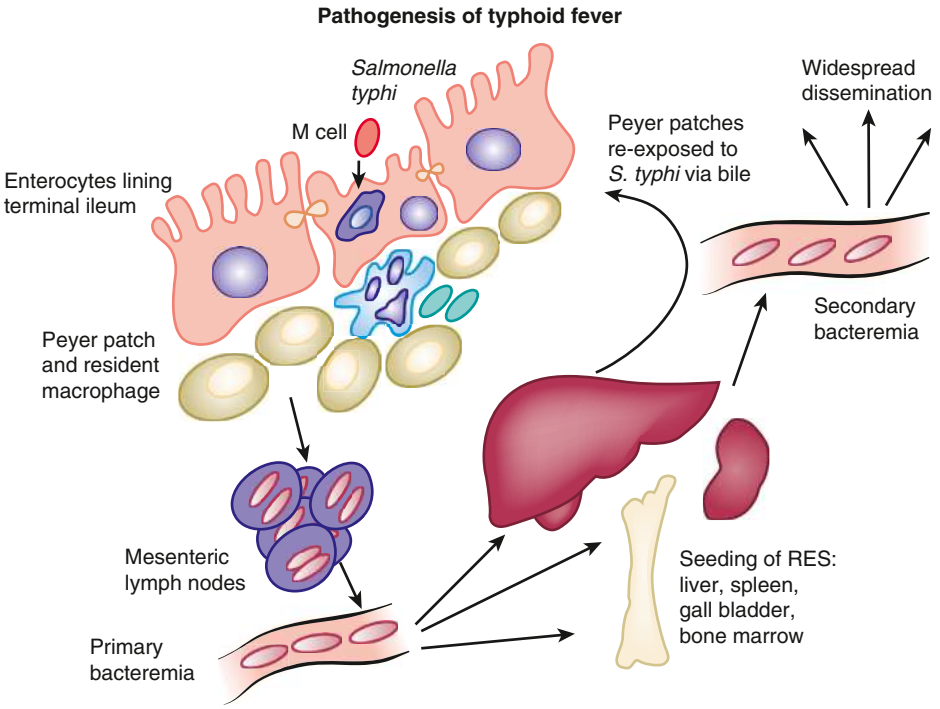

Fig. 244.7 Pathogenesis of typhoid fever, involving invasion of ileal enterocyte and Peyer patches and mesenteric lymph nodes, seeding the reticuloendothelial system (RES). Both primary and secondary bacteremia events can occur and relate to clinical stages of disease. *(Adapted from Richens J. Typhoid fever. In: Cohen J, Powderly WG, Opal SM, eds. Infectious Diseases, 2nd ed. London: Mosby; 2004:1561–1566.)*

approaches. Typhoid toxin has three subunits. Subunit CdtB has DNAse I–like nuclease activity that causes double-stranded breaks in host cell DNA, leading to host G2/M cell cycle arrest and/or cell death. Subunit PltA is a pertussis-like toxin with mono–adenosine diphosphate (ADP)–ribotransferase activity. Subunit PltB is a pertussis-like toxin with receptor binding activity to glycans, especially sialoglycans, terminated in Neu5Ac. The functional typhoid toxin is composed of one CdtB and one PltA subunit, plus five PltB subunits. Typhoid toxin genes are expressed by intracellular *S.* Typhi in the SCV of host cells. The trafficking of the toxin uses an elegant mechanism, in which PltB binding to Neu5Ac is involved in both toxin export and toxin endocytosis into target cells. The fact that Neu5Ac is the target for binding by PltB may help explain the cell tropism of typhoid toxin and also some of the human restriction of typhoidal infections and pathobiology at a molecular level.

The presence/gain/site-specific expression of certain virulence factors by typhoidal *Salmonellae* may help explain disease nuances involved in typhoid fever. Acquisition and spread of resistance genes are also a clear and present danger.

The overall quantity of **pseudogenes** in *S.* Typhi versus nontyphoidal *Salmonella* genomes is also noteworthy. Whereas *S.* Typhi's 200 pseudogenes account for roughly 4% of all its genes, the classic nontyphoidal *Salmonella* exemplar *S.* Typhimurium genome includes less than 1% pseudogenes. One broad conceptual model for this is that *S.* Typhimurium remains more of a "generalist," with a broad host range and more genes to facilitate survival in different hosts. By contrast, *S.* Typhi may have become a "specialist," evolving to infect only humans. Furthermore, *S.* Typhi may infect humans in specific ways that better evade/suppress early mucosal inflammatory events and cause more systemic spread, as well as sustained colonization and long-term shedding. This conceptual model may offer insights to understand the ongoing evolution or emergence of some new nontyphoidal *Salmonella* strains that (akin to typhoidal strains) tend to cause more systemic infections, as highlighted by the evolution of the nontyphoidal *Salmonella* ST313 strain in Africa.

In addition to the virulence of infecting organisms, host factors also influence predisposition to infection. Patients with HIV are at significantly higher risk for infection with *S.* Typhi and *S.* Paratyphi. Patients with *Helicobacter pylori* infection also have an increased risk of acquiring typhoid fever. Compared to most nontyphoidal *Salmonella* infections that are often more severe and systemic in hosts with immune abnormalities, outbreaks of typhoid fever with systemic spread often affect many hosts who do *not* have significant underlying immunocompromise.

CLINICAL MANIFESTATIONS

The incubation period of typhoid fever is usually 7-14 days but depends on the infecting dose and ranges between 3 and 30 days. The presentation varies, from mild illness with low-grade fever and malaise, to a severe clinical picture with profound abdominal discomfort and multiple complications.

Severity and clinical outcome are influenced by many factors. These include duration of illness, age, previous exposure or vaccination history, virulence of the infecting strain, and quantity of the inoculum ingested. Given the profound changes in antimicrobial susceptibility patterns, choice of appropriate antimicrobial therapy is increasingly challenging, both empirically (given multiple various patterns of resistance) and after antimicrobial susceptivity results are secured (given the increasing inadequacy of many previously effective drugs).

The presentation of typhoid fever may vary by patient age. Some reports from South Asia suggest typhoid fever may be more severe in children less than 5 years old in terms of rates of complications and hospitalization. In infancy, complications such as disseminated intravascular coagulation seem more common, with higher case fatality rates. By contrast, neurologic complications and intestinal bleeding or perforation seem less common among children.

Typhoid fever can start as a seemingly mild illness and then progress to a clinical picture that manifests as high-grade fever. It can include a wide variety of associated features, such as anorexia, vomiting, hepatomegaly or splenomegaly, abdominal pain, and/or headache (Table 244.1). In children, diarrhea may occur in earlier stages of the illness but may be followed by constipation, potentially interfering with ready access to stool for important microbial culture and susceptibility testing. In the absence of localizing signs, the early stages of the disease may be very difficult to differentiate from other endemic diseases, such as malaria and dengue fever. In some cases, a macular or maculopapular rash ("rose spots") may be visible around the seventh to tenth day of the illness. These lesions may be difficult to see in dark-skinned children and may occur in crops on the lower

chest and abdomen, typically lasting 2-3 days (Fig. 244.8). Although so-called pulse fever dissociation (relative bradycardia during fevers) has historically been invoked as a feature of typhoid fever, it has low positive predictive value, is nonspecific, and seems much less common in children than in adults.

It is recognized that MDR *S.* Typhi infection is a more severe clinical illness with higher rates of toxicity, complications, and case fatality rates. Depending on the specific infecting strain, this may be related to greater virulence and higher numbers of circulating bacteria.

If no complications occur, symptoms and physical findings gradually resolve within 2-4 weeks. However, illness may contribute to malnutrition. Although enteric fever caused by *S.* Paratyphi has traditionally been considered a more mild illness than that from *S.* Typhi, paratyphoid fever can also be severe, with significant drug resistance, morbidity, and complications.

COMPLICATIONS

Although altered liver function is found in many patients with enteric fever, clinically significant hepatitis, jaundice, and cholecystitis are relatively rare and may be associated with worse outcomes. Intestinal hemorrhage and perforation are infrequent among children. Intestinal perforation may be preceded by marked increase in abdominal pain (often in the right lower quadrant), tenderness, vomiting, and features of peritonitis. Peritoneal signs may be masked in patients receiving steroids.

Rare complications include toxic myocarditis, which may manifest as arrhythmias, sinoatrial block, or cardiogenic shock (Table 244.2). Neurologic complications are relatively uncommon among children; they include delirium, psychosis, increased intracranial pressure, acute cerebellar ataxia, chorea, deafness, and Guillain-Barré syndrome. Although case fatality rates can be higher among patients with neurologic complications, recovery usually occurs without sequelae. Other reported complications include fatal bone marrow necrosis, disseminated intravascular coagulation, hemolytic-uremic syndrome, pyelonephritis, nephrotic syndrome, meningitis, endocarditis, parotitis, orchitis, and suppurative lymphadenitis.

The propensity to become a carrier follows the epidemiology of gallbladder disease and cholelithiasis, generally increasing with patient age and antimicrobial resistance.

DIAGNOSIS

The mainstay of the diagnosis of typhoid fever is a positive culture of *S.* Typhi or *S.* Paratyphi from the blood or other anatomic site. Results of blood cultures are positive in 40–60% of patients seen early in the course of disease, but serial high-volume blood cultures may be required to identify *Salmonella* bacteremia. Stool and urine culture results may also become positive after the first week, and the stool culture may occasionally be positive even during the incubation period. NAATs for *Salmonella* can be part of diagnostic screening, but rectal swab samples are less sensitive than stool samples. In this era of increasing antibiotic resistance (not only common but also heterogeneous patterns), species identification without culture to check antibiotic susceptibilities is suboptimal. *Indeed, antibiotic susceptibility testing is now essential for determining optimal therapy.* Bone marrow culture is highly sensitive (around 90%) and remains positive in more than 50% of cases despite several days of antibiotic therapy. Bone marrow collection is relatively invasive, however, and tends to be employed as part of an extensive workup for patients meeting stringent criteria for a true fever of unknown origin. Punch biopsies from characteristic rose spots may be culture positive in up to 63% of cases, even with prior antibiotic treatment.

Results of other laboratory investigations are largely nonspecific for the diagnosis of typhoid fever. The Widal test has common false-negative and false-positive results, and as a serologic test is highly dependent on geographic area and endemicity. Tests such as coagulation studies, liver function studies, and abdominal imaging are examples of studies that may be of use in assessing for complications of typhoid fever.

Table 244.1 Common Clinical Features of Typhoid Fever in Children*

FEATURE	RATE (%)
High-grade fever	95
Coated tongue	76
Anorexia	70
Vomiting	39

Lesions may be more difficult to identify in darker-skinned people. *(From Huang DB, DuPont HL. Problem pathogens: extra-intestinal complications of Salmonella enterica serotype Typhi infection. Lancet Infect Dis. 2005;5:341–348.)*

Table 244.2 Extraintestinal Infectious Complications of Typhoid Fever Caused by *Salmonella enterica* Serotype Typhi

ORGAN SYSTEM	PREVALENCE (%)	RISK FACTORS	COMPLICATIONS
Central nervous system	3–35	Residence in endemic region, malignancy, endocarditis, congenital heart disease, paranasal sinus infections, pulmonary infections, meningitis, trauma, surgery, osteomyelitis of skull	Encephalopathy, cerebral edema, subdural empyema, cerebral abscess, meningitis, ventriculitis, transient Parkinsonism, motor neuron disorders, ataxia, seizures, Guillain-Barré syndrome, psychosis
Cardiovascular system	1–5	Cardiac abnormalities (e.g., existing valvular abnormalities, rheumatic heart disease, congenital heart defects)	Endocarditis, myocarditis, pericarditis, arteritis, congestive heart failure
Pulmonary system	1–6	Residence in endemic region, past pulmonary infection, sickle cell anemia, alcohol abuse, diabetes, HIV infection	Pneumonia, empyema, bronchopleural fistula
Bone and joint	<1	Sickle cell anemia, diabetes, systemic lupus erythematosus, lymphoma, liver disease, previous surgery or trauma, extremes of age, corticosteroid use	Osteomyelitis, septic arthritis
Hepatobiliary system	1–26	Residence in endemic region, pyogenic infections, intravenous drug use, splenic trauma, HIV, hemoglobinopathy	Cholecystitis, hepatitis, hepatic abscesses, splenic abscess, peritonitis, paralytic ileus
Genitourinary system	<1	Urinary tract abnormalities, pelvic pathology, systemic abnormalities	Urinary tract infection, renal abscess, pelvic infections, testicular abscess, prostatitis, epididymitis
Soft tissue infections	At least 17 cases reported in English-language literature	Diabetes	Psoas abscess, gluteal abscess, cutaneous vasculitis
Hematologic	At least 5 cases reported in English-language literature		Hemophagocytosis syndrome

From Huang DB, DuPont HL. Problem pathogens: extra-intestinal complications of *Salmonella enterica* serotype Typhi infection. *Lancet Infect Dis.* 2005;5:341–348.

DIFFERENTIAL DIAGNOSIS

Typhoid fever may mimic many febrile illnesses without localizing signs. In early stages, it can be confused with alternative conditions, such as gastroenteritis, bronchitis, and bronchopneumonia. As the disease progresses, the differential diagnosis may include bacterial sepsis, malaria, dengue fever, infectious mononucleosis, acute hepatitis, tuberculosis, brucellosis, tularemia, leptospirosis, amebiasis, Q fever, toxoplasmosis, and rickettsial diseases. A classic cause of fevers among travelers returning from endemic areas, typhoid fever can also occur in those with direct, or even unappreciated, contact with other infected people.

TREATMENT

Antibiotic resistance among *S.* Typhi strains is now so heterogeneous and dynamic that the importance of obtaining **antibiotic susceptibility tests** on clinical isolates cannot be overemphasized. Although empiric antibiotics still may be started, final decision-making about optimal treatment should be based on antibiotic susceptibility results. Molecular testing of specific resistance genes can also help assess mechanisms and evolution of resistance.

For years, third-generation cephalosporins (e.g., ceftriaxone or cefotaxime) were a mainstay of empiric therapy. They were considered effective even for **MDR** *S.* Typhi and/or for the increasing number of *S.* Typhi that were quinolone resistant. Yet now, with the recent emergence of **XDR** *S.* Typhi, third-generation cephalosporins may no longer be sufficient.

In *S.* Typhi, MDR isolates are defined as resistant to all the first line of antibiotics previously suggested by the World Health Organization (WHO): ampicillin, trimethoprim-sulfamethoxazole, and chloramphenicol. XDR *S.* Typhi is not only resistant to ampicillin, trimethoprim-sulfamethoxazole, and chloramphenicol but also resistant to third-generation cephalosporins and quinolones. Gene sequencing, including one innovative study using clinical isolates from children with *S.* Typhi septicemia, found the phenotype of the XDR *S.* Typhi isolates matches with their genotypes, featured by the acquisitions of the genes bla_{TEM1}, dhfR7, sul1, catA1, qnrS, and $bla_{CTX\text{-}M\text{-}15}$ and a point mutation on gyrA.

XDR *S.* Typhi cases were first noted by Pakistani health authorities in 2016, originating in Hyderabad, Sindh. By 2018, international transmission of XDR *S.* Typhi cases had been noted. In 2019 and 2020, XDR *S.* Typhi was recovered from patients in the United States, both with and *without* a travel history. Patients without a travel history lived in six widely distributed states and did not appear to be linked or have a common source of infection. An unrelated cluster of ceftriaxone-resistant Typhi infections linked to Iraq has also been reported in the United States and the United Kingdom.

Taken together, this information led to an official CDC Health Advisory in 2021 suggesting the need for empiric carbapenem, azithromycin, or both for patients in the United States with suspected typhoid fever who traveled to Pakistan or Iraq, as well as those who had *not* traveled from the United States. Patients with severe or complicated illness should receive a carbapenem, such as meropenem. Case reports have suggested that patients who do not improve on a carbapenem alone may benefit from the addition of a second antibiotic such as azithromycin. Patients with uncomplicated illness may be treated with oral azithromycin alone. By contrast, for patients in the United States who traveled to countries other than Pakistan or Iraq, ceftriaxone *may* still be effective.

In the United States, resistance to meropenem (a carbapenem) or azithromycin was not reported during 2017–2021. By contrast, roughly 80% of Typhi strains isolated in the United States now are resistant or have decreased susceptibility to quinolones, including ciprofloxacin.

New MDR and XDR strains illustrate the profound importance of recognizing what antimicrobials will likely *not* work. Meanwhile, an encouraging relative reduction in the proportion of MDR strains in some areas of Asia means some patients with susceptible *S.* Typhi infections can be treated with agents recently considered ineffective. Namely, in some highly endemic regions of South and Southeast Asia,

strains susceptible to amoxicillin or trimethoprim-sulfamethoxazole are increasingly common.

The optimal duration of antimicrobial therapy is unclear, but most agents are suggested for at least 10-14 days, with longer courses for amoxicillin or trimethoprim-sulfamethoxazole, 21 days for chloramphenicol, and as little as 7 days for azithromycin. Relapse rates can occur in almost 20% of patients within 4 weeks, especially in immunocompromised patients.

In addition to antimicrobials, supportive treatment and maintenance of appropriate fluid and electrolyte balance are important. Although additional treatment with dexamethasone (3 mg/kg initial dose, followed by 1 mg/kg every 6 hours for 48 hours) is recommended by some for severely ill patients with shock, obtundation, stupor, or coma, corticosteroids should be administered only under strict supervision, because their use may mask signs of abdominal complications.

PROGNOSIS

The prognosis for a patient with enteric fever depends on the rapidity of diagnosis and institution of appropriate antibacterial therapy. Other factors are patient age, underlying health and nutrition, the causative *Salmonella* serotype, and the appearance of complications. Infants and children with underlying malnutrition and infections with resistant isolates are at higher risk of adverse outcomes.

Despite appropriate therapy, 2–4% of infected children may experience relapse. Individuals who excrete *S.* Typhi more than 3 months after infection are regarded as chronic carriers. A chronic urinary carrier state can develop in children with schistosomiasis.

PREVENTION

Of the major risk factors for outbreaks of typhoid fever, contamination of water supplies with sewage is most important. Other risk factors are contact with another acutely infected individual or a chronic carrier and lack of water or sanitation services. During outbreaks, central chlorination and domestic water purification are important. In endemic situations, consumption of street foods, especially ice cream and cut fruit, is recognized as an important risk factor. Human-to-human spread by chronic carriers is also important, and attempts should be made to target food handlers and high-risk groups for *S.* Typhi carriage screening. Chronic carriers can be counseled as to the risk for disease transmission and the importance of handwashing.

In the United States, two vaccines have been licensed by the FDA. Systematic review and meta-analysis of randomized controlled clinical trials estimate the cumulative efficacy of these two vaccines as only roughly 50%. The Ty21a **live attenuated vaccine** can be used in people 6 years and older. It is administered orally, every other day, for a total of four doses to be completed at least 1 week before potential exposure; booster frequency is every 5 years. The Ty21a vaccine induces both cell-mediated and humoral immune responses against *S.* Typhi. It also may provide some protection against *S.* Paratyphi B. The **unconjugated** Vi capsular polysaccharide vaccine can be used in people 2 years and older. It is administered intramuscularly in a single dose to be administered at least 2 weeks before potential exposure; booster frequency is every 2 years. This unconjugated vaccine induces a **T-cell–independent humoral immune response** with lack of prolonged protection.

Conjugated vaccines have been recommended, developed, and now deployed by the WHO. By covalently conjugating the Vi capsular polysaccharide to carrier proteins, conjugate vaccines can induce a **T-cell–dependent humoral immune response**, even in young children. Conjugated typhoid vaccines are under development, using a variety of carrier proteins, including tetanus toxoid, Exoprotein A from *Pseudomonas,* and diphtheria toxoid. The WHO has recommended the introduction of a single-dose typhoid conjugate vaccine for infants and children age 6 months and older. A large study of the Typbar-TCV conjugate vaccine in Hyderabad, Pakistan, found vaccine effectiveness was 55% against suspected typhoid fever and 95% against blood culture–confirmed *S.* Typhi. The vaccine was also 97% effective against XDR *S.* Typhi. In 2019, a historic milestone was successfully achieved in Pakistan with the vaccination in Sindh province of more than 9.4 million children age from 9 months to 15 years against typhoid fever, with a coverage rate of 95%. Pakistan is the first country in the world to introduce the WHO-recommended typhoid conjugate vaccine (TCV) into its routine immunization program.

Chapter 245

Shigella

Patrick C. Seed

Shigellosis, infection by *Shigella* species, is acute invasive enteric infection clinically manifested by diarrhea that is often bloody. The term **dysentery** describes a syndrome of bloody diarrhea with fever, abdominal cramps, rectal pain, and mucoid stools. **Bacillary dysentery** is a term often used to distinguish dysentery caused by *Shigella* from amebic dysentery caused by *Entamoeba histolytica*.

ETIOLOGY

Four species of *Shigella* cause the disease shigellosis: *Shigella dysenteriae* (group A), *Shigella flexneri* (group B), *Shigella boydii* (group C), and *Shigella sonnei* (group D). Serotypes 15, 19, 19, and 1 in groups A-D, respectively, further distinguish the species. Species and group distributions vary geographically and by antimicrobial susceptibility.

EPIDEMIOLOGY

The World Health Organization (WHO) estimates that 80-165 million cases of shigellosis occur each year worldwide, resulting in 600,000 deaths annually. *Shigella* spp. are endemic to temperate and tropical climates and are most common in countries and regions with inadequate public health sanitation and hygiene. In the U.S. Foodborne Disease Active Surveillance Network **(FoodNet)**, *Shigella* remains the third most important pathogen. In 2020, the top three diarrheagenic pathogens, *Campylobacter, Salmonella,* and *Shigella,* had laboratory-confirmed incidence rates (cases per 100,000 population) of 14.35, 13.33, and 3.05, respectively. Although infection can occur at any age, children younger than 10 years, identified as Black and of Hispanic ethnicity, have the highest incidence rates. Males have an approximately 2.7-fold higher incidence than females. Upwards of 30% of children with shigellosis are hospitalized. Death resulting from shigellosis is rare among children (<0.1%). Infection in the first 6 months of life is rare. Breast milk from women living in endemic areas contains antibodies to both virulence plasmid-encoded antigens and lipopolysaccharides, and breastfeeding might partially explain the age-related incidence.

Asymptomatic infection of children and adults occurs frequently in endemic areas. In cases of *Shigella* dysentery, up to 75% of family member contacts may have asymptomatic infection. Infection with *Shigella* occurs most often during the warm months in temperate climates and during the rainy season in tropical climates. In industrialized societies, up to 50% of locally diagnosed cases are associated with international travel; the highest-risk travel designation is Africa, followed by Central America, South America, and parts of Asia. In recent years in the United States, travel to Haiti, the Dominican Republic, or India has been associated with acquisition of antibiotic-resistant (fluoroquinolone) *S. sonnei* infections. Additional risk factors include men who have sex with men (MSM), including recent U.S. outbreaks of azithromycin-resistant *S. sonnei* infections among affected individuals in the Midwest.

In developed countries, *S. sonnei* is the most common cause and *S. flexneri* is the second most common cause of bacillary dysentery; in preindustrial societies, *S. flexneri* is most common and *S. sonnei* second

in frequency. *S. boydii* is found primarily in India. *S. dysenteriae* serotype 1 tends to occur in massive epidemics but is also endemic in Asia and Africa, where it is associated with high mortality rates (5–15%). The epidemiologic transition has favored the emergence of *S. sonnei* as the dominant serogroup in some countries, although the reason for this epidemiologic shift is not clear.

Contaminated food (often a salad or other item requiring extensive handling of the ingredients) and water are important vectors. Exposure to both contaminated freshwater and contaminated salt water is a risk factor for infection. Rapid spread within families, custodial institutions, and childcare centers demonstrates the ability of *Shigella* to be transmitted from one individual to the next and the requirement for ingestion of very few organisms to cause illness. Human challenge studies have demonstrated the high infectivity and low infectious dose for *Shigella* spp. Ten bacteria of the species *S. sonnei* and *S. dysenteriae* can cause dysentery. In contrast, ingestion of 10^8-10^{10} *Vibrio cholerae* is necessary to cause cholera.

PATHOGENESIS

Shigella has specialized mechanisms to survive the low gastric pH. Shigella survives the acid environment in the stomach and moves through the gut to the colon, its target organ. *Shigella* spp. use a coordinated, temperature-controlled program to hijack and invade colonic epithelial cells. A large (220 kb) plasmid encodes a group of polypeptides involved in cell invasion and killing, and loss of the plasmid attenuates virulence. **Enteroinvasive** *Escherichia coli* (EIEC) that harbor a closely related plasmid containing these invasion genes behave clinically similar to *Shigellae* (see Chapter 246). The virulence plasmid encodes a type III secretion system required to trigger entry into epithelial cells and apoptosis in macrophages. This secretion system translocates effector molecules from the bacterial cytoplasm to the membrane and cytoplasm of target host cells through a needle-like appendage. The **type III secretion system** is composed of approximately 50 proteins, including the Mxi and Spa proteins involved in assembly and regulation of the type III secretion system, chaperones (IpgA, IpgC, IpgE, and Spa15), transcription activators (VirF, VirB, and MxiE), translocators (IpaB, IpaC, and IpaD), and approximately 30 effector proteins. In addition to the major plasmid-encoded virulence traits, chromosomally encoded factors are required for full virulence.

Shigellosis mostly affects the distal colon, although pancolitis can occur. *Shigella* spp. traverse the colonic epithelium through M cells in the follicle-associated epithelium overlying the Peyer patches. Localized or diffuse mucosal edema, ulcerations, friable mucosa, bleeding, and exudate may occur. Microscopically, ulcerations, pseudomembranes, epithelial cell death, infiltration extending from the mucosa to the muscularis mucosae by polymorphonuclear leukocytes (PMNs) and mononuclear cells, and submucosal edema occur.

After *Shigella* transcytosis through M cells, it encounters resident macrophages and subverts macrophage killing by activating the inflammasome and inducing pyroptosis, apoptosis, and proinflammatory signaling. Free bacteria invade the epithelial cells from the basolateral side, move into the cytoplasm by actin polymerization, and spread to adjacent cells. Proinflammatory signaling by macrophages and epithelial cells further activates the innate immune response involving natural killer cells and attracts PMNs. The influx of PMNs disintegrates the epithelial cell lining, which initially exacerbates the infection and tissue destruction by facilitating the invasion of more bacteria. Ultimately, PMNs phagocytose and kill *Shigella,* thus contributing to the resolution of the infection.

Some *Shigella* spp. produce toxins, including Shiga toxin and enterotoxins. **Shiga toxin** is a potent exotoxin that inhibits protein synthesis. It is produced in significant amounts by *S. dysenteriae* serotype 1, by a subset of *E. coli* known as **enterohemorrhagic** *E. coli* (EHEC) or Shiga toxin–producing *E. coli,* and occasionally by other *Shigella* spp. Shiga toxin inhibits protein synthesis to injure vascular endothelial cells and trigger the severe complication of hemolytic-uremic syndrome (see Chapter 246). Targeted deletion of the genes for other enterotoxins (*ShET1* and *ShET2*) decreases the incidence of fever and dysentery in human challenge studies. Lipopolysaccharides are virulence factors for all *Shigellae;* other traits are important for only a few serotypes (e.g., Shiga toxin synthesis by *S. dysenteriae* serotype 1 and *ShET1* by *S. flexneri* 2a).

IMMUNITY

In symptomatic infection, *Shigella* activates an intense innate immune response through triggering extracellular and intracellular pathogen recognition systems. The induction of acute inflammation with a massive recruitment of PMNs produces intensive local tissue destruction. In rectal biopsies of infected patients, acute-phase proinflammatory cytokines are induced, including interleukin (IL)-1β, IL-6, IL-8, tumor necrosis factor (TNF)-α, and TNF-β. Concurrently, antiinflammatory genes encoding IL-10 and transforming growth factor-β are also upregulated to mitigate uncontrolled inflammation. Furthermore, interferon-γ expression is induced during human infection and is required to limit *Shigella* invasion in intestinal epithelial cells and macrophages. *Shigella*-specific immunity elicited upon natural infection is characterized by the induction of a humoral response. Local secretory immunoglobulin A (IgA) and serum IgG are produced against lipopolysaccharide and some protein effectors (Ipas). Protection is thought to be serotype specific. Natural protective immunity arises only after several episodes of infection, is of short duration, and seems to be effective in limiting reinfection, particularly in young children. However, children have delayed and reduced antigen-specific antibody-secreting cells with late and reduced mucosa IgA production against *Shigella*. Less effective adaptive immunity may put children at more risk for increased disease severity, mortality, and recurrences.

CLINICAL MANIFESTATIONS AND COMPLICATIONS

Shigella spp. produce intraintestinal and extraintestinal symptoms. *Bacillary dysentery is clinically similar regardless of infecting serotype or species,* but different species produce illnesses with different severity and risk for mortality, with *S. dysenteriae* type 1 most likely to produce any single manifestation and with greater severity. Ingestion of *Shigellae* is followed by an incubation period of 12 hours to several days before symptoms ensue. Severe abdominal pain, emesis, anorexia, generalized toxicity, urgency, and painful defecation characteristically occur (Table 245.1). *The typically high **fever** with shigellosis distinguishes it from EHEC.* The **diarrhea** may be watery and large volume initially, evolving into frequent, small-volume, bloody, mucoid stools. Most children never progress to the stage of bloody diarrhea, but some have bloody stools from the outset. Significant dehydration is related to the fluid and electrolyte losses in stool and emesis. Untreated diarrhea can last 7-10 days; only approximately 10% of patients have diarrhea persisting for >10 days. Persistent diarrhea occurs in malnourished infants, children with AIDS, and occasionally previously normal children. Even nondysenteric disease can be complicated by persistent illness. Physical examination initially shows abdominal distention and tenderness, hyperactive bowel sounds, and a tender rectum on digital examination. **Rectal prolapse** may be present, particularly in malnourished children.

Neurologic findings are among the most common extraintestinal manifestations of bacillary dysentery, occurring in as many as 40% of hospitalized children. EIEC can cause similar neurologic toxicity. Convulsions, headache, lethargy, confusion, nuchal rigidity, or hallucinations may be present before or after the onset of diarrhea. Animal models suggest Shiga toxins activate brain endothelial cells and microglia and increase neurotransmitter levels. However, infections with Shiga toxin–positive and –negative strains can lead to neurologic features. **Seizures** sometimes occur when little fever is present, suggesting that simple febrile convulsions do not explain their appearance. Hypocalcemia or hyponatremia may be associated with seizures in a small number of patients. Although symptoms often suggest central nervous system infection, and cerebrospinal fluid pleocytosis with minimally elevated protein levels can occur, meningitis caused by *Shigellae* is rare. Based on animal studies, it has been suggested that proinflammatory mediators, including TNF-α and IL-1β, nitric oxide, and corticotropin-releasing hormone, play a role in the enhanced susceptibility to *Shigella*-mediated seizures and encephalopathy.

The most common complication of shigellosis is **dehydration** (Table 245.2). Inappropriate secretion of antidiuretic hormone with profound hyponatremia can complicate dysentery, particularly when *S. dysenteriae* is the etiologic agent. Hypoglycemia and protein-losing enteropathy are common and are decreased by early appropriate antibiotic therapy. Severe protein-losing enteropathy is associated with prolonged illness and linear growth shortfalls. **Bacteremia** is uncommon except in girls or women infected with HIV, malnourished children, young infants, and children with *S. dysenteriae* serotype 1 infection. When bacteremia occurs with dysentery (<5%), it is as likely to be caused by other enteric bacteria as by *Shigella* itself. The presence of *E. coli, Klebsiella,* and other enteric bacteria in blood cultures of children with shigellosis may reflect the loss of the barrier function during severe colitis. The mortality rate is high (approximately 20%) when sepsis occurs, with a greater likelihood of occurrence in HIV-infected persons. Other major complications include **disseminated intravascular coagulation** (DIC), particularly in very young, malnourished children. Despite the extent to which the intestinal epithelial barrier is lost, bacteremia and DIC are uncommon.

Neonatal shigellosis is rare, particularly among exclusively breastfed infants. Neonates may have only low-grade fever with mild, nonbloody diarrhea. However, complications occur more often in neonates than in older children and include septicemia, meningitis, dehydration, colonic perforation, and toxic megacolon.

Hemolysis, anemia, and **hemolytic-uremic syndrome** (HUS) frequently complicate *S. dysenteriae* serotype 1 infection. HUS is caused by Shiga toxin–mediated vascular endothelial injury. Shiga toxin–producing non-*dysenteriae Shigella* and *E. coli* that produce Shiga toxins (e.g., *E. coli* O157:H7, *E. coli* O111:NM, *E. coli* O26:H11, and less often, many other serotypes) also cause HUS (see Chapter 560.5).

Rectal prolapse, toxic megacolon or pseudomembranous colitis (usually associated with *S. dysenteriae*), cholestatic hepatitis, conjunctivitis, iritis, corneal ulcers, pneumonia, arthritis (usually 2-5 weeks after enteritis), reactive arthritis, cystitis, myocarditis, and vaginitis (typically with blood-tinged discharge associated with *S. flexneri*) are uncommon events. Although rare, surgical complications of shigellosis can be severe; the most common are intestinal obstruction and appendicitis with and without perforation.

On average, the severity of illness and risk of death are least with disease caused by *S. sonnei* and greatest with infection by *S. dysenteriae* type 1. Risk groups for severe illness and poor outcomes include infants; children who are not breastfed; children with HIV; children recovering from measles; malnourished children and adults; adults >50 years old; and patients with dehydration, unconsciousness, hypothermia or hyperthermia, hyponatremia, or lesser stool frequency who have a history of convulsions when first seen. Death is a rare outcome in well-nourished older children. Multiple factors contribute to death in malnourished children with shigellosis, including illness in the first year of life, altered consciousness, dehydration, hypothermia, thrombocytopenia, anemia, hyponatremia, renal failure, hyperkalemia, hypoglycemia, bronchopneumonia, and bacteremia.

The rare shigellosis-associated Ekiri syndrome, or "lethal toxic encephalopathy," constitutes severe toxicity, convulsions, extreme hyperpyrexia, and headache, followed by brain edema and a rapidly fatal outcome without sepsis or significant dehydration.

DIFFERENTIAL DIAGNOSIS

Although clinical features suggest shigellosis, they usually are insufficiently specific to allow confident diagnosis. Infection by *Campylobacter jejuni, Salmonella* spp., EIEC, Shiga toxin–producing *E. coli* (EHEC, e.g., *E. coli* O157:H7), *Yersinia enterocolitica, Clostridioides difficile,* and *Entamoeba histolytica,* as well as inflammatory bowel disease, produce overlapping features and may challenge the clinician.

DIAGNOSIS

Presumptive data supporting a diagnosis of bacillary dysentery include the finding of fecal leukocytes (usually >50 or 100 PMNs per high-power field, confirming the presence of colitis), fecal blood, and

Table 245.2 Clinical Complications of Shigellosis

INTESTINAL COMPLICATIONS
Rectal prolapse*
Toxic megacolon
Intestinal perforation
Intestinal obstruction
Appendicitis
Persistent diarrhea
EXTRAINTESTINAL COMPLICATIONS
Dehydration
Severe hyponatremia (serum sodium <126 mmol/L)*
Hypoglycemia
Focal infections (e.g., meningitis, osteomyelitis, arthritis, splenic abscesses, vaginitis)
Sepsis, usually in malnourished or immunocompromised persons
Seizure or encephalopathy
Leukemoid reaction (peripheral leukocytes >40000/μL)*
POSTINFECTIOUS MANIFESTATIONS
Hemolytic-uremic syndrome (HUS)*
Reactive arthritis†
Irritable bowel syndrome (IBS)‡
Malnutrition

*Significantly more common in episodes with *Shigella dysenteriae* type 1 than with all other *Shigella* spp. among Bangladeshi children younger than 15 yr during the 1990s (rectal prolapse [52% vs 15%], severe hyponatremia [58% vs 26%], leukemoid reaction [22% vs 2%], and HUS [8% vs 1%]).

†Typical acute symptoms include asymmetric oligoarthritis (usually lower limb), enthesitis, dactylitis, and back pain. Extraarticular manifestations include conjunctivitis and uveitis; urethritis and other genitourinary tract manifestations; oral, skin, and nail lesions; and rarely, cardiac abnormalities.

‡IBS follows approximately 4% of *Shigella* episodes in studies from high-resource settings.

demonstration in peripheral blood of leukocytosis with a dramatic left shift (often with more bands than mature segmented neutrophils). The total peripheral white blood cell count is usually 5,000-15,000 cells/μL, although leukopenia and leukemoid reactions occur.

Culture of both stool and rectal swab specimens optimizes the chance of diagnosing *Shigella* infection. Culture media should include MacConkey agar and selective media such as xylose-lysine-deoxycholate and *Salmonella-Shigella* agar. Transport media should be used if specimens cannot be cultured promptly. Appropriate media should be used to exclude *Campylobacter* and *Salmonella* spp. and other agents. Studies of outbreaks and illness in volunteers show that the laboratory is often not able to confirm the clinical suspicion of shigellosis even when the pathogen is present. Multiple fecal cultures improve the yield of *Shigella*.

Culture-based diagnosis of *Shigella* infection, as with other enteric infections, is being displaced by molecular methods, often multiplexed, allowing testing for a panel of potential agents in a single rapid assay. Studies using molecular methods such as polymerase chain reaction (PCR) suggest that culture significantly underestimates the true frequency of infection. Quantitative PCR improves the ascertainment of *Shigella* burden in children with moderate to severe diarrhea in low-income countries. The generally **high negative predictive value** (NPV) of many molecular tests for *Shigella* (generally >95–97%) make the tests useful for decisions regarding antibiotic use and discontinuation and the necessity to test for additional etiologies of diarrhea. Molecular testing provides no information about antibiotic susceptibility. Stool cultures should be considered where antibiotic-resistant organisms are prevalent. In children who appear toxic, blood cultures should be obtained, especially in very young or malnourished infants, because of their increased risk of bacteremia.

TREATMENT

As with gastroenteritis from other causes, the first concern in a child with suspected shigellosis should be for fluid and electrolyte correction and maintenance (see Chapter 387). Drugs that impair intestinal motility (e.g., diphenoxylate hydrochloride with atropine [Lomotil] or loperamide [Imodium]) should not be used because of the risk of more severe and prolonged illness.

Nutrition is a key concern in areas where malnutrition is common. A high-protein and high-caloric diet during convalescence enhances growth in 6 months after infection. Controlled studies show that cooked green bananas, a food rich in amylase-resistant starches, significantly improves outcome in severe disease. A single large dose of **vitamin A** (200,000 IU) lessens the severity of shigellosis in settings where vitamin A deficiency is common. **Zinc** supplementation (20 mg elemental zinc for 14 days) significantly decreases the duration of diarrhea, improves weight gain during recovery, enhances adaptive immunity to *Shigellae,* and decreases diarrheal disease in malnourished children.

The decision to use **antibiotics** remains challenging (Fig. 245.1). Many experts recommend withholding antibacterial therapy because of the self-limited nature of the infection, the cost of drugs, the risk of emergence of resistant organisms, the risk of prolonging carriage (if *Salmonella* is present), or increasing the risk for HUS (EHEC). When a rapid multiplexed molecular stool pathogen detection test is available, waiting for a definitive diagnosis before administrating antibiotics should be considered. However, a counter-argument of empirical treatment for all children with suspected shigellosis has validity. Untreated illness can cause a child to have prolonged illness; chronic or recurrent diarrhea can ensue. Malnutrition can develop or worsen during prolonged illness, particularly in children in developing countries. The risk of continued excretion and subsequent infection of family contacts further argues against the strategy of withholding antibiotics.

Shigella antimicrobial susceptibility varies by species and geography. In the United States, strains are frequently resistant to ampicillin (74%) and trimethoprim-sulfamethoxazole (TMP-SMX) (36%). In general, the proportion of antibiotic-resistant isolates is lower in North America and Europe than in Asia or Africa. Previously, *Shigella* was widely regarded as susceptible in vitro to azithromycin, ceftriaxone, cefotaxime, cefixime, nalidixic acid, and quinolones. However, the Centers for Disease Control and Prevention (CDC) reports that 87% of *S. sonnei*–related U.S. cases are ciprofloxacin nonsusceptible, of which only approximately half followed international travel. Among MSM, clusters of shigellosis caused by *S. sonnei* and, to a lesser extent, *S. flexneri* were reported with up to 87% azithromycin resistance. International travel increases the risk for antibiotic-resistant infection. For example, Chinese isolates of *S. sonnei* are often resistant to TMP-SMX (94.5%), ampicillin (40.3%), piperacillin (36.5%), and ceftriaxone (12.8%).

Currently, in most developed and resource-poor countries, *Shigella* strains are often resistant to ampicillin and TMP-SMX. Therefore these drugs should not be used for empirical treatment of suspected shigellosis; they should be instituted only if the strain is known to be susceptible (e.g., in an outbreak caused by a defined strain). Empirical therapy in children with dysentery should be given based on considerations of regional infection cluster data and international travel history. **Ceftriaxone** (50-100 mg/kg/24 hr as a single daily dose intravenously or intramuscularly) can be used for empirical therapy, especially for small infants. The oral third-generation cephalosporin **cefixime** (8 mg/kg/24 hr divided every 12-24 hours) may be considered, although treatment failures for *S. sonnei* infections have been reported in adults; oral first- and second-generation cephalosporins are inadequate as alternative drugs despite in vitro susceptibility. **Azithromycin** (12 mg/kg/24 hr orally for the first day, followed by 6 mg/kg/24 hr for the next 4 days) has proved to be an effective alternative drug for shigellosis. **Ciprofloxacin** (20-30 mg/kg/24 hr divided into two doses) is the drug of choice recommended by the WHO for all patients with bloody diarrhea, regardless of age. Note that since 2015, the CDC has tracked increasing resistance and reduced susceptibility to ciprofloxacin and azithromycin in the United States. Concurrent zinc supplementation is recommended with antibiotic therapy.

Although **quinolones** are reported to cause arthropathy in immature animals and are associated with neuropathy, these risks are low in children and are outweighed by the value of these drugs for the treatment of this potentially life-threatening disease. However, some experts recommend that the quinolones be reserved for seriously ill children with bacillary dysentery caused by an organism suspected or known to be resistant to other agents, because overuse of quinolones promotes the development of resistance to these drugs.

Treatment of patients in whom *Shigella* infection is suspected on clinical grounds should be initiated when these patients are first evaluated. Molecular stool testing or culture is obtained to exclude other pathogens and, in the case of culture, to assist in antibiotic changes should a child fail to respond to empirical therapy. A child who has typical dysentery and who responds to initial empirical antibiotic treatment should be continued on that drug for a full 5-day course even if the stool culture is negative, because of the method's low NPV. The logic of this recommendation is based on the proven difficulty of culturing *Shigella* from stools of ill patients during adult volunteer infection studies. In a child who fails to respond to therapy of a dysenteric syndrome in the presence of initially negative stool culture results, additional cultures should be obtained, or molecular testing, where available and cost-permissive, should be performed, and the child should be reevaluated for other possible diagnoses. In the child with negative molecular stool testing for *Shigellae,* the high NPV makes the diagnosis less likely, and alternative diagnoses should be considered.

PREVENTION

Numerous measures have been recommended to decrease the risk of *Shigella* transmission to children. Mothers should be encouraged to *prolong breastfeeding* of infants. Families and daycare personnel

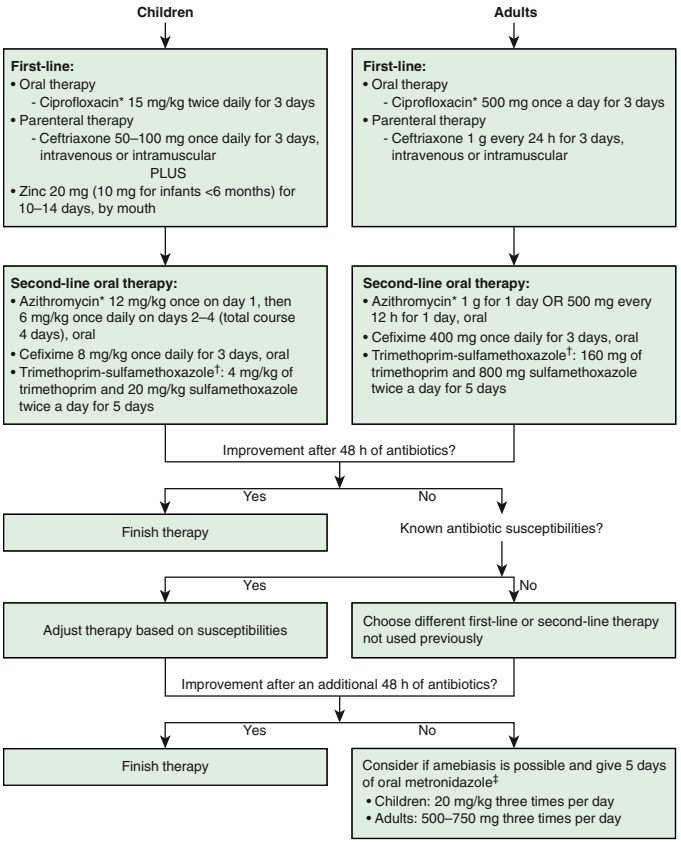

Fig. 245.1 Management algorithm: guidelines for treatment of shigellosis. Empirical therapy should be directed by hospital, clinical laboratory, or public health antibiograms whenever possible. Minimal inhibitory concentrations of 0.12-1.0 μg/mL for ciprofloxacin might be considered susceptible by laboratory standards but could harbor resistance genes known to confer decreased susceptibility. *Fluoroquinolones and azithromycin should be used with caution in patients taking the antimalarial artemether, because these drugs can prolong the QT interval on the electrocardiogram and trigger arrhythmias. †Trimethoprim-sulfamethoxazole should be used if susceptibility is known or expected based on local data. ‡Per WHO recommendations. Another acceptable regimen is a 7- to 10-day course of metronidazole followed by a luminal agent such as paromomycin or diiodohydroxyquinoline. *(Data from The selection and use of essential medicines: report of the WHO Expert Committee, 2017. Geneva: World Health Organization; 2017. WHO technical report series; no. 1006.)*

should be educated in *proper handwashing* techniques and encouraged to wash hands after using the toilet, changing diapers, or engaging in preparation of foods. They should be taught how to manage potentially contaminated materials such as raw vegetables, soiled diapers, and diaper-changing areas. Children with diarrhea should be excluded from childcare facilities. Children should be supervised when handwashing after they use the toilet. Caretakers should be informed of the risk of transmission if they prepare food when they are ill with diarrhea. Families should be educated regarding the danger of swallowing contaminated water from ponds, lakes, or untreated pools. In developing countries, a safe water supply and appropriate sanitation systems are important measures for reducing the risk for shigellosis. There is not yet a vaccine that is effective for preventing infection by *Shigella*. **Measles immunization** can substantially reduce the incidence and severity of diarrheal diseases, including shigellosis. Every infant should be immunized against measles at the recommended age.

Chapter 246

Escherichia coli

Patrick C. Seed

Escherichia coli is an important cause of intraintestinal and extraintestinal infections. **Intraintestinal infections** present as diarrheal illnesses. **Extraintestinal infections** include disease of the urinary tract (see Chapter 575), bloodstream (Chapters 148, 220, and 221), and central nervous system (Chapter 643). *E. coli* causing extraintestinal and intraintestinal infections carry unique genetic attributes that encode different sets of virulence factors and genetic programs. Extraintestinal pathogenic *E. coli* increasingly harbor multidrug resistances, including transferrable plasmids resulting in extended-spectrum β-lactamase (ESBL) production and resistance to penicillins, cephalosporins, and aztreonam. Carbapenemase-bearing *E. coli* have also emerged, often in combination with multi–antibiotic class resistance, resulting in highly drug-resistant strains.

E. coli are members of the Enterobacteriaceae family and are facultative anaerobic, gram-negative bacilli that usually ferment lactose. Most fecal *E. coli* organisms are commensal, are ubiquitous among the human gut microbiota starting in the first month of life, and do not cause diarrhea. Six major groups of **diarrheagenic** *E. coli* pathotypes have been characterized based on clinical, biochemical, and molecular-genetic features: enterotoxigenic *E. coli* (ETEC); enteroinvasive *E. coli* (EIEC); enteropathogenic *E. coli* (EPEC); *Shiga* toxin–producing *E. coli* (STEC), also known as enterohemorrhagic *E. coli* (EHEC) or verotoxin-producing *E. coli* (VTEC); enteroaggregative *E. coli* (EAEC or EggEC); and diffusely adherent *E. coli* (DAEC).

E. coli strains can also be categorized by their serogroup, where *O* refers to the lipopolysaccharide (LPS) O-antigen or serotype and *H* refers to the flagellar antigen, for example, *E. coli* O157:H7. However, because each pathotype contains many serotypes (e.g., 117 ETEC serotypes have been identified) and some serotypes can belong to more than one pathotype (e.g., O26:H11 can be either EPEC or EHEC depending on which specific virulence genes are present), serotyping usually does not provide definitive identification of pathotypes.

Virulence characteristics and the association of those traits with illness define **enteric** *E. coli* pathogenicity (Table 246.1). The mechanism by which *E. coli* produces **diarrhea** typically involves specific adherence to a glycoprotein or glycolipid receptor on a target intestinal cell, followed by production of a factor that injures or disturbs the function of intestinal cells. The genes for virulence properties and antibiotic resistance are often carried on transferable plasmids, pathogenicity islands, or bacteriophages.

In the developing world, diarrheagenic *E. coli* cause frequent infections in the first years of life and are responsible for 30–40% of all diarrhea cases in children worldwide. Cases peak during the warm months in temperate climates and during rainy season months in tropical climates. Most diarrheagenic *E. coli* strains (except STEC) require a large inoculum of organisms to induce disease, thus necessitating exposure to grossly contaminated ingestible materials. Infection is most likely when food-handling or sewage-disposal practices are suboptimal. The diarrheagenic *E. coli* pathotypes are also important in North America and Europe, although their epidemiology is less well defined in these areas than in the developing world. In North America, the various diarrheagenic *E. coli* strains may cause as much as 30% of infectious diarrhea in children <5 years old.

A significant proportion of asymptomatic healthy children living in developing countries carry diarrheagenic *E. coli* pathotypes. **Fecal contamination** (human and animal), which is common in the low-resource environments, facilitates the transmission of pathogens. Modern, highly sensitive microbiologic methods enhance the sensitivity

Table 246.1 Clinical Characteristics, Pathogenesis, and Diagnosis of Diarrheagenic *E. coli*

PATHOGEN	POPULATIONS AT RISK	CHARACTERISTICS OF DIARRHEA			MAIN VIRULENCE FACTORS		DIAGNOSIS
		WATERY	BLOODY	DURATION	ADHERENCE FACTORS	TOXINS	
ETEC	>1 yr old and travelers	+++	–	Acute	Colonization factor antigens (CFs or CFAs); ECP	Heat-labile enterotoxin (LT) Heat-stable enterotoxin (ST)	Detection of enterotoxins (LT and ST) by enzyme immunoassays or PCR *(lt, st)*
EIEC	>1 yr old	+	++	Acute	Invasion plasmid antigen (IpaA-D)		Detection of invasion plasmid antigen of *Shigella (ipaH)* by PCR
EPEC	<2 yr old	+++	+	Acute, prolonged or persistent	A/E lesion, intimin/Tir, EspABD, Bfp	EspF, Map, EAST1, SPATEs *(EspC)*	Detection of intimin gene *(eae)* ± bundle-forming pili (*bfp*A) by PCR and absence of *Shiga* toxins; HEp-2 cells adherence assay (LA, LLA)
STEC (EHEC/ VTEC)	6 mo to 10 yr and elderly persons	+	+++	Acute	A/E lesion, intimin/Tir, EspABD	*Shiga* toxins (Stx1, Stx2, and variants of Stx2)	Detection of *Shiga* toxins by enzyme immunoassays or PCR *(Stx1, Stx2)*; stool culture on MacConkey-sorbitol media to detect *E. coli* O157. Simultaneous culture for O157 and nonculture assays to detect *Shiga* toxins
EAEC	<2 yr old, HIV-infected patients, and travelers	+++	+	Acute, prolonged, or persistent	Aggregative adherence fimbriae (AAF)	SPATEs (Pic, Pet), ShET1, EAST1	Detection of *AggR*, AA plasmid, and other virulence genes: *aap, aatA, astA, set1A* by PCR; HEp-2 cells adherence assay (AA)
DAEC	>1 yr old and travelers	++	–	Acute	Afa/Dr, AIDA-I	SPATEs (Sat)	Detection of Dr adhesins (daaC or daaD) and Dr-associated genes by PCR; HEp-2 cells adherence assay (DA)

–, Not present; +, present; ++, common; +++, very common; A/E lesion, attaching and effacing lesion; AA, aggregative adherence; Bfp, bundle-forming pili; DA, diffuse adherence; DAEC, diffusely adherent *E. coli;* EAEC, enteroaggregative *E. coli;* EAST1, enteroaggregative heat-stable toxin; ECP, *E. coli* common pilus; EHEC, enterohemorrhagic *E. coli;* EIEC, enteroinvasive *E. coli;* EPEC, enteropathogenic *E. coli*; EspABD, *E. coli*–secreted proteins A, B, and D; ETEC, enterotoxigenic *E. coli;* LA, localized adherence; LLA, localized-like adherence; PCR, polymerase chain reaction; ShET1, *Shigella* enterotoxin 1; SPATEs, serine-protease autotransporter of Enterobacteriaceae; STEC, *Shiga* toxin–producing *E. coli*; Tir, translocated intimin receptor; VTEC, verotoxin-producing *E. coli*.

of detection in stool samples, and small numbers of bacteria can be detected in stool samples. Therefore the prevalence of various enteropathogens in children with and without diarrhea must be considered. Excretion of enteropathogens by children without diarrhea may be explained by characteristics of the pathogens (virulence heterogeneity), the host (host susceptibility, age, nutritional status, breastfeeding, immunity), and environmental factors (inoculum size).

ENTEROTOXIGENIC *ESCHERICHIA COLI*

ETEC accounts for a sizable fraction of dehydrating infantile diarrhea in the developing world (10–30%) and of **traveler's diarrhea** (20–60% of cases); ETEC is the most common cause of traveler's diarrhea. The Global Enteric Multicenter Study (GEMS) found heat-*stable* enterotoxin (ST)–expressing ETEC (with or without coexpression of *heat-labile* enterotoxin [LT]) to be a leading cause of diarrhea and increased risk for death in young children in developing countries of Asia and Africa. The typical signs and symptoms include explosive watery, nonmucoid, nonbloody diarrhea; abdominal pain; nausea; vomiting; and little or no fever. The illness is usually self-limited and resolves in 3-5 days but occasionally lasts >1 week.

Diarrhea follows ETEC colonization of the small intestine and elaboration of enterotoxin; however, ETEC causes few to no structural alterations in the gut mucosa. ETEC strains secrete one or two enterotoxins. LT, a large molecule consisting of five receptor-binding subunits

and one enzymatically active subunit, is structurally, functionally, and neutralizing antibody cross-reactive with cholera toxin produced by *Vibrio cholerae*. LT stimulates adenylate cyclase, resulting in increased cyclic adenosine monophosphate. ST is not related to cholera toxin and stimulates guanylate cyclase, resulting in increased cyclic guanosine monophosphate. Each toxin induces ion and water secretion into the intestinal lumen, resulting in profuse watery diarrhea. The toxin genes are carried on plasmids.

Colonization of the intestine requires fimbria **colonization factor antigens (CFAs)**, which promote adhesion to the intestinal epithelium. Over 25 CFA types exist and can be expressed alone or in combination. Roughly 30–50% of ETEC isolates lack a characterized CFA. However, novel CFAs continue to be identified.

CFAs are highly immunogenic, but their multiplicity and allelic variation elude vaccine development. Many strains produce a type IV pilus involved in colonization and shared among other gram-negative bacterial pathogens. ETEC express type 1 pili (the "common pilus"), produced by commensal and pathogenic *E. coli* strains. TibA, a nonfimbrial adherence factor, mediates potent bacterial attachment and invasion of cells. For many years, the O serogroup was used to distinguish pathogenic from commensal *E. coli*. Molecular classification of pathogenic *E. coli* based on specific virulence genes and whole genome phylogeny has largely replaced classic O serogroup typing.

ENTEROINVASIVE *ESCHERICHIA COLI*

EIEC infections produce watery diarrhea or dysentery with blood, mucus, and leukocytes in the stools, as well as fever, systemic toxicity, crampy abdominal pain, tenesmus, and urgency. The illness resembles **bacillary dysentery** because EIEC shares virulence genes with *Shigella* spp. Sequencing of multiple housekeeping genes indicates that EIEC is more related to *Shigella* than to noninvasive *E. coli*. EIEC diarrhea occurs mostly in outbreaks; however, endemic disease occurs in developing countries. In some areas of the developing world, as many as 5% of sporadic diarrhea episodes and 20% of bloody diarrhea cases are caused by EIEC (see Chapter 245).

EIEC behave like *Shigella* in their capacity to invade gut epithelium and cause colonic lesions with ulcerations, hemorrhage, mucosal and submucosal edema, and infiltration by polymorphonuclear leukocytes (PMNs). The invasive process involves initial entry into cells, intracellular multiplication, intracellular and intercellular spread, and host cell death. All bacterial genes necessary for entry into the host cell are clustered within a 30-kb region of a large virulence plasmid; these genes are closely related to those found on the invasion plasmid of *Shigella* spp. This region carries genes encoding the entry-mediating proteins, including proteins that form a needle-like injection apparatus called *type III secretion,* required for secreting the invasins (IpaA-D and IpgD). The Ipas are the primary effector proteins of epithelial cell invasion. EIEC contact with host cells triggers the syringe-like type III secretion apparatus and injection of Ipas into the host cell cytoplasm.

Like *Shigella* spp., EIEC are nonmotile (they lack H or flagellar antigens) and are usually non–lactose fermenting. The serogroups of EIEC share LPS antigens related to *Shigella* LPS.

ENTEROPATHOGENIC *ESCHERICHIA COLI*

EPEC causes acute, prolonged, and persistent diarrhea, primarily in children <2 years old in resource-poor countries, where the organism may account for 20% of infant diarrhea. In developed countries, EPEC causes occasional daycare center and pediatric ward outbreaks. Profuse watery, nonbloody diarrhea with mucus, vomiting, and low-grade fever are common symptoms. Prolonged diarrhea (>7 days) and persistent diarrhea (>14 days) can lead to **malnutrition**, a potentially mortality-associated outcome of EPEC infection in infants in the developing world. Studies show that breastfeeding is protective against diarrhea caused by EPEC.

EPEC colonization causes blunting of intestinal villi, local inflammatory changes, and sloughing of superficial mucosal cells; EPEC-induced lesions extend from the duodenum through the colon. EPEC induces a characteristic attaching and effacing histopathologic lesion, which is defined by the intimate attachment of bacteria to the epithelial surface and effacement of host cell microvilli. Factors responsible for the attaching and effacing lesion formation are encoded by the *locus of enterocyte effacement* (LEE), a pathogenicity island with genes for a type III secretion system, the translocated intimin receptor (Tir) and intimin, and multiple effector proteins such as the *E. coli*–secreted proteins (EspA-B-D). Some strains adhere to the host intestinal epithelium in a pattern known as *localized adherence,* a trait that is mediated in part by the type IV bundle-forming pilus (Bfp) encoded by a plasmid (the EAF plasmid). After initial contact, proteins are translocated through filamentous appendages, forming a physical bridge between the bacteria and the host cell; bacterial effectors (EspB, EspD, Tir) are translocated through these conduits. Tir moves to the surface of host cells, where it is bound by a bacterial outer membrane protein intimin (encoded by the *eae* gene). Intimin-Tir binding triggers polymerization of actin and other cytoskeletal components at the site of attachment. These cytoskeletal changes result in intimate bacterial attachment to the host cell, enterocyte effacement, and pedestal formation.

Other LEE-encoded effectors include Map, EspF, EspG, EspH, and SepZ. Various other effector proteins are encoded outside the LEE and secreted by the type III secretion system (the non–LEE-encoded proteins, or Nle). The contribution of these putative effectors (e.g., NleA/EspI, NleB, NleC, NleD) to virulence is still under investigation. The presence and expression of virulence genes vary among EPEC strains.

The *eae* (intimin) and *bfp*A genes serve as molecular markers of EPEC and genetically subdivide EPEC into typical and atypical strains. *E. coli* strains that are *eae*$^+$/*bfp*A$^+$ are classified as "typical" EPEC; most of these strains belong to common O:H serotypes. *E. coli* strains that are *eae*$^+$/*bfp*A$^-$ are classified as "atypical" EPEC. Current data suggest that atypical EPEC are more prevalent than typical EPEC in both developed and developing countries, even in persistent diarrhea cases. In the GEMS study, typical EPEC was most associated with increased risk of mortality, particularly in infants in Africa.

ENTEROAGGREGATIVE *ESCHERICHIA COLI*

EAEC infection produces (1) acute, prolonged, and persistent pediatric diarrhea in developing countries, most prominently in children <2 years old and in malnourished children; (2) acute and persistent diarrhea in HIV-infected adults and children; and (3) acute traveler's diarrhea; EAEC is the second most common cause of traveler's diarrhea after ETEC. Typical EAEC illness is manifested by watery, mucoid, secretory diarrhea with low-grade fever and little or no vomiting. The watery diarrhea can persist for ≥14 days. Patients with EAEC may have grossly bloody stools, and EAEC cannot be excluded on stool characteristics. EAEC colonization and infection lead to growth retardation and malnutrition in infants in the developing world.

EAEC organisms form a characteristic biofilm on the intestinal mucosa and induce shortening of the villi, hemorrhagic necrosis, and inflammatory responses. The proposed model of pathogenesis of EAEC infection involves three phases: adherence to the intestinal mucosa by way of the aggregative adherence fimbriae or related adhesins, stimulation of enhanced mucus production, and toxin-mediated inflammation that results in damage to the mucosa and intestinal secretion. Diarrhea caused by EAEC is predominantly secretory. The intestinal inflammatory response (elevated fecal lactoferrin, interleukin [IL]-8 and IL-1β) may be related to growth impairment and malnutrition.

EAEC strains adhere in an aggregative, stacked-brick pattern, called *aggregative adherence* (AA), mediated by the AA fimbriae (AAF-I, -II, and -III). Some strains produce toxins, including the plasmid-encoded enterotoxin EAST1 (encoded by *ast*A), a homolog of the ETEC ST; an autotransporter toxin called Pet; other STATE toxins; and the chromosomally encoded enterotoxin ShET1 (encoded by *setA* and *setB*). Other virulence factors include outer membrane and secreted proteins, such as dispersin *(aap),* and the dispersin transport complex (aatPABCD). EAEC is a heterogeneous group of *E. coli*. A transcriptional activator called **AggR** controls the expression of plasmid-borne and chromosomal virulence factors. Identification of AggR appears to reliably identify illness-associated pathogenic EAEC strains ("typical" EAEC). EAEC *agg*R-positive strains carrying one to three of the genes *aap, ast*A, and *set1A* are significantly associated with diarrhea compared

with EAEC isolates lacking these genes. Other than the AAF and AggR factors, EAEC strains are genetically diverse, display variable virulence, and belong to multiple serogroups.

SHIGA TOXIN–PRODUCING *ESCHERICHIA COLI*

The STEC, which include EHEC, produce a range of clinical syndromes from asymptomatic colonization, to mild diarrhea, to severe hemorrhagic colitis. Watery diarrhea that becomes bloody over several days characterizes STEC illness. STEC infrequently causes fever, a distinguishing difference with shigellosis or EIEC disease. Most people with STEC recover from the infection without further complication. However, 5–10% of children with STEC hemorrhagic colitis go on within a few days to develop systemic complications such as **hemolytic-uremic syndrome** (HUS), characterized by acute kidney failure, thrombocytopenia, and microangiopathic hemolytic anemia (see Chapter 560). Severe illnesses occur most often among children 6 months to 10 years old. Young children with STEC-associated bloody diarrhea and neutrophilic leukocytosis in the early course of their diarrhea are at risk for HUS progression. Older individuals can also develop HUS or thrombotic thrombocytopenic purpura.

STEC transmits person to person (e.g., in families and daycare centers) and in contaminated food and water; a small inoculum can lead to infection. STEC food-borne outbreaks have arisen from undercooked hamburger, apple cider, lettuce, spinach, mayonnaise, salami, dry fermented sausage, and unpasteurized dairy products.

STEC primarily affects the colon, where organisms adhere to intestinal cells and produce attaching-effacing lesions such as those seen with EPEC and contain related genes (e.g., *intimin, Tir, EspA-D*). Unlike EPEC, STEC produces two major **Shiga toxins** (Stx1 and Stx2; previously called *verotoxins* and *Shiga-like*). STEC may produce one or both toxins and their closely related variants. **Stx1** is essentially identical to Shiga toxin, the protein synthesis–inhibiting exotoxin of *Shigella dysenteriae* serotype 1. **Stx2** and variants of Stx2 are more distantly related to Shiga toxin, although they share conserved sequences.

STEC Shiga toxins are composed of a single A subunit noncovalently associated with a pentamer composed of identical B subunits. The B subunits bind to globotriaosylceramide (Gb_3), a glycosphingolipid receptor on host cells. The A subunit is taken up by endocytosis. The toxin target is the 28S ribosomal RNA (rRNA), which is depurated by the toxin at a specific adenine residue, causing protein synthesis to cease and affected cells to die. These toxins are carried on bacteriophages that are normally inactive (lysogenic) in the bacterial chromosome; when the phages are induced to replicate (e.g., by the stress induced by many antibiotics), they cause lysis of the bacteria and release of large amounts of toxin. Toxin translocation across the intestinal epithelium into the systemic circulation can lead to damage of vascular endothelial cells, resulting in activation of the coagulation cascade, formation of microthrombi, intravascular hemolysis, and ischemia.

The clinical outcome of an STEC infection depends on a strain-specific combination of epithelial attachment and the toxin factors. The Stx2 toxins are associated with a higher risk of causing HUS. Strains producing only Stx1 often cause only watery diarrhea and, infrequently, HUS.

The most common STEC serotypes are *E. coli* O157:H7, *E. coli* O111:NM, and *E. coli* O26:H11, although several hundred other STEC serotypes have also been described. *E. coli* **O157:H7** is the most virulent serotype and the serotype most frequently associated with HUS; however, other non-O157 serotypes also cause this illness.

ENTEROAGGREGATIVE HEMORRHAGIC *ESCHERICHIA COLI*

In 2011, a massive outbreak of an unusual O104:H4 strain of diarrheagenic *E. coli* began in Germany. Eventually, >4,000 individuals were sickened with hemorrhagic colitis; the outbreak involved primarily adults (<100 children were reported affected). More than 800 people developed HUS, and >50 of these individuals died. Genomic analysis suggested the outbreak strain was most closely related to EAEC and had acquired a lambdoid bacteriophage with genes for Shiga toxin Stx2a. It was thus a **hybrid** pathogen with colonization mechanisms similar to a typical EAEC strain and toxin production typical of an STEC strain. This outbreak strain carries Pic on the chromosome and a pAA-like plasmid encoding AAF, AggR, Pet, ShET1, and dispersin. A second virulence plasmid encodes multiple antibiotic resistances. The high morbidity and mortality associated with this strain may reflect the stronger adherence of EAEC compared with STEC, delivering more Stx to target cells. Alternative terminology for this strain includes **enteroaggregative hemorrhagic *E. coli*** and **Shiga toxin–producing EAEC**. Whether Shiga toxin production in an EAEC background merits separate classification is unclear. Organisms with Shiga toxin genes in an atypical EPEC background were designated as a separate group (referred to as **STEC**, **EHEC**, or **verotoxin-producing *E. coli***) before the relative importance of the various genes was clear. EPEC strains are a heterogeneous group themselves. The important issue is not the nomenclature, but rather the concept that virulence genes can move between *E. coli,* resulting in new variants.

DIFFUSELY ADHERENT *ESCHERICHIA COLI*

Multiple studies in both developed and developing countries find DAEC associated with diarrhea, particularly in children after the first 1-2 years of life. DAEC strains isolated from children and adults seem to represent two different bacterial populations. **Age-dependent susceptibility** or the use of inappropriate detection methods may explain discrepancies among epidemiologic studies. Data suggest that these organisms also cause traveler's diarrhea in adults. DAEC produces prolonged watery diarrhea that is usually not dysenteric.

DAEC strains produce **diffuse adherence** on intestinal epithelial cells using the Afa/Dr-like surface fimbriae (designated F1845). The outer membrane protein AIDA-I also associates with **diffuse adherence**. DAEC secrete the serine-protease autotransporters of Enterobacteriaceae (SPATE) cytotoxin Sat. Bacteria expressing Afa/Dr adhesins interact with membrane-bound receptors, including decay-accelerating factor (DAF). The structural and functional lesions induced by DAEC include loss of microvilli and a decrease in the expression and enzyme activities of functional brush border–associated proteins. Afa/Dr DAEC isolates produce a secreted autotransporter toxin that induces marked fluid accumulation in the intestine. DAEC strains typically induce IL-8 production in vitro.

DIAGNOSIS

The features of suspected *E. coli* diarrheal illness are seldom distinctive enough to allow confident diagnosis strictly on clinical observations and routine laboratory studies such as blood counts. Practical, non–DNA-dependent methods for routine diagnosis of diarrheagenic *E. coli* have been developed primarily for STEC. Serotype O157:H7 is suggested by isolation of an *E. coli* that fails to ferment sorbitol on MacConkey sorbitol medium; latex agglutination confirms that the organism contains O157 LPS. Commercially available enzyme immunoassay or latex agglutination assays detect Shiga toxins in the routine hospital laboratory, although their variable sensitivity may limit their value.

Commercial assays such as the FilmArray Gastrointestinal Panel and Eurofins Diatherix Panel rapidly detect genetic markers for EPEC, EAEC, ETEC, STEC, and EIEC, among other pathogen genes, directly from a fecal sample in several hours and have been shown to reduce hospitalizations and treatment costs. Although some STEC (O157:H7 strains) can be detected in routine microbiology laboratories using selective media and appropriate antisera, the diagnosis of other diarrheagenic *E. coli* infection is traditionally made based on tissue culture assays (e.g., HEp-2-cells assay for EPEC, EAEC, and DAEC) or identification of specific virulence factors of the bacteria by phenotype (e.g., toxins) or genotype. Multiplex, real-time, or conventional polymerase chain reaction (PCR) can be used for presumptive diagnosis of isolated *E. coli* colonies. The genes commonly used for diagnostic PCR are *lt* and *st* for ETEC; *IpaH* or *iaL* for EIEC; *eae* and *bfp*A for EPEC; *eae, Stx1,* and *Stx2* for STEC; *AggR* or the AA plasmid for EAEC; and *daaC* or *daaD* for DAEC.

Serotyping does not provide definitive identification of pathotypes (except for selected cases such as O157:H7) because each pathotype

contains many serotypes and some serotypes can belong to more than one pathotype. Consequently, serotyping should not be used routinely for diarrheagenic *E. coli* identification in clinical laboratories (e.g., to diagnose EPEC in infantile diarrhea), except during an outbreak investigation.

Other laboratory data are, at best, *nonspecific* indicators of etiology. Fecal leukocyte examination of the stool is often positive with EIEC or occasionally positive with other diarrheagenic *E. coli*. With EIEC and STEC there may be an elevated peripheral blood PMN count with a left shift. Determination of *Stx2* blood levels in the early, post-bloody diarrhea period may be useful to identify children at risk of HUS; however, a validated clinical test is not readily available. Fecal lactoferrin, IL-8, and IL-1β can be used as inflammatory markers. Electrolyte changes are nonspecific, reflecting only fluid loss.

TREATMENT

The cornerstone of management is appropriate fluid and electrolyte therapy (Fig. 246.1). In general, this therapy should include oral replacement and maintenance with rehydration solutions such as those specified by the World Health Organization (WHO). Early volume expansion during STEC infection may reduce renal injury and improve patient outcomes. Upon refeeding, continued supplementation with oral rehydration fluids is appropriate to prevent recurrence of dehydration. Early refeeding (within 6-8 hours of initiating rehydration) with breast milk or infant formula or solid foods should be encouraged. Prolonged withholding of feeding can lead to chronic diarrhea and malnutrition. If the child is malnourished, oral zinc should be given to speed recovery and decrease the risk of future diarrheal episodes.

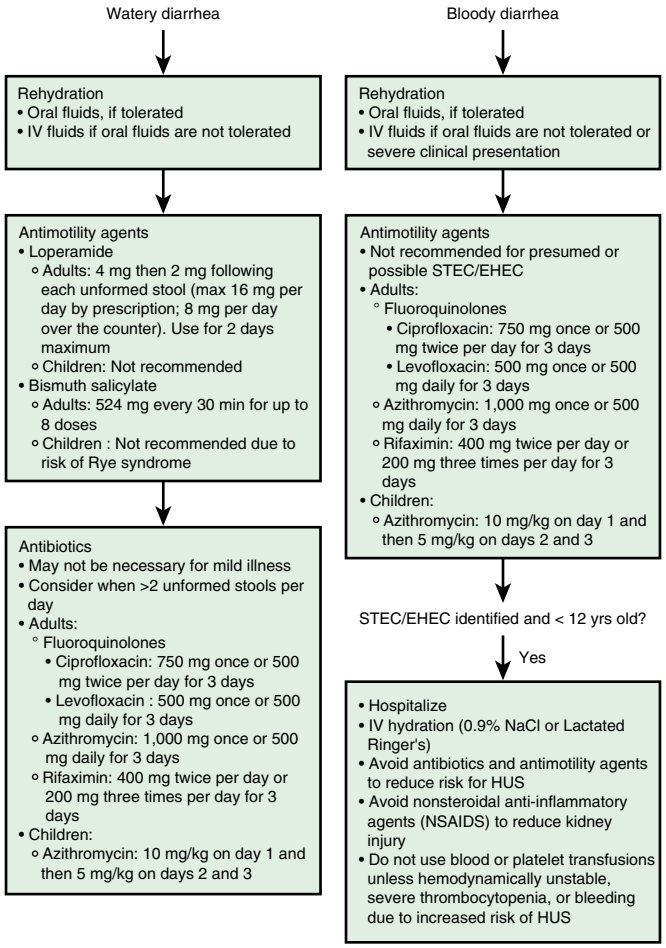

Fig. 246.1 Algorithmic treatment summary for presumed and possible *E. coli* diarrheal illness.

In children, validated criteria for antimicrobial therapy of diarrheal disease do not exist. The routine use of antimicrobials to treat childhood diarrhea is not recommended by the WHO except in severe cases. Nonbloody diarrhea rarely requires antimicrobial therapy. Antimicrobials should be reserved for dysenteric presentations, when host immunity is compromised by specific disorders, malnutrition, and chronic disease (Table 246.2). Antimicrobials should also be considered for severe traveler's diarrhea and diarrhea accompanied by fever and bloody stools. In settings of good healthcare resources, rapid molecular testing for STEC should be performed before initiating antibiotics, which can increase the risk for HUS.

Emerging antimicrobial resistance among diarrheal *E. coli* and other bacterial pathogens complicates treatment. Multiple studies in developing countries have found that diarrheagenic *E. coli* strains typically are resistant to antibiotics such as trimethoprim-sulfamethoxazole (TMP-SMX) and ampicillin (60–70%). Most data come from case series or clinical trials in adults with traveler's diarrhea. ETEC responds to antimicrobial agents such as TMP-SMX when the *E. coli* strains are susceptible. ETEC cases from traveler's diarrhea trials respond to ciprofloxacin, azithromycin, and rifaximin. However, other than for a child recently returning from travel in the developing world, empirical treatment of severe *watery diarrhea* with antibiotics is seldom appropriate.

In resource-poor settings where rapid molecular panel tests are not available, EIEC infections may be treated before culture results are finalized because the clinician suspects shigellosis and has begun empirical therapy. If the organisms prove to be susceptible, TMP-SMX is an appropriate choice. Although treatment of EPEC infection with TMP-SMX intravenously or orally for 5 days may be effective in speeding resolution, the lack of a rapid diagnostic test in the resource-poor setting makes treatment decisions difficult. Ciprofloxacin or rifaximin is useful for EAEC traveler's diarrhea, but pediatric data are sparse. Specific therapy for DAEC has not been defined.

The STEC strains represent a particularly difficult therapeutic dilemma; many antibiotics can induce bacterial stress, toxin production, and phage-mediated bacterial lysis with toxin release. Antibiotics should not be given for STEC infection because they can increase the risk of HUS (see Chapter 560). In settings with rapid molecular diagnostics, a delay in providing antibiotics is rarely consequential and can allow the clinician to more confidently recommend or exclude antibiotics from the therapeutic plan.

PREVENTION OF ILLNESS

In the developing world, prevention of disease caused by pediatric diarrheagenic *E. coli* is probably best done by maintaining prolonged breastfeeding, paying careful attention to personal hygiene, and following proper food- and water-handling procedures. People traveling

Table 246.2 Risk Factors Favoring Antibiotic Therapy in Children with Acute Diarrhea

RISK FACTOR	EVIDENCE
CHILD FACTORS	
Age <3 mo	Poor evidence in general; strong indication for neonates
Severe clinical presentation	Poor evidence but strong indications
Malnutrition	Strong evidence
Chronic disease and immune deficiency	Strong evidence (IBD and HIV); otherwise poor evidence; strong indications
SETTING FACTORS	
Daycare centers, closed institutions, hospitals	Strong evidence if bacteria spread is a potential
Traveler's diarrhea	Evidence for adult is strong; poor evidence in children

to these places can be best protected by handwashing and consuming only processed water, bottled beverages, breads, fruit juices, fruits that can be peeled, or foods that are served steaming hot.

Prophylactic antibiotic therapy is effective in adult travelers but has not been studied in children and is not recommended. Public health measures, including sewage disposal and food-handling practices, have made pathogens that require a large inoculum to produce illness relatively uncommon in industrialized countries where food screening and public health measures are robust. Food-borne outbreaks of STEC are a problem for which no adequate solution has been found. During the occasional hospital outbreak of EPEC disease, attention to enteric isolation precautions and cohorting may be critical.

Protective immunity against diarrheagenic *E. coli* remains an active area of research, and no vaccines are available for clinical use in children. Multiple vaccine candidates based on bacterial toxins and colonization factors have shown promise for prevention of ETEC in adult travelers, but long-term protection with these vaccines has not been optimal, particularly in children.

Chapter 247

Cholera

James P. Nataro

Cholera is a dehydrating diarrheal disease that rapidly leads to death in the absence of immediate initiation of appropriate treatment. Worldwide, 1.3 billion people are at risk for cholera, resulting in an estimated 1-4 million cases and 95,000 deaths annually. Cholera is highly prone to producing outbreaks, and the ongoing outbreaks in Yemen and Haiti emphasize how cholera and potentially other infectious diseases can easily reemerge in areas that have long been considered free of the disease after a natural disaster or war-related conflicts.

ETIOLOGY

Cholera is caused by *Vibrio cholerae,* a gram-negative, comma-shaped bacillus, subdivided into serogroups by its somatic O antigen. Of the >200 serogroups, only serogroups O1 and O139 have been associated with epidemics, although some non-O1, non-O139 *V. cholerae* strains (e.g., O75, O141) are pathogenic and can cause small outbreaks. A flagellar H antigen is present but is not used for species identification. The O1 serogroup is further divided into classical and El Tor biotypes based on its biochemical characteristics. Since the turn of the 21st century, only **O1 El Tor** has been reported; hybrids and variants of *V. cholerae* O1 El Tor possessing classical genes have been reported worldwide. These hybrid and variant strains have been associated with more severe disease.

Each biotype of *V. cholerae* can be further subdivided into Inaba, Ogawa, and Hikojima serotypes based on the antigenic determinants on the O antigen. **Inaba** strains have A and C antigenic determinants, whereas **Ogawa** strains have A and B antigenic determinants. **Hikojima** strains produce all three antigenic determinants but are unstable and rare. Recent studies reveal that serotype switching results from a selection process as yet unidentified.

EPIDEMIOLOGY

The first six cholera pandemics originated in the Indian subcontinent and were caused by classical O1 *V. cholerae*. The seventh pandemic is the most extensive of all and is caused by *V. cholerae* O1 El Tor. This pandemic began in 1961 in Sulawesi, Indonesia, and has spread to the Indian subcontinent, Southeast Asia, Africa, Oceania, Southern Europe, and the Americas. In 1991, *V. cholerae* O1 El Tor first appeared in Peru before rapidly spreading in the Americas. Cholera becomes **endemic** in areas after outbreaks when a large segment of the population develops immunity to the disease after recurrent exposure. Although the Ganges River valley is the historical home of cholera, it is estimated that >90% of global cases now occur in Africa, where the disease remains highly endemic.

In 1992 the first non-O1 *V. cholerae* that resulted in epidemics was identified in India and Bangladesh and was designated *V. cholerae* **O139**. From 1992 to 1994, this organism replaced O1 as the predominant cause of cholera in South Asia but has since been an uncommon etiologic agent.

The hybrid El Tor strains were first identified sporadically in Bangladesh. In 2004, during routine surveillance in Mozambique, isolates of *V. cholerae* O1 El Tor carrying classical genes were identified. Since then, hybrid and variant El Tor strains have been reported in other parts of Asia and Africa and have caused outbreaks in India and Vietnam. Although the classical biotype has virtually disappeared, its genes remain within the El Tor biotype. The current circulating strain in Haiti is closely related to the South Asian strain.

Humans are the only known hosts for *V. cholerae,* but free-living and plankton-associated *V. cholerae* exist in the marine environment. The organism thrives best in moderately salty water but can survive in rivers and freshwater if nutrient levels are high, as occurs when there is organic pollution such as human feces. The formation of a biofilm on abiotic surfaces and the ability to enter a viable but nonculturable state have been hypothesized as factors that allow *V. cholerae* to persist in the environment during interepidemic periods. Surface sea temperature, pH, chlorophyll content, the presence of iron compounds and chitin, and climatic conditions such as amount of rainfall and sea level rise are all important environmental factors that influence the survival of *V. cholerae* in the environment.

Consumption of **contaminated water** and ingestion of **undercooked shellfish** are the main modes of transmission, but additional food sources are becoming increasingly common. In cholera-endemic areas, the incidence is highest among children <2 years old, probably driven by the lack of previous exposure in young children. However, during cholera epidemics, all age-groups are usually affected, particularly in areas with no previous *V. cholerae* transmission. Persons with blood group O, decreased gastric acidity, malnutrition, immunocompromised states, and absence of local intestinal immunity (i.e., prior exposure) are at increased risk for developing severe disease. Household contacts of cholera-infected patients are at high risk of infection, because the stools of infected patients contain high concentrations of the pathogen. Moreover, upon repeated cycles of passage through humans, the organism becomes more virulent, demonstrating an increased number of copies of the cholera toxin-encoding genes.

PATHOGENESIS

Large inocula of bacteria (>10^8 colony-forming units [CFUs]) are required for severe cholera to occur; however, for persons whose gastric barrier is disrupted, a much lower dose (10^5 CFUs) is required, and the infectious dose may be lower after serial propagation of the pathogen through humans. After ingestion of *V. cholerae* from the environment, several changes occur in the microorganisms as they traverse the human intestine: increased expression of genes required for nutrient acquisition, downregulation of chemotactic responses, and expression of motility factors. Freshly excreted organisms (5-24 hours after shedding) are maximally infectious and may represent the predominant pathway for person-to-person transmission during epidemics.

The principal virulence factors of *V. cholerae* O1 are the cholera toxin and the toxin-coregulated pilus, a colonization factor that confers adherence to the epithelium of the small intestine (Fig. 247.1). The cholera toxin consists of five binding B subunits and one active A subunit. The B subunits are responsible for binding to the GM_1 ganglioside receptors located in the small intestinal epithelial cells. After binding, the A subunit is translocated into the cell, where it catalyzes adenosine diphosphate (ADP) ribosylation of the *alpha* subunit of the G_s signaling protein, which becomes constitutively active. G_s stimulates adenylate cyclase, leading to accumulation of cyclic adenosine

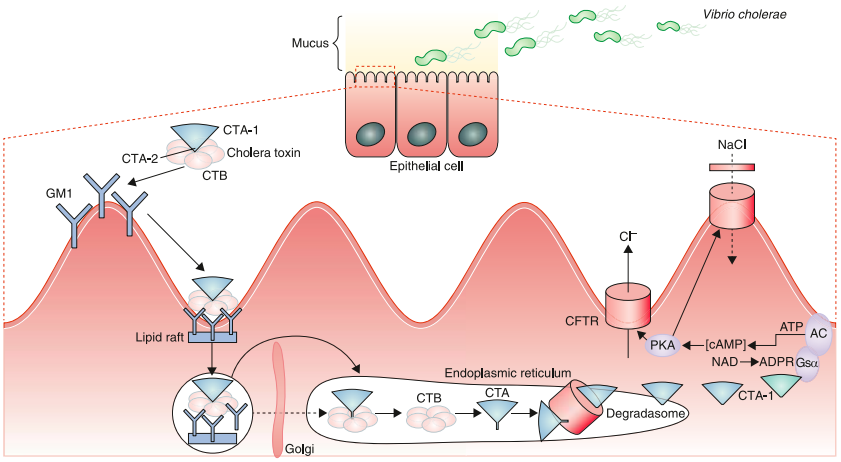

Fig. 247.1 Cholera pathogenesis and cholera toxin action. After ingestion, *Vibrio cholerae* colonize the small intestine and secrete cholera toxin, which has a doughnut-like structure with a central enzymatic toxic-active A (CTA-1 + CTA-2) subunit associated with a pentameric B subunit (CTB). After binding to GM_1 ganglioside receptors on small intestinal epithelial cells, which are mainly localized in lipid rafts on the cell surface, the cholera toxin is endocytosed and transported to the degradosome via the endoplasmic reticulum (ER) by a retrograde pathway, which, dependent on cell type, may or may not involve passage through the Golgi apparatus. In the ER, CTA dissociates from CTB, allowing CTA-1 to reach the cytosol by being translocated through the degradosome pathway. In the cytosol, CTA-1 subunits rapidly refold and bind to the Gsα subunit of adenylate cyclase (AC) in the cell membrane; on binding, CTA-1 adenosine diphosphate (ADP)-ribosylates the Gsα subunit, which stimulates AC activity, leading to an increase in intracellular concentration of cyclic adenosine monophosphate (cAMP), activation of protein kinase A (PKA), phosphorylation of the cystic fibrosis transmembrane conductance regulator (CFTR), a major chloride channel, and extracellular secretion of chloride ions (Cl^-) and water. Cholera toxin–induced Cl^- (and bicarbonate ion) secretion is particularly pronounced in intestinal crypt cells, whereas the increased intracellular cAMP concentrations in villus cells mainly inhibit the uptake of sodium chloride (NaCl) and water. *(Adapted from Clemens J, Shin S, Sur D, et al. New-generation vaccines against cholera. Nat Rev Gastroenterol Hepatol. 2011;8:701–710; by permission of Nature Publishing Group.)*

monophosphate and subsequent hyperactivation of the cystic fibrosis transmembrane conductance regulator (CFTR) chloride channel. Increased chloride and bicarbonate secretion by CFTR is accompanied by sodium and water loss into the small bowel, greatly exceeding the ability of the colon to reabsorb the fluid. These events eventually lead to massive purging of electrolyte-rich stool, potentially resulting in rapid dehydration and depletion of electrolytes, including sodium, chloride, bicarbonate, and potassium. Metabolic acidosis and hypokalemia then ensue.

CLINICAL MANIFESTATIONS

Most cases of cholera are mild or inapparent. Among symptomatic individuals, approximately 20% develop severe **dehydration** that can rapidly lead to death. After a typical incubation period of 1-2 days (range: several hours to 5 days), acute watery **diarrhea** and **vomiting** ensue. The onset may be sudden, with profuse watery diarrhea, but some patients have a prodrome of anorexia and abdominal discomfort and the stool may initially be brown. Diarrhea can progress to painless purging of profuse *rice-water stools* (suspended flecks of mucus) with a fishy smell, which is the hallmark of the disease (Figs. 247.2 and 247.3). Fever is infrequent and suggests a different diagnosis. Vomiting with clear watery fluid is usually present at the onset of the disease. Stool from cholera patients typically contains more sodium (along with potassium and bicarbonate) compared with stool from diarrhea caused by other pathogens; the high stool volume, coupled with the presence of electrolytes, challenges clinicians to avoid dehydration and electrolyte imbalance. Muscle cramping and weakness commonly occur as a result of potassium and calcium imbalance.

The term **cholera gravis** refers to the most severe form of the disease, characterized by rice water stools and fecal purging at rates of up to 500-1,000 mL/hr. This condition inevitably leads to dehydration, manifested by decreased urine output, a sunken fontanel (in infants), sunken eyes, absence of tears, dry oral mucosa, shriveled hands and feet ("washerwoman's hands"), poor skin turgor, thready pulse, and tachycardia. If left untreated, hypotension and vascular collapse are inevitable (see Fig. 247.3). Patients with metabolic acidosis can present with typical Kussmaul breathing. Although patients may be initially thirsty and awake, they rapidly progress to obtundation and coma. If fluid losses are not rapidly corrected, death can occur within hours.

Cholera sicca is an unusual manifestation of severe cholera in which very rapid fluid loss is confined to the intestinal lumen; such patients may succumb to dehydration without frank diarrhea.

LABORATORY FINDINGS

Findings associated with dehydration such as elevated urine specific gravity and hemoconcentration are evident. **Hypoglycemia** is a common finding that is caused by decreased food intake during the acute illness. Serum potassium may be initially normal or even high in the presence of metabolic acidosis; however, as the acidosis is corrected, hypokalemia may become evident. **Metabolic acidosis** caused by bicarbonate loss and tissue hypoperfusion is a prominent finding in severe cholera. Serum sodium and chloride levels may be normal or decreased, depending on the severity of the disease. Serum calcium may be elevated because of hemoconcentration.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

In children who have acute watery diarrhea with severe dehydration residing in a cholera-endemic area or who have recently traveled to an area known to have cholera, the disease may be suspected pending laboratory confirmation. Cholera differs from other diarrheal diseases in that it often occurs in large outbreaks affecting both adults and children. Treatment of dehydration should begin as soon as possible. Diarrhea caused by other etiologies (e.g., enterotoxigenic *Escherichia coli* or rotavirus) may be difficult to distinguish from cholera clinically. Microbiologic isolation of *V. cholerae* remains the gold standard for diagnosis. Although definitive diagnosis is not required for treatment to be initiated, laboratory confirmation is necessary for epidemiologic surveillance. *V. cholerae* may be isolated from stools, vomitus, or rectal swabs. Specimens may be transported on Cary-Blair media if they cannot be processed immediately. Selective media, such as thiosulfate-citrate–bile salts sucrose (TCBS) agar, should be used; *V. cholerae* exhibits a distinctive morphology on this medium, with confirmation made by serotyping. Because most laboratories in industrialized countries do not routinely culture for *V. cholerae,* clinicians should request appropriate cultures for clinically suspected cases.

Rapid diagnostic tests are currently available and show high sensitivity and specificity. These tests may be especially useful in areas with limited laboratory capacity, allowing early identification of cases at the

Fig. 247.3 A child lying on a cholera cot showing typical signs of severe dehydration from cholera. The patient has sunken eyes, lethargic appearance, and poor skin turgor, but within 2 hours was sitting up, alert, and eating normally. *(From Sack DA, Sack RB, Nair GB, et al. Cholera. Lancet. 2004;363:223–233.)*

onset of an outbreak and facilitating a timely response. Molecular identification with the use of polymerase chain reaction and DNA probes is available but often not feasible in areas where cholera exists. Stool examination reveals few fecal leukocytes and erythrocytes because cholera does not cause inflammation. Dark-field microscopy may be used for rapid identification of typical *darting motility* in wet mounts of rice-water stools, a finding that disappears once specific antibodies against *V. cholerae* O1 or O139 are added.

COMPLICATIONS

When optimally treated, patients with cholera typically recover fully without complications. Most adverse outcomes occur as a result of delayed or inadequate rehydration therapy. **Renal failure** from prolonged hypotension can occur. Unless potassium supplementation is provided, **hypokalemia** can lead to nephropathy and focal myocardial necrosis. Hypoglycemia is common among children and can lead to seizures unless it is appropriately corrected. Pneumonia is a frequent complication in young children and may be the result of aspiration during vomiting.

TREATMENT

Rehydration is the mainstay of therapy (see Chapter 74). Appropriate case management substantially decreases case fatalities to <1%. Application of World Health Organization (WHO) recommendations for diarrheal rehydration is recommended for all patients with diarrhea, but particularly when cholera is in the differential diagnosis. Children with mild or moderate dehydration may be treated with oral rehydration solution (ORS) unless the patient is in shock, is obtunded, or has intestinal ileus. Careful monitoring should occur during ORS, with attention to progression to more severe dehydration. Vomiting is not a contraindication to ORS. Severely dehydrated patients (>10% body weight) require intravenous fluid, ideally with lactated Ringer solution. When available, rice-based ORS should be used when oral rehydration is attempted, because this fluid has been shown to be superior to standard ORS in children and adults with cholera. The aim of rehydration should be replacement of the entire fluid deficit within 4 hours, if possible. Careful monitoring of ongoing losses is essential. If stool volumes cannot be measured, losses may be roughly estimated at 10-20 mL/kg of body weight for each episode of diarrhea or vomiting. After initial rehydration, patients should be reassessed every 1-2 hours, or more frequently if profuse diarrhea is ongoing; diarrhea typically begins to remit after 24 hours. Feeding should not be withheld during diarrhea. Frequent, small feedings are better tolerated than less frequent, large feedings.

Antibiotics should only be given in patients with moderately severe to severe dehydration. As soon as vomiting stops (usually within 4-6 hours after initiation of rehydration therapy), an antibiotic to which local *V. cholerae* strains are sensitive must be administered. Antibiotics shorten the duration of illness, decrease fecal excretion of *Vibrio*, decrease the volume of diarrhea, and reduce the fluid requirement during rehydration. Single-dose antibiotics increase compliance and are generally recommended; **doxycycline**, **ciprofloxacin**, and **azithromycin** are effective against cholera. The most clinical evidence for efficacy exists for tetracycline antibiotics (especially a single 300-mg dose of doxycycline). However, there are increasing reports of resistance to tetracyclines and to trimethoprim-sulfamethoxazole and other drugs. Because of these multidrug-resistant strains, antibiotic treatment must be tailored based on available susceptibility results from the area. **Recommendations for single-dose therapy for children include** doxycycline 2-4 mg/kg PO as a single dose up to 300 mg; 300 mg PO should be given to children 12 years of age and older. Alternative single dose regimens include azithromycin 20 mg/kg (max 1 g) PO, or ciprofloxacin 20 mg/kg (max 1 g) PO. Children >12 years of age should receive the adult doses. Cephalosporins and aminoglycosides are not clinically effective against cholera and therefore should not be used, even if in vitro tests show strains to be sensitive.

Zinc should be given as soon as vomiting stops. Zinc deficiency is common among children in many developing countries. Zinc supplementation in children <5 years old shortens the duration of diarrhea and reduces subsequent diarrhea episodes when given daily for 14 days at the time of the illness. Children <6 months old should receive 10 mg of oral zinc daily for 2 weeks, and children >6 months should receive 20 mg of oral zinc daily for 2 weeks.

PREVENTION

Improved personal hygiene, access to clean water, and sanitation are the mainstays of cholera control. Travelers from developed countries often have no prior exposure to cholera and are therefore at risk of developing the disease. Children traveling to cholera-affected areas should avoid drinking potentially contaminated water and eating high-risk

Table 247.1 Available Oral Cholera Vaccines*

VACCINE TRADE NAME	CONTENTS	DOSING SCHEDULE
Dukoral (Crucell)	1 mg of recombinant B subunit of cholera toxin plus 2.5×10^{10} colony-forming units of the following strains of *V. cholerae*: Formalin-killed El Tor Inaba (Phil 6973) Heat-killed classical Inaba (Cairo 48) Heat-killed classical Ogawa (Cairo 50) Formalin-killed classical Ogawa (Cairo 50)	Children 2-6 yr old: 3 doses, 1-6 wk apart Adults and children >6 yr old: 2 doses, 1-6 wk apart
Shanchol (Shantha Biotech) Euvichol (Eubiologics)	*V. cholerae* O1: 600 EU Formalin-killed El Tor Inaba (Phil 6973) 300 EU Heat-killed classical Inaba (Cairo 48) 300 EU Heat-killed classical Ogawa (Cairo 50) 300 EU Formalin-killed classical Ogawa (Cairo 50) *V. cholerae* O139-600 EU of formalin-killed strain 4260B	Adults and children ≥1 yr old: 2 doses, 2 wk apart

*WHO-prequalified vaccines.

foods such as raw or undercooked fish and shellfish. No country or territory requires vaccination against cholera as a condition for entry.

Alarmed by the increasing prevalence of cholera, in 2011 the World Health Assembly recommended the use of oral cholera vaccines to complement existing water, sanitation, and hygiene initiatives for cholera control. In 2016, a live oral cholera vaccine, CVD 103-Hg-R (Vaxchora, PaxVax), was licensed in the United States for use in adults age 18-64 years traveling to cholera-affected areas.

Older-generation parenteral cholera vaccines have not been recommended by the WHO because of the limited protection they confer and their high reactogenicity. Oral cholera vaccines are safe, are protective for approximately 2-5 years and confer moderate herd protection. Three oral cholera vaccines are currently available internationally and recognized by the WHO (Table 247.1). An internationally licensed killed whole cell oral cholera vaccine with recombinant B subunit (Dukoral, Crucell) has been available in >60 countries, including the European Union, and provides protection against cholera in endemic areas as well as cross-protection against certain strains of enterotoxigenic *E. coli*. The two other vaccines (Shanchol, Shantha Biotech; and Euvichol, Eubiologics) are variants of the first vaccine and contain the *V. cholerae* O1 and O139 antigens but do not contain the B subunit. Without the B subunit, these vaccines do not require buffer for administration, thereby reducing administration costs and resources, making them easier to deploy.

Several countries are now using oral cholera vaccines in mass vaccination campaigns where cholera remains a substantial problem. A cholera vaccine stockpile, established by the WHO, is now available and can be accessed by countries at risk for cholera, supplementing efforts to lessen the impact of this ongoing cholera scourge.

Chapter 248

Campylobacter

Ericka V. Hayes

Campylobacter, typically *Campylobacter jejuni* and *Campylobacter coli,* are found globally and are among the most common causes of human intestinal infections. Clinical presentation varies by age and underlying conditions.

ETIOLOGY

More than 20 species of *Campylobacter* are recognized. Most of these have been isolated from humans, and many are considered pathogenic. The most significant of these are *C. jejuni* and *C. coli,* which are believed to cause the majority of human enteritis. More than 100 serotypes of *C. jejuni* have been identified. *C. jejuni* has been subspeciated into *C. jejuni* subsp. *jejuni* and *C. jejuni* subsp. *doylei.* Although *C. jejuni* subsp. *doylei* has been isolated from humans, it is much less common, less hardy, and more difficult to isolate. Other species, including *Campylobacter fetus, Campylobacter lari,* and *Campylobacter upsaliensis,* have been isolated from patients with diarrhea, although much less frequently (Table 248.1). Emerging *Campylobacter* spp. have been implicated in acute gastroenteritis, inflammatory bowel disease, and peritonitis, including *C. concisus* and *C. ureolyticus*. Additional *Campylobacter* spp. have been isolated from clinical specimens, but their roles as pathogens have not been established.

Campylobacter organisms are gram-negative, curved, thin (0.2-0.8 μm wide), non–spore-forming rods (0.5-5 μm long) that usually have tapered ends. They are smaller than most other enteric bacterial pathogens and have variable morphology, including short, comma-shaped or S-shaped organisms and long, multispiraled, filamentous, seagull-shaped organisms. Individual organisms are usually motile with a flagellum at one or both poles depending on the species. Such morphology enables these bacteria to colonize the mucosal surfaces of both the gastrointestinal (GI) and respiratory tracts and move through them in a spiraling motion. Most *Campylobacter* organisms are microaerophilic, occasionally partially anaerobic, and oxidase positive. Most can transform into coccoid forms under adverse conditions, especially oxidation.

EPIDEMIOLOGY

Worldwide, *Campylobacter* enteritis is a leading cause of acute diarrhea. Efforts to reduce *Campylobacter* contamination and use of safe handling practices have led to decreased incidence. *Campylobacter* infections can be both food-borne and water-borne and most frequently result from ingestion of contaminated **poultry** (chicken, turkey) or **raw milk**. Less often, the bacteria come from drinking water, household pets (cats, dogs, hamsters), and farm animals. Infections are more common in resource-limited settings, are prevalent year-round in tropical areas, and can exhibit seasonal peaks in temperate regions (late spring with a peak midsummer in most of the United States, with a smaller secondary peak in late fall). In industrialized countries, *Campylobacter* infections peak in early childhood and again in young adulthood (15-44 years). This second peak is not seen with *Salmonella* and *Shigella* infections. In resource-limited countries, repeated infections are common in childhood, leading to increased immunity and rare disease in adulthood. Each year in the United States, there are an estimated 1.5 million cases of *Campylobacter* infection; in 2022 the incidence of infections with *Campylobacter* was 19.2 infections per 100,000 population. Of these, death is rare, with 50-150 reports annually. In The Netherlands, medical record review shows that, on average, each resident acquires asymptomatic *Campylobacter* colonization every 2 years, progressing to symptomatic infection in approximately 1% of colonized people.

Table 248.1 *Campylobacter* Species Associated with Human Disease

SPECIES	DISEASES IN HUMANS	COMMON SOURCES
C. jejuni	Gastroenteritis, bacteremia, Guillain-Barré syndrome	Poultry, raw milk, cats, dogs, cattle, swine, monkeys, water
C. coli	Gastroenteritis, bacteremia	Poultry, raw milk, cats, dogs, cattle, swine, monkeys, oysters, water
C. fetus	Bacteremia, meningitis, endocarditis, mycotic aneurysm, diarrhea	Sheep, cattle, birds, dogs
C. hyointestinalis	Diarrhea, bacteremia, proctitis	Swine, cattle, deer, hamsters, raw milk, oysters
C. lari	Diarrhea, colitis, appendicitis, bacteremia, UTI	Seagulls, water, poultry, cattle, dogs, cats, monkeys, oysters, mussels
C. upsaliensis	Diarrhea, bacteremia, abscesses, enteritis, colitis, hemolytic-uremic syndrome	Cats, dogs, other domestic pets
C. concisus	Diarrhea, gastritis, enteritis, periodontitis	Human oral cavity, dogs
C. sputorum	Diarrhea, bedsores, abscesses, periodontitis	Human oral cavity, cattle, swine, dogs
C. rectus	Periodontitis	
C. mucosalis	Enteritis	Swine, dogs
C. jejuni subsp. doylei	Diarrhea, colitis, appendicitis, bacteremia, UTI	Swine
C. curvus	Gingivitis, alveolar abscess	Poultry, raw milk, cats, dogs, cattle, swine, monkeys, water, human oral cavity
C. gracilis	Head and neck abscesses, abdominal abscesses, empyema	Dogs
C. cryaerophila	Diarrhea	Swine

Food-borne infection is most common and can be seen with the consumption of raw or undercooked meat and by cross-contamination of other foods. Although **chickens** are the classic source of *Campylobacter,* many animal sources of human food can also harbor *Campylobacter,* including seafood. *C. coli* has been linked to swine. Poultry is more likely to be heavily contaminated, whereas red meats often have fewer organisms. Unpasteurized milk products are also a documented source. Additionally, many pets can carry *Campylobacter,* and flies inhabiting contaminated environments can acquire the organism. Shedding from animals can contaminate water sources. Humans can acquire infection from water, although much less frequently than from contaminated food. **Airborne** (droplet) **transmission** of *Campylobacter* has occurred in poultry workers. Use of antimicrobials in animal foods may increase the prevalence of antibiotic-resistant *Campylobacter* isolated from humans.

Human infection can result from exposure to as few as 500 bacteria, although a higher dose (>9,000 bacteria) is often needed to cause illness reproducibly. Inoculum effectiveness is dependent on host factors, including immune status and stomach acidification. *C. jejuni* and *C. coli* spread person to person, perinatally, and at childcare centers where diapered toddlers are present. People infected with *C. jejuni* usually shed the organism for weeks, but some can shed for months, with children tending toward longer shedding. **Handwashing** is critical to preventing spread in these environments.

PATHOGENESIS

Most *Campylobacter* isolates are acid sensitive and should, in theory, be eradicated in the stomach. Therefore models for the pathogenesis of *C. jejuni* enteritis include mechanisms to transit the stomach, adhere to intestinal mucosal cells, and initiate intestinal lumen fluid accumulation. Host conditions associated with reduced gastric acidity, such as proton pump inhibitor use, and foods capable of shielding organisms in transit through the stomach may help allow *Campylobacter* to reach the intestine. Once there, *Campylobacter* is able to adhere to and invade intestinal mucosal cells through motility, including use of flagellae, and by the use of surface proteins (e.g., PEB1, CadF), large plasmids (e.g., pVir), surface adhesins (e.g., JIpA), and chemotactic factors. Lumen fluid accumulation is associated with direct damage to mucosal cells resulting from bacterial invasion and potentially from an enterotoxin and other cytotoxins. Additionally, *C. jejuni* has mechanisms that enable transit away from the mucosal surface. The factors used depend on the species involved.

Campylobacter spp. differ from other enteric bacterial pathogens in that they have both *N*- and *O*-linked glycosylation capacities. *N*-linked glycosylation is associated with molecules expressed on the bacterial surface, and *O*-linked glycosylation appears limited to flagellae. Slipped-strand mispairing in glycosylation loci results in modified, antigenically distinct surface structures. It is hypothesized that antigenic variation provides a mechanism for immune evasion.

C. fetus possesses a high molecular weight S-layer protein that mediates high-level resistance to serum-mediated killing and phagocytosis and is therefore thought to be responsible for the propensity to produce bacteremia. *C. jejuni* and *C. coli* are generally sensitive to serum-mediated killing, but serum-resistant variants exist. Some suggest these serum-resistant variants may be more capable of systemic dissemination.

Campylobacter infections can be followed by **Guillain-Barré syndrome** (GBS), **reactive arthritis**, and **erythema nodosum**. Such complications are thought to be from molecular mimicry between nerve, joint, and dermal tissue and *Campylobacter* surface antigens. Most *Campylobacter* infections are not followed by immunoreactive complications, indicating that host conditions along with other factors, in addition to molecular mimicry, are required for these complications. It is proposed that low-grade inflammation caused by *Campylobacter,* below the threshold that can be detected by endoscopy, results in cross-talk with gut nerves, leading to symptoms.

CLINICAL MANIFESTATIONS

There are a variety of clinical presentations of *Campylobacter* infections, depending on host factors such as age, immune competence, and underlying conditions. Infection presents most often as gastroenteritis, but also as bacteremia, neonatal infections, and, less often, extraintestinal infections.

Acute Gastroenteritis

Acute gastroenteritis with diarrhea is usually caused by *C. jejuni* (90–95%) or *C. coli* and, rarely, by *C. lari, C. hyointestinalis,* or *C. upsaliensis.* Infections with *C. jejuni* and *C. coli* are indistinguishable by clinical presentation. The average incubation period is 3 days (range: 1-7 days). One third of symptomatic patients can have a prodrome with fever, headache, dizziness, and myalgias; 1-3 days later, they develop cramping abdominal pain and loose, watery stools or, less frequently, mucus-containing bloody stools. In severe cases (approximately 15%), blood appears in the stools 2-4 days after the onset of symptoms. In younger children, >50% may develop blood in their stools. Some patients do not develop diarrhea at all, most often children who are 6-15 years old. Fever may be the only manifestation initially and is most pronounced in patients >1 year old. A reported 60–90% of older children also complain of abdominal pain. The abdominal pain is most frequently periumbilical and sometimes persists after the stools return to normal. The abdominal pain can mimic appendicitis, colitis, or intussusception. Nausea is common, with up to 25% of adults developing vomiting. Vomiting tends to be more common the younger the patient and is most frequent in infants. Infection with species other than *C. jejuni* and *C. coli* may have milder symptoms.

Diarrhea lasts approximately 7 days and will resolve spontaneously. More mild disease can last 1-2 days; 20–30% of patients will have symptoms for 2 weeks, and 5–10% are symptomatic for >2 weeks. Relapse can occur in 5–10% of patients. Persistent or recurrent *Campylobacter* gastroenteritis has been reported in immunocompetent patients, in patients with hypogammaglobulinemia (both congenital and acquired), and in patients with AIDS. Persistent infection can mimic chronic **inflammatory bowel disease** (IBD); therefore *Campylobacter* infection should also be considered when evaluating for IBD. Some evidence supports that *Campylobacter* infection may also be the trigger for development of IBD. Fecal shedding of the organisms in untreated patients usually lasts for 2-3 weeks, with a range from a few days to several months. Shedding tends to occur longer in young children. Acute appendicitis, mesenteric lymphadenitis, and ileocolitis have been reported in patients who have had appendectomy during *C. jejuni* infection.

Bacteremia

Transient bacteremia has been shown in early acute infection in 0.1–1% of patients. With the exception of bacteremia caused by *C. fetus,* bacteremia with *Campylobacter* occurs most often among patients with chronic illnesses or immunodeficiency (e.g., HIV), severe malnutrition, and in extremes of age. However, bacteremia is also well described in patients without underlying disease. The majority of cases of bacteremia are asymptomatic. *C. fetus* causes bacteremia in adults with or without identifiable focal infection, usually in the setting of underlying conditions such as malignancy, immunodeficiency, or diabetes mellitus. When symptomatic, *C. jejuni* bacteremia is associated with fever, headache, malaise, and abdominal pain. Relapsing or intermittent fever is associated with night sweats, chills, and weight loss when the illness is prolonged. Lethargy and confusion can occur, but focal neurologic signs are unusual without cerebrovascular disease or meningitis. Moderate leukocytosis with left shift may be found. Variable presentations have been described, including transient asymptomatic bacteremia, rapidly fatal septicemia, and prolonged bacteremia of 8-13 weeks.

Focal Extraintestinal Infections

Focal infections caused by *C. jejuni* are rare and occur mainly among neonates and immunocompromised patients. Multiple sites have been reported, including meningitis, pneumonia, thrombophlebitis, pancreatitis, cholecystitis, ileocecitis, urinary tract infection, arthritis, peritonitis, pericarditis, and endocarditis. *C. fetus* shows a predilection for vascular endothelium, leading to endocarditis, pericarditis, thrombophlebitis, and mycotic aneurysms. *C. hyointestinalis* has been associated with proctitis, *C. upsaliensis* with breast abscesses, and *C. rectus* with periodontitis.

Perinatal Infections

Perinatal infections are most often acquired at birth from a mother infected with or shedding *Campylobacter.* Maternal *C. fetus* and *C. jejuni* infections may be asymptomatic and can result in abortion, stillbirth, premature delivery, or neonatal infection with sepsis and meningitis. Severe perinatal infections are uncommon and are caused most often by *C. fetus* and, rarely, by *C. jejuni*. Neonatal infection with *C. jejuni* is associated with diarrhea that may be bloody. Nosocomial infections in nurseries have also been described.

DIAGNOSIS

The clinical presentation of *Campylobacter* enteritis can be similar to that of enteritis caused by other bacterial pathogens. The differential diagnosis includes *Shigella, Salmonella, Escherichia coli, Yersinia enterocolitica, Aeromonas, Vibrio parahaemolyticus,* and amebiasis. Fecal leukocytes are found in as many as 75% of cases, and fecal blood is present in 50% of cases (higher in pediatric patients). *Campylobacter* should be considered in patients with bloody stools, fever, and abdominal pain.

The diagnosis of *Campylobacter* enteritis is usually confirmed by identification of the organism in cultures of stool or rectal swabs. Isolation is most likely from selective media such as CAMPY-agar grown in microaerophilic conditions (5–10% oxygen), 1–10% carbon dioxide, with some hydrogen. Some *C. jejuni* grow best at 42°C (107.6°F). Growth on solid media results in small (0.5-1.0 mm), slightly raised, smooth colonies. Organisms can be identified from stool microscopically in approximately 50% of known *Campylobacter* cases. Gram stain is even less sensitive. Stool culture is >90% sensitive and is the standard method of diagnosis. Visible growth on stool culture is most often present in 1-2 days. Visible growth in blood cultures is often not apparent until 5-14 days after inoculation.

Routine culture may be adequate for isolation of *C. jejuni* because of the large numbers of bacteria that are often present. However, because *Campylobacter* organisms grow more slowly under routine conditions than do other enteric bacteria, routine culture can result in failure because of overgrowth of other enteric bacteria. *Campylobacter* culture can be enhanced, when necessary, with selective media. However, selective culture media developed to enhance isolation of *C. jejuni* may inhibit the growth of other *Campylobacter* spp. Filtration methods are available and can preferentially enrich for *Campylobacter* by selecting for their small size. These methods allow subsequent culture of the enriched sample on antibiotic-free media, enhancing rates of isolation of *Campylobacter* organisms inhibited by the antibiotics included in standard selective media. Isolation of *Campylobacter* from normally sterile sites does not require enhancement procedures. Clinically, it is not necessary to speciate *Campylobacter* because the disease is the same. Speciation can be done, when needed, and specialized laboratories can perform strain typing when required for epidemiologic purposes.

For rapid diagnosis of *Campylobacter* enteritis, direct carbolfuchsin stain of fecal smear, indirect fluorescence antibody test, dark-field microscopy, or latex agglutination were used historically. Polymerase chain reaction testing is more specific and sensitive and has become more widely available for rapid testing, often grouped with testing for other bacterial, viral, and parasitic stool pathogens in a multiplex assay. At this time, the recommendation remains to confirm all positive rapid tests with culture, which also allows for susceptibility testing and epidemiologic investigations. Antigen tests are also available, although false-positive results have been reported. Serologic diagnosis is also possible and is most helpful in patients with late-onset reactive arthritis or GBS, because these patients may have negative stool cultures by the time of presentation with these late complications.

COMPLICATIONS

Severe, prolonged *C. jejuni* infection can occur in patients with immunodeficiencies, including hypogammaglobulinemia, malnutrition, and AIDS. In patients with AIDS, increased frequency and severity of *C. jejuni* infection occurs; severity correlates inversely with CD4 count. Complications can include acute complications, as described earlier, and late-onset complications that may present after the acute infection has resolved. The most common late-onset complications include reactive arthritis and GBS.

Reactive Arthritis

Reactive arthritis can accompany *Campylobacter* enteritis in adolescents and adults, especially in patients who are positive for HLA-B27 (see Chapter 198). Reactive arthritis occurs in up to 3% of patients, although up to 13% may have joint symptoms. This manifestation usually appears 1-2 weeks after the onset of diarrhea (range 5-40 days). It involves mainly large joints and resolves without sequelae. The arthritis is typically migratory and occurs without fever. Synovial fluid lacks bacteria. The arthritis responds well to nonsteroidal antiinflammatory drugs and typically resolves after 1 week, though cases are reported with symptoms lasting for several months. Reactive arthritis with conjunctivitis, urethritis, and rash (including erythema nodosum) also occurs but is less common.

Guillain-Barré Syndrome

GBS is an acute demyelinating disease of the peripheral nervous system characterized clinically by acute flaccid paralysis and is the most common cause of neuromuscular paralysis worldwide (see Chapter 656). GBS carries a mortality rate of approximately 2%, and approximately 20% of patients develop major neurologic sequelae. *C. jejuni* has been identified as the trigger in up to 40% of patients with GBS and is most closely linked to the serotypes Penner O19 and O41. It has been reported 1-12 weeks after *C. jejuni* gastroenteritis in 1 of every 1,000 *C. jejuni* infections. Stool cultures obtained from patients with GBS at the onset of neurologic symptoms have yielded *C. jejuni* in >25% of the cases. Serologic studies suggest that 20–45% of patients with GBS have evidence of recent *C. jejuni* infection. Molecular mimicry between nerve tissue GM_1 ganglioside and *Campylobacter* surface antigens may be the triggering factor in *Campylobacter*-associated GBS. The Miller Fisher variant, which more often affects cranial nerves, is characterized by ataxia, areflexia, and ophthalmoplegia and is linked to cross-reacting antibodies to the GQ1b ganglioside found in cranial nerve myelin; the most common serotype for this variant is Penner O2. When associated with *Campylobacter,* GBS is more likely to be the axonal form and has a worse prognosis with slower recovery and more neurologic disability. The management of GBS includes supportive care, intravenous immunoglobulin, and plasma exchange.

Other Complications

Immunoglobulin A nephropathy and immune complex glomerulonephritis with *C. jejuni* antigens in the kidneys have been reported. *Campylobacter* infection has also been associated with hemolytic anemia and hemolytic-uremic syndrome.

Treatment

Fluid replacement, correction of electrolyte imbalance, and supportive care are the mainstays of treatment of children with *Campylobacter* gastroenteritis. Antimotility agents are contraindicated because they can cause prolonged or fatal disease. The need for antibiotic therapy in healthy patients with uncomplicated gastroenteritis is controversial. Most healthy children do not require antibiotic therapy. Data suggest a shortened duration of symptoms (by an average of 1.3 days) and intestinal shedding of organisms if antibiotics are initiated early in the disease. Antibiotics are recommended for patients with bloody stools, high fever, or a severe course and for children who are immunosuppressed or have underlying diseases and individuals at high risk of developing severe disease (e.g., pregnancy). Extraintestinal infections (e.g., bacteremia) should also be treated with antibiotics.

Most *Campylobacter* isolates are susceptible to macrolides, fluoroquinolones, aminoglycosides, chloramphenicol, tetracyclines, and clindamycin (though there is no clinical efficacy data for these last three agents, only in vitro data) and are resistant to cephalosporins, penicillins, and trimethoprim. Resistance to tetracyclines, macrolides, and more often, fluoroquinolones has been increasingly reported. **Antibiotic resistance** among *C. jejuni* has become a serious worldwide problem. Macrolide resistance is increased in areas such as Thailand and Ireland, whereas fluoroquinolone resistance has been reported in Spain, Hungary, and multiple low and middle income countries in >50% of cultured *Campylobacter*. Fluoroquinolone resistance continues to increase in the United States and is related to the use of quinolones in veterinary medicine and food products along with acquisition from travelers and antibiotic overuse. Erythromycin-resistant *Campylobacter* isolates are less common in the United States; therefore **azithromycin** is the drug of choice if therapy is required, particularly in pediatric patients. For treatment of gastroenteritis, the duration is 3-5 days. Drug sensitivities should be determined for patients who do not respond to therapy or any patient with invasive or extraintestinal infection. Sepsis is treated with parenteral antibiotics such as meropenem or imipenem, with or without an aminoglycoside. For extraintestinal infection caused by *C. fetus,* prolonged therapy is advised. *C. fetus* isolates resistant to erythromycin and fluoroquinolones have been reported; therefore empirical therapy for serious *C. fetus* infection should avoid these agents pending susceptibilities.

PROGNOSIS

Although *Campylobacter* gastroenteritis is usually self-limited, immunosuppressed children (including children with AIDS) can experience a protracted or severe course. Septicemia in newborns and immunocompromised hosts has a poor prognosis, with an estimated mortality rate of 30–40%. Additional prognosis is based on the secondary sequelae that may develop.

PREVENTION

Most human *Campylobacter* infections are sporadic and are acquired from infected animals or contaminated foods or water. Interventions to minimize transmission include good hand hygiene; cooking meats thoroughly; preventing recontamination after cooking by not using the same surfaces, utensils, or containers for both uncooked and cooked food; and avoiding unpasteurized dairy products. Also, it is important to ensure that water sources are not contaminated and that water is kept in clean containers. Persons infected with *Campylobacter* should avoid recreational water for at least 1 week after resolution of symptoms or as guided by local public health authorities. Contact with infected animals should be avoided. No specific isolation is required; **standard precautions** are sufficient, although in a hospital or clinic setting with an incontinent child, **contact precautions** are indicated. Outbreaks can occur in childcare settings. Infants and children should be excluded from childcare centers until stools are able to be contained in the diaper or for continent children when they no longer have fecal accidents and stool frequency is no more than two stools above that child's baseline (stools may remain loose). Breastfeeding appears to decrease symptomatic *Campylobacter* disease but does not reduce colonization. All cases of *Campylopbacter* should be reported to local health departments, as it is a nationally notifiable condition.

Several approaches at immunization have been studied, including the use of live-attenuated organisms, subunit vaccines, and killed–whole cell vaccines. No vaccine is currently available.

Chapter 249

Yersinia

Ericka V. Hayes

The genus *Yersinia* is a member of the order Enterobacterales, family Yersiniaceae and comprises more than 14 named species, 3 of which are established as human pathogens. *Yersinia enterocolitica* is by far the most common *Yersinia* species causing human disease and produces fever, abdominal pain that can mimic appendicitis, and diarrhea. *Y. pseudotuberculosis* is most often associated with mesenteric lymphadenitis. *Y. pestis* is the agent of **plague** and typically causes an acute febrile lymphadenitis (bubonic plague) and less often occurs as septicemic, pneumonic, pharyngeal, or meningeal plague. Other *Yersinia* species are uncommon causes of infections in humans, and their identification is often an indicator of immunodeficiency.

Yersinia is enzootic and can colonize pets. Infections in humans are incidental and most often result from contact with infected animals or their tissues; ingestion of contaminated water, milk, or meat; or for *Y. pestis,* the bite of infected fleas or inhalation of respiratory droplets (human, dog, cat). Association with human disease is less clear for *Y. frederiksenii, Y. intermedia, Y. kristensenii*, *Y. aldovae, Y. bercovieri, Y. mollaretii, Y. rohdei,* and *Y. ruckeri*. Some *Yersinia* isolates replicate at low temperatures (1–4°C [33.8–39.2°F]) or survive at high temperatures (50–60°C [122–140°F]). Thus common food preparation and storage and common pasteurization methods might not limit the number of bacteria. Most are sensitive to oxidizing agents.

249.1 *Yersinia enterocolitica*

Ericka V. Hayes

ETIOLOGY

Yersinia enterocolitica is a large, gram-negative coccobacillus that exhibits little or no bipolarity when stained with methylene blue and carbolfuchsin. It ferments glucose and sucrose but not lactose, is oxidase negative, and reduces nitrate to nitrite. These facultative anaerobes grow well on common culture media and are motile at 22°C (71.6°F) but not 37°C (98.6°F). Optimal growth temperature is 25–28°C (77–82.4°F); however, the organism can grow at refrigerator temperature. *Y. enterocolitica* includes pathogenic and nonpathogenic members. It has six different biotypes (1A, 1B, and 2-5). *Y. enterocolitica* relies on other bacteria for iron uptake, and conditions associated with **iron overload** increase the risk of infection.

EPIDEMIOLOGY

Y. enterocolitica is transmitted to humans through food, water, animal contact, and contaminated blood products. Transmission can occur from mother to newborn. *Y. enterocolitica* appears to have a global distribution but is seldom a cause of tropical diarrhea. In 2022, the Centers for Disease Control and Prevention (CDC) Foodborne Diseases Active Surveillance Network (FoodNet) reported an incidence of culture-confirmed *Y. enterocolitica* infection in the United States of 1.97 per 100,000 population (635% increase compared to 2015, and an increase of 216% since 2020). Infection may be more common in Northern Europe. Most infections occur among children <5 years old (incidence: 1.6-1.9 per 100,000 population), with the majority among children <1 year old. It is estimated that *Y. enterocolitica* accounts for 5% of illnesses secondary to major bacterial enteric pathogens in children <5 years old in the United States. Cases are more common in colder months and among males.

Natural reservoirs of *Y. enterocolitica* include pigs, rodents, rabbits, sheep, cattle, horses, dogs, and cats, with **pigs** being the major animal reservoir. Direct or indirect contact with animals, including pets, other domesticated animals, and wild animals, may be responsible for <1% of cases of enteric illnesses caused by *Y. enterocolitica*. Culture and molecular techniques have found the organism in a variety of foods and beverages, including vegetable juice, pasteurized milk, carrots, and water. Consumption of contaminated water or food, particularly undercooked pork, is the most common form of transmission to humans. A source of sporadic *Y. enterocolitica* infections is **chitterlings** (pig intestines, "chitlins"), a traditional dish in the southeastern United States and in Latin America, often in celebration of winter holidays. The infection is often seen in young infants in the household because of contamination of bottle and food preparation when chitterlings are prepared. In one study, 71% of human isolates were indistinguishable from the strains isolated from pigs. *Y. enterocolitica* is an occupational threat to butchers.

In part because of its capacity to multiply at refrigerator temperatures, *Y. enterocolitica* can be transmitted by intravenous injection of contaminated fluids, including blood products.

Patients with conditions leading to iron overload are at higher risk of developing *Yersinia* infections.

PATHOGENESIS

The *Yersinia* organisms most often enter by the gastrointestinal tract and cause mucosal ulcerations in the ileum. Necrotic lesions of Peyer patches and **mesenteric lymphadenitis** occur. If septicemia develops, suppurative lesions can be found in infected organs. Infection can trigger **reactive arthritis** and **erythema nodosum**, particularly in HLA-B27–positive individuals.

Virulence traits of pathogenic biotypes (1B and 2-5) are encoded by chromosomal genes and a highly conserved 70-kb virulence plasmid (pYV/pCD). The chromosomal genes control the production of heat-stable enterotoxins, and the plasmid allows penetration through the intestinal wall. Adherence, invasion, and toxin production are the essential mechanisms of pathogenesis. The bacteria mainly invade the intestinal epithelium in the Peyer patches of the ileum. After invasion, plasmid-encoded type III secretion of three antiphagocytic proteins protects *Yersinia* against the immunologic response of local macrophages. From Peyer patches, bacteria can disseminate to cause local or systemic disease. Motility appears to be required for *Y. enterocolitica* pathogenesis. Bioserotypes most associated with clinical illness in humans are 1B/O:8, 2/O:5,27, 2/O:9, 3/O:3, and 4/O:3, with bioserotype 4/O:3 being the most common type in the United States. *Yersinia* does not produce siderophores and uses analogous siderophores from other bacteria or host-chelated iron stores to thrive, placing patients with iron overload, as in hemochromatosis, thalassemia, and sickle cell disease, at higher risk for infection.

CLINICAL MANIFESTATIONS

Disease occurs most often as enterocolitis with diarrhea, fever, and abdominal pain. Acute enteritis is more common among younger children, and mesenteric lymphadenitis that can mimic appendicitis may be found in older children and adolescents. The incubation period is usually 4-6 days after exposure (range: 1-14 days). Stools may be watery and contain leukocytes and, less often, frank blood and mucus. Duration of diarrhea is often longer for *Y. enterocolitica* than for other causes of acute gastroenteritis, ranging from 12 to 22 days in several studies. Fever is common. Notably, prominent **pharyngitis** may be seen in 20% of patients at presentation, which may help distinguish it from other causes of gastroenteritis. *Y. enterocolitica* is excreted in stool for 1-4 weeks. Family contacts of a patient are often found to be asymptomatically colonized with *Y. enterocolitica. Y. enterocolitica* septicemia is less common and is most often found in very young children (<3 months old) and immunocompromised persons. Systemic infection can be associated with splenic and hepatic abscesses, osteomyelitis, septic arthritis, meningitis, endocarditis, and mycotic aneurysms. Exudative pharyngitis, pneumonia, empyema, lung abscess, and acute respiratory distress syndrome occur infrequently.

Reactive complications include **erythema nodosum**, **reactive arthritis**, and rarely uveitis. These manifestations may be more

common in select populations (Northern Europeans), in association with HLA-B27, and in females.

DIAGNOSIS

Diagnosis is made typically through isolation of the organism, usually from the stool. *Y. enterocolitica* is easily cultured from normally sterile sites but requires special procedures for isolation from stool, where other bacteria can outgrow it. *Yersinia* should be cultured on selective agar (cefsulodin-irgasan-novobiocin [CIN]) at 25–28°C (77–82.4°F) to increase yield. If O:3 serogroup is suspected, MacConkey agar should be used at 25–28°C (77–82.4°F). Multiplex polymerase chain reaction (PCR) testing for *Y. enterocolitica* is also available, including on commercially available multiplex stool panels. Many laboratories do not routinely perform the tests required to detect *Y. enterocolitica;* procedures targeted to this organism must be specifically requested. A history indicating contact with environmental sources of *Yersinia* and detection of fecal leukocytes are helpful indicators of a need to test for *Y. enterocolitica.* The isolation of *Yersinia* from stool should be followed by tests to confirm that the isolate is a pathogen. Serodiagnosis is not readily available, and utility is limited by cross-reactivity.

Differential Diagnosis

The clinical presentation is similar to other forms of bacterial enterocolitis. The most common considerations include *Shigella, Salmonella, Campylobacter, Clostridioides difficile,* enteroinvasive *Escherichia coli, Y. pseudotuberculosis*, and occasionally *Vibrio*-related diarrheal disease. Amebiasis, appendicitis, Crohn disease, ulcerative colitis, diverticulitis, and pseudomembranous colitis should also be considered.

TREATMENT

Enterocolitis in an immunocompetent patient is a self-limited disease, and no benefit from antibiotic therapy is established. Patients with systemic infection and very young children (in whom septicemia is common) should be treated. *Y. enterocolitica* organisms are typically susceptible to trimethoprim-sulfamethoxazole (TMP-SMX), aminoglycosides, third-generation cephalosporins, and quinolones, although strains resistant to quinolones have been reported. *Y. enterocolitica* produces β-lactamases, which are responsible for resistance to penicillins and first-generation cephalosporins. **TMP-SMX is the recommended empirical treatment for enterocolitis in children (generally a 5-day course) because it has activity against most strains and is well tolerated. In severe infections such as bacteremia, third-generation cephalosporins, with or without aminoglycosides, are effective, and usually a 3-week course of therapy is administered, with possible transition to oral therapy.** Patients on deferoxamine should discontinue iron chelation therapy during treatment for *Y. enterocolitica,* especially if they have complicated gastrointestinal (GI) infection or extraintestinal infection.

COMPLICATIONS

Reactive arthritis, erythema nodosum, erythema multiforme, hemolytic anemia, thrombocytopenia, and systemic dissemination of bacteria have been reported in association with *Y. enterocolitica* infection. Septicemia is more common in younger children, and reactive arthritis is more common in older patients. Arthritis appears to be mediated by immune complexes, which form as a result of antigenic mimicry, and viable organisms are not present in involved joints.

PREVENTION

Prevention centers on reducing contact with environmental sources of *Yersinia.* Families should be warned of the high risk of chitterling preparation, especially with young infants and children in the household. The CDC has developed guidance for the public regarding safe practices for chitterling preparation found here: https://www.cdc.gov/yersinia/chitlins.html. Breaking the chain of transmission from animal reservoirs to humans holds the greatest potential to reduce infections, and the techniques applied must be tailored to the reservoirs in each geographic area. There is no licensed vaccine.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

249.2 *Yersinia pseudotuberculosis*

Ericka V. Hayes

Yersinia pseudotuberculosis has a worldwide distribution; *Y. pseudotuberculosis* disease is less common than *Y. enterocolitica* disease. The most common form of disease is a **mesenteric lymphadenitis** that produces an appendicitis-like syndrome. *Y. pseudotuberculosis* is associated with a Kawasaki syndrome–like illness in approximately 8% of cases.

ETIOLOGY

Y. pseudotuberculosis is a small, gram-negative, aerobic, and facultative anaerobic coccobacillus. As with *Y. enterocolitica,* it ferments glucose and does not ferment lactose, is oxidase negative, catalase producing, urea splitting, and shares a number of morphologic and culture characteristics. It is differentiated biochemically from *Y. enterocolitica* on the basis of ornithine decarboxylase activity; fermentation of sucrose, sorbitol, and cellobiose; and other tests, although some overlap between species occurs. Antisera to somatic O antigens and sensitivity to *Yersinia* phages can also be used to differentiate the two species. Subspecies-specific DNA sequences that allow direct probe- and primer-specific differentiation of *Y. pestis, Y. pseudotuberculosis,* and *Y. enterocolitica* have been described. *Y. pseudotuberculosis* is more closely related phylogenetically to *Y. pestis* than to *Y. enterocolitica.*

EPIDEMIOLOGY

Y. pseudotuberculosis is zoonotic, with reservoirs in wild rodents, rabbits, deer, farm animals, various birds, and domestic animals, including cats and canaries. Transmission to humans is by consumption of or contact with contaminated animals or contact with an environmental source contaminated by animals, often water. Direct evidence of transmission of *Y. pseudotuberculosis* to humans by consumption of lettuce and raw carrots has been reported. The organism has a worldwide distribution; however, infections are more commonly reported in Europe, in boys, and in the winter. During 1996–2014, FoodNet reported 224 cases of infections secondary to *Y. pseudotuberculosis* in the United States, with an annual average incidence of 0.03 per 100,000 persons. Compared with *Y. enterocolitica* infections, those caused by *Y. pseudotuberculosis* are more likely to be invasive and occur in adolescents and adults. Iron-overloading conditions, AIDS, other immunodeficiencies, and other debilitating diseases (including liver cirrhosis) may predispose to invasive *Y. pseudotuberculosis* infection.

PATHOGENESIS

Ileal and colonic mucosal ulceration and mesenteric lymphadenitis are hallmarks of the infection. Necrotizing epithelioid granulomas may be seen in the mesenteric lymph nodes, but the appendix is often grossly and microscopically normal. The mesenteric nodes are often the only source of isolation of the organism. *Y. pseudotuberculosis* antigens bind directly to human leukocyte antigen (HLA) class II molecules and can function as **superantigens**, which might account for the clinical illness resembling **Kawasaki syndrome**.

CLINICAL MANIFESTATIONS

Pseudoappendicitis and **mesenteric lymphadenitis** with **abdominal pain** (often right lower quadrant tenderness), fever, and leukocytosis constitute the most common clinical presentation. Enterocolitis and extraintestinal spread are uncommon. Iron overload, diabetes mellitus, and chronic liver disease are often found concomitantly with extraintestinal *Y. pseudotuberculosis* infection. Renal involvement with tubulointerstitial nephritis, azotemia, pyuria, and glucosuria can occur. *Y. pseudotuberculosis* can present as a Kawasaki syndrome–like illness with fever of 1-6 days' duration, strawberry tongue, pharyngeal erythema, scarlatiniform rash, cracked, red, and swollen lips, conjunctivitis, sterile pyuria, periungual desquamation, and thrombocytosis.

Some of these children have had coronary changes. Other uncommon manifestations include septic arthritis, massive lower GI bleeding, postaneurysmal prosthetic vascular infection, and acute encephalopathy.

DIAGNOSIS

PCR of involved tissue can be used to identify *Y. pseudotuberculosis;* isolation by culture can require an extended interval. Involved mesenteric lymph nodes removed at appendectomy can yield the organism by culture. Abdominal CT scan or ultrasound examination of children with unexplained fever and abdominal pain can reveal a characteristic picture of enlarged mesenteric lymph nodes and thickening of the terminal ileum with or without peritoneal findings, including appendiceal inflammation and periappendiceal fluid. *Y. pseudotuberculosis* is rarely recovered from stool. Serologic testing is available in specialized labs.

Differential Diagnosis

Appendicitis (most common), inflammatory bowel disease, and other intraabdominal infections should be considered. Kawasaki syndrome, staphylococcal or streptococcal disease, leptospirosis, Stevens-Johnson syndrome, and collagen vascular diseases, including acute-onset juvenile idiopathic arthritis, can mimic the syndrome with prolonged fever and rash. *C. difficile* colitis, meningitis, encephalitis, enteropathic arthropathies, acute pancreatitis, sarcoidosis, toxic shock syndrome, typhoid fever, and ulcerative colitis may also be considered.

TREATMENT

Uncomplicated mesenteric lymphadenitis caused by *Y. pseudotuberculosis* is a self-limited disease, and antimicrobial therapy is not required. Few data exist on optimal treatment and duration of therapy. Infections with *Y. pseudotuberculosis* can generally be managed the same as those caused by *Y. enterocolitica*. Culture-confirmed bacteremia should be treated with a third-generation cephalosporin with or without an aminoglycoside, TMP-SMX, fluoroquinolones, or chloramphenicol.

COMPLICATIONS

Erythema nodosum and reactive arthritis can follow infection. Coronary aneurysm formation has been described with disease presenting as Kawasaki syndrome–like illness. Rare local complications of GI disease include perforation, obstruction, and intussusception.

PREVENTION

Avoiding exposure to potentially infected animals and good food-handling practices can prevent infection. The sporadic nature of the disease makes application of targeted prevention measures difficult.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

249.3 Plague (*Yersinia pestis*)

Ericka V. Hayes

ETIOLOGY

Y. pestis is a gram-negative, facultative anaerobe that is a pleomorphic, nonmotile, non–spore-forming coccobacillus and a potential agent of bioterrorism. It evolved from *Y. pseudotuberculosis* through acquisition of chromosomal changes and plasmid-associated factors that are essential to its virulence and survival in mammalian hosts and fleas. *Y. pestis* shares bipolar staining appearance with *Y. pseudotuberculosis* and can be differentiated by biochemical reactions, serology, phage sensitivity, and molecular techniques. *Y. pestis* exists in four biovars: Antigua (Africa), Medievalis (Central Asia), Orientalis (widespread), and Microtus (Asia). Of note, Microtus, while highly virulent in mice, does not cause disease in humans.

EPIDEMIOLOGY

Plague is endemic in at least 24 countries, with Democratic Republic of the Congo, Madagascar, and Peru accounting for the highest numbers of cases. Approximately 3,000 cases are reported worldwide per year, with 100-200 deaths. Plague is uncommon in the United States (0-40 reported cases/yr); most of these cases occur west of a line from east Texas to east Montana, with 80% of cases in California, New Mexico, Arizona, and Colorado. In 2015, there was a cluster of 11 cases (with 3 deaths) in 4 months related to exposure at Yosemite National Park in California's Sierra Nevada Mountains. The epidemic form of disease killed approximately 25% of the population of Europe in the Middle Ages in a series of several epidemics and pandemics. The epidemiology of **epidemic** plague involves extension of infection from the zoonotic reservoirs to urban rats, *Rattus rattus* and *Rattus norvegicus,* and from fleas of urban rats to humans. Epidemics are no longer seen. Selective pressure exerted by plague pandemics in medieval Europe is hypothesized for enrichment of a pathogenic deletion variant in the gene encoding CCR5 (CCR5-Δ32). The enhanced frequency of this mutation in European populations endows approximately 10% of European descendants with relative resistance to acquiring HIV-1.

The most common mode of transmission of *Y. pestis* to humans is through **flea bites**. Historically, most human infections are thought to have resulted from bites of fleas that acquired infection from feeding on infected urban rats. Less frequently, infection is caused by contact with infectious body fluids or tissues or inhalation of respiratory secretions of infected animals. Currently, most cases of plague secondary to direct animal contact or inhalation of animal secretions are related to domestic **cats** or **dogs**. Direct transmission from human to human through droplet inhalation is possible but extremely rare. Laboratory transmission of *Y. pestis* has been described as well. Sylvatic plague can exist as a stable enzootic infection or as an epizootic disease with high host mortality. Ground squirrels, rock squirrels, prairie dogs, rats, mice, bobcats, cats, rabbits, and chipmunks may be infected. Transmission among animals is usually by flea bite or by ingestion of contaminated tissue. *Xenopsylla cheopis* is the flea usually associated with transmission to humans, but >30 species of fleas have been demonstrated as vector competent, and *Pulex irritans,* the human flea, can transmit plague and might have been an important vector in some historical epidemics. Both sexes are similarly affected by plague, and transmission is more common in colder regions and seasons, possibly because of temperature effects on *Y. pestis* infections in vector fleas.

PATHOGENESIS

In the most common form of plague, infected fleas regurgitate organisms into a patient's skin during feeding. The bacteria translocate via lymphatics to regional lymph nodes, where *Y. pestis* replicates, resulting in **bubonic plague**. In the absence of rapidly implemented specific therapy, **bacteremia** can occur, resulting in purulent, necrotic, and hemorrhagic lesions in many organs. Both plasmid and chromosomal genes are required for full virulence. Pneumonic plague can be secondary to bacteremia or primary when infected material is inhaled. The organism is highly transmissible from persons with pneumonic plague and from domestic cats with pneumonic infection. This high transmissibility and high morbidity and mortality have provided an impetus for attempts to use *Y. pestis* as a biologic weapon.

CLINICAL MANIFESTATIONS

Y. pestis infection can manifest as several clinical syndromes; infection can also be subclinical. The three principal clinical presentations of plague are bubonic plague, septicemic plague, and pneumonic plague. **Bubonic plague** is the most common form and accounts for 80–90% of cases in the United States. From 2 to 8 days after a flea bite, lymphadenitis develops in lymph nodes closest to the inoculation site, including the inguinal (most common), axillary, or cervical regions. These buboes are very tender. Fever, chills, weakness, prostration, headache, and the development of septicemia are common. The skin might show insect bites or scratch marks. Purpura and gangrene of the extremities can

develop as a result of disseminated intravascular coagulation (DIC). These lesions may be the origin of the name Black Death. Untreated plague results in death in >50% of symptomatic patients. Death can occur within 2-4 days after onset of symptoms.

Occasionally, *Y. pestis* establishes systemic infection and induces the systemic symptoms seen with bubonic plague without causing a bubo **(primary septicemic plague)**. Because of the delay in diagnosis linked to the lack of the bubo, septicemic plague carries an even higher case fatality rate than bubonic plague. In some regions, bubo-free septicemic plague accounts for 25% of cases.

Pneumonic plague is the least common but most dangerous and lethal form of the disease. Incubation for primary pneumonic plague is 1-6 days. Pneumonic plague can result from hematogenous dissemination or, rarely, as primary pneumonic plague after inhalation of the organism from a human or animal with plague pneumonia or potentially from a biologic attack. Signs of pneumonic plague include severe pneumonia with high fever, dyspnea, and hemoptysis.

Meningitis, tonsillitis, and gastroenteritis can occur. Meningitis tends to be a late complication after inadequate treatment. Tonsillitis and gastroenteritis can occur with or without apparent bubo formation or lymphadenopathy.

DIAGNOSIS

Plague should be suspected in patients with fever and history of exposure to small animals in endemic areas. Bubonic plague should be suspected in a patient with a painful swollen lymph node, fever, and prostration who has been potentially exposed to fleas or rodents in the western United States. A history of camping or the presence of flea bites increases the index of suspicion.

Y. pestis is readily transmitted to humans by some routine laboratory manipulations. **Thus it is imperative to clearly notify a laboratory when submitting a sample suspected of containing *Y. pestis*.** Laboratory diagnosis is based on bacteriologic culture or direct visualization using Gram, Giemsa, or Wayson stain of lymph node aspirates, blood, sputum, or exudates. *Y. pestis* grows slowly under routine culture conditions and best at temperatures that differ from those used for routine cultures in many clinical laboratories. Colonies are described as having a classic "fried egg appearance" and grow on sheep blood and chocolate agars, typically growing after 48-72 hours of incubation. Note some automated biochemical bacteria identification systems may misidentify *Y. pestis*. Suspected isolates of *Y. pestis* should be forwarded to a reference laboratory for confirmation. Special containment shipping precautions are required. A rapid antigen test detecting *Y. pestis* F1 antigen in sputum and serum samples exists. PCR testing and immunohistochemical staining for rapid identification are available in some reference and public health laboratories. Cases of plague should be reported to local and state health departments and the CDC. Serologic testing is also available. A single positive serologic test confirms the diagnosis, but in early illness seroconversion may not yet have occurred; negative tests should be interpreted with caution, particularly if there is high clinical suspicion for the diagnosis, and patients should continue to be treated.

Differential Diagnosis

The Gram stain of *Y. pestis* may be confused with *Enterobacter agglomerans*. Mild and subacute forms of bubonic plague may be confused with other disorders causing localized lymphadenitis and lymphadenopathy, including bacterial lymphadenitis, tularemia, and *Bartonella henselae* (cat scratch) lymphadenitis. Septicemic plague may be indistinguishable from other forms of overwhelming bacterial sepsis.

Pulmonary manifestations of plague are similar to those of anthrax, Q fever, and tularemia, all agents with **bioterrorism** and **biologic warfare** potential. Thus the presentation of a suspected case, and especially any cluster of cases, requires immediate reporting. Additional information on this aspect of plague and procedures can be found at https://emergency.cdc.gov/agent/plague/index.asp.

TREATMENT

Patients with suspected plague should be placed on **droplet isolation** until pneumonia is ruled out, sputum cultures are negative, and antibiotic treatment has been administered for 48 hours. The treatment of choice for bubonic plague historically has been **streptomycin** (30 mg/kg/day, maximum 2 g/day, divided every 12 hours intramuscularly [IM] for 10 days). Intramuscular streptomycin is inappropriate for septicemia because absorption may be erratic when perfusion is poor. The poor central nervous system penetration of streptomycin also makes this an inappropriate drug for meningitis. Furthermore, streptomycin might not be widely and immediately available**. Gentamicin (children, 7.5 mg/kg IM or intravenously [IV] every 24 hours; adults, 5 mg/kg IM or IV every 24 hours) has been shown to be as efficacious as streptomycin; in patients with abscesses, an additional agent may be needed in addition to an aminoglycoside because of poor abscess penetration (typically a fluoroquinolone). Dual therapy is recommended for moderate to severe septicemic or pneumonic plague as well as bubonic plague with large buboes or any suspected case of bioterrorism-related plague. Ciprofloxacin** 10 mg/kg every 8 or 12 hr IV or 15 mg/kg every 8 or 12 hr PO (maximum 400 mg/dose IV, 500 mg/dose every 8 hr PO or 750 mg/dose every 12 hr PO) and **levofloxacin** are also effective. Meningitis is usually treated with chloramphenicol or a fluoroquinolone. Resistance to these agents and relapses are rare. *Y. pestis* is susceptible in vitro to **fluoroquinolones**, which are effective in treating experimental plague in animals. *Y. pestis* is susceptible in vitro to penicillin, but penicillin is ineffective in treatment of human disease. Mild bubonic disease may be treated with oral chloramphenicol or doxycycline in children >8 years old. Clinical improvement is usually noted within 48 hours of initiating treatment. Recommended duration of therapy is 10-14 days, with a switch to oral therapy 2 days after defervescence and clinical improvement. Drainage of suppurative buboes may be needed; material is infectious, and appropriate precautions should be taken intraoperatively.

Postexposure prophylaxis should be given to close contacts of patients with pneumonic plague. Antimicrobial prophylaxis is recommended within 7 days of exposure for persons with direct, close contact with a patient with pneumonic plague or those exposed to an accidental or bioterrorist aerosol. Recommended regimens for postexposure prophylaxis for children regardless of age include doxycycline, ciprofloxacin, or levofloxacin for a 7-day course at the treatment doses. Contacts of cases of uncomplicated bubonic plague do not require prophylaxis. *Y. pestis* is a potential agent of bioterrorism that can require mass casualty prophylaxis.

PREVENTION

Avoidance of exposure to infected animals and fleas is the best method of prevention of infection. In the United States, special care is required in environments inhabited by rodent reservoirs of *Y. pestis* and their ectoparasites. Patients with plague should be isolated if they have pulmonary symptoms, and infected materials should be handled with extreme care. There is currently no available licensed vaccine for *Y. pestis* in the United States. Several vaccine development trials are underway, and recombinant subunit vaccines based on rF1 and rV antigens seem to be the most promising. Using baits containing live vaccines for oral immunization of wild animals may be a helpful alternative for control of epidemics.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

Chapter 250

Aeromonas and *Plesiomonas*

Ameneh Khatami and Adam J. Ratner

Aeromonas and *Plesiomonas* are gram-negative bacilli that include species capable of causing enteritis and, less frequently, skin and soft tissue infections and invasive disease. They are common in freshwater and brackish water and colonize animals and plants in these environments.

250.1 *Aeromonas*

Ameneh Khatami and Adam J. Ratner

ETIOLOGY

Aeromonas is a member of the Aeromonadaceae family and includes two major groups of isolates: the nonmotile *psychrophilic* organisms that infect cold-blooded animals, most often fish, and the motile *mesophilic* organisms that infect humans and other warm-blooded animals. *Aeromonas* species are oxidase- and catalase-positive, facultatively anaerobic, gram-negative bacilli that ferment glucose. *Aeromonas* is a diverse genus with difficult taxonomy and species differentiation because of high nucleotide variability and has undergone multiple reclassifications of species and taxa in recent years. Sixteen species are recognized as clinically significant human pathogens, with *Aeromonas hydrophila, Aeromonas veronii* biotype sobria, and *Aeromonas caviae* most frequently associated with human infection. *Aeromonas dhakensis,* which was first isolated from children with diarrhea in Dhaka, Bangladesh, and was initially classified as a subspecies of *A. hydrophila,* has been recognized as a distinct species and an important cause of human infection.

EPIDEMIOLOGY

Aeromonas organisms are found in fresh and brackish aquatic environments, including rivers and streams, well water, both treated and bottled drinking water, and sewage. These organisms are most often detected in aquatic environments during warm-weather months, when they reach greater population densities. Rates of human infection may also exhibit seasonality depending on local conditions. For example, *Aeromonas* is isolated with increased frequency from May to October in the Northern Hemisphere. Some species resist chlorination of water and exhibit tolerance to high salt concentrations. *Aeromonas* has been isolated from meats, milk, seafood, seaweed, and vegetables consumed by humans. Asymptomatic colonization occurs in humans and is more common in inhabitants of tropical regions. Most human infections with *Aeromonas* are associated with exposure to contaminated water but may also be contracted via other routes, including ingestion of contaminated food. A systematic review of cases of traveler's diarrhea worldwide implicated *Aeromonas* in 0.8–3.3% of infections, with highest frequencies in travelers to Southeast Asia and Africa. A study in Bangladesh of >56,000 stool samples from patients with diarrhea found that approximately 25% had a bacterial etiology detected, 13% of which were *Aeromonas*. *Aeromonas* infections have also been acquired at various sites of natural disasters. For example, after the 2004 Thailand tsunami, *Aeromonas* was the leading cause of skin and soft tissue infection among survivors.

PATHOGENESIS

Clinical and epidemiologic data seem to support that *Aeromonas* organisms are **enteric** pathogens, although this point is not universally accepted. Reasons for uncertainty include a lack of outbreaks with clonally distinct isolates, infrequent person-to-person transmission, absence of a robust animal model, and overlapping prevalence in symptomatic and asymptomatic individuals. In addition, there are conflicting data when comparing the human challenge model with characteristics of suspected outbreaks of *Aeromonas* enteritis, further complicating interpretation.

Aeromonas isolates possess a variety of potential virulence factors, including constitutive *polar* and inducible *lateral* flagella, fimbriae, outer membrane proteins, endotoxin (lipopolysaccharide), and capsule. The mechanistic role of many of these factors in human pathogenicity remains unclear. Polar flagella provide motility in liquid media, and lateral flagella may act as adhesins. There are numerous hemolysins, proteases, and heat-labile and heat-stable enterotoxins. *Aeromonas* cytotoxic enterotoxin **(Act/aerolysin)** is secreted by a type II secretion system and is able to lyse erythrocytes, inhibit phagocytosis, and induce cytotoxicity in eukaryotic cells. *Aeromonas* also has a type III secretion system with an effector protein that causes actin reorganization and eventual apoptosis in vitro. A type VI secretion system has been described and functions analogously to a phage tail, with antimicrobial activity.

Aeromonas sobria is the most enterotoxic among clinical isolates, and cytotoxic activity with cytopathic and intracellular effects is found in 89% of isolates. A few strains produce Shiga toxin. Some clinically important species have also been shown to harbor a cholera-like toxin (**Asao toxin**). *Aeromonas* has serine proteases that can cause a cascade of inflammatory mediators, leading to vascular leakage, and in vitro studies show induction of apoptosis in murine macrophages by human isolates of *Aeromonas*. There are limited data on *quorum-sensing* molecules, which coordinate gene expression according to local density and may be involved in biofilm production or population control.

CLINICAL MANIFESTATIONS

Aeromonas may colonize humans asymptomatically or cause illness, including enteritis, focal invasive infections, and septicemia. Although apparently immunologically normal individuals may present with any of these manifestations, invasive disease is more common among immunocompromised persons.

Enteritis

The most common clinical manifestation of infection with *Aeromonas* is enteritis, which occurs primarily among children <3 years old. *Aeromonas* is the third or fourth most common cause of childhood **bacterial diarrhea** and has been isolated from 2% to 10% of patients with diarrhea and 1–5% of asymptomatic controls. One study demonstrated isolation from hospitalized neonates with diarrhea at rates of 0–19% depending on the season. Isolation from human feces also varies geographically based on food habits, level of sanitation, population demographics, aquaculture and farming practices, and laboratory isolation methods used. *Aeromonas* diarrhea is often watery and self-limited, although a dysentery-like syndrome with blood and mucus in the stool has also been described. Fever, abdominal pain, and vomiting are common in children. Choleric diarrhea with "rice-water" stools can also occur. Enteritis caused by *A. hydrophila* and *A. sobria* tends to be acute and self-limited, whereas 30% of patients with *A. caviae* enteritis have chronic or intermittent diarrhea that may last 4-6 weeks. *A. sobria* and *A. caviae* are most frequently associated with **traveler's diarrhea**. Complications of *Aeromonas* enteritis include intussusception, failure to thrive, hemolytic-uremic syndrome, bacteremia, and postinfectious chronic colitis. *Aeromonas* infection may also present as acute segmental colitis, mimicking inflammatory bowel disease or ischemic colitis.

Skin and Soft Tissue Infections

Skin and soft tissue infections are the second most common presentation of *Aeromonas,* most commonly associated with *A. hydrophila, A. veronii,* and *A. schubertii*. Predisposing factors include local trauma and exposure to contaminated fresh water. *Aeromonas* soft tissue infections have been reported after bites from a number of animal species, including alligators, tigers, bears, and snakes, and from tick

bites. These infections have also been reported after sports injuries and medicinal leech therapy. Antibiotic prophylaxis is generally used in conjunction with leech therapy because of the presence of *A. hydrophila* in the gastrointestinal (GI) tract of leeches, where they aid in the breakdown of ingested red blood cells. However, emerging reports of ciprofloxacin-resistant strains of *Aeromonas* isolated from leeches may affect this practice. The spectrum of skin and soft tissue infections is broad, ranging from a localized skin nodule to life-threatening necrotizing fasciitis, myonecrosis, and gas gangrene. Soft tissue infections are most frequently found on the extremities, are often polymicrobial, and are 3 times more likely in men than in women. *Aeromonas* **cellulitis**, the most common skin manifestation, clinically presents similar to other forms of bacterial cellulitis but should be suspected in wounds after contact with a water source, especially during the summer.

Septicemia

Aeromonas septicemia, strongly associated with *A. veronii* biovar sobria and *A. dhakensis* infection, is the third most common presentation of infection and is associated with a mortality rate of 27–73%. Higher incidence occurs during summer months or during the wet season in the tropics. Patients present with the classic signs and symptoms of gram-negative sepsis and may have GI symptoms, including abdominal pain, nausea, vomiting, and diarrhea. From 2% to 4% of patients may present with ecthyma gangrenosum–like lesions. *Aeromonas* may be the only organism isolated or may be part of a polymicrobial bacteremic illness. Most cases (approximately 80%) occur in immunocompromised adults or those with hepatobiliary disease and in young children in whom the source of infection is probably *Aeromonas* in the GI tract. Less frequently, bacteremia can be secondary to trauma-related myonecrosis or infected burns. In such patients, mortality is often higher than in those with primary bacteremia because of the underlying trauma. Rarely, *Aeromonas* bacteremia occurs in otherwise healthy adults exposed to fresh water.

Other Infections

Aeromonas is a rare cause of GI infections such as necrotizing gastroenteritis, peritonitis, cholecystitis, appendicitis, and liver and pancreas abscess formation; cardiovascular infections, including endocarditis and septic embolism; and pulmonary infections, including tracheobronchitis, pneumonia, empyema, and lung abscess formation. *Aeromonas* is also associated with musculoskeletal infections, including osteomyelitis, pyogenic arthritis, pyomyositis, and necrotizing fasciitis, as well as ocular and ear, nose, and throat infections, including endophthalmitis, keratitis, orbital cellulitis, otitis media, and epiglottitis. Other rare infections include meningitis, urinary tract infection, pelvic inflammatory disease, lymphadenitis, hot tub folliculitis, and surgical wound infections. *Aeromonas* is associated with tracheobronchitis and aspiration pneumonia after near-drowning.

DIAGNOSIS

Diagnosis is established by isolation of *Aeromonas* in culture. The organism is generally grown on standard media when the source material is normally sterile. Often, *Aeromonas* is not identified by typical laboratory protocols for examining stool specimens. If *Aeromonas* is suspected, the yield may increase if the laboratory is notified before testing, because overnight enrichment in alkaline peptone water and culture on selective agars may be useful. Most strains (approximately 90%) produce β-hemolysis on blood agar. Lactose-fermenting strains of *Aeromonas* like *A. caviae* may not be identified if the clinical laboratory does not routinely perform oxidase tests on lactose fermenters isolated on MacConkey agar. Aeromonads are resistant to vibriostatic agent O129; however, differentiation of *Aeromonas* from *Vibrio* spp. and identification of *Aeromonas* spp. and subspp. is not reliable using biochemical testing. Similarly, classification of *Aeromonas* strains at the species and subspecies level is difficult to achieve by sequencing regions of the 16S rRNA gene. Sequencing of housekeeping genes, such as *gyrB* and *rpoD,* and multilocus sequence typing are accurate for species identification but are time-, cost- and labor-intensive. Increasingly, laboratories use matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry to rapidly identify organisms because this method is accurate for *Aeromonas* as a genus and for many of the clinically important species. Because stool culture–based diagnosis is time-consuming, labor-intensive, and costly on per positive culture basis, molecular tests for various enteric bacterial pathogens, including multiplex polymerase chain reaction (PCR) assays that include targets for detection of *Aeromonas,* have been developed and are commercially available in some areas.

TREATMENT

Aeromonas **enteritis** is usually self-limited, and antimicrobial therapy may not be indicated, although some studies suggest that **antimicrobial therapy** may shorten the course of the illness. Antimicrobial therapy is reasonable to consider in patients with protracted diarrhea, dysentery-like illness, or underlying conditions such as hepatobiliary disease or an immunocompromised state. Antibiotic sensitivity varies among species and also by geography; therefore it is important to perform **susceptibility testing**. Chromosomally mediated class B, C, and D β-lactamases are found in most species and can be difficult to identify because many are inducible. These include metallo- and AmpC β-lactamases, which can lead to clinical failure if carbapenems or third-generation cephalosporins are used as monotherapy in high-organism-load infections. There is near-uniform resistance to penicillins. Surgical intervention is the primary therapeutic modality in cases of **necrotizing fasciitis**, with most patients requiring more than one **debridement** in the first 48 hours. **Septicemia** can be treated with a **fourth-generation cephalosporin** (e.g., cefepime) or **ciprofloxacin**, with or without an aminoglycoside, although specific therapy should be guided by susceptibility data. Another option for less severe infections includes trimethoprim-sulfamethoxazole (TMP-SMX). Evidence-based recommendations for duration of treatment are lacking, and thus treatment is typically guided by clinical response. In general, diarrhea is treated for 3 days, wound infections for 7-10 days, and bacteremia for 14-21 days, depending on clinical response and host characteristics.

PREVENTION

Reducing contact with contaminated environmental fresh and brackish water and contaminated foods should reduce the risk for *Aeromonas* infections. Some *Aeromonas* outer membrane proteins are immunogenic and are candidate antigens for preclinical vaccine development.

250.2 *Plesiomonas shigelloides*

Ameneh Khatami and Adam J. Ratner

ETIOLOGY

Plesiomonas shigelloides is a facultatively anaerobic, gram-negative, non–spore-forming bacillus that ferments glucose. It is a catalase-, oxidase-, and indole-positive motile organism with polar flagella. A high level of genetic diversity has been recognized among *P. shigelloides* strains, reflecting frequent homologous recombination.

EPIDEMIOLOGY

P. shigelloides is ubiquitous in freshwater and, because it can tolerate salinity of up to 4%, can be found in estuarine or brackish water, as well as animal inhabitants of these ecosystems, including fish, shellfish, crustaceans, water mammals, amphibians, reptiles, and other vertebrates. *P. shigelloides* has been recovered from healthy (colonized)

and diseased animals, including cats. It can cause both sporadic infections and outbreaks in a range of animals. As a mesophile with optimal growth temperature of 35–39°C (95–102.2°F), *P. shigelloides* has been found most often in tropical waters or during warmer months, although there are increasing reports of isolation from surface water in colder climates. Similarly, most cases of infection occur during the warmer months of the year. *P. shigelloides* is not a usual commensal organism in the human GI tract, and infection of humans is thought to be the result of consumption of contaminated water or raw seafood or possibly through contact with colonized animals. The frequency of isolation of *P. shigelloides* from diarrheal stools in these circumstances has been reported to range from 2% to >10%. Mixed infection with *Salmonella, Aeromonas,* rotavirus, or other enteric pathogens may occur in almost one third of patients. The majority of symptomatic patients in North America have a known exposure to potentially contaminated water or seafood (notably oysters) or have traveled abroad. *Plesiomonas* has been reported to be associated with 1.3–5.4% of episodes of **traveler's diarrhea**, with the highest rates associated with travel to South and Southeast Asia. Other risk factors include immune compromise (in particular HIV infection), blood dyscrasias (including sickle cell disease), and young age. The highest rates of *Plesiomonas* **enteritis** occur in children <2 years old. Although *P. shigelloides* has a worldwide distribution, there is unexplained geographic variability in the incidence of enteritis that may be related to water temperatures and a lack of hygiene and sanitation.

PATHOGENESIS

Epidemiologic and microbiologic evidence in the form of a series of food-borne outbreaks attributable to *P. shigelloides* indicates that this organism is an **enteropathogen**. However, the pathogenic capacity of *P. shigelloides* has not been confirmed through oral challenge studies, and these organisms have been isolated from the stools of healthy individuals at a low rate. The mechanism of enteritis is not known, but putative virulence factors have been described, including cholera-like toxin, heat-labile and heat-stable enterotoxins, and lipopolysaccharide. Most strains of *P. shigelloides* also secrete a β-hemolysin, which is thought to be a major virulence factor. In vitro studies show that isolates of *P. shigelloides* can invade and induce apoptosis in cells of enteric origin, as well as exhibiting evidence of modulation of host defenses through inhibition of cathepsins involved in antigen processing and presentation.

CLINICAL MANIFESTATIONS

Clinical disease in humans generally begins 24-48 hours after exposure to the organism, although incubation periods in excess of 4 days have been reported. Diarrhea can occur in all age-groups, including neonates, is typically secretory, and less often presents as invasive dysentery. Secretory **enteritis** usually presents as a mild self-limiting disease with watery diarrhea and abdominal pain, but in 13% of cases diarrhea can persist for >2 weeks. Dehydration, hypokalemia, and peritonitis are uncommon complications; however, there have been several reports of a cholera-like presentation with severe secretory diarrhea. The frequency of secretory vs dysenteric presentation seems to cluster by individual outbreak, suggesting that either the human populations or the bacterial populations involved are associated with each particular presentation. **Dysentery** presents with macroscopic blood and/or mucus in the stool, significant abdominal pain, and vomiting, with more severe cases also associated with fever. Fatal outcomes have been reported with severe cases of *Plesiomonas* dysentery, although in most of these cases the exact role of *P. shigelloides* is unclear.

Extraintestinal infections, usually bacteremia, are rare and usually occur in patients with underlying immunodeficiency. About 90% of these cases are monomicrobial, and in almost half, *P. shigelloides* is also isolated from a site other than blood. Rarely, bacteremia accompanying enteritis has been documented in apparently otherwise normal children. Septicemia also appears to result from ingestion of contaminated water or seafood and has a high mortality rate in adults. Other extraintestinal diseases include pneumonia, meningitis, osteomyelitis, septic arthritis, reactive arthritis, abscesses, and focal infections of the GI or reproductive tracts. Almost one third of all bacteremias occur in neonates who present with early-onset sepsis and meningitis, and although rare, these make up most of the reported cases of *P. shigelloides* meningitis and have a very high mortality rate (80%). In several cases of neonatal disease, *Plesiomonas* has also been isolated from maternal feces, suggesting intrapartum vertical transmission. Compared with *Aeromonas* and *Vibrio* spp., traumatic wounds sustained in aquatic environments less often contain *P. shigelloides*.

DIAGNOSIS

P. shigelloides is a non–lactose-fermenting organism and grows well on traditional enteric media with optimal growth at 30°C (86°F), although selective techniques may be required to isolate the organism from mixed cultures and to differentiate *P. shigelloides* from *Shigella* spp. If enrichment is necessary, alkaline peptone water or bile peptone broth may be used. Colonies are nonhemolytic on 5% blood agar. Many strains cross-react with *Shigella* on serologic testing but can be differentiated easily as oxidase-positive organisms. *P. shigelloides* has a unique biochemical profile and can generally be identified using commercial kits. Rapid identification systems, including MALDI-TOF, can also be used to identify *P. shigelloides*. *P. shigelloides* is included in at least one U.S. Food and Drug Administration (FDA)–approved commercial panel that detects a range of enteropathogens directly from diarrheal stools (culture independent) by PCR.

TREATMENT

Enteritis caused by *P. shigelloides* is usually mild and self-limited. In cases associated with dehydration or with a cholera-like disease, patients usually respond favorably to **oral rehydration solution**. Consideration of **antimicrobial therapy** is reserved for patients with prolonged or bloody diarrhea, those who are immunocompromised, the elderly, and the very young. Data from uncontrolled studies suggest that antimicrobial therapy may decrease the duration of symptoms, although no difference was found in an exclusively pediatric study.

P. shigelloides produces a chromosomally encoded, noninducible β-lactamase, which generally renders strains resistant to the penicillins, including broad-spectrum penicillins. *P. shigelloides* is also usually resistant to aminoglycosides and tetracyclines. Most strains of *P. shigelloides* are susceptible to β-lactam/β-lactamase inhibitor combinations and to TMP-SMX, some cephalosporins, carbapenems, and fluoroquinolones; however, therapy should be guided by **antimicrobial susceptibility testing** because resistance to TMP-SMX, fluoroquinolones, and other agents has been reported.

Severe cases of *P. shigelloides* dysentery should be treated similarly to shigellosis (with empirical **azithromycin** or a **third-generation cephalosporin** for children and ciprofloxacin or azithromycin for adults). Antibiotics are essential for therapy of extraintestinal disease. Empirical therapy with a third-generation cephalosporin is often first-line management, because most isolates are susceptible in vitro. Alternatives include carbapenems, aztreonam, β-lactam/β-lactamase inhibitor combinations, and quinolones. Definitive therapy should be guided by the susceptibility of the individual isolate. Duration of therapy ranges from 1 to 2 weeks but may be extended depending on underlying chronic conditions and clinical response.

Chapter 251

Pseudomonas, Burkholderia, and *Stenotrophomonas*

251.1 *Pseudomonas aeruginosa*

Thomas S. Murray and Ashley C. Howard

ETIOLOGY

Pseudomonas aeruginosa is an aerobic, gram-negative rod. It can multiply in a great variety of environments that contain minimal amounts of organic compounds. Strains from clinical specimens do not ferment lactose, are oxidase positive, and may produce β-hemolysis on blood agar. Many strains produce pigments, including pyocyanin, pyoverdine, and pyorubrin, that diffuse into and color the surrounding medium. Strains of *P. aeruginosa* are differentiated for epidemiologic purposes by a variety of genotyping methods, including restriction fragment length polymorphisms using pulsed-field gel electrophoresis, multilocus sequence typing, and more recently, whole genome sequencing.

EPIDEMIOLOGY

P. aeruginosa is a classic "opportunist." It rarely causes disease in people who do not have a predisposing risk factor. Compromised host defense mechanisms resulting from trauma, neutropenia, mucositis, immunosuppression, or impaired mucociliary transport explain the predominant role of this organism in producing opportunistic infections. In pediatric settings, it is frequently seen in the respiratory secretions of children with **cystic fibrosis** (CF). In a pediatric review of 2,545 facilities from 2015 to 2017 by the National Healthcare Safety Network (NHSN), *P. aeruginosa* ranked among the top 10 organisms to cause **central line–associated bloodstream infections** in all units: 2.8% neonatal intensive care unit (NICU), 5% pediatric intensive care unit (PICU), 5% pediatric oncology units, and 3.1% pediatric wards. *P. aeruginosa* was also the second most common cause of **catheter-associated urinary tract infections** (UTIs) (18.4%) and **ventilator-associated pneumonia** (16.1%) and the third most common cause of postoperative surgical site infections (8.3%). In a multicenter U.S. prospective study of 33 sites from 2014 to 2018, *P. aeruginosa* was isolated in 2.7% of bacteremic episodes in children ≤1 year old and 3.7 % in children ≤17 years of age.

P. aeruginosa and other pseudomonads frequently enter the hospital environment on the clothes, skin, or shoes of patients or hospital personnel, with plants or vegetables brought into the hospital, and in the gastrointestinal (GI) tract of patients. Colonization of any moist or liquid substance may ensue; the organisms may be found growing in any water reservoir, including distilled water, and in hospital kitchen sinks and laundries, some antiseptic solutions, and equipment used for respiratory therapy and urinary procedures. Colonization of skin, throat, stool, and nasal mucosa of patients is low at admission to the hospital but increases to as high as 50–70% with prolonged hospitalization and with the use of broad-spectrum antibiotics, chemotherapy, mechanical ventilation, and urinary catheters. Patients' intestinal microbial flora may be altered by the broad-spectrum antibiotics, reducing resistance to colonization and permitting *P. aeruginosa* in the environment to populate the GI tract. Intestinal mucosal breakdown associated with medications, especially cytotoxic agents, and nosocomial enteritis may provide a pathway by which *P. aeruginosa* spreads to the lymphatics or bloodstream.

PATHOLOGY

The pathologic manifestations of *P. aeruginosa* infections depend on the site and type of infection. Because of its elaboration of toxins and invasive factors, the organism can often be seen invading blood vessels and causing vascular necrosis. In some infections there is spread through tissues with necrosis and microabscess formation. In patients with CF, focal and diffuse bronchitis/bronchiolitis leading to bronchiolitis obliterans has been reported.

Pathogenesis

Invasiveness of *P. aeruginosa* is mediated by a host of virulence factors. Bacterial attachment is facilitated by pili that adhere to epithelium damaged by prior injury or infection. Extracellular proteins, proteases, elastases, and cytotoxins disrupt cell membranes, and in response, host-produced cytokines cause capillary vascular permeability and induce an inflammatory response. Dissemination and bloodstream invasion follow extension of local tissue damage and are facilitated by the antiphagocytic properties of endotoxin, the exopolysaccharide, and protease cleavage of immunoglobulin G. *P. aeruginosa* also produces numerous exotoxins, including exotoxin A, which causes local necrosis and facilitates systemic bacterial invasion. *P. aeruginosa* possesses a type III secretion system composed of a needle structure that inserts into host cell membranes and allows secretion of exotoxins directly into host cells. The host responds to infection with a robust inflammatory response, recruiting neutrophils to the infection site and producing antibodies to *P. aeruginosa* proteins. There is a lack of convincing data that these antibodies are protective against the establishment of infection.

In addition to acute infection, *P. aeruginosa* is also capable of chronic persistence because of the formation of **biofilms**, organized communities of bacteria encased in an extracellular matrix. Biofilm formation requires attachment to a surface, proliferation of the organism, and production of exopolysaccharide as the main bacterial component of the extracellular matrix. A mature biofilm can persist despite an intense host immune response and is resistant to many antimicrobials.

CLINICAL MANIFESTATIONS

Most clinical patterns are related to opportunistic infections in immunocompromised hosts (see Chapter 223) or are associated with shunts and indwelling catheters (see Chapter 224). *P. aeruginosa* may be introduced into a minor wound of a healthy person as a secondary invader, and cellulitis and a localized abscess that exudes green or blue pus may follow. The characteristic skin lesions of *P. aeruginosa,* **ecthyma gangrenosum**, whether caused by direct inoculation or a metastatic focus secondary to septicemia, begin as pink macules and progress to hemorrhagic nodules and eventually to ulcers with ecchymotic and gangrenous centers with eschar formation, surrounded by an intense red areola (Table 251.1 and Fig. 251.1).

Outbreaks of dermatitis and UTIs caused by *P. aeruginosa* have been reported in healthy persons after use of pools or hot tubs. Skin lesions of folliculitis develop several hours to 2 days after contact with these water sources. Skin lesions may be erythematous, macular, papular, or pustular. Illness may vary from a few scattered lesions to extensive truncal involvement. In some children, malaise, fever, vomiting, sore throat, conjunctivitis, rhinitis, and swollen breasts may be associated with dermal lesions. UTIs caused by *P. aeruginosa* are most often nosocomial and are often associated with the presence of an indwelling urinary catheter, urinary tract malformations, and previous antibiotic use. UTIs may be minimized or prevented by prompt removal of the catheter and by early identification and corrective surgery of obstructive lesions when present.

Burns and Wound Infection

The surfaces of burns or wounds are frequently populated by *P. aeruginosa* and other gram-negative organisms; this initial colonization with a low number of adherent organisms is a prerequisite to invasive disease. *P. aeruginosa* colonization of a burn site may develop into **burn wound sepsis**, which has a high mortality rate when the density of organisms reaches a critical concentration. Administration of antibiotics may

Table 251.1 *Pseudomonas aeruginosa* Infections

INFECTION	COMMON CLINICAL CHARACTERISTICS
Endocarditis	Native right-sided (tricuspid) valve disease with intravenous drug abuse
Pneumonia	Compromised local (lung) or systemic host defense mechanisms; nosocomial (respiratory), bacteremic (malignancy), or abnormal mucociliary clearance (cystic fibrosis) may be pathogenetic; cystic fibrosis is associated with mucoid *P. aeruginosa* organisms producing capsular slime
Central nervous system infection	Meningitis, brain abscess; contiguous spread (mastoiditis, dermal sinus tracts, sinusitis); bacteremia or direct inoculation (trauma, surgery)
External otitis	Swimmer's ear; humid warm climates, swimming pool contamination
Malignant otitis externa	Invasive, indolent, febrile, toxic, destructive, necrotizing lesion in young infants, immunosuppressed neutropenic patients, or diabetic patients; associated with seventh nerve palsy and mastoiditis
Chronic mastoiditis	Ear drainage, swelling, erythema; perforated tympanic membrane
Keratitis	Corneal ulceration; contact lens keratitis
Endophthalmitis	Penetrating trauma, surgery, penetrating corneal ulceration; fulminant progression
Osteomyelitis/septic arthritis	Puncture wounds of foot and osteochondritis; intravenous drug abuse; fibrocartilaginous joints, sternum, vertebrae, pelvis; open fracture osteomyelitis; indolent pyelonephritis and vertebral osteomyelitis
Urinary tract infection	Iatrogenic, nosocomial; recurrent UTIs in children, instrumented patients, and those with obstruction or stones
Intestinal tract infection	Immunocompromised, neutropenia, typhlitis, rectal abscess, ulceration, rarely diarrhea; peritonitis in peritoneal dialysis
Ecthyma gangrenosum	Metastatic dissemination; hemorrhage, necrosis, erythema, eschar, discrete lesions with bacterial invasion of blood vessels; also subcutaneous nodules, cellulitis, pustules, deep abscesses
Primary and secondary skin infections	Local infection; burns, trauma, decubitus ulcers, toe web infection, green nail (paronychia); whirlpool dermatitis; diffuse, pruritic folliculitis; vesiculopustular or maculopapular, erythematous lesions

Fig. 251.1 Round, nontender skin lesion on 2-yr-old female's buttock. Note the black ulcerated center of the lesion and its red margin. *(From Ghanaiem H, Engelhard D. A healthy 2-year-old child with a round black skin lesion. J Pediatr. 2013;163:1225.)*

diminish the susceptible microbiologic flora, permitting strains of relatively resistant *P. aeruginosa* to flourish. Multiplication of organisms in devitalized tissues or associated with prolonged use of intravenous or urinary catheters increases the risk for septicemia with *P. aeruginosa*, a major problem in burned patients (see Chapter 89).

Cystic Fibrosis

P. aeruginosa is common in patients with CF, with increasing prevalence as children get older (see Chapter 454). Initial infection is caused by **nonmucoid environmental strains** of *P. aeruginosa*, but after a variable period, **mucoid strains** of *P. aeruginosa* that produce the antiphagocytic exopolysaccharide alginate, which are rarely encountered in other conditions, predominate. Repeated isolation of mucoid *P. aeruginosa* from the sputum is associated with increased morbidity and mortality. The infection begins insidiously or even asymptomatically, and the progression has a highly variable pace. In children with CF, antibody does not eradicate the organism, and antibiotics are only partially effective; thus after infection becomes chronic, it cannot be completely eradicated. Repeated courses of antibiotics select for *P. aeruginosa* strains that are resistant to multiple antibiotics.

Immunocompromised Persons

Children with leukemia or other malignancies, particularly those who are receiving immunosuppressive therapy and who are neutropenic, typically with intravascular catheters, are extremely susceptible to septicemia caused by invasion of the bloodstream by *P. aeruginosa* that is colonizing the respiratory or GI tract. Signs of sepsis are often accompanied by a generalized vasculitis, and hemorrhagic necrotic lesions may be found in all organs, including the skin (ecthyma gangrenosum) (see Fig. 251.1). Hemorrhagic or gangrenous perirectal cellulitis or abscesses may occur, associated with ileus and profound hypotension.

Nosocomial Pneumonia

Although not a frequent cause of community-acquired pneumonia in children, *P. aeruginosa* does cause nosocomial pneumonia, especially ventilator-associated pneumonia, in patients of all ages. *P. aeruginosa* has historically been found to contaminate ventilators, tubing, and humidifiers. Such contamination is uncommon now because of disinfection practices and routine changing of equipment. Nevertheless, colonization of the upper respiratory tract and the GI tract may be followed by aspiration of *P. aeruginosa*–contaminated secretions, resulting in severe pneumonia. Prior use of broad-spectrum antibiotics is a risk factor for colonization with antibiotic-resistant strains of *P. aeruginosa*. One of the most challenging situations is distinguishing between colonization and pneumonia in intubated patients. This distinction can

often only be definitively resolved by using invasive culture techniques such as quantitative bronchoalveolar lavage.

Infants

P. aeruginosa is an occasional cause of **nosocomial bacteremia** in newborns and accounts for 2–5% of positive blood culture results in NICUs. A frequent focus preceding bacteremia is **conjunctivitis**. Older infants rarely present with community-acquired sepsis caused by *P. aeruginosa.* In the few reports describing community-acquired sepsis, preceding conditions included ecthyma-like skin lesions, virus-associated transient neutropenia, and prolonged contact with contaminated bath water or a hot tub.

DIAGNOSIS

P. aeruginosa infection is rarely clinically distinctive. Diagnosis depends on recovery of the organism from the blood, cerebrospinal fluid (CSF), urine, or needle aspirate of the lung or from purulent material obtained by aspiration of subcutaneous abscesses or areas of cellulitis. In the appropriate clinical setting, recovery of *P. aeruginosa* from a coughed or suctioned sputum may represent infection; but it also may only represent colonization, and clinical judgment is required. Rarely, skin lesions that resemble *P. aeruginosa* infection may follow septicemia caused by *Aeromonas hydrophila,* other gram-negative bacilli, and *Aspergillus.* When *P. aeruginosa* is recovered from nonsterile sites such as skin, mucous membranes, or voided urine, quantitative cultures may be useful to differentiate colonization from invasive infection. In general, ≥100,000 colony-forming units/mL of fluid or gram of tissue is evidence suggestive of invasive infection. Quantitative cultures of tissue and skin are not routine and require consultation with the clinical microbiology laboratory.

TREATMENT

Systemic infections with *P. aeruginosa* should be treated promptly with an antibiotic to which the organism is susceptible in vitro. Response to treatment may be limited, and prolonged treatment may be necessary for systemic infection in immunocompromised hosts.

Septicemia and other aggressive infections should be treated with either one or two bactericidal agents. Although the number of agents required is controversial, the evidence continues to suggest that the benefit of adding a second agent is questionable, even when studies have included immunosuppressed patients. *Appropriate antibiotics for single-agent therapy include ceftazidime, cefepime, ticarcillin-clavulanate, and piperacillin-tazobactam. Gentamicin or another aminoglycoside may be used concomitantly for synergistic effect.*

Ceftazidime has proved to be extremely effective in patients with CF, at 150-400 mg/kg/day divided every 6-8 hours intravenously (IV) to a maximum of 6 g/day. Piperacillin or piperacillin-tazobactam 240-400 mg/kg/day divided every 6-8 hours IV to a maximum of 12 g/day also has proved to be effective therapy for susceptible strains of *P. aeruginosa.* Continuous infusions of β-lactam antibiotics are more effective than the same daily dose given as pulse infusions.

Additional effective antibiotics include imipenem-cilastatin, meropenem, and aztreonam. Ciprofloxacin (20-30 mg/kg/day orally every 8-12 hours up to 500 mg/dose) is the only available effective oral *P. aeruginosa* therapy, and although commonly used in children with CF, it is not approved in the United States for persons <18 years old, except for oral treatment of UTIs or when treating multidrug-resistant (MDR) *P. aeruginosa*. Inhaled therapy with either tobramycin or aztreonam is also used for chronic pulmonary infection, with inhaled colistin reserved for the treatment of resistant pseudomonads. Macrolide therapy decreases pulmonary exacerbations in patients with chronic lung disease and *P. aeruginosa* infection. The mechanism relates to altering the virulence properties of *P. aeruginosa* rather than direct bacterial killing.

It is important to base continued treatment on antimicrobial susceptibility tests because **antibiotic resistance** of *P. aeruginosa* is increasing. *P. aeruginosa* has many mechanisms for resistance to multiple classes of antibiotics, including but not limited to pathogenic variants, production of β-lactamases, and drug efflux pumps. Throughout the United States there has been an alarming increase in MDR *P. aeruginosa* isolates resistant to at least three antibiotic classes recovered from children. NHSN data from 2015 to 2017 show 2.8% NICU, 12% PICU, 6% pediatric oncology, and 5.5% pediatric ward *P. aeruginosa* isolates were MDR, with increasing rates of carbapenem and piperacillin/tazobactam resistance as well.

Several newer agents demonstrate efficacy against MDR *P. aeruginosa*. Ceftazidime-avibactam and ceftolozane-tazobactam combine cephalosporins with a β-lactamase inhibitor. Ceftolozane-tazobactam inhibits AmpC and other extended-spectrum β-lactamases but lacks activity against carbapenemases. Ceftazidime-avibactam inhibits class A carbapenemases but not metallo-β-lactamases. Cefiderocol, a siderophore cephalosporin, has enhanced stability to β-lactamases, including metallo-β-lactamases, Amp C, and carbapenemases.

Meningitis can occur by spread from a contiguous focus, as a secondary focus when there is bacteremia, or after invasive procedures. *P. aeruginosa* meningitis is best treated with ceftazidime or meropenem in combination with an aminoglycoside such as gentamicin, both given IV. Concomitant intraventricular or intrathecal treatment with gentamicin may be required when IV therapy fails but is not recommended for routine use.

SUPPORTIVE CARE

P. aeruginosa infections vary in severity from *superficial* to *intense* septic presentations. With severe infections there is often multisystem involvement and a systemic inflammatory response. Supportive care is similar to care for severe sepsis caused by other gram-negative bacilli and requires support of blood pressure, oxygenation, and appropriate fluid management.

PROGNOSIS

The prognosis is dependent primarily on the nature of the underlying factors that predisposed the patient to *P. aeruginosa* infection. In severely immunocompromised patients, the prognosis for patients with *P. aeruginosa* sepsis is poor unless susceptibility factors such as neutropenia or hypogammaglobulinemia can be reversed. The overall mortality rate was 12.3% in one series of 232 children with *P. aeruginosa* bacteremia, with 3% dying within 48 hours of admission. Resistance of the organism to first-line antibiotics also decreases the chance of survival. The outcome may be improved when there is a urinary tract portal of entry, absence of neutropenia or recovery from neutropenia, and drainage of local sites of infection.

P. aeruginosa is recovered from the lungs of most children who die of CF and adds to the slow deterioration of these patients. The prognosis for normal development is poor in the few infants who survive *P. aeruginosa* meningitis.

PREVENTION

Prevention of infections is dependent on limiting contamination of the healthcare environment and preventing transmission to patients. Effective hospital infection control programs are necessary to identify and eradicate sources of the organism as quickly as possible. In hospitals, infection can be transmitted to children by the hands of personnel, from washbasin surfaces, from catheters and other hospital equipment, and from solutions used to rinse suction catheters.

Strict attention to hand hygiene before and between contacts with patients may prevent or interdict epidemic disease. Meticulous care and sterile procedures in the suctioning of endotracheal tubes, insertion and maintenance of indwelling catheters, and removal of catheters as soon as medically reasonable greatly reduce the hazard of extrinsic contamination by *P. aeruginosa* and other gram-negative organisms. Prevention of follicular dermatitis caused by *P. aeruginosa* contamination of whirlpools or hot tubs is possible by maintaining pool water at a pH of 7.2-7.8. Antimicrobial stewardship programs that promote the appropriate use of antibiotics in the hospital setting are critical for reducing the rates of MDR *P. aeruginosa*.

Infections in burned patients may be minimized by protective isolation, debridement of devitalized tissue, and topical applications of bactericidal cream. Administration of intravenous immunoglobulin

may be used. Approaches under investigation to prevent infection include development of a *P. aeruginosa* vaccine. No vaccine is currently licensed in the United States.

251.2 *Burkholderia cepacia* Complex

Ashley C. Howard and Thomas S. Murray

Burkholderia cepacia is a filamentous gram-negative rod now recognized to be a group of related species or **genomovars** *(B. cepacia, B. cenocepacia, B. multivorans)*. It is ubiquitous in the environment but may be difficult to isolate from respiratory specimens in the laboratory, requiring an enriched, selective media oxidation-fermentation base supplemented with polymyxin B–bacitracin-lactose agar (OFPBL) and as long as 3 days of incubation.

B. cepacia is a classic opportunist that rarely infects normal tissue but can be a pathogen for individuals with preexisting damage to respiratory epithelium, especially persons with CF or with immune dysfunction such as chronic granulomatous disease. *B. cepacia* has multiple virulence factors, including lipopolysaccharide, flagella, and a type III secretion system that promotes invasion of respiratory epithelial cells. Resistance to many antibiotics and disinfectants appears to be a factor in the emergence of *B. cepacia* as a nosocomial pathogen. In critical care units it may colonize the tubing used to ventilate patients with respiratory failure. In some patients this colonization may lead to invasive pneumonia and septic shock. Although *B. cepacia* is found throughout the environment, human-to-human spread among CF patients occurs either directly by inhalation of aerosols or indirectly from contaminated equipment or surfaces, accounting for the strict infection control measures for children with CF who are colonized with *B. cepacia*. For example, CF patients colonized with *B. cepacia* are asked not to attend events where other persons with CF will be present. *B. cepacia* infections in persons with CF may represent chronic infection in some patients, but others, especially those with *Burkholderia cenocepacia*, genomovar III, can develop an acute respiratory syndrome of fever, leukocytosis, and progressive respiratory failure, with more rapid decline in pulmonary function and lower survival rate. In 2016-2017, two healthcare-associated *B. cepacia* outbreaks among non-CF patients occurred as a result of contaminated liquid docusate that infected 63 persons from 12 states and prefilled saline flushes that infected 163 persons with 7 deaths. In August 2021, a healthcare-associated outbreak of *B. stabilis* was linked to ultrasound gel used in 59 persons in six states, with 48 cases of bloodstream infection.

Treatment in hospitals should include standard precautions and avoidance of placing colonized and uncolonized patients in the same room. The use of antibiotics is guided by susceptibility studies of a patient's isolates, because the susceptibility pattern of this species is quite variable and resistant strains are common. *Trimethoprim-sulfamethoxazole (TMP-SMX) and doxycycline or minocycline are potential oral therapies for B. cepacia complex. For IV therapy without meningitis, meropenem (20-40 mg/kg/dose every 8 hours with a maximum dose of 6 g/day) with a second agent such as TMP-SMX, doxycycline, minocycline, ceftazidime, or amikacin is recommended.* Extended infusions should be considered for difficult-to-treat infections. Even though there is primary resistance to aminoglycosides, these agents may be useful in combination with other antibiotics. Treatment with two or more agents may be necessary to control the infection and avoid the development of resistance. Cefiderocol, because of its increased stability against β-lactamases, has activity against some MDR *B. cepacia complex.*

BURKHOLDERIA MALLEI (GLANDERS)

Glanders is a severe infectious disease of horses and other domestic and farm animals that is caused by *Burkholderia mallei,* a nonmotile, gram-negative bacillus that is occasionally transmitted to humans. It is acquired by inoculation into the skin, usually at the site of a previous abrasion, or by inhalation of aerosols. Laboratory workers may acquire it from clinical specimens. The disease is relatively common in Asia, Africa, and the Middle East. The clinical manifestations include septicemia, acute or chronic pneumonitis, and hemorrhagic necrotic lesions of the skin, nasal mucous membranes, and lymph nodes. The diagnosis is usually made by recovery of the organism in cultures of affected tissue. Glanders is treated with sulfadiazine, tetracyclines, or chloramphenicol and streptomycin over many months. The disease has been eliminated from the United States, but interest in this organism has increased because of the possibility of its use as a bioterrorism agent (see Chapter 763). Although standard precautions are appropriate when caring for hospitalized infected patients, biosafety level 3 precautions are required for laboratory staff working with *B. mallei.* No vaccine is available.

Fig. 251.2 Thigh abscesses at the sites of mosquito bites in a 15-yr-old Pennsylvania resident who had recently returned from Thailand, July 2016. Photo was taken 7 wk after onset. *(From Mitchell PK, Campbell C, Montgomery MP, et al. Notes from the field: travel–associated melioidosis and resulting laboratory exposures—United States, 2016. MMWR. 2017;66[37]:1001–1002.)*

BURKHOLDERIA PSEUDOMALLEI (MELIOIDOSIS)

Melioidosis is an important disease of Southeast Asia and northern Australia and occurs in the United States mainly in persons returning from endemic areas. The causative agent is *Burkholderia pseudomallei,* an inhabitant of soil and water in the tropics. It is ubiquitous in endemic areas, and infection follows inhalation of dust, ingestion, or direct contamination of abrasions or wounds. Human-to-human transmission has only rarely been reported. Serologic surveys demonstrate that asymptomatic infection occurs in endemic areas. The disease may remain latent and appear when host resistance is reduced, sometimes years after the initial exposure. Diabetes mellitus is a risk factor for severe melioidosis. In 2021, four cases of melioidosis with two deaths occurred in Kansas, Minnesota, Texas, and Georgia in persons, including children, with no known travel. The exposure is unknown but thought to be from a single source, such as a contaminated imported product or animal.

Melioidosis may present as a **primary skin lesion** (vesicle, bulla, or urticaria) (Fig. 251.2). Pulmonary infection may be subacute and mimic tuberculosis or may present as an acute necrotizing pneumonia. Occasionally, septicemia occurs and numerous abscesses are noted in various organs of the body. Myocarditis, pericarditis, endocarditis, intestinal abscess, cholecystitis, acute gastroenteritis, UTIs, septic arthritis, paraspinal abscess, osteomyelitis, mycotic aneurysm, and generalized lymphadenopathy all have been observed. Melioidosis may also present as an encephalitic illness with fever and seizures. It is also an agent of severe wound infections after contact with contaminated water after a tsunami. Diagnosis is based on visualization of characteristic small, gram-negative rods in exudates or growth on laboratory media such as eosin–methylene blue or MacConkey agar. Serologic

tests are available, and diagnosis can be established by a fourfold or greater increase in antibody titer in an individual with an appropriate syndrome. It is recognized as a possible agent of bioterrorism, and if suspected, the clinical microbiology laboratory should be notified immediately (see Chapter 763).

B. pseudomallei is susceptible to many antimicrobial agents, and the U.S. Centers for Disease Control and Prevention (CDC) recommends meropenem or ceftazidime as IV therapies and TMP-SMX or doxycycline as oral therapy. Other choices include aminoglycosides, tetracycline, chloramphenicol, and amoxicillin-clavulanate. Therapy should be guided by antimicrobial susceptibility tests; two or three agents such as ceftazidime or meropenem plus TMP-SMX, sulfisoxazole, or an aminoglycoside are usually chosen for severe or septicemic disease. For severe disease, prolonged treatment for 2-6 months is recommended to prevent relapses. Appropriate antibiotic therapy generally results in recovery.

251.3 *Stenotrophomonas*

Ashley C. Howard and Thomas S. Murray

Stenotrophomonas maltophilia (formerly *Xanthomonas maltophilia* or *Pseudomonas maltophilia*) is a short to medium-sized, straight, gram-negative bacillus. It is ubiquitous in nature and can be found in the hospital environment, especially in tap water or standing water, and may contaminate sinks and hospital equipment such as nebulizers. Strains isolated in the laboratory may be contaminants, may be a commensal from the colonized surface of a patient, or may represent an invasive pathogen. The species is an opportunist and is often recovered from immunosuppressed patients and patients with CF after multiple courses of antimicrobial therapy. Serious infections usually occur among those requiring intensive care, including neonatal intensive care, typically patients with ventilator-associated pneumonia or catheter-associated infections. Prolonged antibiotic exposure appears to be a frequent factor in nosocomial *S. maltophilia* infections, probably because of its endogenous antibiotic-resistance pattern. Common types of infection include pneumonia after airway colonization and aspiration, bacteremia, soft tissue infections, endocarditis, and osteomyelitis. *S. maltophilia* bacteremia is a **nosocomial infection** associated with the presence of a central venous catheter.

Strains vary as to antibiotic susceptibility, and the treatment of *S. maltophilia* can be difficult because of inherent antimicrobial resistance. Data are lacking on whether there is clinical benefit to treat *S. maltophilia* recovered from the respiratory tract of a patient with CF. For invasive infections, ***TMP-SMX*** *(20 mg/kg/day TMP component every 6-8 hours) is the treatment of choice and is the only antimicrobial for which susceptibility is routinely reported.* ***Minocycline*** *monotherapy has recently been shown to be a viable alternative to TMP-SMX* and is reported for TMP-SMX resistance strains with fewer adverse effects and similar clinical outcomes. Mean inhibitory concentration testing is available for other antibiotics, such as ticarcillin-clavulanate, and also reserved for TMP-SMX–resistant isolates. *For resistant organisms or for patients who cannot tolerate sulfa drugs, other options based on clinical outcome include ciprofloxacin and ceftazidime alone or in combination with other agents such as aminoglycosides.*

ACKNOWLEDGMENTS

We would like to acknowledge Dr. Robert S. Baltimore for his contribution to this chapter and Dr. Michelle R. Rychalsky for antibiotic dosing regimens.

Chapter 252

Tularemia (*Francisella tularensis*)

Kevin J. Downes

Tularemia is a **zoonosis** caused by the gram-negative bacterium *Francisella tularensis.* Tularemia is primarily a disease of wild animals; human disease is incidental and usually results from **tick** or **deer fly** bites or from contact with infected live or dead wild animals. The illness caused by *F. tularensis* is manifest by multiple clinical syndromes, the most common consisting of an ulcerative lesion at the site of inoculation with regional **lymphadenopathy** or **lymphadenitis**. *F. tularensis* is also a potential agent of **bioterrorism** (see Chapter 763).

ETIOLOGY

Francisella tularensis is a small, nonmotile, pleomorphic, catalase-positive, gram-negative coccobacillus. It can be classified into four main subspecies: *F. tularensis* subsp. *tularensis* (type A), *F. tularensis* subsp. *holarctica* (type B), *F. tularensis* subsp. *mediasiatica*, and *F. tularensis* subsp. *novicida*. Type A can be further subdivided into four distinct genotypes designated A1a, A1b, A2a, and A2b, with A1b appearing to produce more serious disease in humans. Although all subspecies of *F. tularensis* can cause human infections, types A and B are most common, and type A is the most virulent. *F. tularensis* is an intracellular organism than can infect various host cell types, including macrophages, hepatocytes, and epithelial cells. It is one of the most virulent bacterial pathogens known, with as few as 10 microorganisms causing infections in humans and animals.

EPIDEMIOLOGY

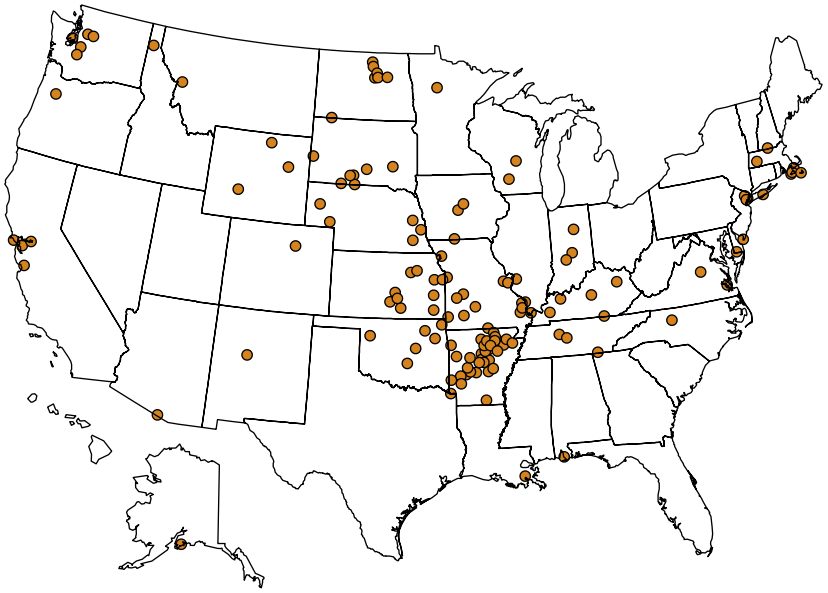
Tularemia is primarily found in the Northern Hemisphere. Type A is found predominantly in North America, whereas type B is found throughout North America, Europe, and Asia. Human infections with type B are usually milder and have lower mortality rates compared to infections with type A. *F. tularensis* subsp. *mediasiatica* appears to be restricted to Central Asia, whereas *F. tularensis* subsp. *novicida* has been isolated in North America, Australia, and Southeast Asia.

According to the Centers for Disease Control and Prevention (CDC), the number of annual reported cases of tularemia in the United States from 2010 to 2019 ranged from 124 to 314 per year. In 2015 the number of cases reported in the United States was the highest it had been over the previous 50 years. Tularemia occurs all over the Unites States, with the majority of cases reported from central states (Fig. 252.1). The U.S. incidence of tularemia from 2010 to 2019 was 0.10 per 100,000 residents; Arkansas (3.1/100,000), South Dakota (1.9/100,000), and Nebraska (0.9/100,000) were the states with the highest incidence.

Although cases of tularemia occur all year, most cases and outbreaks occur in warm summer months (May-September). Tularemia is more common in males, although this is less true in children compared with adults. There is a bimodal distribution based on age with peaks in childhood (5-9 years) and later adulthood (50-69 years), potentially because of greater opportunities for environmental and animal exposures at these ages (Fig. 252.2).

PATHOGENESIS

Of all the zoonotic diseases, tularemia is unusual because of the different modes of transmission of disease. A large number of animals serve as a reservoir for this organism. In the United States, rabbits and ticks are the principal reservoirs. Dogs may be an intermediate vector. In the United States, *Amblyomma americanum* (lone star tick), *Dermacentor variabilis* (dog tick), and *Dermacentor andersoni* (wood tick) are the most common tick vectors. These ticks usually feed on infected small



* One dot is placed randomly within county of residence for each reported case.

Fig. 252.1 Map of reported cases of tularemia—United States, 2020. *(From Centers for Disease Control and Prevention: Tularemia—Statistics, https://www.cdc.gov/tularemia/statistics/index.html, Accessed: August 25, 2021.)*

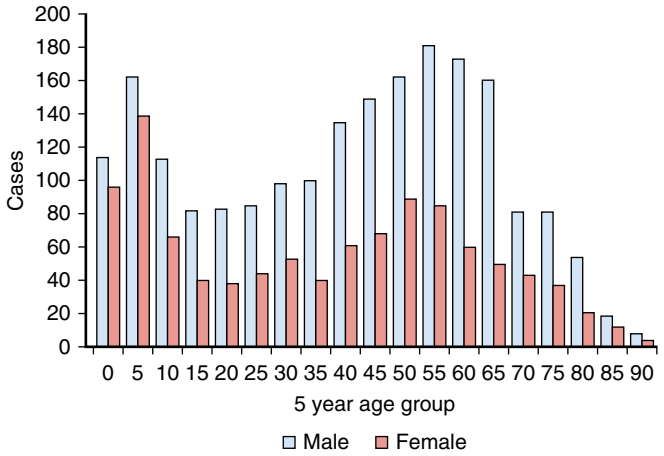


Fig. 252.2 Incidence of reported cases of tularemia by age and sex—United States, 2001–2020. *(From Centers for Disease Control and Prevention: Tularemia—Statistics, https://www.cdc.gov/tularemia/statistics/index.html, Accessed: August 25, 2021.)*

rodents and later feed on humans. Deer flies (*Chrysops* spp.) can also transmit tularemia and are present in the western United States. *F. tularensis* subsp. *tularensis* is carried by rabbits, ticks, and tabanid flies (e.g., deer flies), whereas subsp. *holarctica* is associated with aquatic habitats and transmitted primarily by mosquitoes, but also aquatic rodents (beavers, muskrats), hares, voles, ticks, tabanid flies, and ingestion of contaminated water (e.g., ponds, rivers).

The organism can penetrate both intact skin and mucous membranes (eyes, mouth, gastrointestinal [GI] tract, or lungs), which are the most common portals of entry. Transmission can occur through the bite of infected ticks or other biting insects, by contact with infected animals or their carcasses, by consumption of contaminated foods or water, or through inhalation, as might occur in a laboratory setting or if a machine (e.g., lawn mower) runs over an infected animal carcass. Hunting or skinning infected wild rodents, such as rabbits or prairie dogs, has been the source of infection in numerous reports. Domesticated animals such as cats and hamsters can also transmit tularemia. Importantly, this organism is not transmitted from person to person.

Usually >10^8 organisms are required to produce infection if *F. tularensis* bacteria are ingested, but as few as 10 organisms may cause disease if they are inhaled or injected into the skin (i.e., via an insect bite). Infection with *F. tularensis* stimulates the host to produce antibodies, which have been recognized as important in the immune response to this organism. The *F. tularensis* envelope is largely responsible for virulence and plays major roles in the ability of the organism to evade the immune system, attach to and invade cells, and cause severe disease. The body is most dependent on cell-mediated immunity to contain and eradicate *F. tularensis*. Tularemia is usually followed by specific protection; chronic infection or reinfection is therefore unlikely.

CLINICAL MANIFESTATIONS

Symptoms of tularemia vary based on the mode of transmission. The average incubation period from infection until clinical symptoms is 3 days (range: 1-21 days). Early symptoms of infection are generally nonspecific: fever, chills, myalgias, arthralgias, headache, and fatigue. Bacteremia may be common in the early stages of infection. Acute infections often present with sudden onset of fever, and a pulse-temperature dissociation may be present. Findings on physical examination may include lymphadenopathy, hepatosplenomegaly, or skin lesions. Table 252.1 shows the frequency of various symptoms and examination findings.

The clinical manifestations of tularemia have been divided into six major clinical syndromes (Table 252.2). **Ulceroglandular** and **glandular** disease are the two most common forms of tularemia in children. Infections after the bites of ticks or deer flies take these forms. Within 48-72 hours after inoculation of the skin, an erythematous, tender, or pruritic papule may appear at the portal of entry. This papule may enlarge and form an ulcer with a black base. Ulcers are generally erythematous and painful with raised borders and may last several weeks, especially if untreated. Various other skin lesions have been described, including erythema multiforme and erythema nodosum. Approximately 20% of patients may develop a generalized maculopapular rash that occasionally becomes pustular. The unifying manifestation of glandular and ulceroglandular forms of tularemia is **painful regional lymphadenopathy**. Adenopathy may develop before, concurrent with, or

Table 252.1 Common Clinical Manifestations of Tularemia in Children

SIGN OR SYMPTOM	APPROXIMATE FREQUENCY (%)
Lymphadenopathy	90
Fever (>38.3°C [100.9°F])	85
Ulcer/eschar/papule	45
Pharyngitis	40
Myalgias/arthralgias	40
Nausea/vomiting	35
Hepatosplenomegaly	35

Table 252.2 Clinical Syndromes of Tularemia in Children

CLINICAL SYNDROME	CHARACTERISTICS OF SYNDROME
Ulceroglandular	Skin ulcer/eschar at site of inoculation; painful regional adenopathy
Glandular	Painful regional adenopathy without detectable skin ulceration
Pneumonia	Nonproductive cough, dyspnea, pleuritic chest pain; multilobar/diffuse infiltrates > lobar infiltrates on chest radiography
Oropharyngeal	Pharyngitis, mucosal ulcers, cervical adenopathy
Oculoglandular	Unilateral, painful, and often purulent conjunctivitis; chemosis; conjunctival ulcers; preauricular adenopathy
Typhoidal	Severe systemic disease (sepsis-like syndrome): high fever, headaches, myalgias, arthralgias, neurologic symptoms

after skin ulceration in ulceroglandular disease. Cervical or posterior auricular nodes are involved after bites on the head or neck, whereas enlarged axillary or epitrochlear nodes signal exposure on the arms. Nodes may vary in size from 0.5 to 10 cm and appear singly or in clusters. These affected nodes may become fluctuant and drain spontaneously and are often associated with overlying skin changes. Late suppuration of the involved nodes has been described in 25–30% of patients despite effective therapy. Examination of this material from such lymph nodes usually reveals sterile necrotic material. Mortality with these forms of tularemia is rare, especially with implementation of effective treatment.

Oropharyngeal tularemia results from consumption of poorly cooked meats or contaminated water. This syndrome is characterized by acute pharyngitis, with or without tonsillitis, and cervical lymphadenitis. Infected tonsils may become large and develop a yellowish-white membrane that may resemble the membranes associated with diphtheria. GI disease may also occur and usually presents with mild, unexplained diarrhea or emesis but may progress to rapidly fulminant and fatal disease. GI bleeding can develop in more severe forms associated with intestinal ulcers.

Oculoglandular disease is uncommon, but when it does occur, the portal of entry is the conjunctiva. Contact with contaminated fingers or debris is the most common mechanism of this form of tularemia. Disease is generally unilateral. The conjunctiva is painful and inflamed with yellowish nodules and pinpoint ulcerations. Purulent conjunctivitis with ipsilateral preauricular or submandibular lymphadenopathy can develop and is referred to as **Parinaud oculoglandular syndrome**, although this term is not specific to tularemia. Corneal ulceration and perforation are uncommon but serious complications of this form of disease.

The **typhoidal** form is usually associated with a large inoculum of organisms and is a term used to describe nonlocalizing disease, regardless of the mode of transmission or portal of entry. Patients are often critically ill and bacteremic, and symptoms mimic those with other forms of sepsis: high fevers, confusion, rigors, myalgias, vomiting, and diarrhea. Clinicians practicing in tularemia-endemic regions must always consider this diagnosis in critically ill children. Complications of bacteremia with *F. tularensis* can include the development of meningitis, pericarditis, hepatitis, peritonitis, endocarditis, skin/soft tissue abscesses, and osteomyelitis. Because of its increased virulence, *F. tularensis* subsp. *tularensis* (type A disease) is more often associated with typhoidal tularemia. Patients with tularemia meningitis usually develop a marked cerebrospinal fluid (CSF) pleocytosis with a monocytic predominance. As with other causes of bacterial meningitis, CSF glucose is low and protein is high.

Pneumonia caused by *F. tularensis* **(pneumonic form)** can develop after inhalation (primary pulmonary infection) or secondary to hematogenous spread. Inhalation-related infection has been described in laboratory workers who are working with the organism and results in a relatively high mortality rate. Aerosols from farming activities involving rodent contamination (haying, threshing) or animal carcass destruction with lawn mowers have been reported to cause pneumonia as well. Patients generally complain of a nonproductive cough, dyspnea, or pleuritic chest pain. Chest radiographs of patients with pneumonic tularemia most often reveal diffuse, patchy infiltrates rather than focal areas of consolidation. Pleural effusions can also be present. In pulmonary infections, hilar or mediastinal adenopathy can develop, and in severe forms, necrotizing or hemorrhagic pneumonitis can occur. Mortality with pneumonic tularemia is high if untreated.

DIAGNOSIS

The diagnosis can be delayed because symptoms are often similar to other, more common infections. The history and physical examination of the patient may suggest the diagnosis, especially if the patient has a history of animal or tick exposure. Routine hematologic blood tests are nondiagnostic. **Definitive diagnosis is made by growth of *F. tularensis* in culture.** *F. tularensis* can be isolated in culture of lymph node biopsies or aspirates, blood, wounds, pharyngeal swabs, pleural fluid, or sputum specimens, although cultures are positive in only approximately 10% of cases. The organism can be identified on culture from skin lesions and lymph nodes for as long as a month after onset of disease. Polymerase chain reaction of tissue specimens may be more sensitive than culture but is currently used to make a presumptive diagnosis only.

F. tularensis can be cultured in the microbiology laboratory on cysteine–glucose–blood agar, but care should be taken to alert the personnel in the laboratory if this is attempted so that they can take the proper precautions to protect themselves from acquiring infection; biosafety level 3 containment is necessary to avoid occupational exposure. Histopathologic findings of involved lymph nodes demonstrate granulomas with central necrosis (early) and caseation (late). Unfortunately, these findings cannot distinguish tularemia from other causes of granulomatous lymphadenitis, such as tuberculosis, cat-scratch disease (*Bartonella henselae* infection), or sarcoidosis.

The diagnosis of tularemia is most often established via serology. In the standard tube agglutination (TA) test, a single titer of ≥1:160 in a patient with a compatible history and physical findings can establish the diagnosis. A microagglutination (MA) test is also available, and ≥1:128 is considered positive. Patients often do not produce detectable antibodies until the second week of illness, so negative testing in the acute phase does not rule out infection. A fourfold increase in titer from paired serum samples collected >2 weeks apart (i.e., acute and convalescent titers) can also be considered diagnostic. False-negative serologic responses can be obtained early in the infection or if paired sera are collected too close together. False-positive serologic tests can also result from cross-reactivity with other gram-negative organisms, such as *Brucella* or *Legionella* species, particularly at low titers. Once infected, patients may have a positive agglutination test result (1:20-1:80) that persists for life. Other testing techniques available include enzyme-linked immunosorbent assay (ELISA), analysis of urine for tularemia antigen, indirect immunofluorescent assay, and immunohistochemical staining; these studies have less well-established roles in the diagnosis of tularemia.

Differential Diagnosis

The differential diagnosis of **ulceroglandular** or **glandular** tularemia is broad and includes infection with pathogens that cause acute or subacute lymphadenitis: cat-scratch disease *(B. henselae)*, infectious mononucleosis, typical bacterial pathogens (*Staphylococcus aureus,* group A streptococcus), *Mycobacterium tuberculosis,* nontuberculous mycobacteria, *Toxoplasma gondii, Sporothrix schenckii,* plague *(Yersinia pestis)*, anthrax *(Bacillus anthracis)*, melioidosis *(Burkholderia pseudomallei)*, and rat-bite fever *(Streptobacillus moniliformis, Spirillum minus)*. Noninfectious processes such as sarcoidosis and Kawasaki disease can also present similarly. **Oculoglandular** disease may also occur with other infectious agents, such as *B. henselae, Treponema pallidum, Coccidioides immitis,* herpes simplex virus (HSV), adenoviruses, and the bacterial agents responsible for purulent conjunctivitis. **Oropharyngeal** tularemia must be differentiated from the same diseases that cause ulceroglandular/glandular disease and from cytomegalovirus, HSV, adenovirus, and other viral or bacterial etiologies. **Pneumonic** tularemia must be differentiated from the other atypical pathogens that cause community-acquired pneumonia, such as *Mycoplasma* and *Chlamydophila,* as well as mycobacteria, fungi, and rickettsiae. Inhalation plague, anthrax, and Q fever could also present similarly. **Typhoidal** tularemia must be differentiated from other forms of sepsis and from enteric fever (typhoid and paratyphoid fever) and brucellosis.

TREATMENT

Aminoglycosides are the mainstay of treatment of tularemia: **gentamicin is the drug of choice for the treatment of tularemia in children**, and streptomycin is the drug of choice in adults. Table 252.3 displays therapeutic options for treatment of tularemia and for postexposure prophylaxis. **Ciprofloxacin is often used for mild (localized) cases**, especially those caused by subsp. *holarctica,* but is less commonly prescribed in children. Doxycycline has been used successfully, but the relapse rate is higher than with aminoglycosides, and so it is not generally recommended. Ciprofloxacin and doxycycline are often used as adjunctive therapy for treatment of tularemia meningitis because of the poor penetration of aminoglycosides in the CSF. Ciprofloxacin can also be considered in cases of moderate/severe disease after initial treatment with an aminoglycoside, if an IV-to-PO switch is warranted based on clinical improvement. β-lactam agents demonstrate poor activity against *F. tularensis* and should not be used.

Therapy with aminoglycosides is typically continued for 7-10 days, but a longer course is needed in more severe disease; 5-7 days may be sufficient for mild cases. Ciprofloxacin treatment is typically 10-14 days, although there is no FDA-approved regimen for tularemia specifically. Treatment with doxycycline should be continued for 14-21 days because of an increased risk of relapse, likely because of its bacteriostatic nature.

PROGNOSIS

Poor outcomes are associated with a delay in appropriate treatment, but with rapid recognition and treatment, fatalities are exceedingly rare. The mortality rate for severe untreated disease (e.g., pneumonia, typhoidal disease) can be as high as 30%. Otherwise, the overall mortality rate is <1%. Subspecies *tularensis* is associated with more aggressive disease and worse outcomes than subsp. *holarctica*.

Relapses are uncommon if aminoglycoside therapy is used. Patients typically defervesce within 24-48 hours after starting therapy, although lymphadenopathy can take several weeks to resolve fully. Late suppuration of involved lymph nodes may occur despite adequate therapy. Patients who have not started on appropriate therapy early may respond more slowly to antimicrobial therapy.

PREVENTION

Prevention of tularemia is based on avoiding exposure. Children living in tick-endemic regions should be taught to avoid tick-infested areas. Families should have a tick control plan for their immediate environment and for their pets. Protective clothing should be worn when entering a tick-infested area. Insect repellents can be used safely

Table 252.3 Recommended Treatment for Children with Tularemia

INDICATION	DRUG AND DOSAGE	DURATION
Moderate-severe disease	Gentamicin 5-7.5 mg/kg/day IV or IM divided every 8-12 hr* *or* Streptomycin 30-40 mg/kg/day IM divided every 12 hr (max 1 g/dose)	≥10 days
Mild disease	Gentamicin 5-7.5 mg/kg/day IV or IM divided every 8-12 hr* *or* Ciprofloxacin 20-40 mg/kg/day PO divided every 12 hr (max 500 mg/dose)	5-7 days 10-14 days
Meningitis	Streptomycin or gentamicin (in doses given for moderate-severe disease) *PLUS* Ciprofloxacin (20-40 mg/kg/day IV divided every 12 hr) *or* Doxycycline 4.4 mg/kg/day IV divided every 12 hr (max 100 mg/dose)	≥10 days
Postexposure prophylaxis	Doxycycline 4.4 mg/kg/day PO divided twice daily (max 100 mg/dose) *or* Ciprofloxacin 20-40 mg/kg/day PO divided twice daily (max 500 mg/dose)	14 days

*Once-daily dosing of gentamicin could be considered, although it has not specifically been studied for this indication.
IM, Intramuscularly; IV, intravenously; PO, per os (i.e., by mouth).

in infants and children. Children should undergo frequent tick checks during and after their time in tick-infested areas. If ticks are found on the child, forceps should be used to pull the tick straight out. The skin should be cleansed before and after this procedure. Children should also be taught to avoid sick and dead animals. Children should be encouraged to wear gloves, masks, and eye protection while cleaning wild game. Further, families should cook wild game thoroughly before eating.

Prophylactic antimicrobial agents are generally not effective in preventing tularemia and should not be used after exposure, with the exception of laboratory or bioterrorism exposures. No tularemia vaccine is currently available to the general public (one is available for high-risk laboratory workers through the Department of Defense). Standard precautions are adequate for hospitalized children with tularemia because no cases of person-to-person transmission have been identified.

Chapter 253

Brucella

Kevin J. Downes

Human **brucellosis** is caused by organisms of the genus *Brucella* and continues to be a major public health problem worldwide. Humans are accidental hosts and acquire this **zoonosis** from direct contact with an infected animal (cattle, sheep, camels, goats, and swine) or consumption of products of an infected animal. Although brucellosis is widely recognized as an occupational risk among adults working with livestock, much of the brucellosis in children is food-borne and is associated with consumption of unpasteurized dairy products. *Brucella* spp. are also potential agents of bioterrorism (see Chapter 763).

ETIOLOGY

Brucella abortus (cattle), *Brucella melitensis* (goats and sheep), *Brucella suis* (swine), and *Brucella canis* (dogs) are the most common organisms responsible for human disease. These organisms are small, aerobic, non–spore-forming, nonmotile, gram-negative coccobacillary bacteria. *Brucella* spp. are fastidious in their growth but can be grown on various laboratory media, including blood and chocolate agars.

EPIDEMIOLOGY

Brucellosis is endemic in many parts of the world and is especially prevalent in the Mediterranean basin, Persian Gulf, Indian subcontinent, and parts of Mexico and Central and South America. There are approximately 500,000 new cases annually worldwide, although accurate estimates of the prevalence of disease are lacking because of underreporting and underdiagnosis. Childhood brucellosis accounts for 10–30% of cases.

B. melitensis is the most prevalent species causing human brucellosis and is most often carried by sheep, goats, camels, and buffalo. Elk, caribou, bison, deer, moose, and swine can also be infected. Because of improved sanitation and animal vaccination, brucellosis has become rarer in countries with effective public health and domestic animal health programs, although recreational or occupational exposures continue to occur. **Consumption of raw or unpasteurized dairy products** in a child who has lived in or traveled to an endemic area is the key risk factor for pediatric brucellosis because most childhood cases are acquired via ingestion. In the United States in 2010, >50% of cases occurred in California, Arizona, Florida, and Texas. All age-groups can be infected by *Brucella,* and infections are more common in males, likely because of more frequent occupational and recreational exposures.

B. abortus cattle vaccine strain RB51 is a live, attenuated vaccine that has been used to vaccinate cattle in the United States since 1996. Very rare cases of human infection with this vaccine strain have been reported secondary to consumption of unpasteurized milk from vaccinated cows. These strains are resistant to rifampin, a primary agent used in the treatment of brucellosis, so clinicians should consider RB51 in a patient with the correct exposure history.

PATHOGENESIS

Modes of transmission for these organisms include inoculation through cuts or abrasions in the skin, inoculation of the conjunctiva, inhalation of infectious aerosols, or ingestion of contaminated meat or dairy products. **Infected livestock are the most common source of human infection.** In children the primary means of infection is through eating or drinking unpasteurized or raw dairy products. Individuals in endemic areas with occupational exposures to animals, such as farmers, veterinarians, and slaughterhouse workers, are at highest risk; exposure to an infected animal's abortion products or feces are notable risk factors in such occupations. Laboratory workers are more often exposed to infected aerosols. The risk for infection depends on the nutritional and immune status of the host, the route of inoculation, and the species of *Brucella.* For reasons that remain unclear, it has been suggested that *B. melitensis* and *B. suis* are more virulent than *B. abortus* or *B. canis.*

The major virulence factor for *Brucella* spp. appears to be its cell wall lipopolysaccharide (LPS). Strains containing smooth LPS have been demonstrated to have greater virulence and are more resistant to killing by polymorphonuclear leukocytes. These organisms are facultative intracellular pathogens that can survive and replicate within the mononuclear phagocytic cells (monocytes, macrophages) of the reticuloendothelial system. Even though *Brucella* spp. are chemotactic for entry of leukocytes into the body, the leukocytes are less efficient at killing these organisms than other bacteria despite the assistance of serum factors such as complement. *Brucella* spp. possess multiple strategies to evade immune responses and establish and maintain chronic infection. Specifically, during chronic stages of infection, organisms persist within the liver, spleen, lymph nodes, and bone marrow and result in granuloma formation.

Antibodies are produced against the LPS and other cell wall antigens, providing a means of diagnosis and likely playing a role in long-term immunity. The major factor in recovery from infection appears to be development of a cell-mediated immune response, resulting in macrophage activation and enhanced intracellular killing. Specifically, sensitized T lymphocytes release cytokines (e.g., interferon-γ, tumor necrosis factor-α), which activate the macrophages and enhance their intracellular killing capacity.

CLINICAL MANIFESTATIONS

Brucellosis is a systemic illness that can be quite difficult to diagnose in children. Symptoms can be acute or insidious in nature and are usually nonspecific. The incubation period is generally 2-4 weeks but may be shorter with *B. melitensis*. Fever is present in >75% of cases, and the fever pattern can vary widely. The most common physical complaints are arthralgia, myalgia, and back pain. Systemic symptoms, such as fatigue, sweats, chills, anorexia, headache, weight loss, and malaise, are reported in the majority of adult cases but are less frequent in children. Other associated symptoms include abdominal pain, diarrhea, rash, vomiting, cough, and pharyngitis.

The most common physical manifestation of brucellosis is hepatic and splenic enlargement, which is present in approximately half of cases. Whereas arthralgia is common, arthritis occurs in a minority of cases. Arthritis is typically monoarticular and most

often involves the knee or hip in children and the sacroiliac joint in adolescents and adults. Several types of skin lesions have been described with brucellosis, but there is no typical rash for this infection. Epididymo-orchitis also can occur and is more common in adolescents and adults.

In endemic countries, *Brucella* spp. are an important cause of occult bacteremia in young children. Because of the organism's ability to establish chronic infection, hepatic and splenic abscesses may develop. High-grade fever and elevations in liver enzymes are common among children with primary bacteremia. Children with positive blood cultures typically have more acute presentations with increased markers of inflammation (leukocyte count, CRP, ferritin) compared with culture-negative cases. Recurrent episodes of bacteremia can also occur (<10% of cases), especially with inadequate primary treatment. These recurrent episodes are less often associated with fever (40% of cases), potentially indicating the indolent nature of chronic *Brucella* infections in children.

Serious manifestations of brucellosis include endocarditis, meningitis, osteomyelitis, and **spondylitis**. Although headache and malaise may be demonstrated in patients with uncomplicated brucellosis, invasion of the nervous system occurs in only 1–4% of cases. Death from brucellosis is rare, occurring in less than 1% of cases. Neonatal and congenital infections with these organisms have also been described, resulting from transplacental transmission, breast milk, and blood transfusions. The signs and symptoms associated with congenital/neonatal brucellosis are nonspecific.

Hematologic abnormalities are common with brucellosis but occur in less than half of cases; leukopenia is the most common cytopenia to develop. Hemolytic complications can include microangiopathic hemolytic anemia, thrombotic microangiopathy, and autoimmune hemolytic anemia. Secondary cases of hemophagocytic lymphohistiocytosis have also been described after brucellosis in children. Elevations of liver enzymes occur in approximately half of all cases of brucellosis and are more common when bacteremia is present.

DIAGNOSIS

A definitive diagnosis of brucellosis is established by isolating and identifying the organisms from cultures of the blood (most common), bone marrow, or other fluids and tissues. Unfortunately, cultures are insensitive and positive in only a minority of pediatric cases. In a study of 436 children with brucellosis in Israel from 2005 to 2014, 76% had positive blood cultures. However, the prevalence of bacteremia in this cohort, 64% of whom were hospitalized, was much higher than most prior reports, in which less than half of cases have had positive blood cultures. Isolation of the organism from a blood culture sample may require as long as 4 weeks unless the laboratory is using an automated culture system such as the lysis-centrifugation method, where the organism can be recovered in 5-7 days. Therefore it is prudent to alert the clinical microbiology laboratory that brucellosis is suspected, so that cultures can be held longer. Bone marrow cultures may be superior to blood cultures when evaluating patients who have received previous antimicrobial therapy.

In addition to bacterial isolation, various serologic tests have been applied to the diagnosis of brucellosis. Microagglutination or serum (tube) agglutination tests are the most widely used and detect antibodies against *B. abortus, B. melitensis,* and *B. suis*. These methods do not detect antibodies against *B. canis* or *B. abortus* vaccine strain RB51, which lack the smooth LPS; *B. canis*–specific antigen is required to diagnose this species. Antibodies can also be detected by other tests such as enzyme-linked immunosorbent assay (ELISA). The Rose Bengal plate test (RBT) is a rapid agglutination test that is used as a screening test in many endemic regions. It has good sensitivity (>95%) and low cost, but confirmation of RBT results with microbiologic or other serologic tests is advised.

For a diagnosis to be made via serology alone, acute and convalescent samples taken 2-4 weeks apart are recommended; a fourfold or greater rise in titers is diagnostic of an acute infection. No single titer is ever diagnostic, but most patients with acute infections have titers of ≥1:160; lower titers may be present early in the disease course. Immunoglobulin M (IgM) antibodies can generally be detected within a week of illness onset, whereas IgG is detectable 2-4 weeks after infection.

Because patients with active infection have both an IgM and an IgG response and the serum agglutination test measures the total quantity of agglutinating antibodies, the total quantity of IgG is measured by treatment of the serum with 2-mercaptoethanol. This fractionation is important in determining the significance of the antibody titer because low levels of IgM can remain in the serum for weeks to months after the infection has been treated. IgG titers decrease with effective therapy, and a negative 2-mercaptoethanol test after treatment indicates a favorable response.

It is important to remember that all serologic results must be interpreted in light of a patient's history and physical examination. False-positive results from cross-reacting antibodies to other gram-negative organisms, such as *Yersinia enterocolitica, Francisella tularensis,* and *Vibrio cholerae,* can occur. In addition, the prozone effect can give false-negative results in the presence of high titers of antibody. To avoid this issue, serum that is being tested should be diluted to ≥1:320.

The enzyme immunoassay should only be used for suspected cases with negative serum agglutination tests or for the evaluation of patients in the following situations: (1) complicated cases, (2) suspected chronic brucellosis, or (3) reinfection. Polymerase chain reaction assays have been developed but are not available in most clinical laboratories.

Differential Diagnosis

Brucellosis should be considered in the differential diagnosis of fever of unknown origin in endemic areas. It may present similar to other infections such as tularemia, cat scratch disease, malaria, typhoid fever, histoplasmosis, blastomycosis, and coccidioidomycosis. Infections caused by *Mycobacterium tuberculosis,* atypical mycobacteria, rickettsiae, and *Yersinia* can also present similar to brucellosis.

TREATMENT

Many antimicrobial agents are active in vitro against *Brucella* spp., but clinical effectiveness does not always correlate with these results. Agents that provide good intracellular killing are required for elimination of *Brucella* infections. Because of the risk of relapse with monotherapy, combination therapy is generally recommended. Additionally, prolonged therapy (6 weeks or longer) is necessary to ensure an adequate and sustained response.

For uncomplicated infections in children 8 years of age or older, ≥6 weeks of doxycycline in combination with rifampin is recommended (Table 253.1). For children younger than age 8 years, trimethoprim-sulfamethoxazole (TMP-SMX) plus rifampin is advised because of concerns about prolonged tetracycline use in young children. Although data support that the combination of doxycycline plus an aminoglycoside (streptomycin, gentamicin) is superior to the other oral combination therapies, with fewer treatment failures and relapses, the inconvenience of parenteral therapy may limit this approach in uncomplicated cases, particularly in resource-limited settings. Fluoroquinolones may be a viable alternative to doxycycline or TMP-SMX but have not been studied in children.

In more serious infections (e.g., endocarditis, meningitis, osteoarticular infections), three-drug therapy is advised. An aminoglycoside (streptomycin, gentamicin) should be administered for the first 7-14

Table 253.1 Recommended Therapy for Treatment of Brucellosis

AGE/CONDITION	TREATMENT REGIMEN	DURATION
≥8 yr, uncomplicated infection	Doxycycline (PO; 4.4 mg/kg/day, max 200 mg/day) in 2 divided doses	≥6 wk
	plus	
	Rifampin (PO; 15-20 mg/kg/day, max 600-900 mg/day) in 1-2 divided doses	≥6 wk
	Alternative:	
	Doxycycline (PO; 4.4 mg/kg/day, max 200 mg/day) in 2 divided doses	≥6 wk
	plus	
	Streptomycin (IM/IV; 20-40 mg/kg/day, max 1 g/day) in 2-4 divided doses	2-3 wk
	or	
	Gentamicin (IM/IV; 5-7.5 mg/kg/day) once daily*	1-2 wk
<8 yr, uncomplicated infection	Trimethoprim-sulfamethoxazole (PO; trimethoprim: 10 mg/kg/day, max 480 mg/day; sulfamethoxazole: 50 mg/kg/day, max 2.4 g/day) in 2 divided doses	≥6 wk
	plus	
	Rifampin (PO; 15-20 mg/kg/day, max 600-900 mg/day) in 1-2 divided doses	≥6 wk
Complicated infection (meningitis, endocarditis, osteomyelitis, spondylitis)	Streptomycin (IM/IV; 20-40 mg/kg/day, max 1 g/day) in 2-4 divided doses	1-2 wk
	or	
	Gentamicin (IM/IV; 5-7.5 mg/kg/day) once daily*	1-2 wk
	plus	
	Doxycycline (IV/PO; 4.4 mg/kg/day, max 200 mg/day) in 2 divided doses	≥6 wk†
	(Trimethoprim-sulfamethoxazole should be used for children <8 yr of age)	
	plus	
	Rifampin (IV/PO; 15-20 mg/kg/day, max 600-900 mg/day) in 1-2 divided doses	≥6 wk†

*Gentamicin can be given in divided doses if indicated based on age.
†4-6 mo for meningitis or endocarditis.
Note: Because of resistance of *B. abortus* strain RB51 to rifampin, treatment with doxycycline plus trimethoprim-sulfamethoxazole should be used if this isolate is identified.

days of therapy, along with doxycycline (or TMP-SMX) plus rifampin, which are continued for at least 6 weeks. For meningitis and endocarditis, therapy is often continued for 4-6 months. Surgical intervention should be pursued when appropriate, such as when deep tissue abscesses have developed.

If *B. abortus* RB51 (cattle vaccine strain) is identified (or suspected) as the cause of infection, the use of rifampin should be avoided. This is because the strain was derived by selection in rifampin-enriched media and is thus inherently resistant to rifampin. As a result, a combination of doxycycline and TMP-SMX should be used as treatment.

Although relapse occurs in approximately 5–15% of cases, antimicrobial resistance is rare. Relapse is confirmed by isolation of *Brucella* within weeks to months after therapy has ended. Prolonged treatment is the key to preventing disease relapse, and steps should be taken to assure compliance with the long courses of therapy needed to achieve eradication.

PROGNOSIS

The primary indication of clinical response is resolution of symptoms, which may be slow; the average time to defervescence is 4-5 days. The prognosis after therapy is excellent if patients are compliant with the prolonged therapy. Patients should be followed clinically and serologically for 1-2 years. Before the use of antimicrobial agents, the course of brucellosis was often prolonged and associated with death. Since the institution of specific therapy, most deaths are a result of specific organ system involvement (e.g., endocarditis) in complicated cases. Initiation of antimicrobial therapy may precipitate a Jarisch-Herxheimer–like reaction, presumably because of a large antigen load, but these reactions are rarely associated with serious complications.

PREVENTION

Prevention of brucellosis depends on effective eradication of the organism from livestock. Pasteurization of milk and dairy products for human consumption remains an important aspect of prevention. It should be noted that certification of raw milk does not eliminate the risk of brucellosis acquisition. No vaccine currently exists for use in children, and therefore education of the public continues to have a prominent role in the prevention of brucellosis.

Chapter 254

Legionella

Jeffrey S. Gerber

Legionellosis comprises **Legionnaires' disease** (*Legionella* pneumonia), other invasive extrapulmonary *Legionella* infections, and an acute flulike illness known as **Pontiac fever**. In contrast to the syndromes associated with invasive disease, Pontiac fever is a self-limited illness that develops after aerosol exposure and may represent a toxic or hypersensitivity response to *Legionella.*

ETIOLOGY

Legionellaceae are aerobic, non–spore-forming, nonencapsulated, gram-negative bacilli that stain poorly with Gram stain when performed on smears from clinical specimens. Stained smears of *Legionella pneumophila* taken from colonial growth resemble *Pseudomonas.* Unlike other *Legionella* species, *Legionella micdadei* stains acid fast. Although more than 60 species of the genus have now been identified, the majority (90%) of clinical infections are caused by *L. pneumophila,* and most of the remainder are caused by *L. micdadei, L. bozemanii, L. dumoffii,* and *L. longbeachae.*

The organisms are fastidious and require L-cysteine, ferric ion, and α-keto acids for growth. Colonies develop within 3-5 days on buffered charcoal yeast extract agar, which may contain selected antibiotics to inhibit overgrowth by other microorganisms; *Legionella* rarely grows on routine laboratory media.

EPIDEMIOLOGY

The environmental reservoir of *Legionella* in nature is freshwater (lakes, streams, thermally polluted waters, potable water), and invasive pneumonia (Legionnaires' disease) is related to exposure to human-made water systems (plumbing, showerheads, cooling towers, certain medical devices, decorative fountains, hot tubs) via aerosols containing the bacteria. Growth of *Legionella* occurs more readily in warm water, and exposure to warm-water sources is an important risk factor for disease. Epidemic and sporadic cases (most common) of community-acquired Legionnaires' disease can be attributed to potable water in the local environment of the patient. Risk factors for acquisition of sporadic community-acquired pneumonia include exposure to cooling towers, nonmunicipal water supply, residential plumbing repairs, and lower water heater temperatures, which facilitate growth of bacteria or lead to release of a bolus of biofilm containing *Legionella* into potable water. The mode of transmission may be by inhalation of aerosols or by microaspiration. Outbreaks of Legionnaires' disease have been associated with protozoa in the implicated water source; replication within these eukaryotic cells presumably amplifies and maintains *Legionella* within the potable-water distribution system or in cooling towers. Outbreaks of community-acquired pneumonia and some nosocomial outbreaks have been linked to common sources, including hot water heaters, evaporative condensers, cooling towers, whirlpool baths, water births, humidifiers, and nebulizers. Travel-associated Legionnaires' disease and Pontiac fever are increasingly recognized in major outbreaks. Although person-to-person transmission has been reported, if it does occur, it is extremely rare.

Hospital-acquired infections are most often linked to potable water. Exposure may occur through three general mechanisms: (1) inhalation of contaminated water vapor through artificial ventilation; (2) aspiration of ingested microorganisms, including those in gastric feedings that are mixed with contaminated tap water; and (3) inhalation of aerosols from showers, sinks, and fountains. Extrapulmonary legionellosis may occur through topical application of contaminated tap water into surgical or traumatic wounds. In contrast to Legionnaires' disease, Pontiac fever outbreaks have occurred through exposure to aerosols from whirlpool baths and ventilation systems.

The incidence of legionellosis in the United States continues to rise, and nearly 10,000 cases were reported to the Centers for Disease Control and Prevention (CDC) through the National Notifiable Disease Surveillance System in 2018. Because this is a passive reporting system, these are likely underestimates of the incidence of disease, which is estimated to occur at least twice as often as reported. An active laboratory-based and population-based surveillance system for tracking *Legionella* infections was recently launched by CDC, which will help to better assess its true incidence and epidemiology. (For up-to-date information, see https://www.cdc.gov/legionella/.)

Legionellosis demonstrates geographic differences, and the vast majority of cases are classified as Legionnaires' disease (99.5%), with a small fraction as Pontiac fever (0.5%). *Legionella* infections are reported most frequently in fall and summer, and recent studies show an association with total monthly rainfall and humidity. Approximately 0.5–5.0% of those exposed to a common source develop pneumonia, whereas the attack rate in Pontiac fever outbreaks is very high (85–100%). Although *Legionella* is associated with 0.5–10% of pneumonia cases in adults, it is a rare cause of pneumonia in children, accounting for <1% of cases; however, infrequent testing for *Legionella* might underestimate its prevalence. Acquisition of antibodies to *L. pneumophila* in healthy children occurs progressively over time, although these antibodies presumably reflect subclinical infection, mild respiratory disease, or antibodies that cross-react with other bacterial species. Community-acquired Legionnaires' disease in children is increasingly reported (1.7% of reported cases), and most cases occur in children 15-19 years old, followed by infants. The incidence in infants is reported to be 0.11 per 100,000. Legionnaires' disease is particularly severe in neonates. The epidemiology of hospital-acquired Legionnaires' disease in children is derived almost exclusively from case reports, so the true incidence of this entity is unknown.

PATHOGENESIS

Although *Legionella* can be grown on artificial media, the intracellular environment of eukaryotic cells provides the definitive site of growth. *Legionella* organisms are facultative intracellular parasites of eukaryotic cells. In nature, *Legionella* replicate within protozoa found in freshwater. In humans, the main target cell for *Legionella* is the alveolar macrophage, although other cell types may also be invaded. After entry, virulent strains of *L. pneumophila* stimulate the formation of a special phagosome that permits bacterial replication to proceed. The phagosome consists of components of the endoplasmic reticulum and escapes the degradative lysosomal pathway. Growth in macrophages occurs to the point of cell death, followed by reinfection of new cells, until these cells are activated and can subsequently kill intracellular microorganisms. Acute, severe infection of the lung provokes an acute inflammatory response and necrosis. Early on, more bacteria are found in extracellular spaces as a result of intracellular replication, lysis, and release of bacteria. Subsequently, macrophage activation and other immune responses produce intense infiltration of tissue by macrophages that contain intracellular bacteria, ultimately leading to control of bacterial replication and killing.

Corticosteroid therapy poses a high risk for infection by interfering with T-cell and macrophage function. Although community-acquired Legionnaires' disease may occur in healthy, immunocompetent patients without other comorbid conditions, those who have defects in cellular-mediated immunity are at higher risk for infection. As in other diseases caused by facultative intracellular microorganisms, the outcome is critically dependent on the specific and nonspecific immune responses of the host, particularly macrophage and T-cell responses.

Risk factors for Legionnaires' disease in adults include chronic diseases of the lung (smoking, bronchitis), older age, diabetes, renal failure, immunosuppression associated with organ transplantation, corticosteroid therapy, and episodes of aspiration. In surveys of community-acquired infection, a significant number of adults have no identified risk factors. The number of reported cases of community-acquired Legionnaires' disease in children is small. Among these cases, immunocompromised status, especially corticosteroid treatment, coupled with exposure to contaminated potable water, is the major risk factor.

Infection in a few children with chronic pulmonary disease without immune deficiency has also been reported, but infection in children lacking any risk factors is uncommon. The modes of transmission of community-acquired disease in children include exposure to mists, freshwater, water coolers, and other aerosol-generating apparatuses. Nosocomial *Legionella* infection has been reported more frequently than community-acquired disease in children and usually occurs in those who are immunocompromised (e.g., stem cell transplants, solid organ transplants), those with structural lung disease, or neonates receiving mechanical ventilation. The modes of acquisition include **microaspiration**, frequently associated with nasogastric tubes, and **aerosol inhalation**. Bronchopulmonary *Legionella* infections are reported in patients with cystic fibrosis and have been associated with aerosol therapy or mist tents. Legionnaire's disease is also reported in children with asthma and tracheal stenosis. Chronic corticosteroid therapy for asthma is a reported risk factor for *Legionella* infections in children.

CLINICAL MANIFESTATIONS

Legionnaires' disease was originally believed to cause atypical pneumonia associated with extrapulmonary symptoms and laboratory abnormalities, including diarrhea, confusion, hyponatremia, hypophosphatemia, abnormal liver function studies, and evidence of renal dysfunction. Although a subset of patients may exhibit these classic manifestations, *Legionella* infection typically causes pneumonia that is indistinguishable from pneumonia produced by other infectious agents. The incubation period for Legionnaires' disease is typically between 2 and 10 days, though it occasionally can be 3-4 weeks. Fever, cough, and chest pain are common presenting symptoms; the cough may be productive of purulent sputum or may be nonproductive. Although the classic chest radiographic appearance demonstrates rapidly progressive alveolar filling infiltrates, the chest radiographic appearance is widely variable, with tumor-like shadows, evidence of nodular infiltrates, unilateral or bilateral infiltrates, or cavitation, although cavitation is rarely seen in immunocompetent patients. This picture overlaps substantially with disease caused by *Streptococcus pneumoniae.* Although pleural effusion is less often associated with Legionnaires' disease, its frequency varies so widely that neither the presence nor absence of effusion is helpful in the differential diagnosis.

Most reports of nosocomial *Legionella* pneumonia in children demonstrate the following clinical features: rapid onset, temperature >38.5°C (101.3°F), cough, pleuritic chest pain, tachypnea, and dyspnea. Abdominal pain, headache, and diarrhea are also common. Chest radiographs reveal lobar consolidations or diffuse bilateral infiltrates, and pleural effusions may be noted. Usually there is no clinical response to broad-spectrum β-lactam (penicillins and cephalosporins) or aminoglycoside antibiotics. Concomitant infection with other pathogens, including *Mycoplasma pneumoniae* and *Chlamydia pneumoniae,* occurs in 5–10% of cases of Legionnaires' disease; therefore, detection of another potential pulmonary pathogen does not preclude the diagnosis of legionellosis.

Pontiac Fever

Pontiac fever in adults and children is characterized by a shorter incubation period (1-3 days) followed by high fever, myalgia, headache, and extreme debilitation, lasting for 3-5 days. Cough, breathlessness, diarrhea, confusion, and chest pain may occur, but there is no evidence for invasive infection. The disease is self-limited without sequelae. Virtually all exposed individuals seroconvert to *Legionella* antigens. A very large outbreak in Scotland that affected 35 children was attributed to *L. micdadei,* which was isolated from a whirlpool spa. The onset of illness was 1-7 days (median: 3 days), and all exposed children developed significant titers of specific antibodies to *L. micdadei.* The pathogenesis of Pontiac fever is not known. In the absence of evidence of true infection, the most likely hypothesis is that this syndrome is caused by a toxic or hypersensitivity reaction to microbial antigens.

DIAGNOSIS

Culture of *Legionella* from sputum, other respiratory tract specimens, blood, or tissue is the gold standard against which indirect methods of detection should be compared. If present, pleural fluid should be obtained for culture. Specimens obtained from the respiratory tract that are contaminated with oral flora must be treated and processed to reduce contaminants and plated onto selective media. Because these are costly and time-consuming methods, many laboratories do not process specimens for culture.

The urinary antigen assay that detects *L. pneumophila* serogroup I has revolutionized the diagnosis of *Legionella* infection and has 80% sensitivity and 99% specificity. The assay is a useful method in the prompt diagnosis of Legionnaires' disease caused by this serogroup, which accounts for the majority of symptomatic infections. In the United States, this test is frequently used because it is widely available in reference laboratories. Where available, polymerase chain reaction (PCR) is used to identify *L. pneumophila* from bronchoscopic lavage and other clinical specimens to the exclusion of other respiratory pathogens. Other methods, including direct immunofluorescence, have low sensitivity and are generally not employed. Serological testing is of little clinical utility, as seroconversion may not occur for several weeks after the onset of infection, the available serologic assays do not detect all strains of *L. pneumophila* or all species, and cross reactivity occurs with several other gram-negative organisms.

In view of the low sensitivity of direct detection and the slow growth of the microorganism in culture, multiple diagnostics (culture, urine antigen, PCR if available) should be sent simultaneously and empiric antibiotic therapy considered when there is suggestive clinical evidence, including the lack of response to usual antibiotics.

TREATMENT

In community-acquired pneumonia in adults who are hospitalized, guidelines recommend empiric treatment with a β-lactam plus a macrolide or quinolone for treatment of atypical microorganisms *(Legionella, C. pneumoniae, M. pneumoniae).* Evidence-based guidelines for management of community-acquired pneumonia in children typically do not include *Legionella* in the differential diagnosis or empiric treatment recommendations. Effective treatment of Legionnaires' disease is based in part on the intracellular concentration of antibiotics. **Azithromycin** or the **quinolones** (ciprofloxacin and levofloxacin) have generally replaced erythromycin as therapy for patients with diagnosed *Legionella* infection. **Doxycycline** is an acceptable alternative. In serious infections or in high-risk patients, parenteral therapy is recommended initially, although oral conversion is favored when tolerated, particularly because of the generally high bioavailability of oral macrolides, quinolones, and tetracyclines. The duration of antibiotic therapy for Legionnaires' disease in adults is typically for a minimum of 5 days, although therapy may be continued for 10-14 days in more seriously ill or immunocompromised patients. Treatment of extrapulmonary infections, including prosthetic valve endocarditis and sternal wound infections, may require prolonged therapy. In vitro data and case reports suggest that trimethoprim-sulfamethoxazole may also be effective. A large, retrospective study of hospitalized adults with *Legionella* pneumonia found no difference in mortality between those treated with azithromycin and with quinolones. The role of combination therapy is unknown. Antibiotic treatment for Pontiac fever is not recommended.

PROGNOSIS

The mortality rate for community-acquired Legionnaires' disease in adults who are hospitalized is approximately 15% but may exceed 50% in immunocompromised patients, although reporting bias might inflate these estimates. Precise estimates for children are unknown. The prognosis depends on underlying host factors and possibly on the duration of illness before initiation of appropriate therapy. Despite appropriate antibiotic therapy, patients may succumb to respiratory complications, such as acute respiratory distress syndrome. A high mortality rate is noted in case reports of premature infants and children, virtually all of whom have been immunocompromised. Delay in diagnosis is also associated with increased mortality. Consequently, *Legionella* should be considered in the differential diagnosis of both community-acquired and nosocomial pneumonia in children, especially in cases refractory to empirical therapy or with epidemiologic risk factors for legionellosis.

Chapter 255

Bartonella

Rachel C. Orscheln

The spectrum of disease resulting from human infection with *Bartonella* species includes the association of **bacillary angiomatosis** and **cat scratch disease** with *Bartonella henselae.* There are more than 30 validated species of *Bartonella,* but six major species are responsible for most human disease: *B. henselae, B. quintana, B. bacilliformis, B. elizabethae, B. vinsonii,* and *B. clarridgeiae* (Table 255.1). The remaining *Bartonella* spp. have been found primarily in animals, particularly rodents and moles. However, zoonotic infections from animal-associated strains of *Bartonella* spp. have been reported. In 2013 a novel *Bartonella* agent with the proposed name *Candidatus* Bartonella ancashi *(Bartonella ancashensis)* was described as a cause of **verruga peruana**.

Members of the genus *Bartonella* are gram-negative, oxidase-negative, fastidious, aerobic rods that ferment no carbohydrates. *B. bacilliformis* is the only species that is motile, achieving motility by means of polar flagella. Optimal growth is obtained on fresh media containing ≥5% sheep or horse blood in the presence of 5% carbon dioxide. The use of lysis centrifugation for specimens from blood followed by cultivation on chocolate agar for extended periods (2-6 weeks) enhances recovery.

255.1 Cat Scratch Disease *(Bartonella henselae)*

Rachel C. Orscheln

The most common presentation of *Bartonella* infection is cat scratch disease (**CSD**), which is a subacute, regional lymphadenitis caused most frequently by *B. henselae*. CSD is the most common cause of chronic lymphadenitis that persists for >3 weeks.

ETIOLOGY

B. henselae can be cultured from the blood of healthy cats. *B. henselae* organisms are the small, pleomorphic, gram-negative bacilli visualized with Warthin-Starry stain in affected lymph nodes from patients with CSD. Development of serologic tests that showed prevalence of antibodies in 84–100% of cases of CSD, culturing of *B. henselae* from CSD nodes, and detection of *B. henselae* by polymerase chain reaction (PCR) in the majority of lymph node samples and pus from patients with CSD confirmed the organism as the cause. Occasional cases of CSD may be caused by other organisms, including *B. clarridgeiae, B. grahamii*, *B. alsatica,* and *B. quintana*.

EPIDEMIOLOGY

CSD is common, with >24,000 estimated cases per year in the United States. *B. henselae* is transmitted most frequently by cutaneous inoculation through the bite or scratch of a cat. However, transmission may occur through other routes, such as flea bites. Most patients (87–99%) with CSD have had contact with cats, many of which are kittens <6 months old, and >50% of patients have a definite history of a cat scratch or bite. Cats have high-level bacteremia with *Bartonella* spp. for months without any clinical symptoms; kittens are more frequently bacteremic than adult cats. Transmission between cats occurs through the cat flea, *Ctenocephalides felis.* In temperate zones, most cases occur between September and March, perhaps in relation to the seasonal breeding of domestic cats or to the close proximity of family pets in the fall and winter. In tropical zones, there is no seasonal prevalence. Distribution is worldwide, and infection occurs in all races.

Cat scratches appear to be more common among children, and males are affected more often than females. CSD is a sporadic illness; usually only one family member is affected, even though many siblings play with the same kitten. However, clusters do occur, with family cases within weeks of one another. Anecdotal reports have implicated other sources, such as dog scratches, wood splinters, fishhooks, cactus spines, and porcupine quills.

PATHOGENESIS

The pathologic findings in the primary inoculation **papule** and affected lymph nodes are similar. Both show a central avascular, necrotic area with surrounding lymphocytes, giant cells, and histiocytes. Three stages of involvement occur in affected nodes, sometimes simultaneously in the same node. The first stage consists of generalized enlargement with thickening of the cortex and hypertrophy of the germinal center and with a predominance of lymphocytes. Epithelioid granulomas with Langerhans giant cells are scattered throughout the node. The second stage is characterized by granulomas that increase in density, fuse, and become infiltrated with polymorphonuclear leukocytes, with beginning central necrosis. In the third stage, necrosis progresses with formation of large, pus-filled sinuses. This purulent material may rupture into surrounding tissue. Similar granulomas have been found in the liver, spleen, and osteolytic lesions of bone when those organs are involved.

Table 255.1 *Bartonella* Species Causing the Majority of Human Disease

DISEASE	ORGANISM	VECTOR	PRIMARY RISK FACTOR
Bartonellosis (Carrión disease)	*B. bacilliformis*	Sandfly *(Lutzomyia verrucarum)*	Living in endemic areas (Andes Mountains)
Cat scratch disease	*B. henselae* *B. clarridgeiae*	Cat	Cat scratch or bite
Trench fever	*B. quintana*	Human body louse	Body louse infestation during outbreak
Bacteremia, endocarditis	*B. henselae* *B. elizabethae* *B. vinsonii* *B. quintana*	Cat for *B. henselae* Rat for *B. elizabethae* Vole for *B. vinsonii* Human body louse for *B. quintana*	Severe immunosuppression
Bacillary angiomatosis	*B. henselae* *B. quintana*	Cat for *B. henselae* Human body louse for *B. quintana*	Severe immunosuppression
Peliosis hepatis	*B. henselae* *B. quintana*	Cat for *B. henselae* Human body louse for *B. quintana*	Severe immunosuppression

CLINICAL MANIFESTATIONS

After an incubation period of 7-12 days (range: 3-30 days), one or more 3- to 5-mm red papules develop at the site of cutaneous inoculation, often reflecting a linear cat scratch. These lesions are often overlooked because of their small size but are found in at least 65% of patients when careful examination is performed (Fig. 255.1). Lymphadenopathy is generally evident within 1-4 weeks (Fig. 255.2). **Chronic regional lymphadenitis** is the hallmark, affecting the first or second set of nodes draining the entry site. Affected lymph nodes in order of frequency include the axillary, cervical, submandibular, preauricular, epitrochlear, femoral, and inguinal nodes. Involvement of one or more groups of nodes occurs in 10–20% of patients, although at a given site, half the cases involve several nodes.

Nodes involved are usually tender and have overlying erythema but without cellulitis. They usually range between 1 and 5 cm in size, although they can become much larger. From 10% to 40% eventually suppurate. The duration of enlargement is usually 1-2 months, with persistence up to 1 year in rare cases. Fever occurs in approximately 30% of patients, usually 38–39°C (100.4–102.2°F). Other nonspecific symptoms, including malaise, anorexia, fatigue, and headache, affect less than one third of patients. Transient rashes, which may occur in approximately 5% of patients, are mainly truncal maculopapular rashes. Erythema nodosum, erythema multiforme, and erythema annulare have also been reported.

Fig. 255.1 A child with typical cat scratch disease demonstrating the original scratch injuries and the primary papule that soon thereafter developed proximal to the middle finger. *(Courtesy Dr. V.H. San Joaquin, University of Oklahoma Health Sciences Center, Oklahoma City.)*

Fig. 255.2 Right axillary lymphadenopathy followed the scratches and development of a primary papule in this child with typical cat scratch disease. *(From Mandell GL, Bennett JE, Dolin R, eds. Principles and Practice of Infectious Diseases, 6th ed. Philadelphia: Elsevier; 2006:2737.)*

CSD is usually a self-limited infection that spontaneously resolves within a few weeks to months. The most common ocular presentation of CSD is **Parinaud oculoglandular syndrome**, which is unilateral conjunctivitis followed by preauricular lymphadenopathy and occurs in 5% of patients with CSD (Fig. 255.3). Direct eye inoculation as a result of rubbing with the hands after cat contact is the presumed mode of spread. A conjunctival granuloma may be found at the inoculation site. The involved eye is usually not painful and has little or no discharge but may be quite red and swollen. Submandibular or cervical lymphadenopathy may also occur.

More severe, disseminated illness occurs up to 14% of patients and is characterized by presentation with high fever, often persisting for several weeks. Other prominent symptoms include significant abdominal pain and weight loss. **Hepatosplenomegaly** may occur, although hepatic dysfunction is rare (Fig. 255.4). Granulomatous changes may be seen in the liver and spleen. Another common site of dissemination is bone, with the development of multifocal **granulomatous osteolytic lesions** associated with localized pain but without erythema,

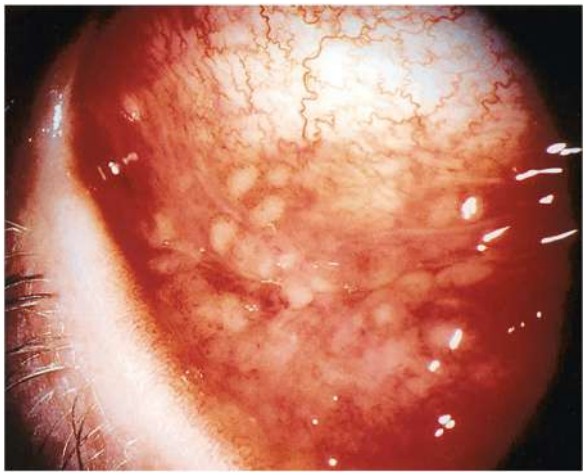

Fig. 255.3 The granulomatous conjunctivitis of Parinaud oculoglandular syndrome is associated with ipsilateral local lymphadenopathy, usually preauricular and, less often, submandibular. *(From Mandell GL, Bennett JE, Dolin R, eds. Principles and Practice of Infectious Diseases, 6th ed. Philadelphia: Elsevier; 2006:2739.)*

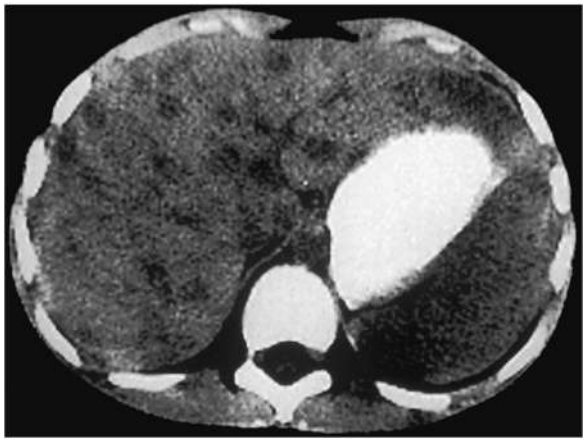

Fig. 255.4 In this CT scan of a patient with hepatic involvement of cat scratch disease, the absence of enhancement of the multiple lesions after contrast infusion is consistent with the granulomatous inflammation of this entity. Treated empirically with various antibiotics without improvement before establishment of this diagnosis, the patient subsequently recovered fully with no further antimicrobial therapy. *(Courtesy Dr. V.H. San Joaquin, University of Oklahoma Health Sciences Center, Oklahoma City.)*

tenderness, or swelling. Other uncommon manifestations are neuroretinitis with papilledema and stellate macular exudates, encephalitis, endocarditis, and atypical pneumonia.

DIAGNOSIS

In most cases the diagnosis can be strongly suspected on clinical grounds in a patient with history of exposure to a cat. Serologic testing can be used to confirm the diagnosis. Most patients have elevated IgG antibody titers at presentation. However, the IgM response to *B. henselae* has frequently resolved by the time testing is considered. There is cross reactivity among *Bartonella* spp., particularly *B. henselae* and *B. quintana*.

If tissue specimens are obtained, bacilli may be visualized with Warthin-Starry and Brown-Hopps tissue stains. *Bartonella* DNA can be identified through PCR analysis of tissue specimens. Culturing of the organism is not generally practical for clinical diagnosis. Next-generation sequencing and 16S rRNA sequencing have been used to identify *Bartonella* species on tissue that is fresh or formalin-fixed, as well as on body fluids other than blood.

Differential Diagnosis

The differential diagnosis of CSD includes virtually all causes of lymphadenopathy (see Chapter 539). The more common entities include pyogenic (suppurative) lymphadenitis, primarily from staphylococcal or streptococcal infections, atypical mycobacterial infections, and malignancy. Less common entities are tularemia, brucellosis, and sporotrichosis. Epstein-Barr virus, cytomegalovirus, and *Toxoplasma gondii* infections usually cause more generalized lymphadenopathy.

LABORATORY FINDINGS

Routine laboratory tests are not helpful. The erythrocyte sedimentation rate is often elevated. The white blood cell count may be normal or mildly elevated. Hepatic transaminases are often normal but may be elevated in systemic disease. Ultrasonography or CT may reveal many granulomatous nodules in the liver and spleen; the nodules appear as hypodense, round, irregular lesions and are usually multiple. However, CSD presenting as a solitary splenic lesion has been reported.

TREATMENT

Antibiotic treatment of CSD is not always needed and is not clearly beneficial. For most patients, treatment consists of conservative symptomatic care and observation. Studies show a significant discordance between in vitro activity of antibiotics and clinical effectiveness. For many patients, diagnosis is considered in the context of failure to respond to β-lactam antibiotic treatment of presumed staphylococcal lymphadenitis.

A small prospective study of oral azithromycin (500 mg on day 1, then 250 mg on days 2-5; for smaller children, 10 mg/kg/24 hr on day 1 and 5 mg/kg/24 hr on days 2-5) showed a decrease in initial lymph node volume in 50% of patients during the first 30 days, but after 30 days there was no difference in lymph node volume. No other clinical benefit was found. For the majority of patients, CSD is self-limited, and resolution occurs over weeks to months without antibiotic treatment. Azithromycin, clarithromycin, trimethoprim-sulfamethoxazole (TMP-SMX), rifampin, ciprofloxacin, and gentamicin appear to be the best agents if treatment is considered.

Suppurative lymph nodes that become tense and extremely painful may require surgical drainage for both therapeutic and diagnostic purposes.

Children with hepatosplenic CSD appear to respond well to treatment with azithromycin with or without the addition of rifampin.

COMPLICATIONS

Encephalopathy can occur in as many as 5% of patients with CSD and typically manifests 1-3 week after the onset of lymphadenitis as the sudden onset of neurologic symptoms, which often include seizures, combative or bizarre behavior, and altered level of consciousness. Imaging studies are generally normal. The cerebrospinal fluid is normal or shows minimal pleocytosis and protein elevation. Recovery occurs without sequelae in almost all patients but may take place slowly over many months.

Other neurologic manifestations include peripheral facial nerve paralysis, myelitis, radiculitis, compression neuropathy, and cerebellar ataxia. One patient has been reported to have encephalopathy with persistent cognitive impairment and memory loss.

Stellate macular retinopathy is associated with several infections, including CSD. Children and young adults present with unilateral or, rarely, bilateral loss of vision with central scotoma, optic disc swelling, and macular star formation from exudates radiating out from the macula. The findings usually resolve completely, with recovery of vision, generally within 2-3 months. The optimal treatment for the neuroretinitis is unknown, although treatment of adults with doxycycline and rifampin for 4-6 weeks has had good results.

Hematologic manifestations include hemolytic anemia, thrombocytopenic purpura, nonthrombocytopenic purpura, and eosinophilia. **Leukocytoclastic vasculitis**, similar to Henoch-Schönlein purpura, has been reported in association with CSD in one child. A systemic presentation of CSD with pleurisy, arthralgia or arthritis, mediastinal masses, enlarged nodes at the head of the pancreas, and atypical pneumonia also has been reported.

PROGNOSIS

The prognosis for CSD in a normal host is generally excellent, with resolution of clinical findings over weeks to months. Recovery is occasionally slower and may take as long as 1 year.

PREVENTION

Person-to-person spread of *Bartonella* infections is not known. Isolation of the affected patient is not necessary. Prevention would require elimination of cats from households, which is not practical or necessarily desirable. Awareness of the risk of cat (and particularly kitten) scratches should be emphasized to parents. Cat scratches or bites should be washed immediately. Cat flea control is helpful.

255.2 Bartonellosis (*Bartonella bacilliformis*)

Rachel C. Orscheln

The first human *Bartonella* infection described was **bartonellosis**, a geographically distinct disease caused by *B. bacilliformis*. There are two predominant forms of illness caused by *B. bacilliformis*: **Oroya fever**, a severe, febrile hemolytic anemia, and **verruca peruana** (verruga peruana), an eruption of hemangioma-like lesions. *B. bacilliformis* also causes asymptomatic infection. Bartonellosis is also called **Carrión disease**.

ETIOLOGY

B. bacilliformis is a small, motile, gram-negative organism with a brush of ≥10 unipolar flagella, which appear to be important components for invasiveness. An obligate aerobe, it grows best at 28°C (82.4°F) in semisolid nutrient agar containing rabbit serum and hemoglobin.

EPIDEMIOLOGY

Bartonellosis is a zoonosis found only in mountain valleys of the Andes Mountains in Peru, Ecuador, Colombia, Chile, and Bolivia at altitudes and environmental conditions favorable for the vector, which is the **sandfly**, *Lutzomyia verrucarum*.

PATHOGENESIS

After the sandfly bite, *Bartonella* organisms enter the endothelial cells of blood vessels, where they proliferate. Found throughout the reticuloendothelial system, they then reenter the bloodstream and parasitize erythrocytes. They bind on the cells, deform the membranes, and then enter intracellular vacuoles. The resultant hemolytic anemia may involve as many as 90% of circulating erythrocytes. Patients who survive this acute phase may or may not experience the cutaneous manifestations, which are nodular hemangiomatous lesions or verrucae ranging in size from a few millimeters to several centimeters.

CLINICAL MANIFESTATIONS

The incubation period is 2-14 weeks. Patients may be totally asymptomatic or may have nonspecific symptoms such as headache and malaise without anemia.

Oroya fever is characterized by fever with rapid development of anemia. Clouding of the sensorium and delirium are common symptoms and may progress to overt psychosis. Physical examination demonstrates signs of severe hemolytic anemia, including icterus and pallor, sometimes in association with generalized lymphadenopathy.

In the preeruptive stage of **verruca peruana** (Fig. 255.5), patients may complain of arthralgias, myalgias, and paresthesias. Inflammatory reactions such as phlebitis, pleuritis, erythema nodosum, and encephalitis may develop. The appearance of verrucae is pathognomonic of the eruptive phase. Lesions vary greatly in size and number.

DIAGNOSIS

The diagnosis of bartonellosis is established on clinical grounds in conjunction with a blood smear demonstrating organisms or with blood culture. The anemia is macrocytic and hypochromic, with reticulocyte counts as high as 50%. *B. bacilliformis* may be seen on Giemsa stain preparation as red-violet rods in the erythrocytes. In the recovery phase, organisms change to a more coccoid form and disappear from the blood. In the absence of anemia, the diagnosis depends on blood cultures. In the eruptive phase, the typical verruca confirms the diagnosis. Antibody testing has been used to document infection.

Fig. 255.5 A single large lesion of verruca peruana on the leg of an inhabitant of the Peruvian Andes. Such lesions are prone to superficial ulceration, and their vascular nature may lead to copious bleeding. Ecchymosis of the skin surrounding the lesion is also evident. *(Courtesy Dr. J.M. Crutcher, Oklahoma State Department of Health, Oklahoma City.)*

TREATMENT

B. bacilliformis is sensitive to many antibiotics, including rifampin, tetracycline, and chloramphenicol. Treatment is highly effective in rapidly diminishing fever and eradicating the organism from the blood. **Chloramphenicol** (50-75 mg/kg/day) is considered the drug of choice because it is also useful in the treatment of concomitant infections such as *Salmonella.* Fluoroquinolones are used successfully as well. Blood transfusions and supportive care are critical in patients with severe anemia. Antimicrobial treatment for verruca peruana is considered when there are >10 cutaneous lesions, if the lesions are erythematous or violaceous, or if the onset of the lesions was <1 month before presentation. Oral rifampin is effective in the healing of lesions. Surgical excision may be needed for lesions that are large and disfiguring or that interfere with function.

PREVENTION

Prevention depends on avoidance of the vector, particularly at night, by the use of protective clothing and insect repellents (see Chapter 218).

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

255.3 Trench Fever *(Bartonella quintana)*

Rachel C. Orscheln

ETIOLOGY

The causative agent of trench fever was first designated *Rickettsia quintana,* was then assigned to the genus *Rochalimaea,* and now has been reassigned as *Bartonella quintana.*

EPIDEMIOLOGY

Trench fever was first recognized as a distinct clinical entity during World War I, when more than a million troops in the trenches were infected. Infection with *B. quintana* is currently rare in the United States and primarily occurs in the setting of conditions favorable to body lice infestations, such as homelessness, crowding, and poor sanitation. When pooled samples of head and body lice have been collected from homeless populations, up to 33% of individuals have lice pools that test positive for *B. quintana.*

Humans are the only known reservoir. No other animal is naturally infected, and usual laboratory animals are not susceptible. The **human body louse**, *Pediculus humanus* var. *corporis,* is the vector and is capable of transmission to a new host 5-6 days after feeding on an infected person. Lice excrete the organism for life; transovarian passage does not occur. Humans may have prolonged asymptomatic bacteremia for years.

CLINICAL MANIFESTATIONS

The incubation period for trench fever averages about 22 days (range: 4-35 days). The clinical presentation is highly variable. Symptoms can be very mild and brief. About half of infected persons have a single febrile illness with abrupt onset lasting 3-6 days. In other patients, prolonged, sustained fever may occur. More commonly, patients have periodic febrile illness with three to eight episodes lasting 4-5 days each, sometimes occurring over 1 year or more. This form is reminiscent of malaria or **relapsing fever** *(Borrelia recurrentis).* Afebrile bacteremia can occur.

Clinical findings usually consist of fever (typically with a temperature of 38.5–40°C [101.3–104°F]), malaise, chills, sweats, anorexia, and severe headache. Common findings include marked conjunctival injection, tachycardia, myalgias, arthralgias, and severe pain in the neck, back, and legs. Crops of erythematous macules or papules may occur on the trunk on as many as 80% of patients. Splenomegaly and mild liver enlargement may be noted.

DIAGNOSIS

In nonepidemic situations, it is impossible to establish a diagnosis of trench fever on clinical grounds because the findings are not distinctive. A history of body louse infection or having been in an area of epidemic disease should heighten suspicions. *B. quintana* can be cultured from the blood with modification to include culture on epithelial cells. Serologic tests for *B. quintana* are available, but there is cross-reaction with *B. henselae*.

TREATMENT

There are no controlled trials of treatment, but bacteremia with *Bartonella* treated with a combination of gentamicin and doxycycline increases the rate of cure compared with other regimens, such as doxycycline or β-lactam antibiotics alone.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

255.4 Bacillary Angiomatosis and Bacillary Peliosis Hepatis (*Bartonella henselae* and *Bartonella quintana*)

Rachel C. Orscheln

Both *B.henselae* and *B.quintana* cause vascular proliferative disease in severely immunocompromised persons, primarily adult patients with acquired immune deficiency syndrome (AIDS), persons receiving cancer chemotherapy, and organ transplant recipients. The subcutaneous and lytic bone lesions of bacillary angiomatosis can be caused by infection with either *B. henselae* or *B. quintana*. The lesions of peliosis hepatis are almost exclusively associated with *B. henselae*.

BACILLARY ANGIOMATOSIS

Lesions of cutaneous bacillary angiomatosis, also known as **epithelioid angiomatosis**, are the most easily identified and recognized form of *Bartonella* infection in immunocompromised hosts. They are found primarily in patients with AIDS who have very low CD4 counts. The clinical appearance can be quite diverse. The vasoproliferative lesions of bacillary angiomatosis may be cutaneous or subcutaneous and may resemble the vascular lesions (verruca peruana) of *B. bacilliformis* in immunocompetent persons, characterized by erythematous papules on an erythematous base with a collarette of scale. They may enlarge to form large, pedunculated lesions and may ulcerate. Trauma may result in profuse bleeding.

Bacillary angiomatosis may be clinically indistinguishable from Kaposi sarcoma. Other considerations in the differential diagnosis are pyogenic granuloma and verruca peruana *(B. bacilliformis)*. Deep soft tissue masses caused by bacillary angiomatosis may mimic a malignancy.

Osseous bacillary angiomatosis lesions typically involve the long bones. These lytic lesions are very painful and highly vascular and are occasionally associated with an overlying erythematous plaque. The high degree of vascularity produces a positive result on a technetium-99m methylene diphosphonate bone scan, resembling that of a malignant lesion.

Lesions can be found in virtually any organ, producing similar vascular proliferative lesions. They may appear raised, nodular, or ulcerative when seen on endoscopy or bronchoscopy. They may be associated with enlarged lymph nodes with or without an obvious local cutaneous lesion. Brain parenchymal lesions have been described.

BACILLARY PELIOSIS

Bacillary peliosis affects the reticuloendothelial system, primarily the liver **(peliosis hepatis)** and, less frequently, the spleen and lymph nodes. It is a vasoproliferative disorder characterized by random proliferation of venous lakes surrounded by fibromyxoid stroma harboring numerous bacillary organisms. Clinical findings include fever and abdominal pain in association with abnormal liver function test results, particularly a greatly increased alkaline phosphatase level. Cutaneous bacillary angiomatosis with splenomegaly may be associated with thrombocytopenia or pancytopenia. The vascular proliferative lesions in the liver and spleen appear on CT scan as hypodense lesions scattered throughout the parenchyma. The differential diagnosis includes hepatic Kaposi sarcoma, lymphoma, and disseminated infection with *Pneumocystis jirovecii* or *Mycobacterium avium* complex.

BACTEREMIA AND ENDOCARDITIS

B. henselae, B. quintana, B. vinsonii, and *B. elizabethae* all are reported to cause bacteremia or endocarditis. They are associated with symptoms such as prolonged fevers, night sweats, and profound weight loss. A cluster of cases in Seattle in 1993 occurred in a homeless population with chronic alcoholism. These patients with high fever or hypothermia were thought to represent *urban trench fever,* but no body louse infestation was associated. Some cases of culture-negative endocarditis may represent *Bartonella* endocarditis. One report described central nervous system involvement with *B. quintana* infection in two children.

DIAGNOSIS

The diagnosis of bacillary angiomatosis is made initially by biopsy. The characteristic small-vessel proliferation with mixed inflammatory response and the staining of bacilli by Warthin-Starry silver distinguish bacillary angiomatosis from pyogenic granuloma or Kaposi sarcoma (see Chapter 304). Travel history can usually preclude verruca peruana.

Culture is impractical for CSD but is the diagnostic procedure for suspected bacteremia or endocarditis. Lysis centrifugation technique or fresh chocolate or heart infusion agar with 5% rabbit blood and prolonged incubation may increase the yield of culture. PCR on tissue can also be a useful tool, and positive serologic testing can provide support for the diagnosis.

TREATMENT

Bartonella infections in immunocompromised hosts caused by both *B. henselae* and *B. quintana* have been treated successfully with antimicrobial agents. Bacillary angiomatosis responds rapidly to erythromycin, azithromycin, and clarithromycin, which are the drugs of choice. Alternative choices are doxycycline or tetracycline. Severely ill patients with peliosis hepatis or patients with osteomyelitis may be treated initially with a macrolide or doxycycline and the addition of rifampin or gentamicin. The use of doxycycline for 6 weeks with the addition of an aminoglycoside for a minimum of 2 weeks is associated with improved prognosis in endocarditis. A Jarisch-Herxheimer reaction may occur. Relapses may follow, and prolonged treatment for several months may be necessary.

PREVENTION

Immunocompromised persons should consider the potential risks of cat ownership because of the risks for *Bartonella* infections as well as toxoplasmosis and enteric infections. Those who elect to obtain a cat should adopt or purchase a cat >1 year old and in good health. Prompt washing of any wounds from cat bites or scratches is essential.

Section 6

Anaerobic Bacterial Infections

Chapter 256

Botulism (*Clostridium botulinum*)

Mark R. Schleiss

There are three naturally occurring forms of human botulism, characterized by mode of acquisition: **infant botulism** (intestinal toxemia), **food-borne botulism**, and **wound botulism**. Infant botulism is the most common form in the United States. Under rare circumstances of altered intestinal anatomy, physiology, and microflora, older children and adults may contract infant-type botulism **(adult intestinal toxemia)**. Two other forms, both human-made, also occur: **inhalational botulism**, from inhaling accidently aerosolized toxin, and **iatrogenic botulism**, from overdosage of botulinum toxin used for therapeutic or cosmetic purposes.

ETIOLOGY

Botulism is the acute, flaccid paralysis caused by the neurotoxin produced by *Clostridium botulinum* or, infrequently, an equivalent neurotoxin produced by the related species *Clostridium butyricum* and *Clostridium baratii. C. botulinum* is a gram-positive, spore-forming, obligate anaerobe whose natural habitat worldwide is soil, dust, and marine sediments. The organism is found in a wide variety of fresh and cooked agricultural products. Remarkably, the spores of some *C. botulinum* strains endure boiling for several hours, enabling the organism to survive efforts at food preservation. In contrast, botulinum toxin is heat labile and easily destroyed by heating at ≥85°C (185°F) for 5 minutes. Neurotoxigenic *C. butyricum* has been isolated from soils near Lake Weishan in China, the site of food-borne botulism outbreaks associated with this organism, and from vegetables, soured milk, and cheeses. Although first recognized in China, cases of infant botulism caused by *C. butyricum* have now been identified in Japan, Europe, and the United States. Little is known about the ecology of neurotoxigenic *C. baratii*.

Botulinum toxin is synthesized as a 150-kDa precursor protein that enters the circulation and is transported to the neuromuscular junction. The toxin is only released by actively replicating (vegetative) bacteria and not the spore form. At the neuromuscular junction, toxin binds to the neuronal membrane on the presynaptic side of the neural synapse. It undergoes proteolysis to a 100-kDa heavy chain and a 50-kDa light chain. These chains are joined via disulfide bond formation. The heavy chain contains the neuronal attachment sites that mediate binding to presynaptic nerve terminals. It also mediates translocation of the light chain into the cell cytoplasm after binding. The light chain, a key component of the toxin, is a member of the zinc metalloprotease family and mediates cleavage of the fusogenic SNARE (Soluble NSF Attachment REceptor) protein family member, SNAP-25. Cleavage of this protein precludes release of acetylcholine from axons at the presynaptic terminal, abrogating nerve signaling and producing paralysis. Botulinum toxin is among the most potent poisons known to humankind; indeed, the parenteral human lethal dose is estimated to be on the order of 10^{-6} mg/kg. The toxin blocks neuromuscular transmission and causes death through airway and respiratory muscle paralysis. At least nine antigenic toxin types, designated by letters A-H and X, are distinguished serologically by demonstration of the inability of neutralizing antibody against one toxin type to protect against a different type. Toxin types are further differentiated into subtypes by differences in the nucleotide sequences of their toxin genes. The gene for botulinum toxin for some toxin types and subtypes resides on a plasmid. Some toxins are fully activated by the bacteria that produce them (proteolytic strains of types A, B, and F), and some require exogenous proteolytic activation (types E and nonproteolytic types B and F).

The toxin types serve as convenient clinical and epidemiologic markers. Toxin types A, B, E, and F are well-established causes of human botulism, whereas types C and D cause illness in other animals. Toxin types A and B cause the majority of cases of infant botulism in the United States. Neurotoxigenic *C. butyricum* strains produce a type E toxin, whereas neurotoxigenic *C. baratii* strains produce a type F toxin. Type G toxin has not been established as a cause of either human or animal disease. Some strains produce two toxins such as B and A or B and F; rare strains may produce three toxins. Dual (bivalent) toxin mediated disease tends to be more severe than single toxin production.

EPIDEMIOLOGY

Infant botulism has been reported from all inhabited continents except Africa. Notably, in a typical case the infant is the only family member who is ill. The most striking epidemiologic feature of infant botulism is its age distribution: approximately 90% of cases involving infants 3 weeks to 6 months of age, with a broad peak spanning 2-4 months of age. Cases have been recognized in infants as young as 1.5 days or as old as 382 days at onset. Identified risk factors for the illness include breastfeeding, the ingestion of honey, a slow intestinal transit time (<1 stool/day), and ingestion of untreated well water (Fig. 256.1). Although breastfeeding appears to provide protection against fulminant sudden death from infant botulism, cases can occur in breastfed infants at the time of introduction of nonhuman milk for feeding.

Although infant botulism is an uncommon and often unrecognized illness, it is the most common form of human botulism in the United States, with approximately 80-140 hospitalized cases diagnosed annually. The Council of State and Territorial Epidemiologists (CSTE) maintains a **National Botulism Surveillance System** for intensive surveillance for cases of botulism in the United States (https://www.cdc.gov/botulism/surveillance.html). In 2017, 182 laboratory-confirmed botulism cases were reported to Centers for Disease Control and Prevention (CDC). Botulism was predominately observed in infants, with 141 such cases reported. A total of 19 (10%) food-borne cases and 19 (10%) wound cases were reported. Infant botulism cases were reported from 26 states and the District of Columbia, with California reporting the

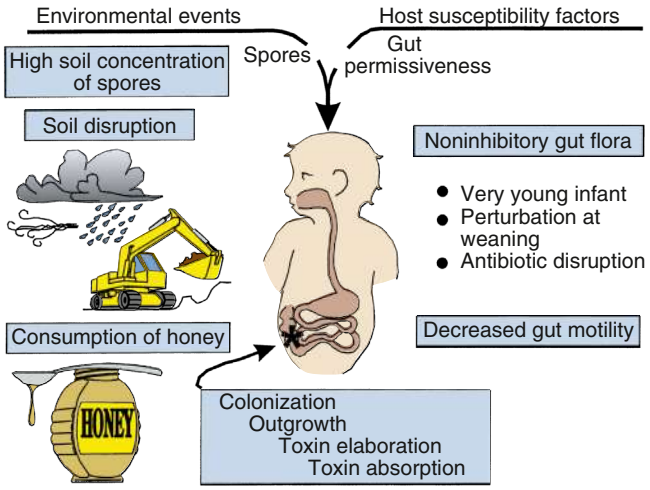

Fig. 256.1 Environmental, host, and pathophysiologic events in infant botulism. *(From Arnon SS, Long SS. Clostridium botulinum [Botulism]. In Long SS, Prober CG, Fischer M, Kimberlin DW, eds. Principles and Practice of Pediatric Infectious Diseases, 6th ed. Philadelphia: Elsevier; 2023: Fig. 189.3, p. 1019.)*

most (n = 48, 34%). Toxin type B (n = 88) predominated. The median age of infants was 4 months (range: 0-12 months), and no deaths were reported.

Food-borne botulism results from the ingestion of a food in which *C. botulinum* has multiplied and produced toxin. Although the traditional view of food-borne botulism has been thought of as resulting chiefly from ingestion of home-canned foods, in fact, outbreaks in North America have been more often associated with restaurant-prepared foods, including nacho cheese in convenience stores, sautéed onions, chopped garlic, and seal blubber (in Alaska). Other outbreaks in the United States have occurred from commercial foods sealed in plastic pouches that relied solely on refrigeration to prevent outgrowth of *C. botulinum* spores. Uncanned foods responsible for food-borne botulism cases include peyote tea, hazelnut flavoring added to yogurt, sweet cream cheese, sautéed onions in patty melt sandwiches, potato salad, and fresh and dried fish, including botulism type E that has been acquired by eating an Egyptian salt-cured fish dish called fesikh. For food-borne botulism cases reported to the 2017 National Botulism Surveillance System, the median age of patients was 42 years (range: 14-85 years), and three deaths were reported. Most of the continental U.S. outbreaks resulted from proteolytic type A or type B strains, whereas in Alaska and Canada, most food-borne outbreaks have resulted from nonproteolytic type E strains. A further hazard of type E strains is their ability to grow at the temperatures maintained by household refrigerators (5°C [41°F]).

Wound botulism is an exceptionally rare disease, with <400 cases reported worldwide, but it is important to pediatrics because adolescents and children may be affected. Although many cases have occurred in young, physically active males who are at the greatest risk for traumatic injury, wound botulism also occurs with crush injuries in which no break in the skin is evident. In recent years, wound botulism from injection has become increasingly common in adult heroin abusers in the western United States and in Europe, not always with concomitant evidence of abscess formation or cellulitis.

A single outbreak of **inhalational botulism** was reported in 1962 in which three laboratory workers in Germany were exposed unintentionally to aerosolized botulinum toxin. Some patients in the United States have been hospitalized by accidental overdose of therapeutic or cosmetic botulinum toxin.

PATHOGENESIS

All forms of botulism produce disease through a final common pathway. Botulinum toxin is carried by the bloodstream to peripheral cholinergic synapses, where it binds irreversibly, blocking acetylcholine release and causing impaired neuromuscular and autonomic transmission. **Infant botulism** results from ingesting the spores of botulinum toxin–producing strains, with subsequent spore germination, multiplication, and production of botulinum toxin in the large intestine. This sequence is distinct from **food-borne botulism**, which is an intoxication that results when preformed botulinum toxin contained in an improperly preserved or inadequately cooked food is swallowed. **Wound botulism** results from spore germination and colonization of traumatized tissue by *C. botulinum;* the pathogenesis of this form of botulism is similar in this respect to that of tetanus. **Inhalational botulism** occurs when aerosolized botulinum toxin is inhaled and could conceivably be a route of exposure generated by a bioterrorist attack.

Because botulinum toxin is not a *cytotoxin,* it does not cause overt macroscopic or microscopic pathology. Pathologic changes (pneumonia, petechiae on intrathoracic organs) may be found at autopsy, but these are secondary changes and not primarily attributable to botulinum toxin. No diagnostic technique is available to identify botulinum toxin binding at the neuromuscular junction. Nerve conduction velocity studies are typically normal. Electromyography (EMG) findings are often nonspecific and nondiagnostic (see later). The healing process in botulism consists of sprouting new terminal unmyelinated motor neurons. Movement resumes when these new nerve terminals locate noncontracting muscle fibers and reinnervate them by inducing formation of a new motor end plate. In experimental animals, this process takes about 4 weeks.

Fig. 256.2 A 3-mo-old infant with botulism just before intubation. Note bilateral ptosis and facial palsy and the absence of tears. *(From Arnon SS, Long SS. Clostridium botulinum [Botulism]. In: Long SS, Prober CG, Fischer M, Kimberlin DW, eds. Principles and Practice of Pediatric Infectious Diseases, 6th ed. Philadelphia: Elsevier; 2023: Fig. 189.4, p. 1020.)*

CLINICAL MANIFESTATIONS

The full clinical spectrum of **infant botulism** ranges from mild to fulminant sudden death. Botulinum toxin is distributed hematogenously. Because relative blood flow and density of innervation are greatest in the bulbar musculature, all forms of botulism manifest neurologically as a symmetric, *descending,* flaccid paralysis beginning with the cranial nerve musculature and progressing over hours to days. **Bulbar palsies** may manifest with such symptoms as poor feeding, weak suck, feeble cry, drooling, and even obstructive apnea. These clinical clues unfortunately may not be recognized as bulbar in origin (Fig. 256.2). Patients with evolving illness may already have generalized weakness and hypotonia in addition to bulbar palsies when first examined. The brain itself is spared in infant botulism, because botulinum toxin does not cross the blood-brain barrier.

In contrast to botulism caused by *C. botulinum,* a majority of the rare cases caused by intestinal colonization with *C. butyricum* are associated with a Meckel diverticulum accompanying abdominal distention, often leading to misdiagnosis as an acute abdomen. The also rare *C. baratii* type F infant botulism cases have been characterized by very young age at onset, rapidity of onset, and greater severity but shorter duration of paralysis.

In older children with **food-borne** or **wound botulism**, the onset of neurologic symptoms follows a characteristic pattern of diplopia, ptosis, dry mouth, dysphagia, dysphonia, and dysarthria, with decreased gag and corneal reflexes. Importantly, because the toxin acts only on motor nerves, paresthesias are not seen in botulism, except when a patient hyperventilates from anxiety. The sensorium remains clear, but this fact may be difficult to ascertain because of the slurred speech.

Food-borne botulism begins with gastrointestinal (GI) symptoms of nausea, vomiting, or diarrhea in approximately 30% of cases. These symptoms are thought to result from metabolic by-products of growth of *C. botulinum* or from the presence of other toxic contaminants in the food, because GI distress is rarely observed in wound botulism. Constipation may occur in food-borne botulism once flaccid paralysis becomes evident. Illness usually begins 12-36 hours after ingestion of

the contaminated food but can range from as short as 2 hours to as long as 8 days. The incubation period in **wound botulism** is 4-14 days. Fever may be present in wound botulism but is absent in food-borne botulism unless a secondary infection (often pneumonia) is present. All forms of botulism display a wide spectrum of clinical severity, from the very mild, with minimal ptosis, flattened facial expression, minor dysphagia, and dysphonia, to the fulminant, with rapid onset of extensive paralysis, frank apnea, and fixed, dilated pupils. *Fatigability with repetitive muscle activity* is the clinical hallmark of botulism.

Infant botulism differs in apparent initial symptoms of illness only because the infant cannot verbalize them. Clinical progression can be more rapid and more severe in very young infants. The incubation period in infant botulism is estimated to be 3-30 days. Usually, the first indication of illness is a decreased frequency or even absence of defecation, and indeed, constipation may be the chief complaint (although this sign is also frequently overlooked). Parents typically notice inability to feed, lethargy, weak cry, and diminished spontaneous movement. Dysphagia may be evident, and an increase in secretions drooling from the mouth may be noted. Gag, suck, and corneal reflexes all diminish as the paralysis advances. Oculomotor palsies may be evident. Paradoxically, the pupillary light reflex may be unaffected until the child is severely paralyzed, or it may be initially sluggish. Loss of head control is typically a prominent sign. Opisthotonos may be observed. Respiratory arrest may occur suddenly from airway occlusion by unswallowed secretions or from obstructive flaccid pharyngeal musculature. Death from botulism results either from airway obstruction or paralysis of the respiratory muscles. Occasionally, the diagnosis of infant botulism is suggested by a respiratory arrest that occurs after the infant is curled into position for lumbar puncture or after the administration of an aminoglycoside antibiotic administered for suspected sepsis (see later).

In mild cases or in the early stages of illness, the physical signs of infant botulism may be subtle and easily missed. Eliciting cranial nerve palsies and fatigability of muscular function requires careful examination. Ptosis may not be seen unless the head of the child is kept erect.

DIAGNOSIS

Definitive diagnosis of botulism is made by specialized laboratory testing that requires hours to days to complete. Therefore clinical diagnosis is the foundation for early recognition of and response to all forms of botulism. Routine laboratory studies, including those of the cerebrospinal fluid (CSF), are normal in botulism unless dehydration, undernourishment (metabolic acidosis and ketosis), or secondary infection is present.

The **classic triad** of botulism is the acute onset of a symmetric, flaccid descending paralysis with clear sensorium, no fever, and no paresthesias. Suspected botulism represents a medical and public health emergency that is immediately reportable by telephone in most U.S. health jurisdictions. State health departments (first call) and the CDC (770-488-7100 at any time) can arrange for diagnostic testing, epidemiologic investigation, and provision of equine antitoxin.

The diagnosis of botulism is unequivocally established by demonstration of the presence of botulinum toxin in serum or of *C. botulinum* toxin or organisms in wound material, enema fluid, or feces. *C. botulinum* is not part of the normal resident intestinal flora of humans, and its presence in the setting of acute flaccid paralysis is diagnostic. An epidemiologic diagnosis of food-borne botulism can be established when *C. botulinum* organisms and toxin are found in food eaten by patients.

Electromyography can sometimes distinguish between causes of acute flaccid paralysis, although results may be variable, including normal, in patients with botulism. The distinctive EMG finding in botulism is facilitation (potentiation) of the evoked muscle action potential at high-frequency (50 Hz) stimulation. In infant botulism, a characteristic pattern known as **BSAP** (Brief, Small, Abundant motor unit action Potentials) is present only in clinically weak muscles. Nerve conduction velocity and sensory nerve function are normal in botulism.

Infant botulism requires a high index of suspicion for early diagnosis (Table 256.1). "Rule-out sepsis" remains the most common admission diagnosis. If a previously healthy infant (usually 2-4 months of age) demonstrates weakness with difficulty in sucking, swallowing, crying, or breathing, infant botulism should be considered a likely diagnosis. A careful cranial nerve examination is then quite helpful. Rare instances of co-infection with *Clostridioides difficile,* respiratory syncytial virus, or influenza virus have occurred.

Table 256.1 Mimics of Initial Diagnosis of Infant Botulism

NEUROMUSCULAR
Spinal muscular atrophy (type 1)
Congenital myasthenia gravis
Guillain-Barré syndrome and its variants
Poliomyelitis
Acute flaccid paralysis
Transverse myelitis
ADEM
Congenital myopathy
Encephalitis (viral, autoimmune)
Global developmental delay
Leukodystrophy
METABOLIC
Medium chain acetyl-coenzyme A deficiency
Carnitine deficiency
Congenital disorders of glycosylation
Urea cycle defects
Mitochondrial disorders
Glutaric aciduria type 1
Maple syrup urine disease
INFECTIOUS
Enteroviral and parechovirus encephalitis
Sepsis
OTHERS
Hypothyroidism
Drug ingestion
Organophosphate poisoning
Heavy metal poisoning (lead, arsenic)

Differential Diagnosis

Botulism is frequently misdiagnosed, most often as a **polyradiculoneuropathy** (Guillain-Barré or Miller Fisher syndrome), myasthenia gravis, or a central nervous system (CNS) disease (Table 256.2). In the United States, botulism is more likely than **Guillain-Barré syndrome**, intoxication, or poliomyelitis to cause a *cluster of cases* of acute flaccid paralysis. Botulism differs from other flaccid paralyses in its initial and prominent cranial nerve palsies that are disproportionate to milder weakness and hypotonia below the neck, in its symmetry, and in its absence of sensory nerve damage. Spinal muscular atrophy may closely mimic infant botulism at presentation.

Additional diagnostic procedures may be useful in rapidly excluding botulism as the cause of paralysis. The CSF is unchanged in botulism but is abnormal in many CNS diseases. Although the CSF protein concentration is eventually elevated in Guillain-Barré syndrome, it may be normal early in the illness. Imaging of the brain, spine, and chest may reveal hemorrhage, inflammation, or neoplasm. A test dose of edrophonium chloride briefly reverses paralytic symptoms in many patients with myasthenia gravis and, reportedly, in some with botulism, although this is rarely performed in infants. A close inspection of the skin, especially the scalp, may reveal an attached tick that is causing paralysis. Possible organophosphate intoxication should be pursued aggressively, because specific antidotes (oximes) are available and because the patient may be part of a commonly exposed group, some of whom have yet to demonstrate illness. Other tests that require days for results include stool culture for *Campylobacter jejuni* as a precipitant of Guillain-Barré syndrome, spinal muscular atrophy and other genetic (including mitochondrial) disorders, and assays for the autoantibodies that cause myasthenia gravis, Lambert-Eaton syndrome, and Guillain-Barré syndrome.

Table 256.2 Conditions Considered in the Differential Diagnosis of Food-Borne Botulism and Wound Botulism

Acute gastroenteritis
Myasthenia gravis
Guillain-Barré syndrome
Organophosphate poisoning
Meningitis
Encephalitis

Psychiatric illness
Cerebrovascular accident
Poliomyelitis
Hypothyroidism
Genetic disorder
Aminoglycoside-associated paralysis
Tick paralysis
Hypocalcemia
Hypermagnesemia
Carbon monoxide poisoning
Hyperemesis gravidarum
Laryngeal trauma
Diabetic complications
Inflammatory myopathy
Overexertion

TREATMENT

Human botulism immune globulin, given intravenously (BIG-IV, also referred to as *BabyBIG*), is licensed for the treatment of infant botulism caused by type A or B botulinum toxin. The purified immunoglobulin is derived from pooled adult plasma from individuals immunized with pentavalent botulinum toxoid who were selected for their high titers of neutralizing antibody against botulinum neurotoxins type A and B. Treatment with BIG-IV consists of a single intravenous infusion of 50 mg/kg (see package insert) that should be given as soon as possible after infant botulism is suspected so as to immediately end the toxemia that is the cause of the illness and arrest progression of paralysis. *When the diagnosis of infant botulism is suspected, treatment should not be delayed for laboratory confirmation.* In the United States, for clinical consultation for a patient with suspected infant botulism, the patient's physician should contact the Infant Botulism Treatment and Prevention Program (IBTPP) on-call physician at (510) 231-7600 (24/7/365). To obtain BabyBIG for a patient with suspect infant botulism, the physician must contact the IBTPP on-call physicians (https://www.infantbotulism.org/physician/obtain.php). The use of BIG-IV shortens mean hospital stay from approximately 6 weeks to 2 weeks. Most of the decrease in hospital stay results from shorter duration of mechanical ventilation and reduced days in intensive care.

Older patients with suspected food, wound, or inhalational botulism may be treated with one vial of licensed equine heptavalent (A-G) botulinum antitoxin (HBAT). (https://www.cdc.gov/mmwr/preview/mmwrhtml/mm5910a4.htm), which is available in the United States through the CDC by way of state and local health departments.

Antibiotic therapy is not part of the treatment of uncomplicated infant or food-borne botulism, because the toxin is primarily an intracellular molecule that is released into the intestinal lumen with vegetative bacterial cell death and lysis. Indeed, there is a theoretical concern that antibiotics with clostridiocidal activity may increase the amount of free toxin in the large bowel and actually worsen an infant's clinical status. Antibiotic use in infant botulism patients is indicated only for the treatment of secondary infections. In these patients, aminoglycosides in particular should be avoided, because this class of antibiotics can potentiate the action of botulinum toxin at the neuromuscular junction. Wound botulism requires aggressive treatment with antibiotics and antitoxin in a manner analogous to that for tetanus (see Chapter 257) and may require wound debridement to remove the source of the toxin.

SUPPORTIVE CARE

Management of botulism rests on the following three principles: (1) fatigability with repetitive muscle activity is the clinical hallmark of the disease, (2) complications are best avoided by anticipating them, and (3) meticulous supportive care is a necessity. The first principle applies mainly to feeding and breathing. Correct positioning is imperative to protect the airway and improve respiratory mechanics. The patient should be positioned face-up on a rigid-bottomed crib (or bed), the head of which is tilted at 30 degrees. A small cloth roll is placed under the cervical vertebrae to tilt the head back so that secretions drain to the posterior pharynx and away from the airway. In this tilted position, the abdominal viscera pull the diaphragm down, thereby improving respiratory mechanics. The patient's head and torso should not be elevated by bending the middle of the bed; in such a position, the hypotonic thorax would slump into the abdomen, and breathing would be compromised.

About half of patients with infant botulism require endotracheal intubation, which is best done prophylactically. The indications include diminished gag and cough reflexes and progressive airway obstruction by secretions. Enteral nutrition should be undertaken using a nasogastric or nasojejunal tube until sufficient oropharyngeal strength and coordination enable oral feeding by breast or bottle. Expressed breast milk is the most desirable food for infants, in part because of its immunologic components (e.g., secretory IgA, lactoferrin, leukocytes). Tube feeding also assists in the restoration of peristalsis, a nonspecific but probably essential part of eliminating *C. botulinum* from the intestinal flora. Intravenous feeding (hyperalimentation) is discouraged because of the potential for infection and the advantages of tube feeding.

Because sensation and cognitive function remain fully intact, providing auditory, tactile, and visual stimuli is beneficial. Maintaining strong central respiratory drive is essential, so sedatives and CNS depressants should be avoided. Full hydration and stool softeners such as lactulose may mitigate the protracted constipation. Cathartics are not recommended. Patients with food-borne and infant botulism excrete *C. botulinum* toxin and organisms in their feces, often for many weeks, and care should be taken in handling their excreta, with full engagement of hospital infection control staff. When bladder palsy occurs in severe cases, gentle suprapubic pressure with the patient in the sitting position with the head supported may help attain complete voiding and reduce the risk for urinary tract infection (UTI). Families of affected patients may require emotional and financial support, especially when the paralysis of botulism is prolonged.

COMPLICATIONS

Almost all the complications of botulism are *nosocomial,* and a few are iatrogenic (Table 256.3). Some critically ill, toxin-paralyzed patients who must spend weeks or months on ventilators in intensive care units inevitably experience some of these complications. Suspected "relapses" of infant botulism usually reflect premature hospital discharge or an inapparent underlying complication such as pneumonia, UTI, or otitis media.

PROGNOSIS

When the regenerating nerve endings have induced formation of a new motor end plate, neuromuscular transmission is restored. In the absence of complications, particularly those related to hypoxia, the prognosis in infant botulism is for full and complete recovery. Hospital stay in untreated infant botulism averages 5.7 weeks but differs significantly by toxin type, with patients with untreated type B disease being hospitalized a mean of 4.2 weeks and those with untreated type A disease being hospitalized a mean of 6.7 weeks.

In the United States, the case fatality ratio for hospitalized cases of infant botulism is <1%. After recovery, patients with untreated infant botulism appear to have an increased incidence of strabismus that requires timely screening and treatment. The case fatality ratio in food-borne and wound botulism varies by age, with younger patients having the best prognosis. Some adults with botulism have reported chronic weakness and fatigue for >1 year as sequelae of the illness.

Table 256.3 Complications of Infant Botulism

Acute respiratory distress syndrome
Aspiration
Clostridioides difficile enterocolitis
Hypotension
Inappropriate antidiuretic hormone secretion
Long bone fractures
Misplaced or plugged endotracheal tube
Nosocomial anemia
Otitis media
Pneumonia
Pneumothorax
Recurrent atelectasis
Seizures secondary to hyponatremia
Sepsis
Subglottic stenosis
Tracheal granuloma
Tracheitis
Transfusion reaction
Urinary tract infection

PREVENTION

Food-borne botulism is best prevented by adherence to safe methods of home canning (pressure cooker and acidification), by avoiding suspicious foods, and by heating all home-canned foods to 85°C (185°F) for ≥5 minutes. Wound botulism is best prevented by not using illicit drugs and by treating contaminated wounds with thorough cleansing, surgical debridement, and provision of appropriate antibiotics.

Many patients with infant botulism are presumed to have inhaled and then swallowed airborne clostridial spores; these cases cannot be prevented. However, a clearly identified and avoidable source of botulinum spores for infants is honey. *Honey is an unsafe food for any child <1 year old.* Corn syrups were once thought to be a possible source of botulinum spores, but evidence indicates otherwise. Breastfeeding appears to slow the onset of infant botulism and to diminish the risk for sudden death in infants in whom the disease develops.

Chapter 257

Tetanus (*Clostridium tetani*)

Mark R. Schleiss

ETIOLOGY

The clinical syndrome of **tetanus** involves an acute, spastic paralytic illness caused by a neurotoxin produced by *Clostridium tetani*. Thus tetanus can be considered a toxin-mediated process more than an acute infectious process per se, because there are few, if any, symptoms elicited either by the presence of replicating microorganisms or through elicitation of the host inflammatory response. Unlike other pathogenic clostridia species, *C. tetani* is not a tissue-invasive organism. Instead, it causes illness through the toxin, **tetanospasmin**, more commonly referred to as *tetanus toxin*. Tetanospasmin is the second most poisonous substance known, surpassed in potency only by botulinum toxin. The human lethal dose of tetanus toxin is estimated to be 10^{-5} mg/kg. *C. tetani* is a motile, gram-positive, spore-forming obligate anaerobe. The organism's natural habitat worldwide is soil, dust, and the alimentary tracts of various animals.

C. tetani forms spores terminally, with a classic morphologic appearance resembling a drumstick or tennis racket when viewed microscopically. The formation of spores is a critical aspect of the organism's persistence in the environment. Spores can survive boiling but not autoclaving, whereas the vegetative cells are killed by antibiotics, heat, and standard disinfectants.

EPIDEMIOLOGY

Tetanus occurs worldwide and is endemic in many developing countries, although its incidence varies considerably. Public health efforts in recent years have had an impressive impact on tetanus-associated mortality, but many challenges remain. In 1990, 314,000 people died because of tetanus, whereas in 2017 there were just slightly over 38,000 deaths. Over half of these deaths (approximately 18,000) were in children under 5 years of age (Fig. 257.1A). Individuals age 15-49 years represent the second most common group to suffer tetanus-related mortality. Global mortality in adults is largely driven by **maternal tetanus**, which results from postpartum, postabortal, or postsurgical wound infection with *C. tetani*. Most mortality related to **neonatal tetanus** (also referred to as **umbilical tetanus**) occurs in South Asia and sub-Saharan Africa. The mortality of neonatal tetanus has been substantially reduced globally, driven by increased rates of maternal tetanus vaccination, although the disease remains endemic in a number of countries (see Fig. 257.1B). Reported tetanus cases in the United States have declined more than 95% since 1947, and deaths caused by tetanus have declined by more than 99% in that same period. From 2009 to 2017, a total of 264 cases and 19 deaths from tetanus were reported in the United States. Sixty (23%) cases were in persons 65 years of age or older, 168 (64%) were in persons 20 through 64 years of age, and 36 (13%) were in persons younger than 20 years, including 3 cases of neonatal tetanus. The majority of childhood cases of tetanus in the United States have occurred in unimmunized children whose parents objected to vaccination.

Most nonneonatal cases of tetanus are associated with a traumatic injury, often a penetrating wound inflicted by a dirty object such as a nail, splinter, fragment of glass, or unsterile injection. Tetanus may also occur in the setting of illicit drug injection. The disease has been associated with the use of contaminated suture material and after intramuscular injection of medicines, most notably quinine for chloroquine-resistant falciparum malaria. The disease may also occur in association with animal bites, abscesses (including dental abscesses), ear and other body piercing, chronic skin ulceration, burns, compound fractures, frostbite, gangrene, intestinal surgery, ritual scarification, infected insect bites, and female circumcision. Rarely, cases may present to clinical attention without an antecedent history of trauma. Tetanus is not transmitted person to person.

PATHOGENESIS

Tetanus typically occurs after spores (introduced by traumatic injury) germinate, multiply, and produce tetanus toxin. A plasmid carries the toxin gene. Toxin is produced only by the vegetative cell, not the spore. It is released after the vegetative phase of replication, with replication occurring under anaerobic conditions. The low oxidation-reduction potential of an infected injury site therefore provides an ideal environment for transition from the spore to the vegetative stage of growth. After bacterial cell death and lysis, **tetanospasmin** is produced. The toxin has no known function for clostridia in the soil environment where they normally reside. Tetanus toxin is a 150-kDa simple protein consisting of a heavy chain (100 kDa) and a light (50 kDa) chain joined by a single disulfide bond. Tetanus toxin binds at the neuromuscular junction and enters the motor nerve by endocytosis, after which it undergoes retrograde axonal transport, facilitated by dyneins, to the cytoplasm of the α-motoneuron. In the sciatic nerve, the transport rate was found to be 3.4 mm/hr. The toxin exits the motoneuron in the spinal cord and next enters adjacent spinal inhibitory interneurons, where it prevents release of the neurotransmitters glycine and γ-aminobutyric acid (GABA). Tetanus toxin thus blocks the normal inhibition of antagonistic muscles on which voluntary coordinated movement depends; as a consequence, affected muscles sustain maximal contraction and cannot relax. This aspect of pathogenesis lead to

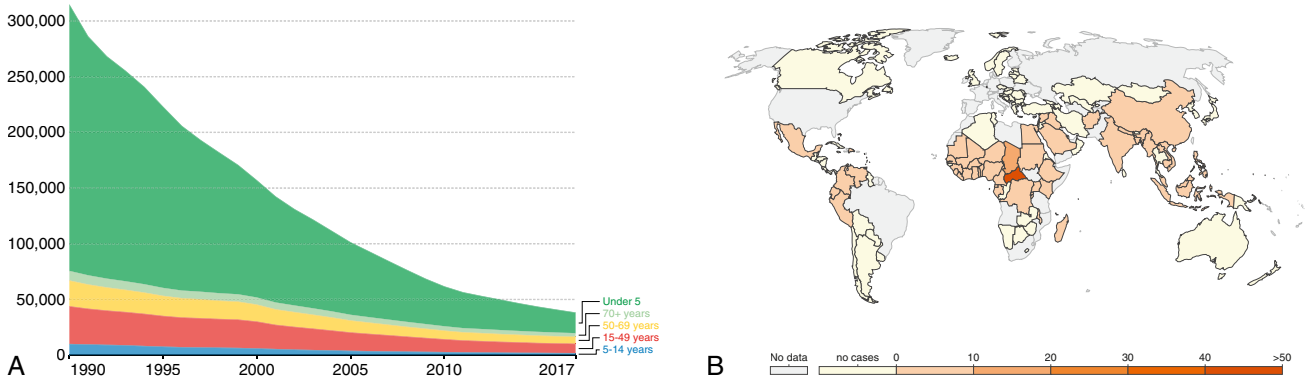

Fig. 257.1 Evolving epidemiology of tetanus. **A,** Deaths from tetanus, by age, globally from 1990 to 2017. Most cases of tetanus occur in children under the age of 5, and this group accounts for ~50% of the global mortality attributable to this infection. (Source: Institute for Health Metrics and Evaluation, Global Burden of Disease). **B,** Global distribution of neonatal tetanus. Number of new cases of neonatal tetanus per million, 2016. Sources: World Health Organization and UN Population Prospects, 2017. *(From Behrens H, Ochmann S, Dadonaite B, Roser M. Tetanus. Published online at OurWorldInData.org, 2019. Retrieved from https://ourworldindata.org/tetanus.)*

the term *lockjaw,* classically applied to the clinical manifestations of tetanus in the affected individual. Neurotransmission at neuromuscular junctions in the autonomic nervous system are also rendered unstable in tetanus, producing "autonomic storm" (described later).

The phenomenal potency of tetanus toxin is enzymatic. The 50-kDa light chain (A-chain) of tetanus toxin is a zinc-containing endoprotease whose substrate is synaptobrevin, a constituent protein of the docking complex that enables the synaptic vesicle to fuse with the terminal neuronal cell membrane. The cleavage of synaptobrevin is the final target of tetanus toxin, and even in low doses the neurotoxin will inhibit neurotransmitter exocytosis in the inhibitory interneurons. The blockage of GABA and glycine causes the physiologic effects of tetanus toxin. The 100-kDa heavy chain (B-chain) of the toxin contains its binding and internalization domains. It binds to disialogangliosides (GD2 and GD1b) on the neuronal membrane. The translocation domain aids the movement of the protein across that membrane and into the neuron.

Because *C. tetani* is not an invasive organism, its toxin-producing vegetative cells remain where introduced into the wound, which may display local inflammatory changes and a mixed bacterial flora.

CLINICAL MANIFESTATIONS

Tetanus is most often generalized but may also be localized. The incubation period typically is 2-14 days but may be as long as months after the injury. In **generalized tetanus**, the presenting symptom in about half of cases is **trismus** (masseter muscle spasm, or lockjaw). Headache, restlessness, and irritability are early symptoms, often followed by stiffness, difficulty chewing, dysphagia, and neck muscle spasm. The so-called **sardonic smile of tetanus *(risus sardonicus)*** results from intractable spasms of facial and buccal muscles. When the paralysis extends to abdominal, lumbar, hip, and thigh muscles, the patient may assume an arched posture of extreme hyperextension of the body, or **opisthotonos**, with the head and the heels bent backward and the body bowed forward. In severe cases, only the back of the head and the heels of the patient are noted to be touching the supporting surface. Opisthotonos is an equilibrium position that results from unrelenting total contraction of opposing muscles, all of which display the typical boardlike rigidity of tetanus. Laryngeal and respiratory muscle spasm can lead to airway obstruction and asphyxiation. Because tetanus toxin does not affect sensory nerves or cortical function, the patient unfortunately remains conscious, in extreme pain, and in fearful anticipation of the next tetanic seizure. The seizures are characterized by sudden, severe tonic contractions of the muscles, with fist clenching, flexion, and adduction of the arms and hyperextension of the legs. Without treatment, the duration of these seizures may range from a few seconds to a few minutes in length with intervening respite periods. As the illness progresses, the spasms become sustained and exhausting. The smallest disturbance by sight, sound, or touch may trigger a tetanic spasm. Dysuria and urinary retention result from bladder sphincter spasm; forced defecation may occur. Fever, occasionally as high as 40°C (104°F), is common and is caused by the substantial metabolic energy consumed by spastic muscles. Notable autonomic effects include tachycardia, dysrhythmias, labile hypertension, diaphoresis, and cutaneous vasoconstriction. The tetanic paralysis usually becomes more severe in the first week after onset, stabilizes in the second week, and ameliorates gradually over the ensuing 1-4 weeks.

Neonatal tetanus, the infantile form of generalized tetanus, typically manifests within 3-12 days of birth. It presents as progressive difficulty in feeding (sucking and swallowing), associated hunger, and crying. Paralysis or diminished movement, stiffness and rigidity to the touch, and spasms, with or without opisthotonos, are characteristic. The umbilical stump, which is typically the portal of entry for the microorganism, may retain remnants of dirt, dung, clotted blood, or serum, or it may appear relatively benign.

Localized tetanus results in painful spasms of the muscles adjacent to the wound site and may precede generalized tetanus. **Cephalic tetanus** is a rare form of localized tetanus involving the bulbar musculature and cranial nerves (particularly cranial nerve VII) that occurs with wounds or foreign bodies in the head, nostrils, or face. It also occurs in association with chronic otitis media. Cephalic tetanus is characterized by retracted eyelids, deviated gaze, trismus, *risus sardonicus,* and spastic paralysis of the tongue and pharyngeal musculature and may mimic a cerebrovascular accident.

DIAGNOSIS

The picture of tetanus is one of the most dramatic in medicine, and the diagnosis may be established clinically. The typical setting is an unimmunized patient (and/or mother) who was injured or born within the preceding 2 weeks, who presents with trismus, dysphagia, generalized muscle rigidity and spasm, and a clear sensorium.

Results of routine laboratory studies are usually normal. A peripheral leukocytosis may result from a secondary bacterial infection of the wound or may be stress-induced from the sustained tetanic spasms. The cerebrospinal fluid analysis is normal, although the intense muscle contractions may raise intracranial pressure. Serum muscle enzymes (creatine kinase, aldolase) may be elevated. Neither the electroencephalogram nor the electromyogram (EMG) shows a characteristic pattern, although EMG may show a continuous discharge of motor subunits and shortening or absence of the silent interval normally observed after an action potential. An assay for antitoxin levels is not readily available, although a serum antitoxin level of 0.01 IU/mL or higher is generally considered protective and makes the diagnosis of tetanus less likely. *C. tetani* is not always visible on Gram stain of wound material and is isolated by culture in only approximately 30% of cases. The **spatula test** is a simple diagnostic

bedside test that involves touching the oropharynx with a spatula or tongue blade. Normally this maneuver will elicit a gag reflex, as the patient tries to expel the spatula (negative test). If tetanus is present, patients develop a reflex spasm of the masseters and bite the spatula (positive test). This bedside diagnostic maneuver is said to have a high sensitivity and specificity.

Differential Diagnosis

Florid and generalized tetanus is typically not mistaken for any other disease. However, trismus may result from parapharyngeal, retropharyngeal, or dental abscesses or, rarely, from acute encephalitis involving the brainstem. Either rabies or tetanus may follow an animal bite, and rabies may manifest as trismus with seizures. Rabies may be distinguished from tetanus by hydrophobia, marked dysphagia, predominantly clonic seizures, and pleocytosis (see Chapter 320). Although strychnine poisoning may result in tonic muscle spasms and generalized seizure activity, it seldom produces trismus, and unlike in tetanus, general relaxation usually occurs between spasms. Hypocalcemia may produce tetany that is characterized by laryngeal and carpopedal spasms, but trismus is absent. Occasionally, epileptic seizures, narcotic withdrawal, or other drug reactions may suggest tetanus.

TREATMENT

Management of tetanus requires eradication of *C. tetani,* correction of wound environment conditions conducive to its anaerobic replication, neutralization of all accessible tetanus toxin, control of seizures and respiration, palliation, provision of meticulous supportive care, and, finally, prevention of recurrences.

Surgical wound excision and debridement are often needed to remove the foreign body or devitalized tissue that created the anaerobic growth conditions necessary for vegetative replication. Surgery should be performed promptly after administration of **human tetanus immunoglobulin (TIG)** and antibiotics. Excision of the umbilical stump in the neonate with tetanus is no longer recommended.

Tetanus toxin cannot be neutralized by TIG after it has begun its axonal ascent to the spinal cord. However, TIG should be given as soon as possible, with the goal of neutralizing toxin that diffuses from the wound into the circulation before the toxin can bind at distant muscle groups. The optimal dose of TIG has not been determined. Most experts recommend that a **single intramuscular (IM) injection of 500 units of TIG** is sufficient to neutralize systemic tetanus toxin; although doses as high as 3,000-6,000 have been recommended by some experts, they do not seem to confer better outcomes. Infiltration of part of the dose of TIG into the wound is no longer recommended by the Red Book Committee of the American Academy of Pediatrics, and the entire dose can be administered IM. If TIG is unavailable, use of human intravenous immunoglobulin (at a dose of 200-400 mg/kg) can be considered. Intravenous immunoglobulin contains 4-90 units/mL of TIG; the optimal dosage of intravenous immunoglobulin for treating tetanus is not known, and its use is not approved for this indication. In parts of the world where it is available, another alternative may be equine-derived tetanus antitoxin (TAT). This product is no longer available in the United States. A dose of 1,500-3,000 U is recommended and should be administered after appropriate testing for sensitivity and desensitization, because up to 15% of patients given the usual dose of TAT will experience serum sickness. The human-derived immunoglobulins are much preferred because of their longer half-lives (30 days) and the virtual absence of allergic and serum sickness adverse effects. Results of studies examining the potential benefit of intrathecal administration of TIG are conflicting. The TIG preparation available for use in the United States is neither licensed nor formulated for intrathecal or intravenous use.

Oral (or intravenous) **metronidazole** (30 mg/kg per day, given at 6-hour intervals; maximum dose, 4 g/day) decreases the number of vegetative forms of *C. tetani* and is currently considered the antibiotic of choice. **Parenteral penicillin G** (100,000 U/kg per day, administered at 4- to 6-hour intervals, with a daily maximum of 12 million U) is an alternative treatment. Antimicrobial therapy for a total duration of 7-10 days is recommended (https://publications.aap.org/redbook/book/347/chapter-abstract/5757094/Tetanus-Lockjaw).

Supportive care and pharmacologic interventions targeted at control of tetanic spasms are of critical importance in the management of tetanus. In light of this goal, all patients with generalized tetanus should receive muscle relaxants. **Diazepam** provides both relaxation and seizure control. For neonatal tetanus, an initial dose of 0.1-0.2 mg/kg every 3-6 hours given intravenously is subsequently titrated to control the tetanic spasms (continuous IV infusion doses of 15-40 mg/kg/day have been recommended, titrated to control the spasm). After 5-7 days, the dosage can be decreased by 5-10 mg/day, with the drug given orally or by the nasogastric route, after which the effective dose is sustained for 2-6 weeks before a tapered withdrawal. **Magnesium sulfate** may be useful in controlling autonomic dysfunction: a loading dose of 40 mg/kg IV over 30 minutes has been recommended in a study in tetanus patients >15 years of age, in which the loading dose was followed by 2 g/hr continuously for patients weighing >45 kg, or 1.5 g/hr continuously for patients weighing <45 kg. For neonatal tetanus, a loading dose of 50 mg/kg of magnesium sulfate, followed by a maintenance infusion of 30-50 mg/kg/hr (titrated against clinical effect) has been recommended. Monitoring of serum magnesium levels at least every 6 hours is recommended. In addition to diazepam, other benzodiazepines **(midazolam)**, **chlorpromazine**, **dantrolene**, and **baclofen** are also used. Intrathecal baclofen produces such complete muscle relaxation that apnea often ensues; like most other agents listed, baclofen should be used only in an intensive care unit setting. Favorable survival rates in generalized tetanus have been described with the use of neuromuscular blocking agents such as vecuronium and pancuronium, which produce a general flaccid paralysis that is then managed by mechanical ventilation. Autonomic instability is regulated with standard α- or β- (or both) blocking agents; morphine has also proved useful.

SUPPORTIVE CARE

Meticulous supportive care in a quiet, dark, secluded setting is most desirable. Because tetanic spasms may be triggered by minor stimuli, the patient should be sedated and protected from all unnecessary sounds, sights, and touch, and all therapeutic and other manipulations must be carefully scheduled and coordinated. Endotracheal intubation may not be required, but it should be done to prevent aspiration of secretions before laryngospasm develops. A tracheostomy kit should be immediately at hand for unintubated patients. Endotracheal intubation and suctioning easily provoke reflex tetanic seizures and spasms, so early tracheostomy should be considered in severe cases not managed by pharmacologically induced flaccid paralysis. Therapeutic botulinum toxin has been used for this purpose (i.e., to overcome trismus). Cardiorespiratory monitoring, frequent suctioning, and maintenance of the patient's substantial fluid, electrolyte, and caloric needs are fundamental. Careful nursing attention to mouth, skin, bladder, and bowel function is needed to avoid ulceration, infection, and obstipation. Prophylactic subcutaneous heparin has been suggested to be of value, but it must be balanced with the risk for hemorrhage. Enoxaparin would be an alternative for the patient for whom deep venous thrombosis (DVT) prophylaxis is warranted.

COMPLICATIONS

The seizures and the severe, sustained rigid paralysis of tetanus predispose the patient to many complications. Aspiration of secretions with attendant pneumonia is an important complication to consider and may be present at the time of the initial diagnosis. Maintaining airway patency often mandates endotracheal intubation and mechanical ventilation with their attendant hazards, including pneumothorax and mediastinal emphysema. The seizures may result in lacerations of the mouth or tongue, in intramuscular hematomas or **rhabdomyolysis** with myoglobinuria and renal failure, or in long bone or spinal fractures. Venous thrombosis, pulmonary embolism, gastric ulceration with or without hemorrhage, paralytic ileus, and decubitus ulceration are described as complications. Excessive use of muscle relaxants, which are an integral part of care, may produce iatrogenic apnea. Cardiac arrhythmias, including asystole, unstable blood pressure, and labile temperature regulation, reflect disordered autonomic nervous system control that may be aggravated by inattention to maintenance of intravascular volume needs.

Table 257.1 Tetanus Vaccination and Immune Globulin Use in Wound Management

HISTORY OF ABSORBED TETANUS TOXOID	CLEAN, MINOR WOUNDS		ALL OTHER WOUNDS*	
	DTaP, Tdap, OR Td†	TIG‡	DTaP, Tdap, Or TD†	TIG‡
Uncertain or <3 doses	Yes	No	Yes	Yes
3 or more doses	No, if <10 yr since last dose of tetanus-containing vaccine	No	No, if <5 yr since last tetanus-containing vaccine‖	No
	Yes, if ≥10 yr since last dose of tetanus-containing vaccine	No	Yes, if ≥5 yr since last tetanus-containing vaccine dose	No

*Including but not limited to wounds contaminated with dirt, feces, and saliva; puncture wounds; avulsions; wounds resulting from missiles, crushing, burns, and frostbite.
†DTaP is used for children younger than 7 yr. Tdap is preferred over Td for underimmunized children 7 yr and older who have not received Tdap previously.
‡Intravenous immune globulin should be used when TIG is unavailable.
‖More frequent boosters are not needed and can accentuate adverse events.
DT, Diphtheria and tetanus toxoid vaccine; DTaP, combined diphtheria toxoid–tetanus toxoid–acellular pertussis vaccine; Td, tetanus toxoid and reduced diphtheria toxoid vaccine; Tdap, tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine; TIG, tetanus immune globulin.
Data from American Academy of Pediatrics. Tetanus (lockjaw). In Kiberlin DW, Barnett ED, Lynfield R, Sawyer MH, eds. *Red Book: 2021–2024 Report of the Committee on Infectious Diseases*, 32nd ed. Itasca, IL: American Academy of Pediatrics, 2021;750–755.

PROGNOSIS

Recovery in tetanus occurs through regeneration of synapses within the spinal cord that results in restoration of muscle relaxation. Interestingly, an episode of tetanus does not result in the production of toxin-neutralizing antibodies, presumably because the infinitesimally small amounts of toxin required to cause disease are not sufficient to elicit an immune response. Therefore active immunization with tetanus toxoid during convalescence and/or at discharge, with provision for completion of the primary vaccine series, is mandatory.

The most important factor that influences outcome is the quality of supportive care. Mortality is highest in the very young and the very old. A favorable prognosis is associated with a long incubation period, absence of fever, and localized disease. An unfavorable prognosis is associated with onset of trismus <7 days after injury and with onset of generalized tetanic spasms <3 days after onset of trismus. Sequelae of hypoxic brain injury, especially in infants, include cerebral palsy, diminished mental abilities, and behavioral difficulties. Most fatalities occur within the first week of illness. Reported case fatality rates for generalized tetanus are 5–35%, and for neonatal tetanus they extend from <10% with intensive care treatment to >75% without it. Cephalic tetanus has an especially poor prognosis because of breathing and feeding difficulties.

PREVENTION

Tetanus is an entirely and easily preventable disease. A serum antibody titer of ≥0.01 units/mL is considered protective. Active immunization should begin in early infancy with combined diphtheria toxoid–tetanus toxoid–acellular pertussis (DTaP) vaccine at 2, 4, 6, and 15-18 months of age, with boosters at 4-6 years (DTaP) and 11-12 years (Tdap) of age, and at 10-year intervals thereafter throughout adult life with tetanus and reduced diphtheria toxoid (Td). Recovery from tetanus does not confer permanent protective immunity, so immunization is recommended in those who have survived documented infection. Immunization of women with tetanus toxoid prevents neonatal tetanus, and pregnant women should receive one dose of reduced diphtheria and pertussis toxoids (Tdap) during each pregnancy, preferably at 27-36 weeks of gestation. Recommended immunization schedules are regularly updated; the most current versions may be found at http://www.cdc.gov/vaccines/schedules.

Arthus reactions (type III hypersensitivity reactions), a localized vasculitis associated with deposition of immune complexes and activation of complement, are reported rarely after tetanus vaccination. Mass immunization campaigns in developing countries have occasionally provoked a widespread hysterical reaction.

Wound Management

Tetanus prevention measures after trauma consist of inducing active immunity to tetanus toxin and of passively providing antitoxic antibody (Table 257.1). Tetanus prophylaxis is an essential part of all wound management, but specific measures depend on the nature of the injury and the immunization status of the patient. Prevention of tetanus must be included in planning for the consequences of bombings, natural disasters, and other possible civilian mass-casualty events.

Tetanus toxoid should always be given after a dog or other animal bite, even though *C. tetani* is infrequently found in canine mouth flora. **Nonminor wounds require human TIG** except those in a fully immunized patient (i.e., ≥3 doses of adsorbed tetanus toxoid). In any other circumstance (e.g., patients with an unknown or incomplete immunization history; crush, puncture, or projectile wounds; wounds contaminated with saliva, soil, or feces; avulsion injuries; compound fractures; or frostbite), TIG 250 units should be administered intramuscularly, regardless of the patient's age or weight. If TIG is unavailable, use of human intravenous immunoglobulin may be considered. If neither of these products is available, then 3,000-5,000 units of equine-derived TAT (in regions of the world where it is available) may be given intramuscularly after testing for hypersensitivity. Serum sickness may occur with this agent. Human monoclonal antibodies against the tetanus neurotoxin have recently been generated and characterized, but these are not yet available for clinical use.

The wound should undergo immediate, thorough surgical cleansing and debridement to remove foreign bodies and any necrotic tissue in which anaerobic conditions might develop. Tetanus toxoid should be given to stimulate active immunity and may be administered concurrently with **TIG** (or TAT); if a tetanus toxoid-containing vaccine and TIG are administered at the same time, then separate syringes and sites should be used. A tetanus toxoid booster (preferably Tdap) is administered to all persons with any wound if the tetanus immunization status is unknown or incomplete. A booster is administered to injured persons who have completed the primary immunization series if (1) the wound is clean and minor, but 10 or more years have passed since the last booster, or (2) the wound is more serious, and 5 or more years have passed since the last booster (see Table 257.1). Persons who experienced an Arthus reaction after a dose of tetanus toxoid–containing vaccine should not receive Td more frequently than every 10 years, even for tetanus prophylaxis as part of wound management. In a situation of delayed wound care, active immunization should be started at once.

Chapter 258

Clostridioides difficile Infection

David P. Galloway and Mitchell B. Cohen

Clostridioides difficile (formerly *Clostridium difficile*) infection **(CDI)**, also known as **pseudomembranous colitis** or *C. difficile*–associated diarrhea, refers to gastrointestinal (GI) colonization with *C. difficile* resulting in a diarrheal illness. It is a common cause of **antibiotic-associated diarrhea** and the most common cause of healthcare-associated infections in the United States, accounting for 12% of these infections. An increase in inpatient and outpatient (community) acquisition of **CDI** has been observed, and additional risk factors have been identified.

ETIOLOGY

C. difficile is a gram-positive, spore-forming, anaerobic bacillus that is resistant to killing by alcohol. It is acquired from the environment or by the fecal-oral route. Organisms causing symptomatic intestinal disease produce **toxin A** and/or **toxin B**. These toxins affect intracellular signaling pathways, resulting in inflammation and cell death. The cytotoxic **binary toxin**, which belongs to the AB toxin family, is not present in the majority of strains but has been detected in epidemic strains.

EPIDEMIOLOGY

The incidence of **CDI** is increasing in pediatric patients, and the setting of acquisition is changing. There is both high incidence in hospitalized children and an emergence of community-onset infection. National data from the Centers for Disease Control and Prevention (CDC) estimate three cases of community-acquired **CDI** in children for every healthcare-acquired case. In addition to an overall increase in all strains, a *hypervirulent strain,* denoted **NAP1/BI/027** (also called **BI**), has emerged and is estimated to cause 10–20% of pediatric infections. This strain produces **binary toxin** and exhibits 16- and 23-fold increases in the production of toxins A and B, respectively.

Asymptomatic carriage occurs with potentially pathogenic strains and is common in neonates and infants ≤1 year old. A carrier frequency rate of 50% may occur in children <1 year old. Colonization rates decrease to less than 5% in healthy children >5 years old. Asymptomatic colonization with *C. difficile* is common in recently hospitalized patients, with rates of 20%. Carriers can infect other susceptible individuals.

Risk factors for **CDI** include the use of broad-spectrum antibiotics, hospitalization, exposure to a household member with diarrhea or an asymptomatic carrier, GI surgery, inflammatory bowel disease (IBD), Hirschsprung disease, chemotherapy, enteral tube feeding, proton pump inhibitor (PPI) or H_2-receptor antagonist use, malnutrition, and chronic illness.

PATHOGENESIS

Disease is caused by GI infection with a toxin-producing strain. Any process that disrupts normal flora, impairs the acid barrier defense, alters the normal GI immune response (e.g., IBD), or inhibits intestinal motility may lead to infection. Normal bowel flora appears to be protective, conferring *colonization resistance*.

By affecting intracellular signaling pathways and cytoskeletal organization, toxins induce an inflammatory response and cell death, leading to diarrhea and pseudomembrane formation. Antibodies against **toxin A** have been shown to confer protection against symptomatic disease, and failure of antibody production occurs in patients with recurrent disease.

CLINICAL MANIFESTATIONS

Infection with toxin-producing strains of *C. difficile* leads to a spectrum of disease ranging from mild, self-limited diarrhea, to explosive, watery diarrhea with occult blood or mucus, to **pseudomembranous colitis**, and even death. **Pseudomembranous colitis** is characterized by bloody diarrhea with accompanying fever, abdominal pain/cramps, nausea, and vomiting. Rarely, small-gut involvement, **toxic megacolon**, bacteremia, abscess formation, intestinal perforation, and death can occur.

Symptoms of **CDI** generally begin less than a week after colonization and may develop during or weeks after antibiotic exposure. Symptoms are generally more severe in certain populations, including patients receiving chemotherapy, patients with chronic GI disease (e.g., IBD), and some patients with cystic fibrosis (CF). **CDI**-associated **reactive arthritis** is an occasional complication, occurring in approximately 1.4% of children with **CDI**. Reactive arthritis begins a median of 10 days after initial GI symptoms, often accompanied by fever or rash. Joint involvement may be migratory or polyarticular and may resemble septic arthritis.

DIAGNOSIS

Evaluation for **CDI** should be reserved for children with **diarrhea**, defined as the passage of at least three loose stools within a 24-hour period or bloody diarrhea (Fig. 258.1 and Table 258.1). **CDI** is diagnosed by the detection of a *C. difficile* toxin in the stool of a symptomatic patient. Most patients present with a history of recent antibiotic

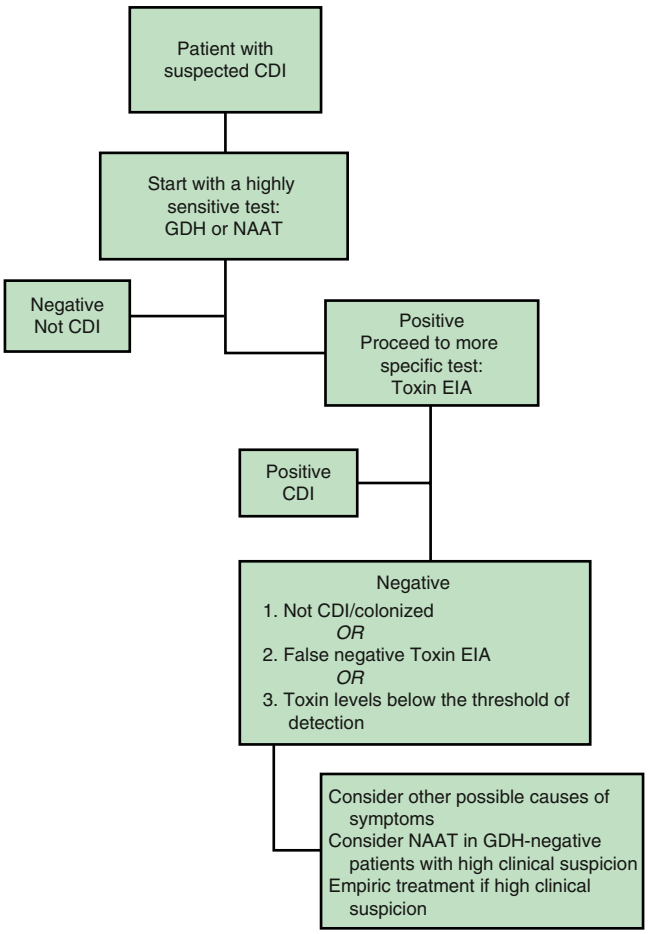

Fig. 258.1 Proposed algorithm for testing of *Clostridioides difficile* infection (CDI). EIA, Enzyme immunoassay; GDH, glutamate dehydrogenase; NAAT, nucleic acid amplification testing. *(From Kelly CR, Fischer M, Allegretti JR, et al. ACG clinical guidelines: prevention, diagnosis, and treatment of Clostridioides difficile in infections. Am J Gastroenterol. 2021;116:1124–1147, Fig. 1.)*

Table 258.1 Diagnosis of *C. difficile* Disease

- *Clostridium difficile* (renamed *Clostridioides difficile*) infection is diagnosed by a combination of clinical and laboratory findings.
- Diagnosis requires a positive test for the presence of *C. difficile* toxins.
- Glutamate dehydrogenase (GDH), produced by *C. difficile*, can be detected in stool. However, it is not specific and can be produced by nontoxigenic *C. difficile*.
- Enzyme immunoassay testing for toxin A and/or B has a variable sensitivity and specificity, a turnaround time of about 24 hours and correlates well with disease activity.
- Polymerase chain reaction testing has a high sensitivity and specificity, a turnaround time of less than 4 hours, and correlates less with disease activity, thus identifying patients with colonization and active infection. Increasingly, combination testing is being employed to improve diagnostic accuracy.
- Laboratory testing for *C. difficile* toxins should only be performed on patients with at least three unformed stools per 24 hours, who are not on laxatives, and is not useful as a test of cure.
- Pathologic findings can help to confirm the diagnosis.

From Semel JD. *Clostridioides difficile* colitis. In: Kellerman RD, Rakel DP, Heidelbaugh JJ, Lee EM, eds. *Conn's Current Therapy 2023.* Philadelphia: Elsevier; 2023:561.

use, but the absence of antibiotic exposure should not dissuade the clinician from considering this diagnosis and ordering the appropriate test. Conversely, high carriage rates without illness among infants should prompt careful consideration when testing and treating children <3 years old.

The standard test for toxin is the **enzyme immunoassay** (EIA), a same-day test for **toxin A** and/or **toxin B** with sufficient specificity (94–100%) but less-than-ideal sensitivity (88–93%). Many laboratories use **nucleic acid amplification tests** (NAATs) to supplement or supplant **EIA** with the goal of improving sensitivity. The sensitivities of the real-time polymerase chain reaction (PCR) assay for **toxin A/B** are superior compared with **EIA** for **toxin A/B** (95% vs 35%, respectively), and the specificity is equal (100%). However, some have questioned the clinical significance of low copy number–positive tests. For example, positive *C. difficile* PCR results occur with similar frequency in patients with IBD with and without an IBD exacerbation. A positive result in a highly sensitive PCR assay that detects low copy numbers of a toxin gene in *C. difficile* may reflect colonization in a subset of patients (e.g., with IBD), confounding clinical decision-making in managing disease exacerbations. To address this, **NAAT**-positive tests may be "confirmed" by toxin assays. In addition, eliminating certain high carrier populations from testing (e.g., children under 1 year of age) will increase the positive predictive value of laboratory testing. Because sensitivity is so high with molecular tests, if the first test is negative, repeat testing during the same episode of diarrhea is discouraged, as repeat testing in this setting is more likely to result in another negative or a false-positive test than a true positive test. Because shedding of *C. difficile* in stool can persist for several months after symptom resolution, tests of cure are impractical and are not performed.

Culture for organism isolation is a sensitive test but is labor intensive, taking several days. Culture alone is not specific because it does not differentiate between toxin-producing and non–toxin-producing strains.

Pseudomembranous nodules and characteristic plaques may be seen in colonoscopy or sigmoidoscopy, but endoscopy is usually not performed to make the diagnosis.

TREATMENT

Initial treatment of **CDI** involves discontinuation of any nonvital antibiotic therapy and administration of fluid and electrolyte replacement. For mild cases, this treatment may be curative. Drugs that decrease intestinal motility should be avoided. Asymptomatic patients should not be treated. Persistent symptoms or moderate to severe disease warrant antimicrobial therapy directed against *C. difficile*.

Oral metronidazole or vancomycin is the first-line therapy for mild to moderate **CDI** in children (Table 258.2). In adults, vancomycin or fidaxomicin are the preferred first-line therapies. For more severe infection, oral vancomycin is approved by the U.S. Food and Drug Administration (FDA) for CDI. Vancomycin exhibits ideal pharmacologic properties for treatment of this enteric pathogen because it is not absorbed in the gut. Vancomycin is suggested as a first-line agent for severe disease, as manifested by hypotension, peripheral leukocytosis, or severe pseudomembranous colitis. Fidaxomicin is approved for use in children at least 6 months of age and is a narrow-spectrum macrolide antibiotic with noninferior efficacy to vancomycin but superior recurrence prevention. Because treatment of CDI continues to evolve, adult-based protocols (Table 258.3) may be relevant to older children and adolescents.

Table 258.2 Treatment Recommendations for *Clostridioides difficile* Infection in Children

CDI CLASSIFICATION	ANTIBIOTIC REGIMEN
First episode or first recurrence,* nonsevere	Metronidazole 7.5 mg/kg/dose (max 500 mg/dose) PO tid × 10 days; *OR* Vancomycin 10 mg/kg/dose (max 125 mg/dose) PO qid × 10 days
Second or subsequent† recurrence, nonsevere	Vancomycin in a tapered and pulsed regimen‡; *OR* Vancomycin (dosing and duration as above) followed by rifaximin 10 mg/kg/dose (max 400 mg/dose) PO tid × 20 days§; *OR* Fidaxomicin 16 mg/kg/dose (max 200 mg/dose) PO bid × 10 days; *OR* Fecal microbiota transplantation
Severe/fulminant‖ (first or recurrent¶ episode)	Vancomycin 10 mg/kg/dose (max 500 mg/dose) PO qid × 10 days If critically ill, consider adding metronidazole 7.5 mg/kg/dose (max 500 mg/dose) IV tid × 10 days

*For first recurrence, consider vancomycin if metronidazole was used to treat initial episode.
†Recommend tapered and pulsed regimen if vancomycin was used for the initial infection.
‡Tapered and pulsed regimen: vancomycin 10 mg/kg/dose (max 125 mg/dose) qid × 10-14 days, then 10 mg/kg/dose (max 125 mg/dose) bid × 1 wk, then 10 mg/kg/dose (max 125 mg/dose) qd × 1 wk, and then 10 mg/kg/dose (max 125 mg/dose) every 2-3 days for 2-8 wk.
§Pediatric rifaximin dosing is not available and not FDA-approved for children younger than 12 yr.
‖Definitions for severe and fulminant CDI are based on expert consensus for adult patients and have not been validated. Severe: leukocytosis with a white blood cell count of ≥15,000 cells/μL or a serum creatinine level >1.5 mg/dL. Fulminant: hypotension or shock, ileus, megacolon.
¶If treating a recurrent episode that is severe/fulminant, consider extending vancomycin in a pulsed, tapering fashion as indicated above§ or fecal microbiota transplantation when clinically improved.
Data from McDonald LC, Gerding DN, Johnson S, et al. Clinical practice guidelines for *Clostridium difficile* infection in adults and children: 2017 update by the Infectious Diseases Society of America (IDSA) and Society for Healthcare Epidemiology of America (SHEA). *Clin Infect Dis.* 2018; 66(7):e1–e48.

PROGNOSIS AND RECURRENCE

The response rate to initial treatment of CDI can reach >95%. Studies have demonstrated a variation in response rates based on the severity of CDI and the treatment agent. Treatment failure and recurrence have been increasing; the risk of subsequent reappearance increases with each recurrence.

Recurrences occur in 5–20% of patients, are diagnosed clinically, and generally occur within 4 weeks of treatment. Some recurrences result from incomplete eradication of the original strain, and others are caused by reinfection with a different strain. Treatment for the initial recurrence involves retreatment with the original antibiotic course.

Table 258.3 Recommendations for the Treatment of *C. difficile* Infection in Adults

CLINICAL DEFINITION		SUPPORTIVE CLINICAL DATA	RECOMMENDED TREATMENT*	STRENGTH OF RECOMMENDATION/QUALITY OF EVIDENCE
Initial infection		Leukocytosis with white blood cell count of ≤15,000 cells/mL and serum creatinine level <1.5 mg/dL	Fidaxomicin 200 mg bid × 10 days	Strong/high
			Vancomycin 125 mg qid × 10 days	Strong/high
			Alternate if previous agents are unavailable: metronidazole 500 mg tid PO × 10-14 days	Weak/high
	Fulminant	Hypotension or shock, ileus, megacolon	Vancomycin 500 mg qid PO or by nasogastric tube	Strong/moderate (oral vancomycin), weak/low (rectal vancomycin), strong/moderate (intravenous metronidazole)
			If ileus, consider adding rectal instillation of vancomycin; intravenous metronidazole (500 mg every 8 hr) should be administered with oral or rectal vancomycin, particularly if ileus is present	
Recurrence	First recurrence, nonsevere		Fidaxomicin 200 mg bid × 10 days, or bid × 5 days, then qod for 20 days *or*	Weak/low
			Use prolonged tapered and pulsed vancomycin regimen (if standard regimen was used for initial episode) 125 mg qid for 10-14 days, bid for 1 wk, qd for 1 wk, and then every 2 or 3 days for 2-8 wk, *or*	Weak/low
			Vancomycin 125 mg qid × 10 days (if metronidazole was used for the initial episode)	Weak/moderate
	Second or subsequent recurrence		Fidaxomicin 200 mg bid × 10 days, *or* bid × 5 days, then qod for 20 days	Weak/low
			Vancomycin in a tapered or pulsed regimen *or*	Weak/low
			Vancomycin 125 mg qid × 10 days, followed by rifaximin 400 mg tid × 20 days, *or*	Weak/low
			Fecal microbiota transplantation†	Strong/moderate

*All randomized trials have compared 10-day treatment courses, but some patients (particularly those treated with metronidazole) may have delayed response to treatment, and clinicians should consider extending treatment duration to 14 days in those circumstances.

†The opinion of the panel is that appropriate antibiotic treatments for at least two recurrences (i.e., three CDI episodes) should be tried before offering fecal microbiota transplantation. For adult patients with a recurrent CDI episode within the last 6 months, current guidelines suggest using bezlotoxumab in addition to appropriate antibiotics as the first approach.

PO, Orally (by mouth); qd, once daily; bid, twice daily; tid, 3 times daily; qid, 4 times daily; qod, every other day.

Adapted from McDonald LC, Gerding DN, Johnson S, et al. Clinical practice guidelines for *Clostridium difficile* infection in adults and children: 2017 update by the Infectious Diseases Society of America (IDSA) and Society for Healthcare Epidemiology of America (SHEA). *Clin Infect Dis*. 2018;66(7):e1–e48, Table 1; and Johnson S, Lavergne V, Skinner AM, et al. Clinical practice guideline by the Infectious Diseases Society of America (IDSA) and Society for Healthcare Epidemiology of America (SHEA): 2021 focused update guidelines on management of *Clostridioides difficile* infection in adults. *Clin Infect Dis*. 2021;73(5):e1029–e1044, Table 1.

Recurrences of CDI may be caused by a suboptimal immune response, failure to kill organisms that have sporulated, or failure of delivery of antibiotic to the site of infection in the case of ileus or toxic megacolon. Subsequent treatment with pulsed or tapered vancomycin decreases recurrence rates. In addition to this approach, other antibiotics (rifaximin or nitazoxanide), toxin-binding polymers (Tolevamer), and probiotics (*Saccharomyces boulardii* or *Lactobacillus* GG) have been used as adjunctive therapy. For adult patients with a recurrent CDI episode within the last 6 months, guidelines suggest using bezlotoxumab, a humanized monoclonal antibody against *C. difficile* toxin B, as a co-intervention. Because treatment of CDI continues to evolve, adult-based protocols (see Table 258.3) may be applicable for treatment of older children and adolescents.

Because failure to manifest an adequate antitoxin immune response is associated with a higher frequency of recurrent CDI, intravenous immune globulin has been used to treat recurrent disease. In the case of ileus or toxic megacolon, an enema of vancomycin may be used to place the antibiotic directly at the site of infection, although most often intravenous therapy is first attempted in this circumstance.

Fecal microbiota transplantation (FMT) has been used to address the disruption in normal gut flora thought to allow colonization with *C. difficile* (see Table 258.3). FMT involves the instillation of fecal material from a healthy donor into the patient's GI tract by nasoenteric tube, enema, capsules, or colonoscopy. Published FMT results in children with recurrent CDI are limited to case reports and small case series. There are few data to guide clinicians on the indications, route, efficacy, and safety of FMT in children. Initial reports indicate an overall success rate of approximately 90% in patients with recurrent CDI. Current approaches to FMT are not specific and involve complete reconstitution of the gut microbiome. The gut microbiota has been shown to influence susceptibility to genetic and environmentally acquired conditions. Transplantation of healthy donor fecal material to patients with CDI may reestablish the "normal" composition of the gut microbiota but has the theoretical concern of adding new, microbiome-based susceptibilities derived from the donor microbiome.

The FDA has approved an orally administered commercially available fecal microbiotic product for patients ≥18 years old, following antibiotic therapy for recurrent CDI. The goal is to prevent recurrence of CDI. Fecal-derived live bacteria from screened donors is administered once daily for 3 days.

It is important to recognize that postinfectious diarrhea may result from other causes, such as postinfectious irritable bowel syndrome, microscopic colitis, and IBD.

PREVENTION

The strategies for prevention of CDI include recognition of common sites of acquisition (hospitals, childcare settings, extended-care facilities); effective environmental cleaning (i.e., use of chlorinated cleaning solutions); appropriate antibiotic (antibiotic stewardship) and PPI prescription practices; cohorting of infected patients; contact precautions; and proper handwashing with soap and water. Probiotics may possibly reduce the incidence of *C. difficile*–associated diarrhea.

Chapter 259

Other Anaerobic Infections

Michael E. Russo

Anaerobic bacteria are among the most numerous organisms colonizing humans and are also present widely in the soil. **Obligate anaerobes** are markedly or entirely intolerant of exposure to oxygen. **Facultative anaerobes** can survive in the presence of environmental oxygen but grow better in settings of reduced oxygen tension. This chapter concentrates on obligate anaerobes and associated infections.

Infections with endogenous anaerobes usually occur adjacent to mucosal surfaces, often as polymicrobial infections with aerobes. In many of these polymicrobial infections, it is unclear how direct a role anaerobes are playing in illness versus just being present by virtue of breached mucosal barriers. Traumatized areas that have been devascularized with resultant low oxygen tension provide ideal sites for anaerobic infection. Abscess formation can evolve over days to weeks and generally involves both aerobes and anaerobes. An example of such an infection is ruptured appendicitis leading to secondary peritonitis and intrabdominal abscesses. Pure anaerobic infections from endogenous bacteria are much less common (although certain relevant clinical syndromes such as Lemierre syndrome are discussed later).

The most common and clinically relevant anaerobic bacteria in pediatrics are listed in Table 259.1 and discussed further later in the chapter. The taxonomy has undergone significant changes over the years, and many species that would not have been easily identifiable may now be identified in clinical specimens with the widespread use of matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF MS). Our understanding of anaerobic bacteria in infections is largely limited to easily culturable species. As many anaerobes of the human microbiota remain unculturable, our understanding of anaerobic infections will continue to evolve with culture-independent methods such as metagenomic sequencing.

Bacteroides fragilis and related species are the predominant anaerobes of the large intestine and thus are involved in complicated intraabdominal infections. *Prevotella* spp., *Porphyromonas* spp., and *Fusobacterium* spp. reside in the upper respiratory tract and intestine and are most frequently involved in complications of pharyngitis and sinusitis or in aspiration pneumonia. The gram-positive anaerobic cocci (GPAC) have undergone significant taxonomic changes in recent years, with most prior *Peptostreptococcus* spp. being reclassified into the genera of *Finegoldia, Parvimonas, Anaerococcus,* and *Peptoniphilus*. It is not clear yet how clinically relevant this reclassification is Collectively, the GPAC are normal flora of the skin and upper respiratory, intestinal, and genital mucosa. They may be involved in complications of infections of any of these areas, but they are relatively less virulent than other anaerobic bacteria, and their recovery in culture may or may not be clinically relevant. The gram-positive anaerobic bacilli can be divided into spore forming (*Clostridium* spp.) and non–spore-forming (*Cutibacterium acnes* [formerly *Propionibacterium acnes*] and *Actinomyces* spp.). *C. acnes* lives within hair follicles and sebaceous glands and is an important cause of prosthetic infections, particularly related to ventricular shunts. Some *Actinomyces* spp. are obligate or facultative anaerobes and are discussed in Chapter 235. *Clostridium* spp. cause disease by proliferation and often by production of toxins. Of the >60 species that have been identified, only a few cause infections in humans. The most frequently implicated *Clostridium* spp. are *C. difficile* (see Chapter 258), *C. perfringens* (discussed further later), *C. botulinum* (see Chapter 256), and *C. tetani* (see Chapter 257).

CLINICAL MANIFESTATIONS

Anaerobic infections occur in a variety of sites throughout the body, with examples including complications of pharyngitis such as peritonsillar abscess and Lemierre syndrome (see Chapter 432), dental abscesses (see Chapter 358), complications of sinusitis such as orbital cellulitis (see Chapter 674) and brain abscess (see Chapter 644), aspiration pneumonia (see Chapter 447) and lung abscess (see Chapter 453), secondary peritonitis (see Chapter 419), appendicitis (see Chapter 391), necrotizing enterocolitis (see Chapter 136), and pelvic inflammatory disease and tubo-ovarian abscesses (see Chapter 163).

Table 259.1 Clinically Relevant Anaerobic Bacteria in Common Pediatric Infections

Gram-positive cocci	*Peptostreptococcus, Finegoldia, Parvimonas, Anaerococcus,* and *Peptoniphilus* spp.
Gram-positive, spore-forming rods	*Clostridium* spp.
Gram-positive, non–spore-forming rods	*Cutibacterium acnes* Some *Actinomyces* spp.
Gram-negative bacilli	*Bacteroides fragilis* *Prevotella, Porphyromonas,* and *Fusobacterium* spp.

Anaerobic Bacteremia

Anaerobic bacteremia is relatively rare in children, and the yield of routine anaerobic blood cultures in various settings and patient populations continues to be debated. There is wide practice variation on the routine collection of anaerobic blood culture bottles, and multiple studies have failed to consistently identify predictive risk factors for anaerobic bacteremia in children. *B. fragilis* bacteremia has been seen most frequently (albeit uncommonly) in two settings: early-onset sepsis in premature infants and sepsis in those with compromised lower gastrointestinal tract mucosa (perforation, surgery, or chemotherapy-induced mucositis). *Fusobacterium* spp. bacteremia is typically seen in the setting of Lemierre syndrome: **septic thrombophlebitis** of the internal jugular vein as a complication of pharyngitis.

Myonecrosis (Gas Gangrene)

C. perfringens is the major etiologic cause of myonecrosis, a rapidly progressive anaerobic soft tissue infection. Gas gangrene usually affects muscles compromised by surgical or trauma sites that become contaminated with *C. perfringens* spores from soil or other foreign material. Infection progresses rapidly (within 24 hours) with swelling, edema, crepitus, and myonecrosis. Severe shock and multiorgan dysfunction are common. A clue to the diagnosis of gas gangrene is pain out of proportion to the clinical appearance of the wound. Exudate from surgical specimens reveals gram-positive bacilli but few leukocytes. Early and complete debridement with excision of necrotic tissue is key to controlling the infection. Repeated, frequent assessment of tissue viability in the operating room is required; however, the prognosis is poor, and morbidity and mortality are high. The role of adjunctive hyperbaric oxygen therapy is uncertain.

Food Poisoning

C. perfringens can also produce an enterotoxin that causes **food poisoning**. This intoxication results in the acute onset of watery diarrhea and crampy abdominal pain. Therapy is mainly supportive and consists of rehydration and electrolyte replacement if necessary. The illness resolves spontaneously within 24 hours of onset, and thus specific etiologic diagnosis is rarely made unless a large outbreak is investigated by public health authorities. Frequent sources of infection include meat and other animal products served in group settings during which food is allowed to sit for hours at temperatures warm enough to promote growth of *C. perfringens*.

DIAGNOSIS

The diagnosis of anaerobic infection requires a high index of suspicion and the collection of appropriate and adequate specimens for anaerobic culture (Table 259.2). Culture specimens should be obtained in a manner that protects them from contamination with mucosal bacteria. Aspirates of infected sites, abscess material, and biopsy specimens are appropriate for anaerobic culturing. Specimens should be protected from atmospheric oxygen and transported to the laboratory immediately. Anaerobic transport medium increases the likelihood of recovery of obligate anaerobes. Gram staining is useful, because even if the organisms do not grow in culture, they can be seen on the smear. Once growth has occurred, many clinically relevant anaerobes may now be identified by MALDI-TOF MS. 16S ribosomal RNA (rRNA) gene sequencing at a reference laboratory can identify less common bacteria.

Table 259.2 Clues to the Presumptive Diagnosis of Anaerobic Infections*

Infection contiguous to or near a mucosal surface colonized with anaerobic bacteria (oropharynx, intestinal-genitourinary tract)
Severe tissue necrosis, abscesses, gangrene, or fasciitis
Gas formation in tissues (crepitus on exam or gas visible on imaging)
Failure to culture organisms using conventional aerobic microbiologic methods, despite the presence of visible organisms on Gram stain
Toxin-mediated syndromes: botulism, tetanus, gas gangrene, food poisoning, pseudomembranous colitis

*Suspicion of anaerobic infection is critical before specimens are sampled for culture to ensure optimal microbiologic techniques.

Antimicrobial resistance among anaerobes has increased over time, and the susceptibility of anaerobes to certain antibiotics has become less predictable. A rapid and simple screening test for β-lactamase production and presumptive penicillin resistance can be performed on some anaerobic gram-negative bacilli. More detailed susceptibility testing is usually only available at reference laboratories and may be recommended for isolates recovered from sterile body sites that are deemed clinically important and are known to have variable or unique susceptibilities. Because anaerobic bacteria are less routinely submitted for susceptibility testing, local antibiogram data are frequently limited and extrapolated from larger national case series.

TREATMENT

Treatment of anaerobic infections usually requires adequate drainage and appropriate antimicrobial therapy. Anaerobes can be generally lumped into groups of predicted susceptibility, but because most anaerobic infections are polymicrobial, the choice of agents is frequently driven by the aerobic bacteria suspected or proven to be involved. The specific dose, frequency, and duration vary widely by the specific clinical syndrome.

ANAEROBIC GRAM-NEGATIVE BACILLI

Most *B. fragilis* produces a β-lactamase that hydrolyzes penicillins but is inhibited by most β-lactamase inhibitors (clavulanate, sulbactam, and tazobactam but not avibactam). They also produce a cephalosporinase that hydrolyzes most cephalosporins but not cephamycins. Neither of the enzymes hydrolyzes carbapenems. Hence, most isolates are susceptible to ampicillin-sulbactam, amoxicillin-clavulanate, piperacillin-tazobactam, cefoxitin, and carbapenems (imipenem, meropenem, doripenem, and ertapenem). Notably, ceftazidime-avibactam is the exception to the reliability of β-lactamase inhibitors and does not have reliable *B. fragilis* activity. *Prevotella, Porphyromonas,* and *Fusobacterium* spp. are all generally less resistant than *Bacteroides*. They less frequently produce a β-lactamase, and many remain susceptible to penicillin. *Fusobacterium* spp. are usually susceptible to cephalosporins such as ceftriaxone, but *Prevotella* and *Porphyromonas* have more variable susceptibility.

Metronidazole is reliably active against nearly all anaerobic gram-negative bacilli. Clindamycin resistance in *B. fragilis* has increased over the years, and thus clindamycin is no longer recommended for empiric treatment, leading to the admonition against using clindamycin for infections "below the diaphragm." The other anaerobic gram-negative bacilli are usually still susceptible to clindamycin. Because of increasing resistance, moxifloxacin is no longer recommended as first-line therapy for infections involving anaerobic gram-negative bacilli.

ANAEROBIC GRAM-POSITIVE ORGANISMS

Most non–spore-forming, positive bacilli and some GPAC are resistant to metronidazole. Most are highly susceptible to penicillin but variably susceptible to clindamycin. Treatment of clostridial infections varies widely by the specific clinical syndrome and may or may not involve antibiotics and/or specific antitoxins.

Section 7

Mycobacterial Infections

Chapter 260

Principles of Antimycobacterial Therapy

Stacene R. Maroushek

The treatment of mycobacterial infection and disease can be challenging. Patients require therapy with multiple agents, the offending pathogens commonly exhibit complex drug resistance patterns, and patients often have underlying conditions that affect drug choice and monitoring. Several of the drugs have not been well studied in children, and current recommendations are extrapolated from the experience in adults.

Single-drug therapy of *Mycobacterium tuberculosis* and nontuberculous mycobacteria is not recommended because of the high likelihood of developing antimicrobial resistance. Susceptibility testing of mycobacterial isolates often can aid in therapeutic decision-making.

AGENTS USED AGAINST MYCOBACTERIUM TUBERCULOSIS

Commonly Used Agents

Isoniazid

Isoniazid **(INH)** is a hydrazide form of isonicotinic acid and is bactericidal for rapidly growing *M. tuberculosis.* The primary target of INH involves the *INHA* gene, which encodes the enoyl acyl carrier protein (ACP) reductase needed for the last step of the mycolic acid biosynthesis pathway of cell wall production. Resistance to INH occurs after pathogenic variants in the *INHA* gene or in other genes encoding enzymes that activate INH, such as *katG*.

INH is indicated for the treatment of *M. tuberculosis, M. kansasii,* and *M. bovis.* The pediatric dosage is 10-15 mg/kg/day orally (PO) in a single dose, not to exceed 300 mg/day. The adult dosage is 5 mg/kg/day PO in a single dose, not to exceed 300 mg/day. Alternative pediatric dosing is 20-30 mg/kg PO in a single dose, not to exceed 900 mg/dose, given twice weekly under **directly observed therapy (DOT)**, in which patients are observed to ingest each dose of antituberculosis medication to maximize the likelihood of completing therapy. The duration of treatment depends on the disease being treated (Table 260.1). INH needs to be taken 1 hour before or 2 hours after meals because food decreases absorption. It is available in liquid, tablet, intravenous (IV; not approved by the U.S. Food and Drug Administration [FDA]), and intramuscular (IM) preparations.

Major **adverse effects** include hepatotoxicity in 1% of children and approximately 3% of adults (increasing with age) and dose-related peripheral neuropathy. Pyridoxine can prevent the peripheral neuropathy and is indicated for breastfeeding infants and their mothers, children and youth on milk- or meat-deficient diets, pregnant adolescents, and symptomatic HIV-infected children. Minor adverse events include rash, worsening of acne, epigastric pain with occasional nausea and vomiting, decreased vitamin D levels, and dizziness. The liquid formulation of INH contains sorbitol, which often causes diarrhea and stomach upset.

INH is accompanied by significant drug-drug interactions (Table 260.2). The metabolism of INH is by acetylation. Acetylation rates have minimal effect on efficacy, but **slow acetylators** have an increased risk for hepatotoxicity, especially when INH is used in combination with rifampin. Routine baseline liver function testing or monthly monitoring is only indicated for persons with underlying hepatic disease or those receiving concomitant hepatotoxic drugs, including other antimycobacterial agents, acetaminophen, or alcohol. Monthly clinic visits while taking INH alone are encouraged to monitor adherence, adverse effects, and worsening of infection.

Rifamycins

The rifamycins (rifampin, rifabutin, rifapentine) are a class of macrolide antibiotics developed from *Streptomyces mediterranei.* Rifampin is a synthetic derivative of rifamycin B, and rifabutin is a derivative of rifamycin S. Rifapentine is a cyclopentyl derivative. The rifamycins inhibit the DNA-dependent RNA polymerase of mycobacteria, resulting in decreased RNA synthesis. These agents are generally bactericidal at treatment doses, but they may be bacteriostatic at lower doses. Resistance is from a pathogenic variant in the DNA-dependent RNA polymerase gene *(rpoB)* that is often induced by previous incomplete therapy. Cross-resistance between rifampin and rifabutin has been demonstrated.

Rifampin is active against *M. tuberculosis, M. leprae, M. kansasii,* and *M. avium* complex. Rifampin is an integral drug in standard combination treatment of active *M. tuberculosis* disease and can be used as an alternative to INH in the treatment of latent tuberculosis infection in children who cannot tolerate INH. **Rifabutin** has a similar spectrum, with increased activity against *M. avium* complex. **Rifapentine** is undergoing pediatric clinical trials and appears to have activity similar to the activity of rifampin. The pediatric dosage of rifampin is 10-15 mg/kg/day PO in a single dose, not to exceed 600 mg/day. The adult dosage of rifampin is 5-10 mg/kg/day PO in a single dose, not to exceed 600 mg/day. Commonly used rifampin preparations include 150- and 300-mg capsules and a suspension that is usually formulated at a concentration of 10 mg/mL. The shelf life of rifampin suspension is short (approximately 4 weeks), so it should not be compounded with other antimycobacterial agents. An IV form of rifampin is also available for initial treatment of patients who cannot take oral preparations. Dosage adjustment is needed for patients with liver failure. Other rifamycins (rifabutin and rifapentine) have been poorly studied in children and are not recommended for pediatric use.

Rifampin can be associated with **adverse effects** such as transient elevations of liver enzymes; gastrointestinal (GI) upset with cramps, nausea, vomiting, and anorexia; headache; dizziness; and immunologically mediated fever and flulike symptoms. Thrombocytopenia and hemolytic anemias can also occur. Rifabutin has a similar spectrum of toxicities, except for an increased incidence of rash (4%) and neutropenia (2%). Rifapentine has fewer adverse effects but is associated with hyperuricemia and cytopenias, especially lymphopenia and neutropenia. All rifamycins can turn urine and other secretions (tears, saliva, stool, sputum) *orange,* which can stain contact lenses. Patients and families should be warned about this common but otherwise innocuous adverse effect.

Rifamycins induce the hepatic cytochrome P450 (CYP) isoenzyme system and are associated with the increased metabolism and decreased level of several drugs when administered concomitantly. These drugs include digoxin, corticosteroids such as prednisone and dexamethasone, dapsone, fluconazole, phenytoin, oral contraceptives, warfarin, and many antiretroviral agents, especially protease inhibitors and nonnucleoside reverse transcriptase inhibitors. Rifabutin has less of an effect on lowering protease inhibitor levels.

The use of pyrazinamide in combination with rifampin for short-course latent tuberculosis therapy has been associated with serious liver dysfunction and death. This combination has never been well studied or recommended for pediatric patients and should not be used.

Table 260.1 Recommended Usual Treatment Regimens for Drug-Susceptible Tuberculosis in Infants, Children, and Adolescents

INFECTION/DISEASE CATEGORY	REGIMEN	COMMENTS
LATENT *MYCOBACTERIUM TUBERCULOSIS* INFECTION*		
Isoniazid susceptible	12 wk of isoniazid plus rifapentine once a wk *or*	
	4 mo of rifampin once a day *or*	Continuous daily therapy is required. Intermittent therapy even by DOT is not recommended.
	9 mo of isoniazid once a day	If daily therapy is not possible, DOT twice a week can be used for 9 mo.
Isoniazid resistant	4 mo of rifampin once a day	Continuous daily therapy is required. Intermittent therapy even by DOT is not recommended.
Isoniazid-rifampin resistant	Consult a tuberculosis specialist.	Moxifloxacin or levofloxacin with or without ethambutol or pyrazinamide.
PULMONARY AND EXTRAPULMONARY INFECTION		
Except meningitis†	2 mo of isoniazid, rifampin, pyrazinamide, and ethambutol daily or twice weekly, followed by 4 mo of isoniazid and rifampin‡ by DOT§ for drug-susceptible *M. tuberculosis*	Some experts recommend a three-drug initial regimen (isoniazid, rifampin, and pyrazinamide) if the risk of drug resistance is low. DOT is highly desirable. If hilar adenopathy only and the risk of drug resistance is low, 6-mo course of isoniazid and rifampin is sufficient. Drugs can be given 2 or 3 times/wk under DOT.
	9-12 mo of isoniazid and rifampin for drug-susceptible *Mycobacterium bovis*	
Meningitis	2 mo of isoniazid, rifampin, pyrazinamide and an aminoglycoside‖ or ethionamide once daily, followed by 7-10 mo of isoniazid and rifampin once daily or twice weekly (9-12 mo total) for drug-susceptible *M. tuberculosis* At least 12 mo of therapy without pyrazinamide for drug-susceptible *M. bovis*	For patients who may have acquired tuberculosis in geographic areas where resistance to streptomycin is common, kanamycin, amikacin, or capreomycin can be used instead of streptomycin.

*Positive TST or IGRA result, no disease. See text for comments and additional acceptable/alternative regimens.
†Duration of therapy may be longer for human immunodeficiency virus (HIV)–infected people, and additional drugs and dosing intervals may be indicated
‡Medications should be administered daily for the first 2 wk to 2 mo of treatment and then can be administered 2-3 times/wk by DOT. (Twice-weekly therapy is not recommended for HIV-infected people.)
§If initial chest radiograph shows pulmonary cavities and sputum culture after 2 mo of therapy remains positive, the continuation phase is extended to 7 mo, for a total treatment duration of 9 mo.
‖Streptomycin, kanamycin, amikacin, or capreomycin.
DOT, Directly observed therapy; IGRA, interferon-γ release assay; TST, tuberculin skin test.
Adapted from American Academy of Pediatrics: *Red Book: 2018–2021 report of the Committee on Infectious Diseases*, 31st ed. Elk Grove Village, IL: AAP, 2018: Table 3.85.

Table 260.2 Isoniazid Drug-Drug Interactions

DRUG USED WITH ISONIAZID	EFFECTS
Acetaminophen, alcohol, rifampin	Increased hepatotoxicity of isoniazid or listed drugs
Aluminum salts (antacids)	Decreased absorption of isoniazid
Carbamazepine, phenytoin, theophylline, diazepam, warfarin	Increased level, effect, or toxicity of listed drugs due to decreased metabolism
Itraconazole, ketoconazole, oral hypoglycemic agents	Decreased level or effect of listed drugs due to increased metabolism
Cycloserine, ethionamide	Increased central nervous system adverse effects of cycloserine and ethionamide
Prednisolone	Increased isoniazid metabolism

No routine laboratory monitoring for rifamycins is indicated unless the patient is symptomatic. In patients with signs of toxicity, complete blood count (CBC) and kidney and liver function tests are indicated.

Pyrazinamide

Pyrazinamide **(PZA)** is a synthetic pyrazine analog of nicotinamide that is bactericidal against intracellular *M. tuberculosis* organisms in acidic environments, such as within macrophages or inflammatory lesions. A bacteria-specific enzyme (pyrazinamidase) converts PZA to pyrazinoic acid, which leads to low pH levels not tolerated by *M. tuberculosis*. Resistance is poorly understood but can arise from bacterial pyrazinamidase alterations.

PZA is indicated for the initial treatment phase of active tuberculosis in combination with other antimycobacterial agents. The pediatric dosage is 30-40 mg/kg/day PO in a single dose, not to exceed 2,000 mg/day. Twice-weekly dosing with DOT only is with 50 mg/kg/day PO in a single dose, not to exceed 4,000 mg/day. It is available in a 500-mg tablet and can be made into a suspension of 100 mg/mL.

Adverse effects include GI upset (e.g., nausea, vomiting, poor appetite) in approximately 4% of children, dosage-dependent hepatotoxicity, and elevated serum uric acid levels that can precipitate gout in susceptible adults. Approximately 10% of pediatric patients have elevated uric acid levels but with no associated clinical sequelae. Minor reactions include arthralgias, fatigue, and, rarely, fever.

Use of PZA in combination with rifampin for short-course treatment of latent tuberculosis is associated with serious liver dysfunction and death, and this combination should be avoided.

No routine laboratory monitoring for PZA is required, but monthly visits to reinforce the importance of therapy are desirable.

Ethambutol

Ethambutol is a synthetic form of ethylenedi-imino-di-1-butanol dihydrochloride that inhibits RNA synthesis needed for cell wall formation. At standard dosages, ethambutol is bacteriostatic, but at dosages >25 mg/kg, it has bactericidal activity. The mechanism of resistance to ethambutol is unknown, but resistance develops rapidly when ethambutol is used as a single agent against *M. tuberculosis.*

Ethambutol is indicated for the treatment of infections caused by *M. tuberculosis, M. kansasii, M. bovis,* and *M. avium* complex. Ethambutol should only be used as part of a combination treatment regimen for *M. tuberculosis.* Daily dosing is 15-25 mg/kg PO in a single dose, not to exceed 2,500 mg/day. Twice-weekly dosing is with 50 mg/kg PO in a single dose, not to exceed 2,500 mg/day. Dosage adjustment is needed in renal insufficiency. Ethambutol is available in 100- and 400-mg tablets.

The major adverse effect with ethambutol is **optic neuritis**, and thus ethambutol should generally be reserved for children old enough to have visual acuity and color discrimination reliably monitored. Visual changes are usually dosage dependent and reversible. Other adverse events include headache, dizziness, confusion, hyperuricemia, GI upset, peripheral neuropathy, hepatotoxicity, and cytopenias, especially neutropenia and thrombocytopenia.

Routine laboratory monitoring includes baseline and periodic visual acuity and color discrimination testing, CBC, serum uric acid levels, and kidney and liver function tests.

Less Commonly Used Agents

Aminoglycosides

The aminoglycosides used for mycobacterial infections include streptomycin, amikacin, kanamycin, and capreomycin. **Streptomycin** is isolated from *Streptomyces griseus* and was the first drug used to treat *M. tuberculosis.* **Capreomycin**, a cyclic polypeptide from *Streptomyces capreolus,* and **amikacin**, a semisynthetic derivative of kanamycin, are newer agents that are recommended when streptomycin is unavailable. Aminoglycosides act by binding irreversibly to the 30S subunit of ribosomes and inhibiting subsequent protein synthesis. Streptomycin exhibits concentration-dependent bactericidal activity, and capreomycin is bacteriostatic. Resistance results from a pathogenic variant in the binding site of the 30S ribosome, by decreased transport into cells, or by inactivation by bacterial enzymes. Cross-resistance between aminoglycosides has been demonstrated.

The aminoglycosides are indicated for the treatment of *M. tuberculosis* and *M. avium* complex. All are considered second-line drugs in the treatment of *M. tuberculosis* and should be used only when resistance patterns are known. Aminoglycosides are poorly absorbed orally and are administered by IM injection. Pediatric dosing ranges for streptomycin are 20 mg/kg/day if given daily and 20-40 mg/kg/day if given twice weekly; dosing is IM in a single daily dose. Capreomycin, amikacin, and kanamycin dosages are 15-30 mg/kg/day IM in a single dose, not to exceed 1 g/day. Dosage adjustment is necessary in renal insufficiency.

Aminoglycosides have **adverse effects** on proximal renal tubules, the cochlea, and the vestibular apparatus of the ear. Nephrotoxicity and ototoxicity account for most of the significant adverse events. Rarely, patients exhibit fever or rash with administration of aminoglycosides. Concomitant use of other nephrotoxic or ototoxic agents should be avoided, because adverse effects may be additive. An infrequent but serious synergistic, dosage-dependent aminoglycoside effect with nondepolarizing neuromuscular blockade agents can result in respiratory depression or paralysis.

Hearing and kidney function should be monitored at baseline and periodically. Early signs of ototoxicity include tinnitus, vertigo, and hearing loss. Ototoxicity appears to be irreversible, but early kidney damage may be reversible. As with other aminoglycosides, peak and trough drug levels are helpful in dosing and managing early toxicities.

Cycloserine

Cycloserine, derived from *Streptomyces orchidaceous* or *Streptomyces garyphalus,* is a synthetic analog of the amino acid D-alanine that interferes with bacterial cell wall synthesis through competitive inhibition of D-alanine components to be incorporated into the cell wall. It is bacteriostatic, and the mechanism of resistance is unknown.

Cycloserine is used to treat *M. tuberculosis* and *M. bovis*. The dosage is 10-20 mg/kg/day PO divided into two doses, not to exceed 1 g/day. It is available in a 250-mg capsule.

The major adverse effect is **neurotoxicity** with significant psychologic disturbance, including seizures, acute psychosis, headache, confusion, depression, and personality changes. The neurotoxic effects are additive with ethionamide and INH. Cycloserine has also been associated with megaloblastic anemia. It must be dosage-adjusted in patients with kidney impairment and should be used with caution in patients with underlying psychiatric illness.

Routine laboratory monitoring includes kidney and hepatic function, CBC, and cycloserine levels. Psychiatric symptoms are less common at blood levels <30 μg/mL.

Ethionamide

Ethionamide is structurally related to INH and is an ethyl derivative of thioisonicotinamide that inhibits peptide synthesis by an unclear mechanism thought to involve nicotinamide adenine dinucleotide (NAD) and NAD phosphate dehydrogenase disruptions. Ethionamide is bacteriostatic at most therapeutic levels. Resistance develops quickly if ethionamide is used as a single-agent therapy, although the mechanism is unknown.

Ethionamide is used as an alternative to streptomycin or ethambutol in the treatment of *M. tuberculosis* and has some activity against *M. kansasii* and *M. avium* complex. A metabolite, ethionamide sulfoxide, is bactericidal against *M. leprae.* Ethionamide has been shown to have good central nervous system (CNS) penetration and has been used as a fourth drug in combination with rifampin, INH, and PZA. The pediatric dosing is 15-20 mg/kg/day PO in two divided doses, not to exceed 1 g/day. It is available as a 250-mg tablet.

GI upset is common, and other **adverse effects** include neurologic disturbances (anxiety, dizziness, peripheral neuropathy, seizures, acute psychosis), hepatic enzyme elevations, hypothyroidism, hypoglycemia, and hypersensitivity reaction with rash and fever. Ethionamide should be used with caution in patients with underlying psychiatric or thyroid disease. The psychiatric adverse effects can be potentiated with concomitant use of cycloserine.

In addition to close assessment of mood, routine monitoring includes thyroid and liver function tests. In diabetic patients taking ethionamide, blood glucose levels should be monitored.

Fluoroquinolones

The fluoroquinolones are fluorinated derivatives of the quinolone class of antibiotics. Ciprofloxacin is a first-generation fluoroquinolone, and levofloxacin is the more active l-isomer of ofloxacin. **Moxifloxacin** and **gatifloxacin** are agents with emerging use in pediatric mycobacterial disease. Fluoroquinolones are not indicated for use in children <18 years old, but studies of their use in pediatric patients continue to indicate that they may be used in special circumstances. Fluoroquinolones are bactericidal and exert their effect by inhibition of DNA gyrase. The alterations in DNA gyrase result in relaxation of supercoiled DNA and breaks in double-stranded DNA. The mechanism of resistance is not well defined but likely involves pathogenic variants in the DNA gyrase.

Levofloxacin is an important second-line drug in the treatment of multidrug-resistant (MDR) *M. tuberculosis.* **Ciprofloxacin** has activity against *M. fortuitum* complex and against *M. tuberculosis.* The pediatric dosage of ciprofloxacin is 20-30 mg/kg/day PO or IV, not to exceed 1.5 mg/day PO or 800 mg/day IV. The adult dosage of ciprofloxacin is 500-750 mg/dose PO in two divided doses or 200-400 mg/dose IV every 12 hours. Ciprofloxacin is available in 100-, 250-, 500-, and 750-mg tablets and can be made in 5% (50 mg/mL) or 10% (100 mg/mL) suspensions. The dosage of levofloxacin for children is 5-10 mg/kg/day

given once daily either PO or IV, not to exceed 1,000 mg/day, and for adults, 500-1,000 mg/day PO or IV, not to exceed 1,000 mg/day. Levofloxacin is available in 250-, 500-, and 750-mg tablets, and a 50 mg/mL suspension can be extemporaneously compounded. The suspension has a shelf life of only 8 weeks.

The most common adverse effect of fluoroquinolones is **GI upset**, with nausea, vomiting, abdominal pain, and diarrhea, including pseudomembranous colitis. Other less common adverse effects include bone marrow depression, CNS effects (e.g., lowered seizure threshold, confusion, tremor, dizziness, headache), elevated liver transaminases, photosensitivity, and arthropathies. The potential for arthropathies (e.g., tendon ruptures, arthralgias, tendinitis) is the predominant reason that fluoroquinolones are not recommended for pediatric use. The mechanism of injury appears to involve the disruption of extracellular matrix of cartilage and depletion of collagen, a particular concern related to the bone and joint development of children.

Fluoroquinolones induce the CYP isoenzymes that can increase the concentrations of dually administered theophylline and warfarin. Nonsteroidal antiinflammatory drugs (NSAIDs) can potentiate the CNS effects of fluoroquinolones and should be avoided while taking a fluoroquinolone. Both ciprofloxacin and levofloxacin should be dosage-adjusted in patients with significant renal dysfunction.

While taking fluoroquinolones, patients should be monitored for hepatic and renal dysfunction, arthropathies, and hematologic abnormalities.

Linezolid

Linezolid is a synthetic oxazolidinone derivative. This drug is not currently approved for use against mycobacterial infection in pediatric or adult patients but has activity against some mycobacterial species. Studies on efficacy of treatment of mycobacterial infections are under way. Linezolid inhibits translation by binding to the 23S ribosomal component of the 50S ribosome subunit, preventing coupling with the 70S subunit. Resistance is thought to be from a point a pathogenic variant at the binding site but is poorly studied because only a few cases of resistance have been reported.

The approved indications for linezolid are for bacterial infections other than mycobacteria, but studies reveal in vitro activity against rapidly growing mycobacteria (*M. fortuitum* complex, *M. chelonae, M. abscessus*), *M. tuberculosis,* and *M. avium* complex. The dosage for 0- to 11-year-old children is 10 mg/kg/day PO or IV in divided doses every 8-12 hours. For persons >12 years old, the dosage is 600 mg PO or IV every 12 hours. Linezolid is available in 400- and 600-mg tablets and as a 20-mg/mL suspension.

Adverse effects of linezolid include GI upset (e.g., nausea, vomiting, diarrhea), CNS disturbances (e.g., dizziness, headache, insomnia, peripheral neuropathy), lactic acidosis, fever, myelosuppression, and pseudomembranous colitis. Linezolid is a weak inhibitor of monoamine oxidase A, and patients are advised to avoid foods with high tyramine content. Linezolid should be used cautiously in patients with preexisting myelosuppression.

In addition to monitoring for GI upset and CNS perturbations, routine laboratory monitoring includes CBC at least weekly.

Paraaminosalicylic Acid

Paraaminosalicylic acid **(PAS)** is a structural analog of paraaminobenzoic acid (PABA). It is bacteriostatic and acts by competitively inhibiting the synthesis of folic acid, similar to the action of sulfonamides. Resistance mechanisms are poorly understood.

PAS acts against *M. tuberculosis.* The dosage is 150 mg/kg/day PO in two or three divided doses. PAS is dispensed in 4-g packets, and the granules should be mixed with liquid and swallowed whole.

Common **adverse effects** include GI upset, and less common events include hypokalemia, hematuria, albuminuria, crystalluria, and elevations of hepatic transaminases. PAS can decrease the absorption of rifampin, and co-administration with ethionamide potentiates the adverse effects of PAS.

In addition to monitoring for weight loss, routine laboratory monitoring includes liver and kidney function tests.

Bedaquiline Fumarate

This oral diarylquinoline has been recommended for the treatment of MDR tuberculosis. Bedaquiline fumarate should be used as part of combination therapy and administered by direct observation. Although approved for patients ≥18 years old, bedaquiline may be considered for children on a case-by-case basis.

Serious **adverse effects** include hepatotoxicity and a prolonged QT interval.

Delamanid

Delamanid is a dihydro-nitroimidazooxazole derivative recently approved for use in the treatment of MDR tuberculosis. It acts by inhibiting the synthesis of mycobacterial cell wall compounds such as methoxymycolic acid and ketomycolic acid. Limited studies are available in the pediatric population, and delamanid should be used only in conjunction with a tuberculosis specialist.

Adverse effects include nausea, vomiting, dizziness, anxiety, shaking, and QT prolongation.

AGENTS USED AGAINST *MYCOBACTERIUM LEPRAE*

Dapsone

Dapsone is a sulfone antibiotic with characteristics similar to sulfonamides. Similar to other sulfonamides, dapsone acts as a competitive antagonist of PABA, which is needed for the bacterial synthesis of folic acid. Dapsone is bacteriostatic against *M. leprae.* Resistance is not well understood but is thought to occur after alterations at the PABA-binding site.

Dapsone is used in the treatment of *M. leprae* in combination with other antileprosy agents (rifampin, clofazimine, ethionamide). The pediatric dosage is 1-2 mg/kg/day PO as a single dose, not to exceed 100 mg/day, for a duration of 3-10 years. The adult dosage is 100 mg/day PO as a single dose. Dapsone is available in 25- and 100-mg scored tablets and as an oral suspension of 2 mg/mL. The dosage should be adjusted in renal insufficiency.

Dapsone has many reported **adverse effects**, including dosage-related hemolytic anemia, especially in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, pancreatitis, renal complications (acute tubular necrosis, acute renal failure, albuminuria), increased liver enzymes, psychosis, tinnitus, peripheral neuropathy, photosensitivity, and a hypersensitivity syndrome with fever, rash, hepatic damage, and malaise. Treatment may produce a *lepra reaction,* which is a nontoxic, paradoxical worsening of lepromatous leprosy with the initiation of therapy. This hypersensitivity reaction is not an indication to discontinue therapy. Dapsone should be used with caution in patients with G6PD deficiency or taking other folic acid antagonists. Dapsone levels can decrease with concomitant rifampin use and can increase with concomitant clotrimazole use.

Routine laboratory monitoring includes CBC weekly during the first month of therapy, weekly through 6 months of therapy, and then every 6 months thereafter. Other periodic assessments include kidney function with creatine levels, urinalysis, and liver function tests.

Clofazimine

Clofazimine is a synthetic phendimetrazine tartrate derivative that acts by binding to the mycobacterial DNA at guanine sites. It has slow bactericidal activity against *M. leprae.* Mechanisms of resistance are not well studied. No cross-resistance between clofazimine and dapsone or rifampin has been shown.

Clofazimine is indicated as part of a combination therapy for the treatment of *M. leprae.* It appears there may be some activity against other mycobacteria such as *M. avium* complex, although treatment failures are common. The safety and efficacy of clofazimine are poorly studied in children. The pediatric dosage is 1 mg/kg/day PO as a single dose, not to exceed 100 mg/day, in combination with dapsone and rifampin for 2 years and then additionally as a single agent for >1 year. The adult dosage is 100 mg/day PO. Clofazimine should be taken with food to increase absorption.

The most common adverse effect is a dosage-related, reversible, pink to tan-brown discoloration of the skin and conjunctiva. Other **adverse**

effects include a dry, itchy skin rash, headache, dizziness, abdominal pain, diarrhea, vomiting, peripheral neuropathy, and elevated hepatic transaminases.

Routine laboratory monitoring includes periodic liver function tests.

AGENTS USED AGAINST NONTUBERCULOUS MYCOBACTERIA

Cefoxitin

Cefoxitin, a cephamycin derivative, is a second-generation cephalosporin that, like other cephalosporins, inhibits cell wall synthesis by linking with penicillin-binding proteins to create an unstable bacterial cell wall. Resistance develops by alterations in penicillin-binding proteins.

Cefoxitin is often used in combination therapy for mycobacterial disease (Table 260.3). Pediatric dosing is based on disease severity, with a range of 80-160 mg/kg/day divided every 4-8 hours, not to exceed 12 g/day. Adult dosages are 1-2 g/dose, not to exceed 12 g/day. Cefoxitin is available in IV and IM formulations. Increased dosing intervals are needed with renal insufficiency.

Adverse effects are primarily hematologic (eosinophilia, granulocytopenia, thrombocytopenia, hemolytic anemia), GI (nausea, vomiting,

Table 260.3 Treatment of Nontuberculous Mycobacteria Infections in Children

ORGANISM	DISEASE	INITIAL TREATMENT
SLOWLY GROWING SPECIES		
Mycobacterium avium complex (MAC); *Mycobacterium haemophilum; Mycobacterium lentiflavum*	Lymphadenitis	Complete excision of lymph nodes; if excision incomplete or disease recurs, clarithromycin or azithromycin plus ethambutol and/or rifampin (or rifabutin).
	Pulmonary infection	Clarithromycin or azithromycin plus ethambutol with rifampin or rifabutin (pulmonary resection in some patients who fail to respond to drug therapy). For severe disease, an initial course of amikacin or streptomycin often is included. Clinical data in adults with mild to moderate disease support that 3-times-weekly therapy is as effective as daily therapy, with less toxicity. For patients with advanced or cavitary disease, drugs should be given daily.
Mycobacterium chimaera	Prosthetic valve endocarditis	Valve removal, prolonged antimicrobial therapy based on susceptibility testing.
	Disseminated	See text.
Mycobacterium kansasii	Pulmonary infection	Rifampin plus ethambutol with isoniazid daily. If rifampin resistance is detected, a three-drug regimen based on drug susceptibility testing should be used.
	Osteomyelitis	Surgical debridement and prolonged antimicrobial therapy using rifampin plus ethambutol with isoniazid.
Mycobacterium marinum	Cutaneous infection	None, if minor; rifampin, TMP-SMX, clarithromycin, or doxycycline* for moderate disease; extensive lesions may require surgical debridement. Susceptibility testing not routinely required.
Mycobacterium ulcerans	Cutaneous and bone infections	Daily intramuscular streptomycin and oral rifampin for 8 wk; excision to remove necrotic tissue, if present; potential response to thermotherapy.
RAPIDLY GROWING SPECIES		
Mycobacterium fortuitum group	Cutaneous infection	Initial therapy for serious disease is amikacin plus meropenem IV, followed by clarithromycin, doxycycline,* TMP-SMX, or ciprofloxacin PO on the basis of in vitro susceptibility testing; may require surgical excision. Up to 50% of isolates are resistant to cefoxitin.
	Catheter infection	Catheter removal and amikacin plus meropenem IV; clarithromycin, TMP-SMX, or ciprofloxacin orally on the basis of in vitro susceptibility testing.
Mycobacterium abscessus	Otitis media; cutaneous infection	There is no reliable antimicrobial regimen because of variability in drug susceptibility. Clarithromycin plus an initial course of amikacin plus cefoxitin or imipenem/meropenem; may require surgical debridement on the basis of in vitro susceptibility testing (50% are amikacin resistant).
	Pulmonary infection (in cystic fibrosis)	Serious disease; clarithromycin, amikacin, and cefoxitin or imipenem/meropenem on the basis of susceptibility testing; most isolates have very low MIC to tigecycline; may require surgical resection.
Mycobacterium chelonae	Catheter infection, prosthetic valve endocarditis	Catheter removal; debridement, removal of foreign material; valve replacement; and tobramycin (initially) plus clarithromycin, meropenem, and linezolid.
	Disseminated cutaneous infection	Tobramycin and meropenem or linezolid (initially) plus clarithromycin.

*Doxycycline can be used for short durations (i.e., ≤21 days) without regard to patient age but is not recommended for longer treatment durations in children <8 yr old. Only 50% of isolates of *M. marinum* are susceptible to doxycycline.

IV, Intravenously; MIC, minimum inhibitory concentration; PO, orally (by mouth); TMP-SMX, trimethoprim-sulfamethoxazole.

From Kimberlin DW, Barnett ED, Lynfield R, Sawyer MH, eds. *Red Book: 2021–2024 Report of the Committee on Infectious Diseases*, 32nd ed. Itasca, IL: American Academy of Pediatrics; 2021.

diarrhea with possible pseudomembranous colitis), and CNS related (dizziness, vertigo). Potential additive adverse effects can occur when cefoxitin is used with aminoglycosides.

Routine laboratory monitoring with long-term use includes CBC and liver and renal function tests.

Doxycycline

Doxycycline is in the tetracycline family of antibiotics and has limited use in pediatrics. As with other tetracyclines, doxycycline acts to decrease protein synthesis by binding to the 30S ribosome and to transfer RNA. It can also cause alterations to the cytoplasmic membrane of susceptible bacteria.

Doxycycline is used to treat *M. fortuitum* (see Table 260.3). Although it can be used to treat *M. marinum,* adult treatment failures have occurred. Pediatric dosing is based on age and weight. For children >8 years old who weigh <45 kg, the dosage is 4.4 mg/kg/day divided twice daily. Dosing for larger children and adults is 100 mg twice daily. Doxycycline is available as 50- and 100-mg capsules or tablets and in 25-mg/5 mL and 50-mg/5 mL suspensions.

Doxycycline use in children is limited by a **permanent tooth discoloration**, which becomes worse with long-term use. Other **adverse effects** include photosensitivity, liver and kidney dysfunction, and esophagitis, which can be minimized by dosing with large volumes of liquid. Doxycycline can decrease the effectiveness of oral contraceptives. Rifampin, carbamazepine, and phenytoin can decrease the concentration of doxycycline.

Routine laboratory monitoring with long-term use includes kidney and liver function tests as well as CBC.

Macrolides

Clarithromycin and azithromycin belong to the macrolide family of antibiotics. Clarithromycin is a methoxy derivative of erythromycin. Macrolides act by binding the 50S subunit of ribosomes, subsequently inhibiting protein synthesis. Resistance mechanisms for mycobacteria are not well understood but might involve binding site alterations. Clarithromycin appears to have synergistic antimycobacterial activity when combined with rifamycins, ethambutol, or clofazimine.

Clarithromycin is widely used for the prophylaxis and treatment of *M. avium* complex disease and also has activity against *M. abscessus, M. fortuitum,* and *M. marinum.* Azithromycin has significantly different pharmacokinetics compared with other macrolide agents and has not been studied and is not indicated for mycobacterial infections. The pediatric dosage of clarithromycin for primary prophylaxis of *M. avium* complex infections is 7.5 mg/kg/dose PO given twice daily, not to exceed 500 mg/day. This dosage is used for recurrent *M. avium* complex disease in combination with ethambutol and rifampin. The adult dosage is 500 mg PO twice daily to be used as a single agent for primary prophylaxis or as part of combination therapy with ethambutol and rifampin. Dosage adjustment is needed for renal insufficiency but not liver failure. Clarithromycin is available in 250- and 500-mg tablets and suspensions of 125 mg/5 mL and 250 mg/5 mL.

The primary adverse effect of clarithromycin is **GI upset**, including vomiting (6%), diarrhea (6%), and abdominal pain (3%). Other **adverse effects** include taste disturbances, headache, and QT prolongation if used with inhaled anesthetics, clotrimazole, antiarrhythmic agents, or azoles. Clarithromycin should be used cautiously in patients with renal insufficiency or liver failure.

Routine laboratory monitoring with prolonged use of clarithromycin includes periodic liver enzyme tests. Diarrhea is an early sign of pseudomembranous colitis.

Trimethoprim-Sulfamethoxazole

Trimethoprim-sulfamethoxazole (TMP-SMX) is formulated in a fixed ratio of one part TMP to five parts SMX. SMX is a sulfonamide that inhibits synthesis of dihydrofolic acid by competitively inhibiting PABA, similar to dapsone. TMP blocks production of tetrahydrofolic acid and downstream biosynthesis of nucleic acids and protein by reversibly binding to dihydrofolate reductase. The combination of the two agents is synergistic and often bactericidal.

TMP-SMX is often used in combination therapy for mycobacterial disease (see Table 260.3). Oral or IV pediatric dosage for serious infections is TMP 15-20 mg/kg/day divided every 6-8 hours, and for mild infections, TMP 6-12 mg/kg/day divided every 12 hours. The adult dosage is 160 mg TMP and 800 mg SMX every 12 hours. Dosage reduction may be needed in renal insufficiency. TMP-SMX is available in single-strength tablets (80/400 mg TMP-SMX) and double-strength tablets (160/800 mg TMP-SMX) and in a suspension of 40 mg TMP and 200 mg SMX per 5 mL.

The most common adverse effect with TMP-SMX is **myelosuppression**. It must be used with caution in patients with G6PD deficiency. Other **adverse effects** include renal abnormalities, rash, aseptic meningitis, GI disturbances (e.g., pancreatitis, diarrhea), and prolonged QT interval if co-administered with inhaled anesthetics, azoles, or macrolides.

Routine laboratory monitoring includes monthly CBC and periodic electrolytes and creatinine to monitor renal function.

Chapter 261

Tuberculosis (*Mycobacterium tuberculosis*)

Lindsay H. Cameron and Jeffrey R. Starke

Mycobacterium tuberculosis has caused human disease for more than 4,000 years and is one of the most important infectious diseases worldwide. There are five closely related mycobacteria in the *Mycobacterium tuberculosis* complex: *M. tuberculosis, M. bovis, M. africanum, M. microti,* and *M. canetti. M. tuberculosis* is the most important cause of tuberculosis (TB) disease in humans. The tubercle bacilli are non–spore-forming, nonmotile, pleomorphic, weakly gram-positive curved rods 1-5 µm long, typically slender, and slightly bent. They can appear beaded or clumped under microscopy. They are obligate aerobes that grow in synthetic media containing glycerol as the carbon source and ammonium salts as the nitrogen source (Löwenstein-Jensen culture media). These mycobacteria grow best at 37–41°C (98.6–105.8°F), produce niacin, and lack pigmentation. A lipid-rich cell wall accounts for resistance to the bactericidal actions of antibody and complement. A hallmark of all mycobacteria is **acid fastness**—the capacity to form stable mycolate complexes with arylmethane dyes (crystal violet, carbolfuchsin, auramine, and rhodamine). They resist decoloration with ethanol and hydrochloric or other acids.

M. tuberculosis grows slowly, with a generation time of 12-24 hours. Isolation from clinical specimens on solid synthetic media usually takes 3-6 weeks, and drug susceptibility testing requires an additional 2-4 weeks. Growth can be detected in 1-3 weeks in selective liquid medium using radiolabeled nutrients (e.g., BACTEC radiometric system), and drug susceptibilities can be determined in an additional 3-5 days. Once mycobacterial growth is detected, the species of mycobacteria present can be determined within hours using high-pressure liquid chromatography analysis (identifying the mycolic acid fingerprint of each species) or DNA probes/nucleic amplification tests (NAATs).

NAATs are used to identify genes associated with *M. tuberculosis* drug resistance and complement phenotypic drug susceptibility testing. Results are available in hours, which expedites management decisions. Phenotypic drug susceptibility testing is necessary to confirm susceptibility to each drug. Restriction fragment length polymorphism genetic profiling of mycobacteria is a helpful tool to study the epidemiology of TB strain relatedness in both outbreaks and routine epidemiology of TB in a community.

CLINICAL STAGES

There are three major clinical stages of TB: exposure, infection, and disease. **Exposure** means a child has had recent significant contact (shared the air) with an adult or adolescent with infectious TB but lacks proof of infection. In this stage, the tuberculin skin test (TST) or interferon-γ release assay (IGRA) result is negative, the chest radiograph is normal, the physical examination is normal, and the child lacks signs or symptoms of disease. However, the child may be infected and develop TB disease rapidly, because there may not have been enough time for the TST or IGRA to turn positive. **Tuberculosis infection (TBI)** occurs when the individual inhales droplet nuclei containing *M. tuberculosis,* which survive intracellularly within the lung and associated lymphoid tissue. The hallmark of TBI is a positive TST or IGRA result. In this stage the child has no signs or symptoms and has a normal physical examination, and the chest radiograph is either normal or reveals only granuloma or calcifications in the lung parenchyma. **Disease** occurs when signs or symptoms or radiographic manifestations caused by *M. tuberculosis* become apparent. Not all infected individuals have the same risk of developing disease. An immunocompetent adult with untreated TBI has approximately a 5–10% lifetime risk of developing disease. In contrast, an infected child <1 year old has a 40% chance of developing TB disease within 9 months.

EPIDEMIOLOGY

TB remains a leading cause of death from an infectious disease worldwide. The global burden of TB is influenced by several factors, including the HIV pandemic; the development of **multidrug-resistant (MDR) tuberculosis**; the disproportionately low access of populations in low-resource settings worldwide to both diagnostic tests and effective medical therapy; and the COVID-19 pandemic.

The World Health Organization (WHO) 2020 Global Tuberculosis Report estimates that the COVID-19 pandemic could have a significant impact on access to essential TB services (human capital, financial), which may increase the rates of TB-associated morbidity and mortality. Many countries have had to allocate public health resources from TB prevention efforts toward COVID-19 prevention, including contact tracing and using GeneXpert machines for COVID-19 testing. The WHO predicts that this resource diversion from TB case-finding, testing, treatment, and prevention may result in an increase of global TB-associated deaths by 0.2-0.4 million per year.

Approximately 95% of TB cases occur in the developing world. In 2019, the 30 high-TB-burden countries accounted for 87% of incident cases (Fig. 261.1). Two thirds of cases occurred in eight countries, including India, Indonesia, China, the Philippines, Pakistan, Nigeria, Bangladesh, and South Africa. An estimated 10 million incident cases and 1.4 million TB-associated deaths occurred worldwide in 2019. The WHO 2020 Global Tuberculosis Report estimates that in 2019 there were 1.2 million childhood incident cases and 230,000 TB-associated deaths among children, including 32,000 TB-associated deaths among children living with HIV.

The incidence of drug-resistant TB has increased in some areas of the world in both adults and children. In 2019, the WHO reported a global total of 206,030 cases of multidrug- or rifampicin-resistant TB, a 10% increase from 2018 (Fig. 261.2). Isoniazid (INH)–monoresistant TB is resistance to INH alone, rifampicin-resistant TB (RR-TB) is resistance to at least rifampin, MDR-TB is defined as resistance to at least isoniazid and rifampin, and extensively drug-resistant tuberculosis TB (XDR-TB) includes MDR-TB plus resistance to any fluoroquinolone and at least one of three injectable drugs (kanamycin, capreomycin, or amikacin). In 2014, the worldwide estimate for MDR-TB in children was 2.9% of all cases and 0.1% for XDR-TB. The highest incidence of MDR-TB in children occurs in the Southeast Asian, African, and Western Pacific regions; however, the proportion of drug-resistant cases is highest in countries belonging to the Russian Federation, where over 30% of children with TB have a drug-resistant organism.

In the United States, TB case rates decreased steadily during the first half of the 20th century, long before the advent of antituberculosis drugs, as a result of improved living conditions and likely genetic selection favoring persons resistant to developing disease. A resurgence of TB in the late 1980s was associated primarily with the HIV epidemic, transmission of the organism in congregate settings including healthcare institutions, disease occurring in recent immigrants, and poor conduct of community TB control. Since 1992, the TB incidence in the

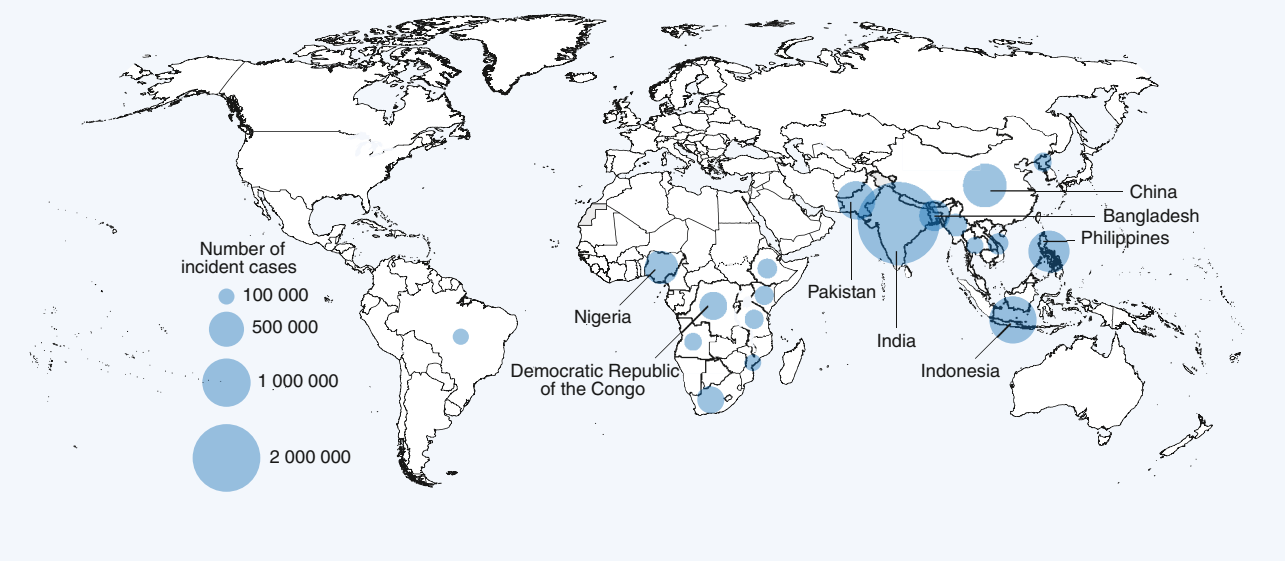

Fig. 261.1 Countries that had at least 100,000 incident cases of TB in 2021. The countries that rank first to eighth in terms of numbers of cases and that accounted for about two thirds of global cases in 2021 are labeled. *(From the World Health Organization: Global Tuberculosis Report 2022. Geneva: World Health Organization; 2022, Fig 12. License: CC BY-NC-SA 3.0 IGO.)*

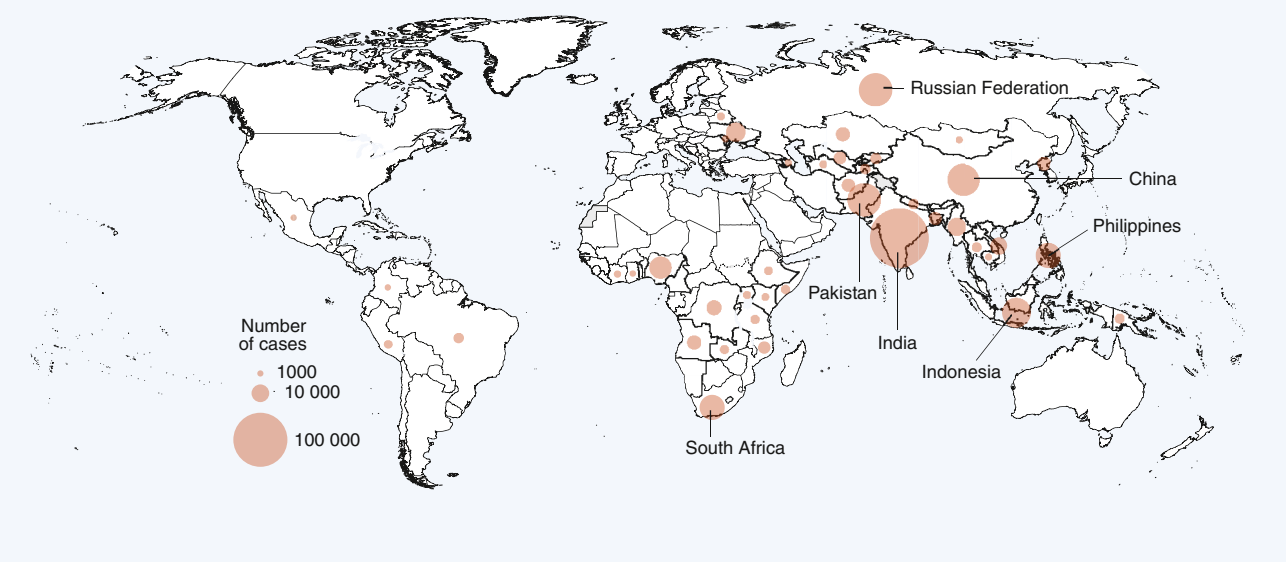

Fig. 261.2 Percentage of new TB cases with MDR-/RR-TB. The seven countries with the highest burden in terms of numbers of MDR/RR -TB cases and that accounted for two thirds of global MDR-/RR-TB cases in 2021 are labeled. *(From the World Health Organization: Global Tuberculosis Report 2022. Geneva: World Health Organization; 2022, Fig 17. License: CC BY-NC-SA 3.0 IGO.)*

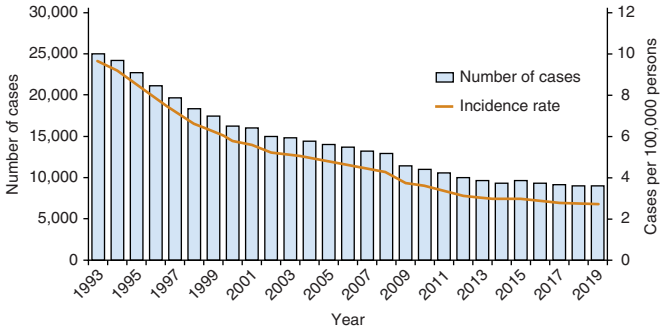

Fig. 261.3 Reported tuberculosis cases in the United States for 1993–2019 (as of October 29, 2020). *(From Centers for Disease Control and Prevention. Trends in Tuberculosis, 2019. Atlanta: U.S. Department of Health and Human Services; 2020.)*

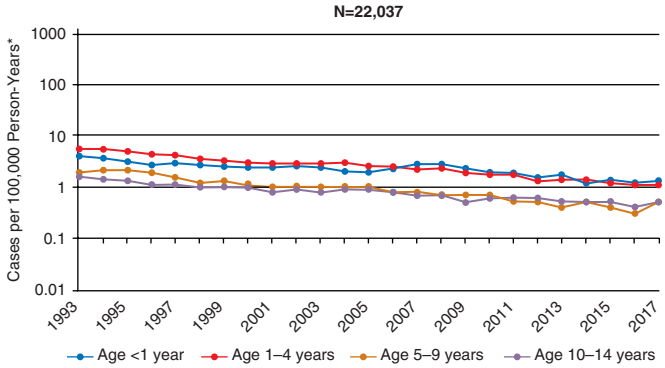

Fig. 261.4 Reported pediatric tuberculosis (TB) cases in the United States by age-group for the years 1993-2017. *Rates are presented on a logarithmic scale. *(From Centers for Disease Control and Prevention, National Center for HIV/AIDS, Viral Hepatitis, STD and TB Prevention. Pediatric Tuberculosis in United States, 1993–2017. Atlanta: U.S. Department of Health and Human Services; 2018.)*

United States has decreased over time. In 2020, the case rate was at the all-time low of 2.2 per 100,000 persons (Fig. 261.3).

In 2017, the incidence rate of TB among children <15 years was 0.7 cases per 100,000 person-years, a decline of 41% from 1993. The TB incidence rates were highest in children less than 12 months of age (1.3 per 100,000 person-years), followed by children age 1-4 years (1.1 per 100,000 person-years), and were lowest among children age 5-14 years (0.5 per 100,000 person-years) (Fig. 261.4).

From 1993 to 2017, non-United States–born children, children born to non-United States–born parents, and children of racial or ethnic minority status were disproportionately affected by TB. Non-United States–born children accounted for approximately 25% of the total number of childhood TB cases, the majority being from Mexico, followed by the Philippines, Somalia, Vietnam, Ethiopia, and Haiti (Fig. 261.5).

According to data reported to the National TB Surveillance System from 2007 to 2017, among United States–born children, the incidence rates of TB if both parents were non-United States–born and if one parent was non-United States–born were eight and three times higher, respectively, compared to United States–born children with both parents being United States–born. This is supported by prior research that found that 75% of United States–born children with TB had some international connection through a family member or previous travel or residence in a TB-endemic country. Similar to adults in the United

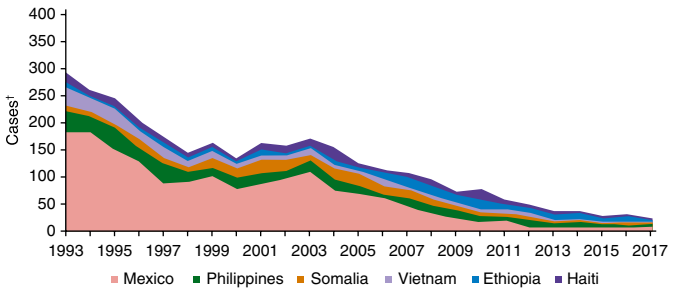

Fig. 261.5 Top six countries of birth for non–United States–born* pediatric TB cases for the years 1993-2017. *Non-United States–born refers to persons born outside the United States or its territories or not born to a US citizen. †Cases in United States–born children of non-United States–born parents are included in United States–born counts and thus not displayed in this figure. *(From Centers for Disease Control and Prevention, National Center for HIV/AIDS, Viral Hepatitis, STD and TB Prevention. Pediatric Tuberculosis in United States, 1993–2017. Atlanta: U.S. Department of Health and Human Services; 2018.)*

States, TB among children of racial-ethnic minority status occurs disproportionately. The incidence rates of TB among children of Native Hawaiian or Pacific Islander, Asian, Native American or Native Alaskan, Black, and Hispanic children were 144, 44, 22, 19, and 18 times higher, respectively, than among non-Hispanic White children.

The rates of drug-resistant TB in children in the United States remain low. A total of 89 childhood cases of MDR-TB were reported in the United States in 2015; of those, 70.8% were non-United States–born. Among children with culture-confirmed TB in the United States in 2015, 15.2% had organisms with resistance to at least one first-line drug and 0.9% had MDR organisms.

Most children are infected with *M. tuberculosis* in their home by someone close to them, but outbreaks of childhood TB also have occurred in elementary and high schools, nursery schools, daycare centers and homes, churches, school buses, and sports teams. Adults living with HIV who have pulmonary TB can transmit *M. tuberculosis* to children, and children living with HIV are at increased risk for developing TB after infection. Other specific groups are at high risk for acquiring TBI and progressing to tuberculosis disease (Table 261.1).

Table 261.1 Groups at High Risk for Acquiring Tuberculosis Infection and Developing Disease in Countries with Low Incidence

RISK FACTORS FOR TUBERCULOSIS INFECTION
Children exposed to high-risk adults
Foreign-born persons from high-prevalence countries
Homeless persons
Persons who inject drugs
Present and former residents or employees of correctional institutions, homeless shelters, and nursing homes
Healthcare workers caring for high-risk patients (if infection control is not adequate)
RISK FACTORS FOR PROGRESSION OF TUBERCULOSIS INFECTION TO TUBERCULOSIS DISEASE
Infants and children ≤4 yr old, especially those <2 yr old
Adolescents and young adults
Persons co-infected with human immunodeficiency virus
Persons with skin test conversion in the past 1-2 yr
Persons who are immunocompromised, especially in cases of malignancy and solid organ transplantation, immunosuppressive medical treatments including anti–tumor necrosis factor therapies, diabetes mellitus, chronic renal failure, silicosis, and malnutrition
RISK FACTORS FOR DRUG-RESISTANT TUBERCULOSIS
Personal or contact history of treatment for tuberculosis
Contacts of patients with drug-resistant tuberculosis
Birth or residence in a country with a high rate of drug resistance
Poor response to standard therapy
Positive sputum smears (acid-fast bacilli) or culture ≥2 mo after initiating appropriate therapy

TRANSMISSION

Transmission of *M. tuberculosis* is usually by inhalation of airborne mucus droplet nuclei, particles 1-5 μm in diameter that contain *M. tuberculosis.* Transmission rarely occurs by direct contact with an infected discharge or a contaminated fomite. The chance of transmission increases when the patient has a positive acid-fast smear of sputum, an extensive upper lobe infiltrate or cavity, copious production of thin sputum, and severe and forceful cough (although the absence of cough does not eliminate the risk of TBI). Environmental factors such as poor air circulation enhance transmission. Within several days to 2 weeks after beginning adequate chemotherapy, most adults no longer transmit the organism, but some patients remain infectious for many weeks. Young children with TB rarely infect other children or adults; tubercle bacilli are sparse in their endobronchial secretions, and cough is often absent or lacks the tussive force required to suspend infectious particles of the correct size. However, adolescents often present with adult-type cavity or endobronchial TB and can easily transmit the organism.

Airborne transmission of *M. bovis* and *M. africanum* also occurs rarely. *M. bovis* can penetrate the gastrointestinal (GI) mucosa or invade the lymphatic tissue of the oropharynx when large numbers of the organism are ingested. Human infection with *M. bovis* is rare in developed countries as a result of the pasteurization of milk and effective TB control programs for cattle. Approximately 46% of culture-proven childhood TB cases from the San Diego, California, region since 1994 were caused by *M. bovis,* likely acquired by children when visiting Mexico or another country or consuming dairy products from countries with suboptimal veterinary TB control programs.

Zoonotic transmission is an uncommon source of *M. tuberculosis* that has been reported in adults exposed to elephants and potentially cattle.

PATHOGENESIS

The **primary complex** (or **Ghon complex**) of TB includes local infection at the portal of entry and the regional lymph nodes that drain the area. The lung is the portal of entry in >98% of cases. The tubercle bacilli multiply initially within alveoli and alveolar ducts. Most of the bacilli are killed, but some survive within nonactivated macrophages, which carry them through lymphatic vessels to the regional lymph nodes. When the primary infection is in the lung, the hilar lymph nodes usually are involved, although an upper lobe focus can drain into paratracheal nodes. The tissue reaction in the lung parenchyma and lymph nodes intensifies over the next 2-12 weeks as the organisms grow in number and **tissue hypersensitivity** develops. The parenchymal portion of the primary complex often heals completely by fibrosis or calcification after undergoing caseous necrosis and encapsulation (Fig. 261.6). Occasionally, this portion continues to enlarge, resulting in focal pneumonitis and pleuritis. If caseation is intense, the center of the lesion liquefies and empties into the associated bronchus, leaving a residual cavity.

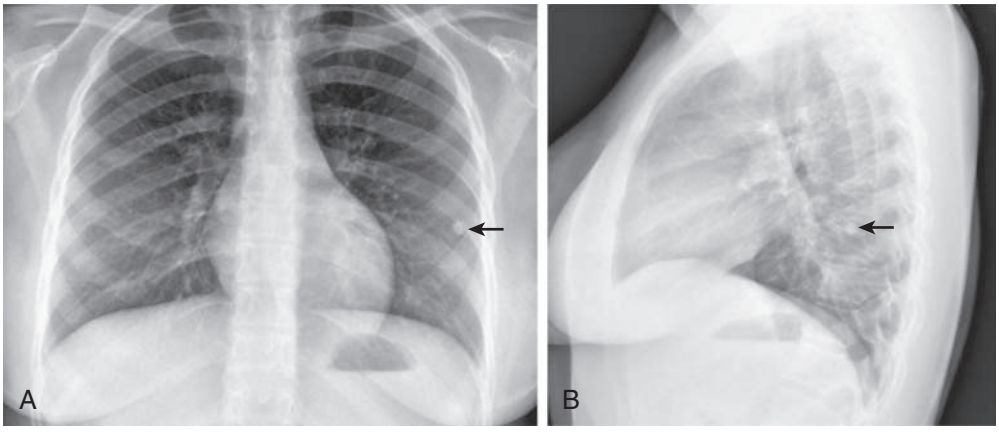

Fig. 261.6 Posteroanterior (A) and lateral (B) chest radiographs of an adolescent showing a 7-mm calcified granuloma in the left lower lobe *(arrows). (From Lighter J, Rigaud M. Diagnosing childhood tuberculosis: traditional and innovative modalities. Curr Probl Pediatr Adolesc Health Care. 2009;39:55–88.)*

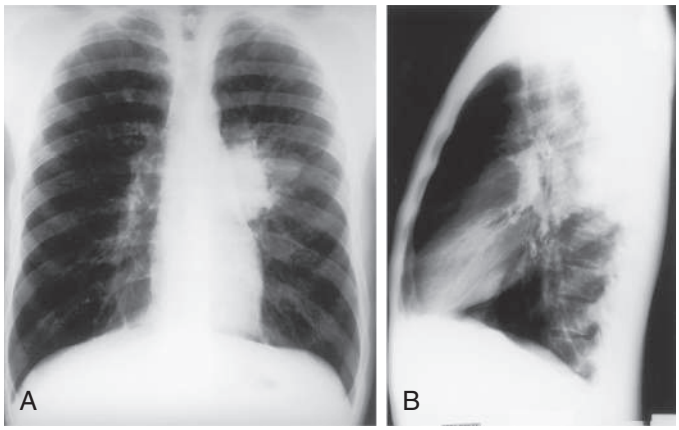

Fig. 261.7 A 14-yr-old child with proven primary tuberculosis. Frontal (**A**) and lateral (**B**) views of the chest show hyperinflation, prominent left hilar lymphadenopathy, and alveolar consolidation involving the posterior segment of the left upper lobe and the superior segment of the left lower lobe. *(From Hilton SVW, Edwards DK, eds. Practical Pediatric Radiology, 3rd ed. Philadelphia: Saunders; 2003:334.)*

Fig. 261.8 An 8-yr-old child with a history of cough. A single frontal view of the chest shows marked right hilar and paratracheal lymphadenopathy with alveolar disease involving the right middle and lower lung fields. This was also a case of primary tuberculosis. *(From Hilton SVW, Edwards DK, eds. Practical Pediatric Radiology, 3rd ed. Philadelphia: Saunders; 2003:335.)*

The foci of infection in the regional lymph nodes develop some fibrosis and encapsulation, but healing is usually less complete than in the parenchymal lesion. Viable *M. tuberculosis* can persist for decades within these foci. In most cases of initial TBI, the lymph nodes remain normal in size. However, hilar and paratracheal lymph nodes that enlarge significantly as part of the host inflammatory reaction can encroach on a regional bronchus (Figs. 261.7 and 261.8). Partial obstruction of the bronchus caused by external compression can cause hyperinflation in the distal lung segment. Complete obstruction results in atelectasis. Inflamed caseous nodes can attach to the bronchial wall and erode through it, causing endobronchial TB or a fistula tract. The caseum causes complete obstruction of the bronchus. The resulting lesion is a combination of pneumonitis and atelectasis and has been called a **collapse-consolidation lesion** or **segmental lesion** (Fig. 261.9).

During the development of the primary complex, tubercle bacilli are carried to most tissues of the body through the blood and lymphatic vessels. Although seeding of the organs of the reticuloendothelial system is common, bacterial replication is more likely to occur in organs with conditions that favor their growth, such as the lung apices, brain, kidneys, and bones. **Disseminated tuberculosis** occurs if the number of circulating bacilli is large and the host's cellular immune response is inadequate. More often, the number of bacilli is small, leading to

Fig. 261.9 Right-sided hilar lymphadenopathy and collapse-consolidation lesions of primary tuberculosis in a 4-yr-old child. *(From Kimberlin DW, Barnett ED, Lynfield R, Sawyer MH (eds). Red Book: 2021-2024 Report of the Committee on Infectious Diseases, 32nd ed. Itasca, IL: American Academy of Pediatrics, 2021. p 805-806; with data from Furin J, Seddon J, Becerra M, et al. Management of Multi-drug-Resistant Tuberculosis Children: A Field Guide, 4th ed. Boston: The Sentinel Project for Pediatric Drug-Resistant Tuberculosis, 2019. clinically inapparent metastatic foci in many organs. These remote foci usually become encapsulated, but they may be the origin of both **extrapulmonary tuberculosis** and **reactivation pulmonary tuberculosis**.

The time between initial infection and clinically apparent TB disease is variable. Disseminated and meningeal TB are early manifestations, often occurring within 2-6 months of acquisition. Significant lymph node or endobronchial TB usually appears within 3-9 months. Lesions of the bones and joints take several years to develop, whereas renal lesions become evident decades after infection. Extrapulmonary manifestations are more common in children than in adults and develop in 25–35% of children with TB vs approximately 10% of immunocompetent adults.

Pulmonary TB that occurs >1 year after the primary infection is usually caused by endogenous regrowth of bacilli persisting in partially encapsulated lesions. This **reactivation TB** is rare in young children but is common among adolescents and young adults. The most common form is an infiltrate or cavity in the apex of the upper lobes, where oxygen tension and blood flow are highest.

The risk for dissemination of *M. tuberculosis* is very high in persons living with HIV. Reinfection also can occur in persons with advanced HIV or AIDS. In immunocompetent persons, the response to the initial infection with *M. tuberculosis* usually provides protection against reinfection when a new exposure occurs. However, exogenous reinfection has been reported to occur in adults and children without immune compromise in highly endemic areas.

Immunity

Conditions that adversely affect cell-mediated immunity predispose to progression from TBI to disease. Rare specific genetic defects (Mendelian susceptibility to mycobacterial disease [MSMD]) associated with deficient cell-mediated immunity in response to mycobacteria include interleukin (IL)-12 receptor B1 deficiency *TYK2* pathogenic gene variants; ~15 other genes associated with primary immunodeficiencies such as *NEMO, STAT1, JAK1,* and *RORC;* and complete and partial interferon (IFN)-γ receptor 1 chain deficiencies. TBI is associated with a humoral antibody response, which plays a little known role in host defense. Shortly after infection, tubercle bacilli replicate in both free alveolar spaces and inactivated alveolar macrophages. Sulfatides in the

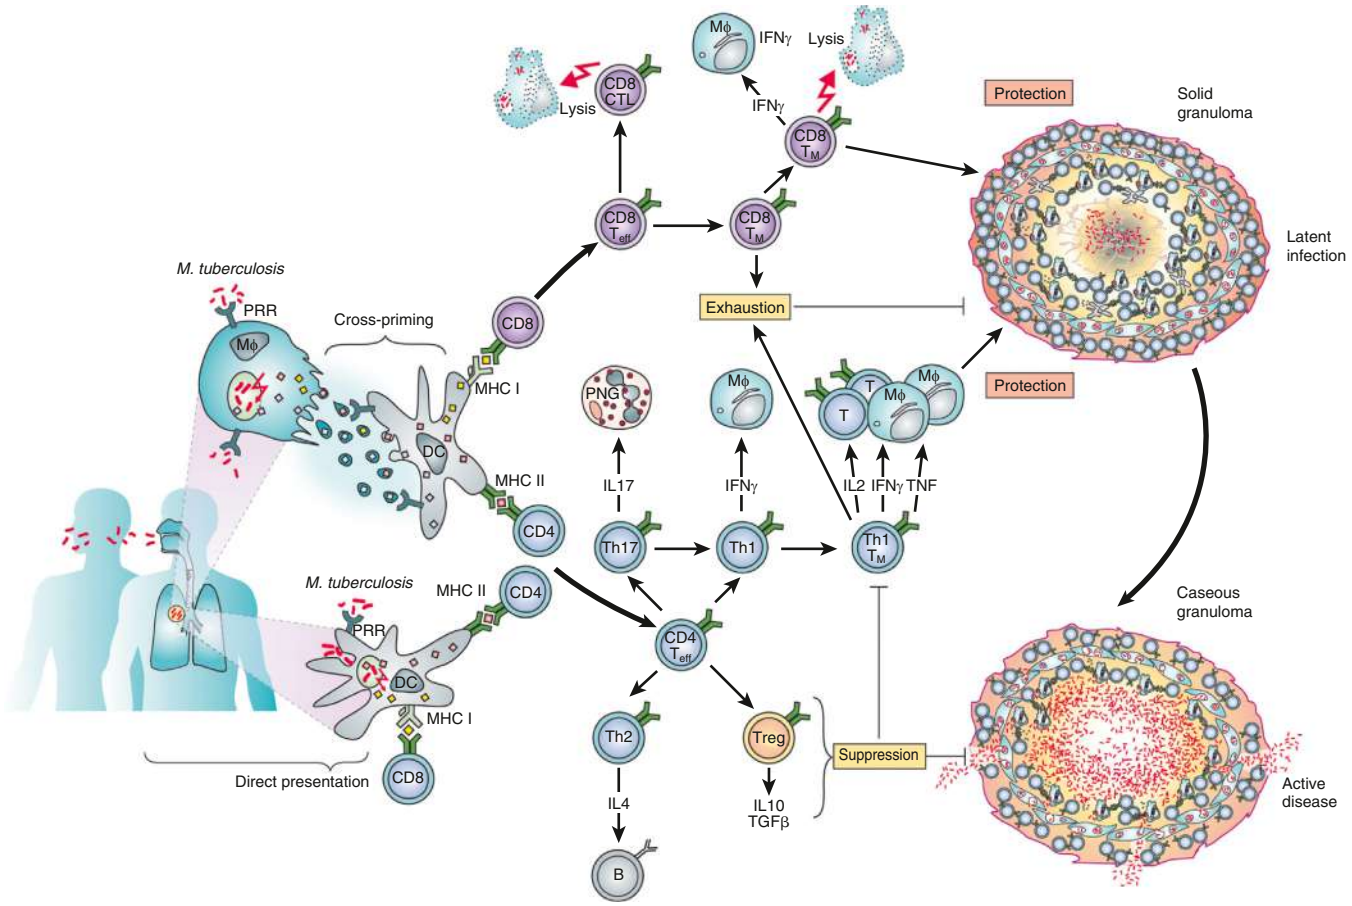

Fig. 261.10 Overview of the immune response in tuberculosis. Control of *Mycobacterium tuberculosis* is mainly the result of productive teamwork between T-cell populations and macrophages (Mø). *M. tuberculosis* survives within macrophages and dendritic cells (DCs) inside the phagosomal compartment. Gene products of major histocompatibility complex (MHC) class II are loaded with mycobacterial peptides that are presented to CD4 T cells. CD8 T-cell stimulation requires loading of MHC I molecules by mycobacterial peptides in the cytosol, either by egression of mycobacterial antigens into the cytosol or cross-priming, by which macrophages release apoptotic bodies carrying mycobacterial peptides. These vesicles are taken up by DCs and peptides presented. The CD4 T-helper (Th) cells polarize into different subsets. DCs and macrophages express pattern recognition receptors (PRRs), which sense molecular patterns on pathogens. Th1 cells produce interleukin (IL)-2 for T-cell activation, interferon-γ (IFN-γ), or tumor necrosis factor (TNF) for macrophage activation. Th17 cells, which activate polymorphonuclear granulocytes (PNGs), contribute to the early formation of protective immunity in the lung after vaccination. Th2 cells and regulatory T cells (Treg) counterregulate Th1-mediated protection via IL-4, transforming growth factor-β (TGF-β), or IL-10. CD8 T cells produce IFN-γ and TNF, which activate macrophages. They also act as cytolytic T lymphocytes (CTLs) by secreting perforin and granulysin, which lyse host cells and directly attack *M. tuberculosis*. These effector T cells (Teff) are succeeded by memory T cells (T_M). T_M cells produce multiple cytokines, notably IL2, IFN-γ, and TNF. During active containment in solid granuloma, *M. tuberculosis* recesses into a dormant stage and is immune to attack. Exhaustion of T cells is mediated by interactions between T cells and DCs through members of the programmed death 1 system. Treg cells secrete IL-10 and TGF-β, which suppress Th1. This process allows resuscitation of *M. tuberculosis,* which leads to granuloma caseation and active disease. B, B cell. *(From Kaufman SHE, Hussey G, Lambert PH. New vaccines for tuberculosis. Lancet. 2010;375:2110–2118.)*

mycobacterial cell wall inhibit fusion of the macrophage phagosome and lysosomes, allowing the organisms to escape destruction by intracellular enzymes. **Cell-mediated immunity** develops 2-12 weeks after infection, along with tissue hypersensitivity (Fig. 261.10). After bacilli enter macrophages, lymphocytes that recognize mycobacterial antigens proliferate and secrete lymphokines and other mediators that attract other lymphocytes and macrophages to the area. Certain lymphokines activate macrophages, causing them to develop high concentrations of lytic enzymes that enhance their mycobactericidal capacity. A discrete subset of regulator helper and suppressor lymphocytes modulates the immune response. Development of specific cellular immunity prevents progression of the initial infection in most persons.

The pathologic events in the initial TBI seem to depend on the balance among the mycobacterial antigen load; cell-mediated immunity (which enhances intracellular killing); and tissue hypersensitivity, which promotes extracellular killing. When the antigen load is small and the degree of tissue sensitivity is high, granuloma formation results from the organization of lymphocytes, macrophages, and fibroblasts. When both antigen load and degree of sensitivity are high, granuloma formation is less organized. Tissue necrosis is incomplete, resulting in formation of caseous material. When the degree of tissue sensitivity is low, as often occurs in infants or immunocompromised persons, the reaction is diffuse and the infection is not well contained, leading to dissemination and local tissue destruction. Tumor necrosis factor (TNF) and other cytokines released by specific lymphocytes promote cellular destruction and tissue damage in susceptible persons.

CLINICAL MANIFESTATIONS

Primary Pulmonary Disease

The **primary complex** includes the parenchymal pulmonary focus and the regional lymph nodes. Approximately 70% of lung foci are subpleural, and localized pleurisy is common. The initial parenchymal inflammation usually is not visible on chest radiograph, but a localized, nonspecific infiltrate may be seen before the development of tissue hypersensitivity. All lobar segments of the lung are at equal risk for initial infection. Two or more primary foci are present in 25% of cases. The hallmark of primary TB in the lung is the relatively large size of the regional lymphadenitis compared with the relatively small size

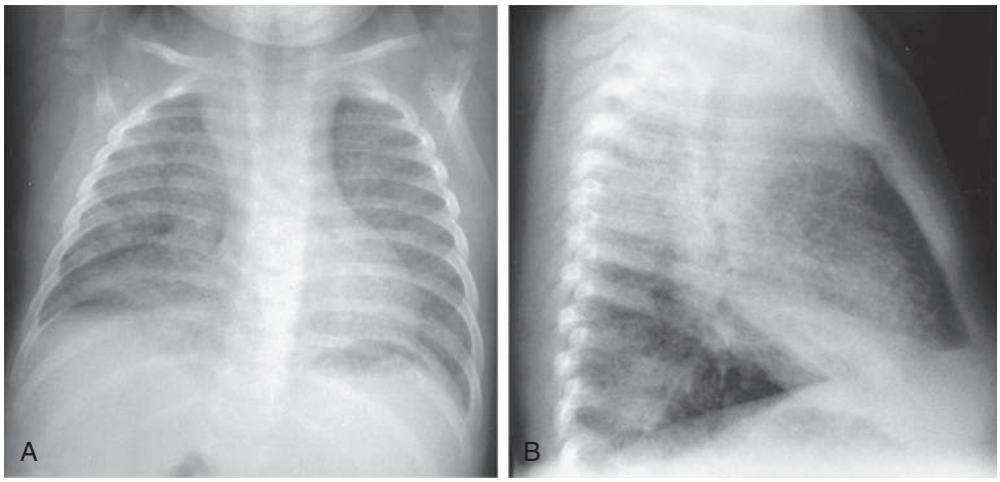

Fig. 261.11 Posteroanterior (A) and lateral (B) chest radiographs of an infant with miliary tuberculosis. The child's mother had failed to complete treatment for pulmonary tuberculosis twice within 3 years of this child's birth.

of the initial lung focus (see Figs. 261.7 and 261.8). As delayed-type hypersensitivity develops, the hilar lymph nodes continue to enlarge in some children, especially infants, compressing the regional bronchus and causing obstruction. The usual sequence is *hilar lymphadenopathy, focal hyperinflation,* and then *atelectasis.* The resulting radiographic shadows have been called **collapse-consolidation** or *segmental* TB (see Fig. 261.9). Rarely, inflamed caseous nodes attach to the endobronchial wall and erode through it, causing endobronchial TB or a fistula tract. The caseum causes complete obstruction of the bronchus, resulting in extensive infiltrate and collapse. Enlargement of the subcarinal lymph nodes can cause compression of the esophagus and, rarely, a bronchoesophageal fistula.

Most cases of tuberculous bronchial obstruction in children resolve fully with appropriate treatment. Occasionally, there is residual calcification of the primary focus or regional lymph nodes. The appearance of calcification implies that the lesion has been present for at least 6-12 months. Healing of the segment can be complicated by scarring or contraction associated with cylindrical bronchiectasis, but this is rare.

Children can have lobar TB pneumonia without impressive hilar lymphadenopathy. If the primary infection is progressively destructive, liquefaction of the lung parenchyma can lead to formation of a thin-walled primary TB cavity. Rarely, bullous tuberculous lesions occur in the lungs and lead to pneumothorax if they rupture. Erosion of a parenchymal focus of TB into a blood or lymphatic vessel can result in dissemination of the bacilli and a **miliary** pattern, with small nodules evenly distributed on the chest radiograph (Fig. 261.11).

The symptoms and physical signs of primary pulmonary TB in children are surprisingly meager considering the degree of radiographic changes often present. When active case finding is performed, up to 50% of infants and children with radiographically moderate to severe pulmonary TB have no physical findings. Infants are more likely to experience signs and symptoms. Nonproductive cough and mild dyspnea are the most common symptoms. Systemic complaints such as fever, night sweats, anorexia, and decreased activity occur less often. Some infants have difficulty gaining weight or develop a true failure-to-thrive syndrome that often does not improve significantly until several months of effective treatment have been taken. Pulmonary signs are even less common. Some infants and young children with bronchial obstruction have localized wheezing or decreased breath sounds that may be accompanied by tachypnea or, rarely, respiratory distress. These pulmonary symptoms and signs are occasionally alleviated by antibiotics, suggesting bacterial superinfection.

Progressive Primary Pulmonary Disease

A rare but serious complication of TB in a child occurs when the primary focus enlarges steadily and develops a large caseous center. Liquefaction can cause formation of a primary cavity associated with large numbers of tubercle bacilli. The enlarging focus can slough necrotic debris into the adjacent bronchus, leading to further intrapulmonary dissemination. Significant signs or symptoms are common in locally progressive disease in children. High fever, severe cough with sputum production, weight loss, and night sweats are common. Physical signs include diminished breath sounds, rales, and dullness or egophony over the cavity. The prognosis for full recovery is excellent with appropriate therapy.

Reactivation Tuberculosis

Pulmonary TB in adults usually represents endogenous reactivation of a site of TBI established previously in the body. This form of TB is rare in childhood but can occur in adolescence. Children with a healed TBI acquired when they were <2 years old rarely develop chronic reactivation pulmonary disease, which is more common in those who acquire the initial infection when they are >7 years old. The most common pulmonary sites are the original parenchymal focus, lymph nodes, and the apical seedings **(Simon foci)** established during the hematogenous phase of the early infection. This form of TB disease usually remains localized in the lungs, because the established immune response prevents further extrapulmonary spread. The most common radiographic findings are extensive infiltrates and thick-walled cavities in the upper lobes.

Older children and adolescents with reactivation TB are more likely to experience fever, anorexia, malaise, weight loss, night sweats, productive cough, hemoptysis, and chest pain than children with primary pulmonary TB. However, physical examination findings usually are minor or absent, even when cavities or large infiltrates are present. Most signs and symptoms improve within several weeks of starting effective treatment, although the cough can last for several months. This form of TB may be highly contagious if there is significant sputum production and cough. The prognosis for full recovery is excellent with appropriate therapy.

Pleural Effusion

Tuberculous pleural effusions, which can be local or general, originate in the discharge of bacilli into the pleural space from a subpleural pulmonary focus or caseated lymph node. Asymptomatic local pleural effusion is so common in primary TB that it is considered part of the primary complex. Larger and clinically significant effusions occur months to years after the primary infection. Tuberculous pleural effusion is uncommon in children <6 years old and rare in children <2 years old. Effusions are usually unilateral but can be bilateral. They are rarely associated with a segmental pulmonary lesion and are uncommon in disseminated TB. Often the radiographic abnormality is more extensive than would be suggested by physical findings or symptoms (Fig. 261.12).

Clinical onset of tuberculous pleurisy is often sudden and characterized by low to high fever, shortness of breath, chest pain on deep inspiration, and diminished breath sounds. The fever and other symptoms can last for several weeks after the start of antituberculosis chemotherapy. The TST is positive in 70–80% of cases. The prognosis is

Fig. 261.12 Pleural tuberculosis in 16-yr-old female.

excellent, but radiographic resolution often takes months. Scoliosis is a rare complication from a long-standing effusion.

Examination of pleural fluid and the pleural membrane is important to establish the diagnosis of tuberculous **pleurisy**. The pleural fluid is usually yellow and only occasionally tinged with blood. The specific gravity is usually 1.012-1.025, the protein level is usually 2-4 g/dL, and the glucose concentration may be low, although it is usually in the low-normal range (20-40 mg/dL). Typically, there are several hundred to several thousand white blood cells per microliter (WBCs/μL), with an early predominance of polymorphonuclear leukocytes (PMNs) followed by a high percentage of lymphocytes. Acid-fast smears of the pleural fluid are rarely positive. Cultures of the fluid are positive in <30% of cases. Measurement of adenosine deaminase (ADA) levels may enhance the diagnosis of pleural TB. Biopsy of the pleural membrane is more likely to yield a positive acid-fast stain or culture, and granuloma formation can be demonstrated.

Pericardial Disease

The most common form of cardiac TB is pericarditis. It is rare, occurring in 0.5–4% of TB cases in children. Pericarditis usually arises from direct invasion or lymphatic drainage from subcarinal lymph nodes. The presenting symptoms are nonspecific, including low-grade fever, malaise, and weight loss. Chest pain is unusual in children. A pericardial friction rub or distant heart sounds with pulsus paradoxus may be present. The pericardial fluid is typically serofibrinous or hemorrhagic. Acid-fast smear of the fluid rarely reveals the organism, but cultures are positive in 30–70% of cases. ADA levels are elevated in TB pericarditis. The culture yield from pericardial biopsy may be higher, and the presence of granulomas often suggests the diagnosis. Partial or complete pericardiectomy may be required when constrictive pericarditis develops.

Lymphohematogenous (Disseminated) Disease

Tubercle bacilli are disseminated to distant sites, including the liver, spleen, skin, and lung apices, in all cases of TBI. Lymphohematogenous spread is usually asymptomatic. Rare patients experience protracted hematogenous TB caused by the intermittent release of tubercle bacilli as a caseous focus erodes through the wall of a blood vessel in the lung. The clinical picture subsequent to lymphohematogenous dissemination depends on the burden of organisms released from the primary focus to distant sites and the adequacy of the host's immune response. Although the clinical picture may be acute, more often it is indolent and prolonged, with spiking fever accompanying the release of organisms into the bloodstream. Multiple organ involvement is common, leading to hepatomegaly, splenomegaly, lymphadenitis in superficial or deep nodes, and papulonecrotic tuberculids appearing on the skin. Bones and joints or kidneys also can become involved. Meningitis occurs only late in the course of the disease. Early pulmonary involvement is surprisingly mild, but diffuse involvement becomes apparent with prolonged infection.

The most clinically significant form of disseminated TB is miliary disease, which occurs when massive numbers of tubercle bacilli are released into the bloodstream, causing disease in two or more organs. **Miliary tuberculosis** usually complicates the primary infection, occurring within 2-6 months of the initial infection. Although this form of disease is most common in infants and young children, it is also found in adolescents and older adults, resulting from the breakdown of a previously healed primary pulmonary lesion. The clinical manifestations of miliary TB are protean, depending on the number of organisms that disseminate and where they lodge. Lesions are often larger and more numerous in the lungs, spleen, liver, and bone marrow than in other tissues. Because this form of TB is most common in infants and malnourished or immunosuppressed patients, the host's immune incompetence likely plays a role in pathogenesis.

Rarely, the onset of miliary TB is explosive, and the patient can become gravely ill in several days. More often, the onset is insidious, with early systemic signs, including anorexia, weight loss, and low-grade fever. At this time, abnormal physical signs are usually absent. Generalized lymphadenopathy and hepatosplenomegaly develop within several weeks in approximately 50% of cases. The fever can then become higher and more sustained, although the chest radiograph usually is normal and respiratory symptoms are minor or absent. Within several more weeks, the lungs can become filled with tubercles, and dyspnea, cough, rales, or wheezing occur. The lesions of miliary TB are usually <2-3 mm in diameter when first visible on chest radiograph (see Fig. 261.11). The smaller lesions coalesce to form larger lesions and sometimes extensive infiltrates. As the pulmonary disease progresses, an alveolar air block syndrome can result in frank respiratory distress, hypoxia, and pneumothorax or pneumomediastinum. Signs or symptoms of meningitis or peritonitis are found in 20–40% of patients with advanced disease. Chronic or recurrent headache in a patient with miliary TB usually indicates the presence of meningitis, whereas the onset of abdominal pain or tenderness is a sign of tuberculous peritonitis. **Cutaneous lesions** include papulonecrotic tuberculids, nodules, or purpura. Choroid tubercles occur in 13–87% of patients and are highly specific for the diagnosis of miliary TB. Unfortunately, the TST is nonreactive in up to 40% of patients with disseminated TB.

Diagnosis of disseminated TB can be difficult, and a high index of suspicion by the clinician is required. Often the patient presents with fever of unknown origin (FUO). Early sputum or gastric aspirate cultures have a low sensitivity. Biopsy of the liver or bone marrow with appropriate bacteriologic and histologic examinations more often yields an early diagnosis. The most important clue is usually a history of recent exposure to an adult with infectious TB.

The resolution of miliary TB is slow, even with proper therapy. Fever usually declines within 2-3 weeks of starting chemotherapy, but the chest radiographic abnormalities might not resolve for many months. Occasionally, corticosteroids hasten symptomatic relief, especially when air block, peritonitis, or meningitis is present. The prognosis is excellent with early diagnosis and adequate chemotherapy.

Upper Respiratory Tract Disease

TB of the upper respiratory tract is rare in developed countries but is still observed in developing countries. Children with laryngeal TB have a crouplike cough, sore throat, hoarseness, and dysphagia. Most children with laryngeal TB have extensive upper lobe pulmonary disease, but occasional patients have primary laryngeal disease with a normal chest radiograph. TB of the middle ear results from aspiration of infected pulmonary secretions into the middle ear or from hematogenous dissemination in older children. The most common signs and symptoms are painless unilateral otorrhea, tinnitus, decreased hearing, facial paralysis, and a perforated tympanic membrane. Enlargement of

Fig. 261.13 Scrofula. Axial CT image of the neck in 8-yr-old male shows calcified right cervical lymphadenopathy *(black arrow)* and tonsillar swelling *(white arrow). (From Lighter J, Rigaud M. Diagnosing childhood tuberculosis: traditional and innovative modalities. Curr Probl Pediatr Adolesc Health Care. 2009;39:55–88.)*

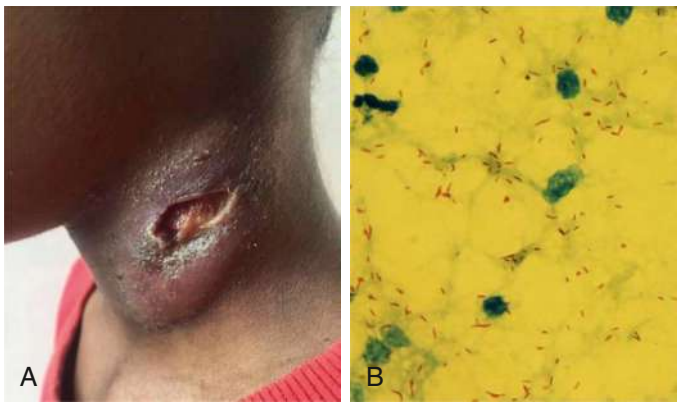

Fig. 261.14 Scrofula. A, Ulcerative lesion 3.2 × 2.1 cm with undermined edges and necrotic base with surrounding induration. B, Acid-fast bacilli. *(From Sharawat IK. Scrofula. J Pediatr. 2017;189:236.)*

lymph nodes in the preauricular or anterior cervical chains can accompany this infection. Diagnosis is difficult, because stains and cultures of ear fluid are often negative, and histology of the affected tissue often shows a nonspecific acute and chronic inflammation without granuloma formation.

Lymph Node Disease

TB of the superficial lymph nodes, often referred to as **scrofula**, is the most common form of extrapulmonary TB in children (Figs. 261.13-261.15). Historically, scrofula was usually caused by drinking unpasteurized cow's milk laden with *M. bovis*. Most current cases occur within 6-9 months of initial infection by *M. tuberculosis,* although some cases appear years later. The tonsillar, anterior cervical, submandibular, and supraclavicular nodes become involved secondary to extension of a primary lesion of the upper lung fields or abdomen. Infected nodes in the inguinal, epitrochlear, or axillary regions result from regional

Fig. 261.15 Scrofula. Tuberculous lymphadenitis with fistula in 4-yr-old male associated with scrofuloderma *(arrows). (From Pereira C, Cascais M, Felix M, Salgado M. Scrofula in a child. J Pediatr. 2017;189:235.)*

lymphadenitis associated with TB of the skin or skeletal system. The nodes usually enlarge gradually in the early stages of lymph node disease. They are discrete, nontender, and firm but not hard. The nodes often feel fixed to underlying or overlying tissue. Disease is most often **unilateral**, but bilateral involvement can occur because of the crossover drainage patterns of lymphatic vessels in the chest and lower neck. As infection progresses, multiple nodes are infected, resulting in a mass of matted nodes. Systemic signs and symptoms other than a low-grade fever are usually absent. The TST is usually reactive. The chest radiograph is often normal (in 70% of cases). The onset of illness is occasionally more acute, with rapid enlargement, tenderness, and fluctuance of lymph nodes and with high fever. The initial presentation is rarely a fluctuant mass with overlying cellulitis or skin discoloration.

Lymph node TB can resolve if left untreated but more often progresses to caseation and necrosis. The capsule of the node breaks down, resulting in the spread of infection to adjacent nodes. Rupture of the node usually results in a draining sinus tract that can require surgical removal. **Tuberculous lymphadenitis** can usually be diagnosed by fine-needle aspiration (FNA) of the node and responds well to antituberculosis therapy, although the lymph nodes do not return to normal size for months or even years. Surgical removal is not usually necessary and must be combined with antituberculosis medication, because the lymph node disease is only one part of a systemic infection.

A definitive diagnosis of tuberculous adenitis usually requires histologic, bacteriologic, or molecular confirmation, which is best accomplished by FNA for culture, molecular testing, stain, and histology. If FNA is not successful in establishing a diagnosis, excisional biopsy of the involved node is indicated. Culture of lymph node tissue yields the organism in only approximately 50% of cases. Many other conditions can be confused with tuberculous adenitis, including infection caused by **nontuberculous mycobacteria (NTM)**, cat scratch disease *(Bartonella henselae),* tularemia, brucellosis, toxoplasmosis, pyogenic infection, or noninfectious causes, including tumor, branchial cleft cyst, and cystic hygroma. The most common problem is distinguishing infection caused by *M. tuberculosis* from lymphadenitis caused by NTM in geographic areas where NTM are common. Both conditions are usually associated with a normal chest radiograph and a reactive TST. An important clue to the diagnosis of tuberculous adenitis is an epidemiologic link to an adult with infectious TB. In areas where both diseases are common, culture or PCR testing of the involved tissue may be necessary to establish the exact cause of the disease.

Central Nervous System Disease

TB of the central nervous system (CNS) is the most serious complication in children and is fatal without prompt and appropriate treatment. **Tuberculous meningitis** usually arises from the formation of a metastatic caseous lesion in the cerebral cortex or meninges that develops

during the lymphohematogenous dissemination of the primary infection. This initial lesion increases in size and discharges small numbers of tubercle bacilli into the subarachnoid space. The resulting gelatinous exudate infiltrates the corticomeningeal blood vessels, producing inflammation, obstruction, and subsequent infarction of the cerebral cortex. The brainstem is often the site of greatest involvement, which accounts for the commonly associated dysfunction of cranial nerves III, VI, and VII. The exudate also interferes with the normal flow of cerebrospinal fluid (CSF) in and out of the ventricular system at the level of the basilar cisterns, leading to a communicating hydrocephalus. The combination of vasculitis, infarction, cerebral edema, and hydrocephalus results in the severe damage that can occur gradually or rapidly. Profound abnormalities in electrolyte metabolism from salt wasting or the syndrome of inappropriate antidiuretic hormone secretion (SIADH) also contribute to the pathophysiology of tuberculous meningitis.

Tuberculous meningitis complicates approximately 0.3% of untreated TBIs in children. It is most common in children 6 months to 4 years old. Occasionally, tuberculous meningitis occurs many years after the infection, when rupture of one or more of the subependymal tubercles discharges tubercle bacilli into the subarachnoid space. The clinical progression of tuberculous meningitis may be rapid or gradual. Rapid progression tends to occur more often in infants and young children, who can experience symptoms for only several days before the onset of acute hydrocephalus, seizures, and cerebral edema. More often, the signs and symptoms progress slowly over weeks and are divided into three stages.

The **first stage** typically lasts 1-2 weeks and is characterized by nonspecific symptoms such as fever, headache, irritability, drowsiness, and malaise. Focal neurologic signs are absent, but infants can experience a stagnation or loss of developmental milestones. The **second stage** usually begins more abruptly. The most common features are lethargy, nuchal rigidity, seizures, positive Kernig and Brudzinski signs, hypertonia, vomiting, cranial nerve palsies, and other focal neurologic signs. The accelerating clinical illness usually correlates with the development of hydrocephalus, increased intracranial pressure, and vasculitis. Some children have no evidence of meningeal irritation but can have signs of encephalitis, such as disorientation, movement disorders, or speech impairment. The **third stage** is marked by coma, hemiplegia or paraplegia, hypertension, decerebrate posturing, deterioration of vital signs, and eventually death.

The prognosis of tuberculous meningitis correlates most closely with the clinical stage of illness at the time treatment is initiated. The majority of patients in the first stage have an excellent outcome, whereas most patients in the third stage who survive have permanent disabilities, including blindness, deafness, paraplegia, diabetes insipidus, or mental retardation. The prognosis for young infants is generally worse than for older children. It is imperative that antituberculosis treatment be considered for any child who develops basilar meningitis and hydrocephalus, cranial nerve palsy, or stroke with no other apparent etiology. Often the key to the correct diagnosis is identifying an adult who has infectious TB and is in contact with the child. Because of the short incubation period of tuberculous meningitis, the illness has not yet been diagnosed in the adult in many cases.

The diagnosis of tuberculous meningitis can be difficult early in its course, requiring a high degree of suspicion on the part of the clinician. The TST is nonreactive in up to 50% of cases, and 20–50% of children have a normal chest radiograph. The most important laboratory test for the diagnosis of tuberculous meningitis is examination and culture of the lumbar CSF. The CSF leukocyte count usually ranges from 10 to 500 cells/μL. PMNs may be present initially, but lymphocytes predominate in the majority of cases. The CSF glucose is typically <40 mg/dL but rarely <20 mg/dL. The protein level is elevated and may be extremely high (400-5,000 mg/dL) secondary to hydrocephalus and spinal block. Although the lumbar CSF is grossly abnormal, ventricular CSF can have normal chemistries and cell counts because this fluid is obtained from a site proximal to the inflammation and obstruction. During early stage one, the CSF can resemble that of viral aseptic meningitis, only to progress to the more severe CSF profile over several weeks. The success of the microscopic examination of acid-fast–stained CSF and mycobacterial culture is related directly to the volume of the CSF sample. Examinations or culture of small amounts of CSF are unlikely to demonstrate *M. tuberculosis.* It is recommended that serial collections of large-volume lumbar CSF (up to 15 mL) be obtained for acid-fast stain and culture. When 5-10 mL of lumbar CSF can be obtained, the acid-fast stain of the CSF sediment is positive in up to 30% of cases and the culture is positive in 50–70% of cases. Polymerase chain reaction (PCR) testing of the CSF and ADA levels can improve the diagnosis. Cultures of other body fluids can help confirm the diagnosis.

Radiographic studies can aid in the diagnosis of tuberculous meningitis. CT or MRI of the brain of patients with tuberculous meningitis may be normal during early stages of the disease. As the disease progresses, basilar enhancement and communicating hydrocephalus with signs of cerebral edema or early focal ischemia are the most common findings (Fig. 261.16). Some young children with tuberculous meningitis have one or several clinically silent tuberculomas, occurring most often in the cerebral cortex or thalamic regions.

Another manifestation of CNS TB is the **tuberculoma,** a tumor-like mass resulting from aggregation of caseous tubercles that usually manifests clinically as a brain tumor. Tuberculomas account for up to 30% of brain tumors in some areas of the world but are rare in North America. In adults, tuberculomas are most often supratentorial, but in children, they are often infratentorial, located at the base of the brain near the cerebellum (Fig. 261.17). Lesions are most often singular but may be multiple. The most common symptoms are headache, fever, focal neurologic findings, and convulsions. The TST is usually reactive, but the chest radiograph is usually normal. Surgical excision is sometimes necessary to distinguish tuberculoma from other causes of brain tumor. However, surgical removal is not necessary because most tuberculomas resolve with medical management. Corticosteroids are administered during the first few weeks of treatment or in the immediate postoperative period to decrease cerebral edema. On CT or MRI of the brain, tuberculomas usually appear as discrete lesions with a significant amount of surrounding edema. Contrast medium enhancement is often impressive and can result in a ringlike lesion. Since the advent of CT, the paradoxical development of tuberculomas in patients with tuberculous meningitis who are receiving ultimately effective chemotherapy has been recognized. The cause and nature of these tuberculomas are poorly understood, but they do not represent failure of antimicrobial treatment. This phenomenon should be considered whenever a child with tuberculous meningitis deteriorates or develops focal neurologic findings during treatment. Corticosteroids

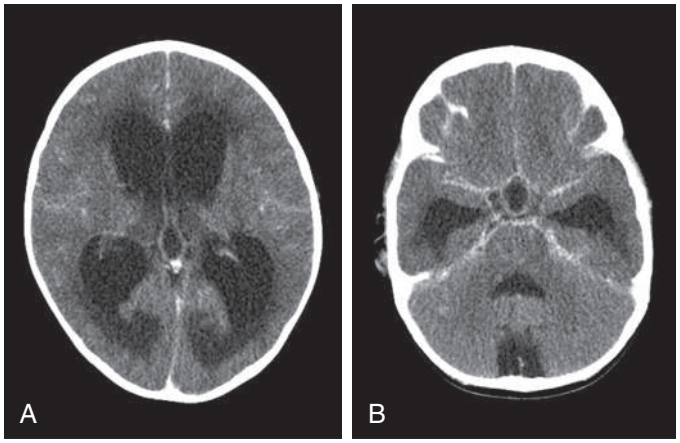

Fig. 261.16 Tuberculous meningitis in a child. **A** and **B**, Postcontrast CT images demonstrate intense enhancement in the suprasellar cistern, sylvian cistern, and prepontine cistern. Dilation of the ventricular system is seen, consistent with associated hydrocephalus. *(From Lerner A, Rajamohan A, Shiroishi MS, et al. Cerebral infections and inflammation. In Haaga JR, Boll DT, eds. CT and MRI of the Whole Body, 6th ed. Philadelphia: Elsevier; 2017: Fig 10-20.)*

can alleviate the occasionally severe clinical signs and symptoms that occur. These lesions can persist for months or years.

Cutaneous Disease

Cutaneous TB is rare in the United States but occurs worldwide and accounts for 1–2% of tuberculosis (see Chapter 706).

Bone and Joint Disease

TB involving bone or joints is most likely to involve the vertebrae. The classic manifestation of **tuberculous spondylitis** is progression to **Pott disease**, in which destruction of the vertebral bodies leads to gibbus deformity and kyphosis (Fig. 261.18) (see Chapter 720.4). **Skeletal tuberculosis** is a late complication of TB and has become a rare entity since the availability of antituberculosis therapy but is more likely to occur in children than in adults. Tuberculous bone lesions can resemble pyogenic and fungal infections or bone tumors. *Multifocal bone involvement can occur.* A bone biopsy is essential to confirm the diagnosis. Surgical intervention is generally not necessary for cure, and the prognosis is excellent with adequate medical treatment. A sterile polyarticular (large joint) arthritis may also be noted in patients with active TB at another site.

Abdominal and Gastrointestinal Disease

TB of the oral cavity or pharynx is quite unusual. The most common lesion is a painless ulcer on the mucosa, palate, or tonsil with enlargement of the regional lymph nodes. TB of the parotid gland has been reported rarely in endemic countries. TB of the esophagus is rare in children but may be associated with a tracheoesophageal fistula in infants. These forms of TB are usually associated with extensive pulmonary disease and swallowing of infectious respiratory secretions. They can occur in the absence of pulmonary disease, by spread from mediastinal or peritoneal lymph nodes.

Tuberculous peritonitis occurs most often in young males and is uncommon in adolescents and rare in children. Generalized peritonitis can arise from subclinical or miliary hematogenous dissemination. Localized peritonitis is caused by direct extension from an abdominal lymph node, intestinal focus, or genitourinary TB. Rarely, the lymph nodes, omentum, and peritoneum become matted and can be palpated as a doughy, irregular, nontender mass. Abdominal pain or tenderness, ascites, anorexia, and low-grade fever are typical manifestations. The TST is usually reactive. The diagnosis can be confirmed by paracentesis with appropriate stains and cultures, but this procedure must be performed carefully to avoid entering a bowel that is adherent to the omentum.

Tuberculous enteritis is caused by hematogenous dissemination or by swallowing tubercle bacilli discharged from the patient's own lungs. The jejunum and ileum near Peyer patches and the appendix are the most common sites of involvement. The typical findings are shallow ulcers that cause pain, diarrhea or constipation, weight loss, and low-grade fever. Mesenteric adenitis usually complicates the infection. The enlarged nodes can cause intestinal obstruction or erode through the omentum to cause generalized peritonitis. The clinical presentation of tuberculous enteritis is nonspecific, mimicking other infections and conditions that cause diarrhea. The disease should be suspected in any child with chronic GI complaints and a reactive TST or positive IGRA. Biopsy, acid-fast stain, and culture of the lesions are usually necessary to confirm the diagnosis.

Genitourinary Disease

Renal TB is rare in children because the incubation period is several years or longer. Tubercle bacilli usually reach the kidney during lymphohematogenous dissemination. The organisms often can be recovered from the urine in cases of miliary TB and in some patients with pulmonary TB in the absence of renal parenchymal disease. In true renal TB, small caseous foci develop in the renal parenchyma and release *M. tuberculosis* into the tubules. A large mass develops near the renal cortex that discharges bacteria through a fistula into the renal pelvis. Infection then spreads locally to the ureters, prostate, or epididymis. Renal TB is often clinically silent in its early stages, marked only by sterile pyuria and microscopic hematuria. Dysuria, flank or abdominal pain, and gross hematuria develop as the disease progresses. Superinfection by other bacteria is common and can delay recognition of the underlying TB. Hydronephrosis or ureteral strictures can complicate the disease. Urine cultures for *M. tuberculosis* are positive in 80–90% of cases, and acid-fast stains of large volumes of urine sediment are positive in 50–70% of cases. The TST is nonreactive in up to 20% of patients. A pyelogram or CT scan often reveals mass lesions, dilation of the proximal ureters, multiple small filling defects, and hydronephrosis if ureteral stricture is present. Disease is most often unilateral.

Genital tract TB is uncommon in prepubescent males and females. This condition usually originates from lymphohematogenous spread, although it can be caused by direct spread from the intestinal tract or bone. Adolescent females can develop genital tract TB during the primary infection. The fallopian tubes are most often involved (90–100% of cases), followed by the endometrium (50%), ovaries (25%), and cervix (5%). The most common symptoms are lower abdominal pain and dysmenorrhea or amenorrhea. Systemic manifestations are usually absent, and the chest radiograph is normal in the majority of cases. The TST is usually reactive. Genital TB in adolescent males causes epididymitis or orchitis. The condition usually manifests as a painless, unilateral nodular swelling of the scrotum. Involvement of the glans

penis is extremely rare. Genital abnormalities and a positive TST in an adolescent male or female suggest genital tract TB.

Pregnancy and the Newborn

Pulmonary and particularly extrapulmonary TB other than lymphadenitis in a pregnant woman is associated with increased risk for prematurity, fetal growth retardation, low birthweight, and perinatal mortality. **Congenital TB** is rare because the most common result of female genital tract TB is infertility. Primary infection in the mother just before or during pregnancy is more likely to cause congenital infection than is reactivation of a previous infection. Congenital transmission usually occurs from a lesion in the placenta through the umbilical vein, when tubercle bacilli infect the fetal liver, where a primary focus with periportal lymph node involvement can occur. Organisms pass through the liver into the main fetal circulation and infect many organs. The bacilli in the lung usually remain dormant until after birth, when oxygenation and pulmonary circulation increase significantly. Congenital TB can also be caused by aspiration or ingestion of infected amniotic fluid. However, the most common route of infection for the neonate is postnatal airborne transmission from an adult with infectious pulmonary TB.

Perinatal Disease

Symptoms of congenital TB may be present at birth but usually begin by the second or third week of life. The most common signs and symptoms are respiratory distress, fever, hepatic or splenic enlargement, poor feeding, lethargy or irritability, lymphadenopathy, abdominal distention, failure to thrive, ear drainage, and skin lesions. The clinical manifestations vary in relation to the site and size of the caseous lesions. Many infants have an abnormal chest radiograph, most often with a miliary pattern. Some infants with no pulmonary findings early in the course of the disease later develop profound radiographic and clinical abnormalities. Hilar and mediastinal lymphadenopathy and lung infiltrates are common. Generalized lymphadenopathy and meningitis occur in 30–50% of infants.

The clinical presentation of TB in newborns is similar to that caused by bacterial sepsis and other congenital infections, such as syphilis, toxoplasmosis, and cytomegalovirus. The diagnosis should be suspected in an infant with signs and symptoms of bacterial or congenital infection whose response to antibiotic and supportive therapy is poor and in whom evaluation for other infections is unrevealing. The most important clue for rapid diagnosis of congenital TB is a maternal or family history of TB. Often, the mother's disease is discovered only after the neonate's diagnosis is suspected. The infant's TST is negative initially but can become positive in 1-3 months. A positive acid-fast stain of an early morning gastric aspirate from a newborn usually indicates TB. Direct acid-fast stains on middle ear discharge, bone marrow, tracheal aspirate, or tissue biopsy (especially liver) can be useful. The CSF should be examined, cultured, and sent for PCR testing. The mortality rate of congenital TB remains very high because of delayed diagnosis. Many children have a complete recovery if the diagnosis is made promptly and adequate chemotherapy is started.

Tuberculosis Disease in Children Living with HIV

In the United States, the rate of TB disease in children living with untreated HIV is 30 times higher than in children without HIV. Establishing the diagnosis of TB in a child living with HIV may be difficult because TST reactivity can be absent (also with a negative IGRA), culture confirmation is difficult, and the clinical features of TB are similar to many other HIV-related opportunistic infections and conditions. TB in children living with HIV is often more severe, progressive, and likely to occur in extrapulmonary sites. Radiographic findings are similar to those in children with normal immune systems, but lobar disease and lung cavitation are more common. Nonspecific respiratory symptoms, fever, and weight loss are the most common complaints. Rates of drug-resistant TB tend to be higher in adults living with HIV and probably are also higher in children living with HIV. Recurrent TB disease and relapsed TB occur more frequently in children living with HIV. The prognosis generally is good if TB disease is not far advanced at diagnosis and appropriate antituberculosis drugs are available.

The mortality rate of children living with HIV with TB is high, especially as the CD4 lymphocyte numbers decrease. In adults, the host immune response to TBI appears to enhance HIV replication and accelerate the immune suppression caused by HIV. Increased mortality rates are attributed to progressive HIV infection rather than TB. Therefore children living with HIV with potential TB exposures and/or recent TBI should be promptly evaluated and treated for TB. Conversely, all children with TB disease should be tested for HIV infection.

Children living with HIV who are given highly active antiretroviral therapy (HAART) are at high risk of developing **immune reconstitution inflammatory syndrome (IRIS)**. IRIS should be suspected in patients who experience a worsening of TB symptoms while receiving antituberculosis therapy (*paradoxical* IRIS) or who develop new-onset TB symptoms and radiographic findings after initiation of HAART (*unmasking* IRIS). Factors suggesting IRIS are temporal association (within 3 months of starting HAART), unusual clinical manifestations, unexpected clinical course, exclusion of alternative explanations, evidence of preceding immune restoration (rise in CD4 lymphocyte count), and decrease in HIV viral load. The most common clinical manifestations of IRIS in children are fever, cough, new skin lesions, enlarging lymph nodes in the thorax or neck, and appearance or enlargement of tuberculomas in the brain, with or without accompanying meningitis. The treatment of TB-associated IRIS in children living with HIV often included steroids but should be undertaken by a clinician with specific expertise in TB treatment.

IMMUNE-BASED TESTING ("TESTS OF TUBERCULOSIS INFECTION")

Tuberculin Skin Testing

The development of delayed-type hypersensitivity in most persons infected with the *M. tuberculosis* complex organisms makes the TST a useful diagnostic tool. The **Mantoux TST** is the intradermal injection of 0.1 mL purified protein derivative stabilized with Tween 80. T cells sensitized by prior infection are recruited to the skin, where they release lymphokines that induce induration through local vasodilation, edema, fibrin deposition, and recruitment of other inflammatory cells to the area. The amount of induration in response to the test should be measured by a trained person 48-72 hours after administration. In some patients, the onset of induration is >72 hours after placement; this is also a positive result. Immediate hypersensitivity reactions to tuberculin or other constituents of the preparation are short-lived (<24 hours) and not considered a positive result. Tuberculin sensitivity develops 3 weeks to 3 months (most often in 4-8 weeks) after inhalation of organisms.

Host-related factors, including very young age, malnutrition, immunosuppression by disease or drugs, viral infections (measles, mumps, varicella, influenza), vaccination with live-virus vaccines, and overwhelming TB, can depress the skin test reaction in a child infected with *M. tuberculosis*. Corticosteroid therapy can decrease the reaction to tuberculin, but the effect is variable; TST done at the time of initiating corticosteroid therapy is usually reliable. Approximately 10% of immunocompetent children with TB disease (up to 50% of those with meningitis or disseminated disease) do not react initially to purified protein derivative; most become reactive after several months of antituberculosis therapy. False-positive reactions to tuberculin can be caused by cross-sensitization to antigens of NTM, which generally are more prevalent in the geographic environment as one approaches the equator. These cross-reactions are usually transient over months to years and produce <10-12 mm of induration, but larger areas of induration can occur. Previous vaccination with bacille Calmette-Guérin (BCG) also can cause a reaction to a TST, especially if a person has received two or more BCG vaccinations. Approximately 50% of the infants who receive a BCG vaccine never develop a reactive TST, and the reactivity usually wanes in 2-3 years in those with initially positive skin test results. Older children and adults who receive a BCG vaccine are more likely to develop tuberculin reactivity, but most lose the reactivity by 5-10 years after vaccination. However,

Table 261.2 Tuberculin Skin Test (TST) or Interferon-γ Release Assay (IGRA): Recommendations for Infants, Children, and Adolescents*

CHILDREN FOR WHOM IMMEDIATE TST OR IGRA IS INDICATED†
Contacts of people with confirmed or suspected contagious tuberculosis (contact investigation)
Children with radiographic or clinical findings suggesting tuberculosis disease
Children immigrating from countries with endemic infection (e.g., Asia, Middle East, Africa, Latin America, countries from former Soviet Union), including international adoptees
Children with travel histories to countries with endemic infection and substantial contact with indigenous people from such countries‡
Children who should have annual TST or IGRA: Children infected with human immunodeficiency virus
CHILDREN AT INCREASED RISK FOR PROGRESSION OF TUBERCULOSIS INFECTION TO TUBERCULOSIS DISEASE
Children with other medical conditions, including diabetes mellitus, chronic renal failure, malnutrition, and congenital or acquired immunodeficiencies, and children receiving tumor necrosis factor (TNF) antagonists deserve special consideration. Without recent exposure, these children are not at increased risk of acquiring tuberculosis infection. Underlying immune deficiencies associated with these conditions theoretically would enhance the possibility for progression to severe disease.
Initial histories of potential exposure to tuberculosis should be included for all of these patients. If these histories or local epidemiologic factors suggest a possibility of exposure, immediate and periodic TST or IGRA should be considered.
An initial TST or IGRA should be performed before initiation of immunosuppressive therapy, including prolonged corticosteroid administration, organ transplantation, or use of TNF-α antagonists or blockers, or immunosuppressive therapy in any child requiring these treatments.

*Bacille Calmette-Guérin immunization is not a contraindication to a TST.
†Beginning as early as 3 mo of age.
‡If the child is well and has no history of exposure, the TST or IGRA should be delayed up to 10 wk after return.
From Kimberlin DW, Barnett ED, Lynfield R, Sawyer MH, eds. *Red Book: 2021–2024 Report of the Committee on Infectious Diseases*, 32nd ed. Itasca, IL: American Academy of Pediatrics; 2021:789.

Table 261.3 Definitions of Positive Tuberculin Skin Test (TST) Results in Infants, Children, and Adolescents*

INDURATION ≥5 MM
Children in close contact with known or suspected contagious people with tuberculosis disease
Children suspected to have tuberculosis disease: • Findings on chest radiograph consistent with active or previously tuberculosis disease • Clinical evidence of tuberculosis disease†
Children receiving immunosuppressive therapy‡ or with immunosuppressive conditions, including HIV infection
INDURATION ≥10 MM
Children at increased risk of disseminated tuberculosis disease: • Children <4 yr old • Children with other medical conditions, including Hodgkin disease, lymphoma, diabetes mellitus, chronic renal failure, or malnutrition (see Table 261.2)
Children with increased exposure to tuberculosis disease: • Children born in high-prevalence regions of the world • Children often exposed to adults with HIV infection, homeless, users of illicit drugs, residents of nursing homes, incarcerated or institutionalized, or migrant farm workers • Children who travel to high-prevalence regions of the world
INDURATION ≥15 MM
Children ≥4 yr old without any risk factors

*These definitions apply regardless of previous BCG immunization; erythema at TST site does not indicate a positive test result. Tests should be read at 48-72 hr after placement.
†Evidence by physical examination or laboratory assessment that would include tuberculosis in the working differential diagnosis (e.g., meningitis).
‡Including immunosuppressive doses of corticosteroids or tumor necrosis factor-α antagonists.
BCG, Bacille Calmette-Guérin; HIV, human immunodeficiency virus.
From Kimberlin DW, Barnett ED, Lynfield R, Sawyer MH, eds. *Red Book: 2021–2024 Report of the Committee on Infectious Diseases*, 32nd ed. Itasca, IL: American Academy of Pediatrics; 2021:788.

some individuals maintain tuberculin reactivity from BCG vaccine for many years. When present, skin test reactivity usually causes <10 mm of induration, although larger reactions occur in some persons.

The appropriate size of induration indicating a positive Mantoux TST result varies with related epidemiologic and risk factors. In children with no TB risk factors, skin test reactions are usually false-positive results. The American Academy of Pediatrics (AAP) and Centers for Disease Control and Prevention (CDC) discourage routine testing of all children and recommend targeted tuberculin testing of children at risk identified through periodic screening questionnaires (Table 261.2). Possible exposure to an adult with or at high risk for infectious pulmonary TB is the most crucial risk factor for children. Reaction size limits for determining a positive TST result vary with the person's risk for infection (Table 261.3). In those at highest risk of progression to TB disease, TST sensitivity is most important, whereas specificity is more important for persons at low risk of progression.

Interferon-γ Release Assay

Two blood tests—T-SPOT.*TB* (Oxford Immunotec; Marlborough, MA) and QuantiFERON-TB Gold/Gold Plus (QFT, Qiagen; Germantown, MD) detect IFN-γ generation by the patient's T cells in response to specific *M. tuberculosis* antigens (ESAT-6, CFP-10, and TB7.7). The QFT test measures whole blood concentrations of IFN-γ, and the T-SPOT.*TB* test measures the number of lymphocytes/monocytes producing IFN-γ. The test antigens are not present on *M. bovis*–BCG (vaccine) and *M. avium* complex, the major group of environmental mycobacteria, so one would expect higher specificity compared with the TST and fewer false-positive results. Both IGRAs have internal positive and negative controls. Internal positive controls allow for detection of an anergic test response, which is useful in children who are young and immunocompromised. Indeterminate (QFT)/invalid (T-SPOT.*TB*) responses occur when the test sample is negative but the positive control has insufficient activity or if the negative control has high background activity. Indeterminate/invalid results are also caused by technical factors (e.g., insufficient shaking of QFT tubes, delayed processing time). Most studies report indeterminate or invalid rates in children of 0–10%, which is influenced by a child's age and immune status. In children <2 years old, indeterminate rates can be as high as 8.1% vs 2.7% in older children, although more recent studies generally report much lower rates. *An indeterminate or invalid IGRA result is neither negative nor positive and cannot be used to guide treatment decisions.*

Some IGRAs cannot differentiate between TBI and TB disease. If available, certain IGRA tests will test CD4 and CD8 T-cell reactivity, which may help differentiate latent from active disease. Two clear advantages of the IGRAs are the need for only one patient encounter (vs two with TST) and the lack of cross-reaction with BCG vaccination and most other mycobacteria, thereby increasing test specificity for TBI. Studies comparing IGRA and TST performance in children have shown comparable sensitivity (85% in culture-confirmed children) between the two tests and superior IGRA specificity (95% vs 49%) in BCG-immunized, low-risk children.

Neither the TST nor the IGRAs perform well in infants and young children who are malnourished, severely immunocompromised, or have disseminated TB disease. It is now standard to use an IGRA in the evaluation of healthy young children ≥2 years of age, and most experts use IGRAs in younger children who are at low risk of TB infection, especially in those who have received a BCG vaccine. Both TST and

Table 261.4 Recommendations for Use of Tuberculin Skin Test (TST) and Interferon-γ Release Assay (IGRA) in Children

TST preferred, IGRA acceptable:
- Children <2 yr of age*

IGRA preferred, TST acceptable:
- Children ≥2 yr of age who have received BCG vaccine
- Children ≥2 yr of age who are unlikely to return for TST reading

TST and IGRA should be considered when:
- The initial and repeat IGRAs are indeterminate or invalid
- The initial test (TST or IGRA) is negative and:
  - Clinical suspicion for TB disease is moderate to high†
  - The child has a TB risk factor and is at high risk of progression and poor outcome (especially therapy with an immunomodulating biologic agent, e.g., TNF-α antagonist)†
- The initial TST is *positive* and:
  - ≥2 yr old and history of BCG vaccination
  - Additional evidence needed to increase adherence with therapy

*Some experts do not use an IGRA for children younger than 2 yr because of a relative lack of data for this age-group and the high risk of progression to disease.
†Positive result of either test is considered significant in these groups.
BCG, Bacille Calmette-Guérin; TB, tuberculosis, TNF, tumor necrosis factor.
Adapted from Starke JR, AAP Committee of Infectious Diseases. Interferon-γ release assays for diagnosis of tuberculosis infection and disease in children. *Pediatrics.* 2014;134(6):e1763–1773.

IGRA testing should be considered in children whose initial TST or IGRA result is negative for whom the risk of TB is high (to enhance the sensitivity of the combination of the two tests).

Technical advantages of the IGRAs over the TST include the need for a single patient encounter (vs two spaced in time with the TST), the lack of cross-reaction with BCG vaccination and most environmental mycobacteria, and eliminating the need for experience in correctly interpreting the TST. IGRAs are also useful for those who are unlikely to return for TST interpretation, those whose family is reluctant to treat a child with TBI based on a TST result alone, and those with a positive TST result in whom NTM disease is suspected (Table 261.4).

Most studies have shown no consistent, significant difference between the two commercially available IGRAs, and the CDC recommends no preference. Because of cost constraints, the WHO does not endorse IGRA use in low- and middle-income countries, even in those with a high prevalence of tuberculosis.

MYCOBACTERIAL SAMPLING, SUSCEPTIBILITY, AND CULTURE

The most specific confirmation of pulmonary TB is isolation of *M. tuberculosis* from a clinical sample. Sputum specimens for culture should be collected from adolescents and older children who are able to expectorate. Induced sputum with a jet nebulizer, inhaled saline, and chest percussion followed by nasopharyngeal suctioning is effective in children as young as 1 year. Sputum induction provides samples for both culture and acid-fast bacilli (AFB) staining. The traditional culture specimen in young children is the early morning gastric acid obtained before the child has arisen and peristalsis has emptied the stomach of the pooled respiratory secretions that have been swallowed overnight. However, even under optimal conditions, three consecutive morning gastric aspirates yield the organisms in <50% of cases. The culture yield from bronchoscopy is even lower, but this procedure can demonstrate the presence of endobronchial disease or a fistula. To improve the sensitivity of a diagnosis of TB in children, in high-burden TB settings, there is an increasing trend to collect nontraditional specimens, including stool, nasopharyngeal, and urine specimens. These specimens are easier to obtain than respiratory specimens but less sensitive in diagnosing TB in children compared to sputum or serial gastric aspirate specimens. Their diagnostic utility is increased when multiple specimens are collected in conjunction with traditional respiratory specimens. *Negative cultures never exclude the diagnosis of TB in a child.* The presence of a positive TST or IGRA, an abnormal chest radiograph consistent with TB, and history of recent exposure to an adult with infectious TB is highly suggestive of the clinical diagnosis of TB disease. If a likely adult source case has been identified, drug susceptibility test results of the isolate from the adult source usually can be used to determine the best therapeutic regimen for the child, except in very high-incidence areas, where the apparent source case might not be the actual one. Cultures should be always obtained from the child whenever the source case is unknown, there are multiple possible source cases, or the source case has possible or confirmed drug-resistant TB.

Confirmation of extrapulmonary TB is best achieved with a positive culture or PCR testing. However, for many forms of TB, the culture yield is only 25–50%, and probable diagnosis is by a combination of clinical signs and symptoms, analysis of body fluids when possible, radiographic or histopathologic evidence of TB, PCR testing, and elimination of other possible diagnoses.

Nucleic Acid Amplification Tests

The main NAAT studied in children with TB is PCR, which uses specific DNA sequences as markers for microorganisms. Compared with a clinical diagnosis of pulmonary TB in children, the sensitivity of PCR has varied from 25% to 83%, and specificity has varied from 80% to 100%. A negative PCR result never eliminates the diagnosis of TB, and the diagnosis is not confirmed by a positive PCR result.

NAAT identifies genes associated with drug resistance and is used to supplement culture-based (phenotypic) methods for drug susceptibility testing. It also decreases the time to identification of drug resistance from weeks to hours, which expedites the initiation of optimal therapy. Culture-based, phenotypic, drug susceptibility testing is necessary to confirm susceptibility to each drug; the absence of resistance genes is not always predictive of drug susceptibility. The interpretation of molecular-based drug susceptibility testing is constantly evolving, and an expert in the management of pediatric TB should be involved when drug resistance is suspected.

Gene Xpert MTB/RIF cartridge and Xpert MTB Ultra cartridge (Xpert; Cepheid, Sunnyvale, CA) are real-time PCR assays for *M. tuberculosis* that simultaneously detect **rifampin resistance**, which is often used as a proxy for MDR-TB. These assays use a self-contained cartridge system, which yields results from direct specimens in 2 hours and is less operator dependent than traditional PCR detection methods. Sensitivity and specificity of Xpert MTB/RIF have averaged 72–77% and 99% in AFB sputum smear–negative adults and 98–99% and 99–100% in AFB sputum smear–positive adults, respectively. Pediatric studies reveal that, compared to culture, the sensitivity and specificity of Xpert MTB/RIF is 62% and 98% on induced or expectorated sputa and 66% and 98% on gastric aspirates, respectively. For other specimen types (nasopharyngeal aspirate and stool), Xpert MTB/RIF pooled sensitivity for pulmonary TB ranges between 46% and 73% with a pooled specificity of 98% and 100%. Compared with smear microscopy, Xpert improved the sensitivity of detecting pediatric TB cases by 36–44%. For lymph node aspirates or biopsies, Xpert MTB/RIF compared with culture had a sensitivity and specificity of 90%. Compared to culture, Xpert MTB/RIF's sensitivity and specificity to detect rifampin resistance in respiratory specimens collected from children with suspected pulmonary TB are 86% and 98%, respectively.

Xpert Ultra is a next-generation assay that has enhanced performance in children who often have paucibacillary or smear-negative TB. The pooled sensitivity of Ultra for detection of *M. tuberculosis* was 73% in sputum samples, 64% in gastric aspirate samples, 53% in stool specimens, and 46% in nasopharyngeal samples. The pooled specificity was 98% in sputum samples, 98% in nasopharyngeal aspirate specimens, 98% in stool samples, and 95% in gastric aspirate samples. The WHO recommends use of Xpert Ultra in sputum and nasopharyngeal specimens collected from children for the diagnosis of TB and rifampin resistance, in addition to the use of Xpert MTB/RIF in sputum, gastric aspirate, nasopharyngeal aspirate, and stool specimens. Although cartridges for the Xpert systems are expensive, they offer advantages in rapid detection of MDR-TB and are especially useful in settings lacking

laboratory infrastructure. In many low-resource settings, Xpert has replaced smear microscopy; however, it has not replaced mycobacterial cultures and drug susceptibility studies.

TREATMENT

The basic principles of management of TB disease in children and adolescents are the same as in adults. Several drugs are used to effect a relatively rapid cure and prevent the emergence of secondary drug resistance during therapy (Tables 261.5 to 261.8). The choice of regimen depends on the extent of TB disease, the host, and the likelihood of drug resistance (see Chapter 260, Table 260.1). As recommended by the WHO and AAP, *the standard therapy of intrathoracic, presumed or confirmed drug-susceptible TB (pulmonary disease and/or hilar lymphadenopathy) in children is a 4- to 6-month regimen of multidrug therapy. The initial treatment regimen includes isoniazid, rifampin, pyrazinamide, and ethambutol.* The ethambutol can be discontinued once the organism is known to be susceptible to the other first-line drugs. Pyrazinamide is discontinued after 2 months, and isoniazid and rifampin are continued for an additional 2-4 months. Several clinical trials have shown that a 6-month regimen yields a success rate approaching 100%, with an incidence of clinically significant adverse reactions of <2%. Data from the SHINE trial (Shorter Treatment for Minimal Tuberculosis in Children) found that a 4-month treatment regimen in children age 0-16 years (≥3 kg) with nonsevere, smear negative, presumed drug-susceptible TB was noninferior to a 6-month course. Based on the results of this trial, the WHO supports the use of a 4-month treatment regimen in eligible children. Most experts recommend that all drug administration be either directly observed or electronically observed, meaning that a healthcare worker watches when the medications are administered to/or taken by the patients. When in-person **directly observed therapy (DOT)** or video directly observed therapy (VDOT) is used, intermittent (twice or thrice weekly) administration of drugs after an initial period as short as 2 weeks of daily therapy is as effective for drug-susceptible TB in children as daily therapy for the entire course.

Table 261.5 Dosage Recommendations for the Treatment of TB in Adults and Children[1]

			DOSE IN MG/KG (MAXIMUM DOSAGE IN PARENTHESES)			
DRUG	**ADULTS/CHILDREN[2]**		**DAILY**	**1 TIME/WK[3]**	**2 TIMES/WK[3]**	**3 TIMES/WK[3]**
Isoniazid	Adults		5 mg/kg (300 mg)	15 mg/kg (900 mg)	15 mg/kg (900 mg)	15 mg/kg (900 mg)
	Children		10– 15 mg/kg (300 mg)	—	20– 30 mg/kg (900 mg)	—
Rifampin	Adults		10 mg/kg (600 mg)	—	10 mg/kg (600 mg)	10 mg/kg (600 mg)
	Children		10– 20 mg/kg (600 mg)	—		10– 20 mg/kg (600 mg)
Rifabutin	Adults		5 mg/kg (300 mg)	—	5 mg/kg (300 mg)	5 mg/kg (300 mg)
	Children ≥12 yr		Appropriate dosing for children unknown			
Rifapentine	Adults		—	10 mg/kg (600 mg; continuation phase)	—	—
	Children					
Pyrazinamide	Adults (weight)	40– 55 kg	18.2– 25 mg/kg (1000 mg)	—	36.4– 50 mg/kg (2000 mg)	27.3– 37.5 mg/kg (1500 mg)
		56– 75 kg	20– 26.8 mg/kg (1500 mg)	—	40– 53.6 mg/kg (3000 mg)	33.3– 44.6 (2500 mg)
		76– 90 kg	22.2– 26.3 mg/kg (2000 mg)	—	44.4– 52.6 mg/kg (4000 mg)	33.3– 39.5 mg/kg (3000 mg)
	Children <40 kg		30– 40 mg/kg (2000 mg)	—		50 mg/kg (2000 kg)
Ethambutol[4]	Adults (weight)	40– 55 kg	14.5– 20 mg/kg (800 mg)	—	36.4– 50 mg/kg (2000 mg)	21.8– 30 mg/kg (1200 mg)
		56– 75 kg	16– 21.4 mg/kg (1200 mg)	—	37.3– 50 mg/kg (2800 mg)	26.7– 35.7 mg/kg (2000 mg)
		76– 90 kg	17.8– 21.1 mg/kg (1600 mg)	—	44.4– 52.6 mg/kg (4000 mg)	26.7– 31.6 mg/kg (2400 mg)
	Children		15– 20 mg/kg (1000 mg)	—	50 mg/kg (2500 mg)	—

[1]Although these regimens are broadly applicable, modifications may be needed for certain circumstances (patients on antiretroviral therapy [ART]). For more information, refer to treatment of tuberculosis guidelines. *MMWR* 2003; 52 (No.RR-11).
[2]For purposes of this document, adult dosing begins at age 15 years. Children weighing more than 40 kg should be dosed as adults. Adjust doses as the patient's weight changes.
[3]All patients prescribed an intermittent regimen should be given DOT.
[4]Ethambutol should be used with caution in young children since it is difficult to monitor their vision. However, if they have TB that is resistant to INH or RIF, a dose of 15 mg/kg per day can be used.

Table 261.6 Common Adverse Reactions to TB Drugs

CAUSED BY	ADVERSE REACTION	SIGNS AND SYMPTOMS	SIGNIFICANCE OF REACTION*
Any drug	Allergic	• Skin rash	May be serious or minor
Ethambutol	Eye damage	• Blurred or changed vision • Changed color vision	Serious
Isoniazid Pyrazinamide Rifampin	Hepatic toxicity	• Abdominal pain • Abnormal liver function test results • Dark urine • Fatigue • Fever for 3 or more days • Flulike symptoms • Lack of appetite • Nausea • Vomiting • Yellowish skin or eyes	Serious
Isoniazid	Nervous system damage	• Dizziness; tingling or numbness around the mouth	Serious
	Peripheral neuropathy	• Tingling sensation in hands and feet	Serious
Pyrazinamide	Stomach upset	• Stomach upset • Vomiting • Lack of appetite	May be serious or minor
	Gout	• Abnormal uric acid level** • Joint aches	Serious
Rifampin	Bleeding problems	• Easy bruising • Slow blood clotting	Serious
	Discoloration of body fluids	• Orange urine, sweat, or tears • Permanently stained soft contact lenses	Minor
	Drug interactions	• Interferes with certain medications such as birth control pills, birth control implants, and methadone treatment	May be serious or minor
	Sensitivity to the sun	• Frequent sunburn	Minor

*Patients should stop medication for serious adverse reactions and consult a clinician immediately. Patients can continue taking medication if they have minor adverse reactions.
**Asymptomatic elevated uric acid levels are expected with PZA treatment. Acute gouty arthritis, which is rare without preexisting gout, is a contraindication to PZA use.

Table 261.8 Drug Grouping for the Treatment of MDR-TB

GROUP	INSTRUCTIONS	DRUG
Group A	Include all three drugs (unless they cannot be used), add delamanid if age >3 yr	Levofloxacin OR moxifloxacin Bedaquiline Linezolid
Group B	Add both drugs (unless they cannot be used)	Clofazimine Cycloserine or terizidone
Group C	Add to complete regimen (of four to five agents) Add when drugs from groups A or B cannot be used	Ethambutol Delamanid Pyrazinamide Imipenem-cilastatin Meropenem Amikacin OR streptomycin Ethionamide OR prothionamide *p*-Aminosalicylic acid

Extrapulmonary tuberculosis is usually caused by small numbers of mycobacteria. In general, the treatment for most forms of extrapulmonary TB in children, including cervical lymphadenopathy, is the same as for pulmonary TB. *Exceptions are bone and joint, disseminated, and CNS TB, for which there are inadequate data to recommend 6 months of therapy; these conditions are usually treated for 9-12 months.* Surgical debridement in bone and joint disease and ventriculoperitoneal shunting in CNS disease may be necessary adjuncts to medical therapy.

The optimal treatment of TB in children living with HIV has not been established. Adults living with HIV with TB disease can be treated successfully with standard regimens that include isoniazid, rifampin, pyrazinamide, and ethambutol. The total duration of therapy should be 6-9 months or 6 months after culture of sputum becomes sterile, whichever is longer. Data for children are limited to relatively small series. *Most experts believe that children living with inadequately controlled HIV who have drug-susceptible TB should receive the standard four-drug regimen for the first 2 months followed by isoniazid and rifampin for a total duration of at least 9 months. However, all treatment should be daily, not intermittent.* Children living with HIV appear to have more frequent adverse reactions to antituberculosis drugs and must be monitored closely during therapy. Co-administration of rifampin and some antiretroviral agents results in subtherapeutic blood levels of protease inhibitors and nonnucleoside reverse transcriptase inhibitors and toxic levels of rifampin. Concomitant administration of these drugs is not recommended. Treatment of children living with HIV with TB is often empirically based on epidemiologic and radiographic information because the radiographic appearance of other pulmonary complications of HIV in children, such as lymphoid interstitial pneumonitis and bacterial pneumonia, may be similar to that of TB. Therapy should be considered when TB cannot be excluded.

Drug-Resistant Tuberculosis

The incidence of drug-resistant TB is increasing in many areas of the world, including North America. There are two major types of drug resistance. **Primary resistance** occurs when a person is infected with *M. tuberculosis* that is already resistant to a particular drug. **Secondary resistance** occurs when drug-resistant organisms emerge as the dominant population during treatment. The major causes of secondary drug resistance are poor adherence to the medication by the patient or inadequate treatment regimens prescribed by the physician. Nonadherence to one drug is more likely to lead to secondary resistance than is failure to take all drugs. Secondary resistance is rare in children because of the small size of their mycobacterial population. Consequently, most drug resistance in children is primary, and patterns of drug resistance among children tend to mirror those found among adults in the same population. The main predictors of drug-resistant TB among adults are history of previous antituberculosis treatment, co-infection with HIV, and exposure to another adult with infectious drug-resistant TB.

Treatment of drug-resistant TB is successful only when at least two bactericidal drugs are given to which the infecting strain of M. tuberculosis is susceptible. When a child has possible drug-resistant TB, usually at least four or five drugs should be administered initially until the susceptibility pattern is determined and a more specific regimen can be designed. The specific treatment plan must be individualized for each patient according to the results of susceptibility testing on the isolates from the child or the adult source case. Treatment duration of 9 months with rifampin, pyrazinamide, and ethambutol is usually adequate for isoniazid-resistant TB in children. High-dose isoniazid is often added in those with low-level isoniazid-resistant TB. The recommendations for the treatment of MDR-TB have rapidly evolved in recent years. In 2019, the WHO advocated for the use of all-oral (injectable-free) regimens and reprioritized the order of the available oral drugs (Tables 261.8 and 261.9). Treatment regimens should prioritize administering group A and B drugs in addition to delamanid for children older than 3 years of age. Bedaquiline can be used in those older than 6 years of age. First-line treatment includes an all-oral regimen using three group A drugs and at least one group B drug. If only one or two group A medications are used, then group B drugs should be added to make a regimen of four drugs. Group C drugs are only used if the isolate is susceptible and when drugs from groups A and B cannot be used. The WHO recommends treatment of those with severe MDR-TB disease for 12-18 months; however, in children younger than 15 years with less severe MDR-TB disease, the treatment duration can be shortened to 9-12 months. The WHO defines severe MDR-TB disease as children with cavities or bilateral parenchymal disease on chest radiography or extrapulmonary forms of disease other than lymphadenopathy. Those with severe malnutrition; advanced immunosuppression; or positive smear, NAAT, or culture are also often treated with a longer course of therapy.

The second-line drugs require close monitoring for adverse effects and toxicity (see Table 261.9). The prognosis of single-drug–resistant or MDR-TB in children with nonsevere disease is good if the drug resistance is identified early in the treatment, if appropriate drugs are administered under DOT, if adverse reactions from the drugs are minor, and if the child and family are in a supportive environment. The treatment of drug-resistant TB in children always should be undertaken by a clinician with specific expertise in TB treatment.

Corticosteroids

Corticosteroids are useful in treating some children with TB disease. They are most beneficial when the host inflammatory reaction contributes significantly to tissue damage or impairment of organ function. There is convincing evidence that corticosteroids decrease mortality rates and long-term neurologic sequelae in some patients with **tuberculous meningitis** by reducing vasculitis, inflammation, and ultimately intracranial pressure. Lowering the intracranial pressure limits tissue damage and favors circulation of antituberculosis drugs through

Table 261.9 Drugs Used for Treating Drug-Resistant Tuberculosis in Infants, Children, and Adolescents*

DRUGS	DOSAGE, FORMS	DAILY DOSAGE (mg/kg)	MAXIMUM DOSE	ADVERSE REACTIONS
Amikacin†	Vials: 500 mg, 1 g	15-20 (IV or IM administration)	1 g	Auditory and vestibular toxic effects, nephrotoxic effects
Amoxicllin-clavulanate	(Strength expressed in terms of amoxicillin component) Syrup: 50 mg/mL 80 mg/mL 120 mg/mL (ES 600) Tablets: 500 mg 875 mg 1000 mg (XR tablet)	40 (amoxicillin component), twice daily	4 g (amoxicillin) 500 mg (clavulanate)	Abdominal pain, diarrhea, rash
Bedaquiline	Tablets: 20 mg, 100 mg	Adults and children ≥5 yr, 15 to <30 kg weeks 1-2: 200 mg/day; weeks 3-24: 100 mg 3x/week > 30 kg weeks 1-2: 400 mg/day; weeks 3-24: 200 mg 3x/week	600 mg/week	QTc prolongation, reduced levels with efavirenz co-administration
Clofazimine	Gelcaps: 50 mg 100 mg	2-5 per day	100 mg	QTc prolongation, reversible skin pigmentation
Cycloserine or terizidone	Capsules: 250 mg	10-20, given in 2 divided doses	1 g	Psychosis, personality changes, seizures, rash
Delamanid	Tablets: 50 mg 100 mg	6–11 years: 50 mg 2x/day 12–17 years: 100 mg 2x/day	100 mg/dose	QTc prolongation, adverse events with hypoalbuminemia, avoid if metronidazole allergic
Ethambutol	Tablets: 100 mg 400 mg	Children <40 kg: 15–25 Children ≥40 kg: 40-55 kg: 800 mg/ day PO 56-75 kg: 1200 mg/ day PO 76-90 kg: 1600 mg/ day PO	2.5 g	Optic neuritis (usually reversible), decreased red-green color discrimination, gastrointestinal tract disturbances, hypersensitivity
Ethionamide	Tablets: 125 mg 250 mg	15-20, given in 1–2 divided doses	1 g	GI tract disturbances, hepatotoxic effects, hypersensitivity reactions, hypothyroidism
Imipenem-cilastatin		60-100 per day, divided in 4 doses	4 g	Anemia, thrombocytopenia, eosinophilia, elevated liver enzymes
Levofloxacin	Tablets: 250 mg 500 mg 750 mg Oral solution: 25/mL Vials: 25 mg/mL	Adults: 750-1000 mg (daily) Children: 15-20 mg/kg daily	1 g	Theoretic effect on growing cartilage, joint pain, GI tract disturbances, rash, headache, restlessness, confusion
Linezolid	Tablets: 400 mg 600 mg Syrup: 20 mg/mL	Children <16 kg: 15 mg/kg once daily Children >16 kg: 10-12 mg/kg/day once daily	600 mg if ≥12 yr 300 mg if <12 yr	Bone marrow suppression, peripheral neuropathy, lactic acidosis, potential overlapping toxicity with nucleoside reverse transcriptase inhibitors
Moxifloxacin	Tablets: 400 mg IV solution: 400 mg/250 mL in 0.8% saline	Adults/adolescents: 400 mg Children: 10-15 mg/kg daily	400 mg; maximum doses of 600-800 mg per day are used for higher MIC or in malabsorption	Arthropathy, arthritis
p-Aminosalicylic acid (PAS)	Packets: 3 g	200-300 (2-4 times a day)	10 g	GI tract disturbances, hypersensitivity, hepatotoxic effects
Prothionamide	Tablets: 250 mg 500 mg	15-20 (divided twice daily)	1 g	GI tract disturbances, hepatotoxic effects, hypersensitivity reactions, hypothyroidism

Table 261.9 Drugs Used for Treating Drug-Resistant Tuberculosis in Infants, Children, and Adolescents*—cont'd

DRUGS	DOSAGE, FORMS	DAILY DOSAGE (mg/kg)	MAXIMUM DOSE	ADVERSE REACTIONS
Pyrazinamide	Scored tablets: 500 mg	30-40	2 g	Hepatotoxic effects, hyperuricemia, arthralgias, gastrointestinal tract upset
Streptomycin†	Vials: 1 g 4 g	20-40 (IM administration)	1 g	Auditory and vestibular toxic effects, nephrotoxic effects, rash

the brain and meninges. Short courses of corticosteroids also may be effective for children with **endobronchial tuberculosis** that causes respiratory distress, localized emphysema, or segmental pulmonary lesions. Several randomized clinical trials have shown that corticosteroids can help relieve symptoms and constriction associated with acute tuberculous **pericardial effusion**. Corticosteroids can cause dramatic improvement in symptoms in some patients with tuberculous pleural effusion and shift of the mediastinum. However, the long-term course of the disease is probably unaffected. Some children with severe **miliary tuberculosis** have dramatic improvement with corticosteroid therapy if the inflammatory reaction is so severe that alveolocapillary block is present. There is no convincing evidence to support a specific corticosteroid preparation. The most common regimen is **prednisone** 1-2 mg/kg/day in one to two divided doses orally for 4-6 weeks followed by a taper.

Supportive Care

Children receiving TB treatment should be followed carefully to promote **adherence** to therapy, to monitor for toxic reactions to medications, and to ensure that the TB is being adequately treated. Adequate **nutrition** is important. Patients should be seen at monthly intervals and should be given just enough medication to last until the next visit. **Anticipatory guidance** with regard to the administration of medications to children is crucial. The physician should foresee difficulties that the family might have in introducing several new medications in inconvenient dosage forms to a young child. The clinician must report all cases of suspected TB in a child to the local health department to be sure that the child and family receive appropriate care and evaluation.

Nonadherence to TB treatment is the major problem. The patient and family must know what is expected of them through verbal and written instructions in their primary language. Approximately 30–50% of patients taking long-term treatment are significantly nonadherent with self-administered medications, and clinicians are usually not able to determine in advance which patients will be nonadherent. Preferably, DOT should be instituted by the local health department.

Mycobacterium tuberculosis Infection

The following aspects of the natural history and treatment of TBI, often referred to as *latent TB infection,* in children must be considered in the formulation of recommendations about therapy:

1. Infants and children <5 years old with TBI who have been infected recently.
2. The risk for progression to disease is high.
3. Untreated infants with TBI have up to a 40% chance of development of TB disease.
4. The risk for progression decreases gradually through childhood until adolescence, when the risk increases.
5. Infants and young children are more likely to have life-threatening forms of TB, including meningitis and disseminated disease.
6. Children with TBI have more years at risk for development of disease than adults.

Because of these factors and the excellent safety profile of isoniazid, rifampin, and rifapentine in children, there is a tendency to err on the side of overtreatment in infants, young children, and adolescents.

The main TBI treatment regimens used in children are summarized in Table 261.7. The regimens include 6-9 months of **isoniazid** (daily or twice weekly by DOT), 3 months of daily **rifampin** and isoniazid, 4 months of daily rifampin, and once-weekly isoniazid and **rifapentine** (3HP) for 12 total doses. Because of improved treatment completion rates and noninferiority, the rifamycin-based, shorter treatment regimens are often favored over isoniazid monotherapy. The main indication for the use of isoniazid is if the child is at risk of drug-drug interactions with rifamycins.

Isoniazid therapy for TBI appears to be more effective for children than for adults, with several large clinical trials demonstrating a risk reduction of 70–90%. The risk of isoniazid-related hepatitis is minimal in infants, children, and adolescents, who tolerate the drug better than adults. Analysis of data from several studies demonstrates that the efficacy decreased significantly if isoniazid was taken for <9 months. However, the international standard is 6 months of treatment with isoniazid because of resource considerations. Isoniazid given twice weekly has been used extensively to treat TBI in children, especially schoolchildren and close contacts of case patients. DOT or VDOT should be considered when it is unlikely that the child and family will adhere to daily self-administration or if the child is at increased risk for rapid development of disease (newborns and infants, recent contacts, immunocompromised children). For healthy children taking isoniazid but no other potentially hepatotoxic drugs, routine biochemical monitoring and supplementation with pyridoxine are not necessary. Rifampin alone for 4 months is now frequently used for the treatment of TBI in infants, children, and adolescents. This regimen is most often used when a shorter, self-administered treatment regimen is preferred, when isoniazid cannot be tolerated, or the child has had contact with a source case infected with an isoniazid-resistant but rifamycin-susceptible organism. If a child is identified with TBI during a contact investigation or if the cost of rifampin is prohibitive for families, administration of the medication through VDOT programs offered by health departments should be considered. Rifapentine is a rifamycin with a very long half-life, allowing for weekly administration in conjunction with high-dose isoniazid. Studies have demonstrated that 12 doses of once-weekly isoniazid and rifapentine (3HP) are as effective for treating TBI and as safe as 9 months of daily isoniazid in children as young as 2 years. This is becoming the preferred regimen for the treatment of TBI in age-eligible children who are exposed to a contact with presumed pan-susceptible TB. Given the risk of selecting for drug-resistant isolates by missing intermittent doses of rifamycins, this treatment regimen currently is recommended only with DOT under the supervision of local health departments. The main reason children or adolescents are unable to complete this regimen is the inability to crush the tablets and the high pill burden. In these situations, the children are often transitioned to an alternative treatment regimen. A 3-month daily regimen of rifampin and isoniazid has been used throughout

Europe. Although this regimen has not been used regularly in the United States, experts believe it is favorable in children less than 5 years of age in whom the pill burden of 3HP is difficult. Studies have revealed that the shorter treatment regimens for TBI in children are equally efficacious as 9 months of isoniazid and are associated with superior treatment completion rates.

For children with MDR-TB, the regimen will depend on the drug-susceptibility profile of the contract case's organism; an expert in TB should be consulted. There are data that support the use of levofloxacin or moxifloxacin for treatment of MDR-TBI.

Few controlled studies have been published regarding the efficacy of any form of treatment for TBI in children living with HIV. A 9-month course of daily isoniazid is recommended. Most experts recommend that routine monitoring of serum hepatic enzyme concentrations be performed and pyridoxine be given when children living with HIV are treated with isoniazid. The optimal duration of rifampin therapy in children living with HIV with TBI is not known, but many experts recommend at least a 6-month course.

Isoniazid or rifampin should be given to children <5 years old who have a negative TST or IGRA result but who have a known recent exposure to an adult with potentially contagious TB disease. This practice is often referred to as **window prophylaxis**. By the time delayed hypersensitivity develops (2-3 months), an untreated child already may have developed severe TB. For these children, TST or IGRA is repeated 8-10 weeks after contact with the source case for TB has been broken (*broken contact* is defined as physical separation or adequate initial treatment of the source case). If the second test result is positive, the child should complete a treatment course for TBI (either 9 months of isoniazid or 4 months of rifampin). There is a benefit to using rifampin over isoniazid for window prophylaxis (unless contraindicated because of drug-drug interactions or prohibitive because of cost). By the time of the second test result (8-10 weeks later), if positive, the child receiving rifampin has approximately 2 months of therapy to complete compared to 7 months of isoniazid. Alternatively, if a new, shorter TBI treatment course is started after the second test result becomes positive (either 4 months of rifampin [if isoniazid was given as window prophylaxis], 12 weekly doses of isoniazid and rifapentine, or 3 months of isoniazid and rifampin), the treatment start date is day 1 of the new regimen. If the second test result is negative, TBI treatment can be stopped.

PREVENTION

The highest priority of any TB control program should be case finding and treatment, which interrupt transmission of infection between close contacts. All children and adults with symptoms suggestive of TB disease and those in close contact with an adult with suspected infectious pulmonary TB should be tested for TBI (by TST or IGRA) and examined as soon as possible. On average, 30–50% of household contacts to infectious cases are also infected, and 1% of contacts already have overt disease. This scheme relies on effective and adequate public health response and resources. Children, particularly young infants, should receive high priority during contact investigations because their risk for infection is high and they are more likely to rapidly develop severe forms of TB.

Mass testing of large groups of children for TBI is an inefficient process. When large groups of children at low risk for TB are tested, the vast majority of TST reactions are actually false-positive reactions because of biologic variability or cross-sensitization with NTM. However, testing of high-risk groups of adults or children should be encouraged because most of these persons with positive TST or IGRA results have TBI. Testing should take place only if effective mechanisms are in place to ensure adequate evaluation, follow-up, and treatment of the persons who test positive.

Bacille Calmette-Guérin Vaccination

The only available vaccine against TB is the BCG vaccine. The original vaccine organism was a strain of *M. bovis* attenuated by subculture every 3 weeks for 13 years. This strain was distributed to dozens of laboratories that continued to subculture the organism on different media under various conditions. The result has been production of many BCG vaccines that differ widely in morphology, growth characteristics, sensitizing potency, and animal virulence.

The administration route and dosing schedule for the BCG vaccines are important variables for efficacy. The preferred route of administration is intradermal injection with a syringe and needle because it is the only method that permits accurate measurement of an individual dose.

The BCG vaccines are extremely safe in immunocompetent hosts. Local ulceration and regional suppurative adenitis occur in 0.1–1% of vaccine recipients. Local lesions do not suggest underlying host immune defects and do not affect the level of protection afforded by the vaccine. Most reactions are mild and usually resolve spontaneously, but chemotherapy is needed occasionally. Surgical excision of a suppurative draining node is rarely necessary and should be avoided if possible. **Osteitis** is a rare complication of BCG vaccination that appears to be related to certain strains of the vaccine that are no longer in wide use. Systemic complaints such as fever, convulsions, loss of appetite, and irritability are extraordinarily rare after BCG vaccination. Profoundly immunocompromised patients can develop disseminated BCG infection after vaccination. Children living with HIV appear to have rates of local adverse reactions to BCG vaccines that are comparable with rates in immunocompetent children. However, the incidence in these children of disseminated infection months to years after vaccination is currently unknown.

Recommended vaccine schedules vary widely among countries. The official WHO recommendation is a single dose administered during infancy in populations where the risk for TB is high. However, *infants with known or suspected HIV infection should not receive a BCG vaccination.* In some countries, repeat vaccination is universal, although no clinical trials support this practice. In others, it is based on either TST or the absence of a typical scar. The optimal age for BCG administration and dosing schedule are unknown because adequate comparative trials have not been performed.

Although dozens of BCG trials have been reported in various human populations, the most useful data have come from several controlled trials. The results of these studies have been disparate. Some demonstrated substantial protection from BCG vaccines, but others showed no efficacy at all. A meta-analysis of published BCG vaccination trials suggested that BCG is 50% effective in preventing pulmonary TB in adults and children. The protective effect for disseminated and meningeal TB appears to be slightly higher, with BCG preventing 50–80% of cases. A variety of explanations for the varied responses to BCG vaccines have been proposed, including methodologic and statistical variations within the trials, interaction with NTM that either enhances or decreases the protection afforded by BCG, different potencies among the various BCG vaccines, and genetic factors for BCG response within the study populations. BCG vaccination administered during infancy has little effect on the ultimate incidence of TB in adults, suggesting waning protection with time.

BCG vaccination has worked well in some situations but poorly in others. Clearly, BCG vaccination has had little effect on the ultimate control of TB throughout the world, because >5 billion doses have been administered, but TB remains epidemic in most regions. BCG vaccination does not substantially influence the chain of transmission, because cases of contagious pulmonary TB in adults that can be prevented by BCG vaccination constitute a small fraction of the sources of infection in a population. The best use of BCG vaccination is to prevent life-threatening forms of TB in infants and young children.

BCG vaccination has never been adopted as part of the strategy for TB control in the United States. Widespread use of the vaccine would render subsequent TSTs less useful. However, BCG vaccination can contribute to TB control in select population groups. BCG is recommended for TST-negative, HIV-negative infants and children who are at high risk for intimate and prolonged exposure to persistently untreated or ineffectively treated adults with infectious

pulmonary TB and who cannot be removed from the source of infection or placed on long-term preventive therapy. It also is recommended for those who are continuously exposed to persons with TB who have bacilli that are resistant to isoniazid and rifampin. Any child receiving BCG vaccination should have a documented negative TST before receiving the vaccine. After receiving the vaccine, the child should be separated from the possible sources of infection until it can be demonstrated that the child has had a vaccine response, as evidenced by tuberculin reactivity, which usually develops within 1-3 months.

Prevention of Perinatal Tuberculosis

The most effective way of preventing TB infection and disease in the neonate or young infant is through appropriate testing and treatment of the mother and other family members. High-risk pregnant women should be tested with TST or IGRA, and those with a positive test result should receive a chest radiograph with appropriate abdominal shielding. If the mother has a negative chest radiograph and is clinically well, no separation of the infant and mother is needed after delivery. The child needs no special evaluation or treatment if the child remains asymptomatic. Other household members should undergo testing for TBI and further evaluation as indicated.

If the mother has suspected TB at the time of delivery, the newborn should be separated from the mother until the chest radiograph is obtained. If the mother's chest radiograph is abnormal, separation should be maintained until the mother has been evaluated thoroughly, including examination of the sputum. If the mother's chest radiograph is abnormal but the history, physical examination, sputum examination, and evaluation of the radiograph show no evidence of current active TB, it is reasonable to assume that the infant is at low risk for infection. The mother should receive appropriate TB treatment, and she and her infant should receive careful follow-up care.

If the mother's chest radiograph or AFB sputum smear shows evidence of current TB disease, additional steps are necessary to protect the infant. Isoniazid therapy for newborns has been so effective that separation of the mother and infant is no longer considered mandatory. Separation should occur only if the mother is ill enough to require hospitalization, has been or is expected to become nonadherent to treatment, or has suspected drug-resistant TB. Isoniazid treatment for the infant should be continued until the mother is sputum culture negative for ≥3 months. At that time, a TST should be placed on the child. If the test is positive, isoniazid is continued for a total duration of 9-12 months; if the TST is negative, isoniazid can be discontinued. Once the mother and child are taking adequate therapy, it is usually safe for the mother to breastfeed, because the medications, although found in milk, are present in low concentrations. If isoniazid resistance is suspected or the mother's adherence to medication is in question, continued separation of the infant from the mother should be considered. The duration of separation must be at least as long as is necessary to render the mother noninfectious. A TB expert should be consulted if the young infant has potential exposure to the mother or another adult with TB disease caused by an isoniazid-resistant strain of *M. tuberculosis*.

Although isoniazid is not thought to be teratogenic, the treatment of pregnant women who have asymptomatic TBI is often deferred until after delivery. However, symptomatic pregnant women or those with radiographic evidence of TB disease should be appropriately evaluated. Because pulmonary TB is harmful to both the mother and the fetus and represents a great danger to the infant after delivery, TB in pregnant women always should be treated. The most common regimen for drug-susceptible TB is isoniazid, rifampin, and ethambutol. The aminoglycosides and ethionamide should be avoided because of their teratogenic effect. The safety of pyrazinamide in pregnancy has not been established.

Chapter 262

Hansen Disease (*Mycobacterium leprae*)

Cristina Tomatis Souverbielle and Asuncion Mejias

Leprosy (Hansen disease [**HD**]) is a heterogeneous, curable infection caused by *Mycobacterium leprae* that primarily affects the upper airway, skin, and peripheral nerves. Disease manifestations are mainly determined by the host's immunologic response to infection, resulting in a wide clinical spectrum. The majority of exposed individuals never develop clinical disease. HD is currently the accepted designation of leprosy, and contrary to popular folklore, HD is *not* highly transmissible and *is* treatable. In addition, the associated morbidity and disability can be prevented with early diagnosis and appropriate treatment.

MICROBIOLOGY

M. leprae is an obligate, intracellular, acid-fast, gram-positive bacillus of the family Mycobacteriaceae measuring 1-8 μm in length. It grows optimally at 27–33°C (80.6–91.4°F) yet cannot be cultured in vitro. The bacillus multiplies slowly, with a doubling time of 11-13 days. It is the only bacterium known to infect **Schwann cells** of peripheral nerves. Identification of acid-fast bacilli (AFB) in peripheral nerves is pathognomonic of leprosy.

EPIDEMIOLOGY

The prevalence of leprosy is variable, with most cases being identified in tropical and subtropical areas. The World Health Organization (WHO) goal to eliminate leprosy as a public health problem, defined as a reduction in its prevalence to less than 1 case per 10,000 population, was achieved at the global level in 2000. Despite an overall decline in reported prevalence, HD continues to afflict more than 2 million people worldwide. In 2022, 174,059 new cases were reported globally, with most cases occurring in Southeast Asia (mostly India), Africa, and South America (mostly Brazil). Of those, 5.92% occurred in children <15 years. In 2018, the WHO reviewed the available evidence on key issues related to the elimination of leprosy and developed a guidance WHO Guidelines for the Diagnosis, Treatment and Prevention of Leprosy. More recently, the WHO released Towards Zero Leprosy – Global Leprosy (Hansen's Disease) Strategy 2021-2030, which was aligned with the 2021-2030 road map for neglected tropical diseases during the same period.

Since 1984, HD has been a *notifiable disease* in the United States, with about 14,000 cases recorded since then. Since the 1990s, an average of 175 new cases are reported annually. Of the 159 new U.S. cases reported in 2020, 69% were identified in Texas, Louisiana, Hawaii, California, Florida, and New York. Most new cases (~75%) in the United States were identified among immigrants from HD-endemic countries or in citizens who have worked abroad in endemic areas. However, over one third of U.S. cases are **autochthonous** and do not report contact with foreign countries or people with leprosy.

The likelihood of developing HD is determined by several variables: age (with two incidence peaks: 10-14 years and 30 years), gender (male/female ratio 2:1, with no differences observed in children), genetics, immune status, type of leprosy (with higher risk in those exposed to patients with multibacillary disease), and possibly through exposure to **armadillos**. Whole genome sequencing has allowed identification of genes and polymorphisms associated with increased susceptibility to leprosy and found that approximately 5% of people are genetically susceptible to *M. leprae* infection. HD in immunocompromised

hosts has been reported in solid organ and bone marrow transplant recipients and patients receiving tumor necrosis factor (TNF)–blocking monoclonal antibodies. Patients with HIV infection do not appear to be at increased risk of acquiring leprosy, increased disease severity, or poor response to treatment. However, clinicians should be aware that concomitant HIV infection and leprosy can result in worsening of symptoms of leprosy during HIV treatment as a result of an immune reconstitution inflammatory syndrome.

The exact mechanism of transmission is not fully understood but is thought to occur primarily by the respiratory route. Natural infection occurs in humans and armadillos, which are the only recognized nonhuman reservoir. The risk of transmission from armadillos to humans seems low, and again, the mechanism is not fully understood. The incubation period between natural infection and overt clinical disease in humans ranges from 3 months to 20 years, with a mean of 4 years for **tuberculoid** leprosy and 10 years for **lepromatous** leprosy. Up to 10^7 viable bacilli per day can be shed in respiratory secretions of patients with **multibacillary** leprosy. The relative risk for developing disease in household contacts is 8- to 10-fold for lepromatous disease and 2- to 4-fold for the tuberculoid form. Transmissions by breast milk, the transplacental route, and through broken skin have been reported. Environmental factors and subclinically infected humans may also play a role in disease transmission. The infectivity of patients with HD becomes negligible within 24 hours of the first administration of effective therapy.

PATHOGENESIS

In the skin, *M. leprae* shows affinity for keratinocytes, macrophages, and histiocytes, and in peripheral nerves, the organism can be found in the Schwann cells. The mechanism of mycobacterial dissemination from the respiratory tract to the skin and nerves is thought to occur hematogenously but has not been completely elucidated. *M. leprae* induces demyelination and binds to the laminin-2 glycoprotein present in the basal lamina of Schwann cells in peripheral nerves, where it replicates slowly over several years. Infection stimulates the dedifferentiation of Schwann cells to immature cells through the activation of the Erk1/2 pathway. This reprogramming of Schwann cells seems to be linked to disease dissemination. In addition to the direct nerve invasion, the immune response to infection also contributes to nerve damage. Schwann cells express human leukocyte antigen (HLA) class II molecules and present mycobacterial peptides to the HLA class II restricted $CD4^+$ T cells, which initiate an inflammatory response. These events explain the nerve damage seen in paucibacillary disease and in reversal reactions. Swelling within the perineurium leads to ischemia, further nerve damage, and eventually fibrosis and axonal death.

DISEASE CLASSIFICATION

Disease classification is important to determine potentially infectious cases and prognosis. Based on the cellular immune response and disease dissemination, two classification schemes for leprosy are frequently used: the Ridley-Jopling scale and the WHO classification:

A. The **Ridley-Jopling scale** is used in the United States and describes the five types of leprosy, according to clinical spectrum of disease, bacillary load, and findings on histopathology.
   1. *Tuberculoid form*: Patients usually have a vigorous and specific cellular immune response to *M. leprae* antigens and have a small number of skin lesions, generally one to three well-demarcated macules or plaques with elevated borders (Fig. 262.1) and reduced or absent sensation. The lesions are infiltrated by T-helper 1 (Th1) cells producing abundant interferon (IFN)-γ and TNF-α, forming well-demarcated granulomas, with few, if any, bacilli found within the lesions.
   2. *Borderline tuberculoid form*
   3. *Borderline form*
   4. *Borderline lepromatous*
   5. *Lepromatous form*: Patients have an absence of specific cellular immunity to *M. leprae* (but intact immunity to *Mycobacterium tuberculosis*) and present the most severe form of disease. They manifest clinically apparent infiltration of peripheral nerves and skin lesions (usually many lesions and not all hypoesthetic or anesthetic), with a high load of bacilli in the absence of an effective cell-mediated immune response. Skin biopsies reveal extensive infiltration of the skin and nerves, containing messenger RNA for Th2 cytokines such as interleukin (IL)-4 and IL-10, poorly formed granulomas, and uncontrolled proliferation of bacilli within foamy macrophages. A large amount of circulating antibody to *M. leprae* is present but does not confer protective immunity. Over time, patients with the lepromatous form develop a systemic disease with symmetric peripheral nerve involvement and a diffuse infiltrative dermopathy that includes thickening of the facial skin and hair loss of the eyelashes and eyebrows (madarosis), leading to the classic presentation of the *leonine facies*. They also have involvement of the nasal mucosa causing nasal congestion and epistaxis.
   6. The majority of patients will present with a borderline form. From borderline tuberculoid to borderline lepromatous forms, there is a progressive reduction in cellular immune responses, an increase in bacillary load, more frequent hypopigmented skin lesions and nerve involvement, and higher antibody titers (Fig. 262.2). Patients with the extreme forms of the disease (tuberculoid and lepromatous) are considered to have stable cell-mediated immunity, because their disease manifestations do not change much over time. In contrast, patients with borderline disease have unstable cell-mediated immunity and demonstrate changes in their clinical manifestations over time toward the polar forms (downgrade) or present sudden reversal reactions (upgrade). *Indeterminate leprosy* is the earliest form of the disease and is seen most frequently in young children. Patients usually have a single hypopigmented macule with poorly defined borders, without erythema or induration. Anesthesia is minimal or absent, especially if the lesion is on the face. The diagnosis is

Fig. 262.1 Tuberculous leprosy in a patient who has a single skin lesion with a raised border and flattened center.

Fig. 262.2 Borderline leprosy in a patient who has numerous hypopigmented lesions with poorly defined borders.

usually one of exclusion in the setting of a contact investigation. Tissue biopsies show diagnostic evidence of leprosy but do not meet sufficient criteria for classification. Up to 50–75% of these lesions will heal spontaneously, and the rest will progress to another form of leprosy.

B. The **WHO classification** can be used when histologic evaluation and confirmatory diagnosis is unavailable, a common scenario in the field. This simplified scheme is based on the number of skin lesions:
   1. Paucibacillary (1-5 patches)
   2. Multibacillary (>5 patches)

CLINICAL MANIFESTATIONS

The host immune response determines the clinical spectrum of leprosy. Skin and serologic studies suggest that up to 90% of infected people develop immunity after exposure, without manifesting clinical disease. In genetically susceptible individuals with sufficient exposure to become infected, the cellular host's immunologic response to infection and unique tropism for peripheral nerves determine the wide spectrum of clinical (and histologic) manifestations. Regardless of the disease subtype, HD affects the skin and peripheral nerves. Leprosy lesions usually do not itch or hurt. Polymorphisms in vitamin D and its receptor have been proposed to play a role in the manifestations of leprosy.

Skin Involvement

The most common skin lesions are **macules** or **plaques** with unclear outer limits, with or without neurologic symptoms. Diffuse infiltrative lesions and subcutaneous nodules are less common. Initial lesions are insidious hypopigmented macules, although they may appear erythematous on pale skin. Lesions may involve any area of the body, are more pronounced in cooler areas (e.g., earlobes, nose), and occur less frequently in the scalp, axillae, or perineum. Approximately 70% of skin lesions have reduced sensation; the degree of hypoesthesia depends on the location and size of the lesion and the degree of Th1 immune response. Examination of the skin should ideally be performed in natural sunlight and include testing for hypoesthesia to light touch, pinprick, temperature, and anhidrosis. Studies in endemic areas in children <15 years old have shown a predominance of **paucibacillary** forms, with a predominance of single lesions.

Nerve Involvement

Peripheral nerves are most frequently affected early in the disease and should be palpated for thickness and tenderness (Fig. 262.3), as well as evaluated for both motor and sensory function, particularly temperature and light touch. The posterior tibial nerve (medial malleolus) is the most common nerve affected, followed by the ulnar (elbow), median (wrist), lateral popliteal (fibular neck), and facial nerves. The skin lesions overlying a nerve trunk distribution predict the involvement of nerves in the vicinity. There is a pure **neuritic** form of leprosy, usually occurring in India and Nepal, in which patients present with asymmetric neuropathy but lack skin lesions.

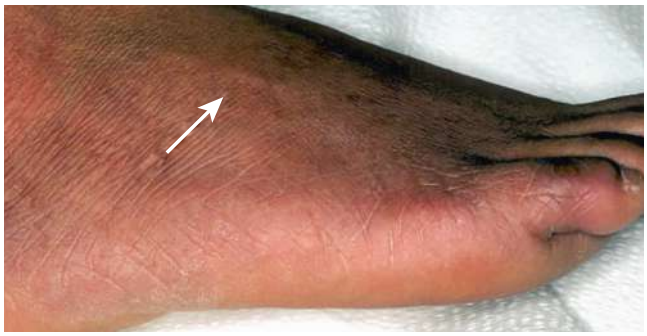

Fig. 262.3 Thickened, superficial peroneal nerve of leprosy.

Other Organ Involvement

Ocular involvement leading to vision loss results from both direct bacillary invasion of the eye and optic nerve damage. **Lagophthalmos** occurs when there is destruction of the facial nerve (cranial nerve VII), and trigeminal nerve (cranial nerve V) destruction causes anesthesia of the cornea and conjunctiva, leading to abrasions. Facial skin lesions are associated with a 10-fold higher risk of facial nerve damage. Systemic involvement of other organs is seen mainly in patients with lepromatous leprosy, where a high bacillary burden leads to infiltration of the nasal mucosa, bones, and testes. Renal involvement and amyloidosis are rare findings.

Immunologic Reactions

Leprosy reactions are acute clinical exacerbations reflecting disturbances of the immunologic balance to *M. leprae* infection and occurring in 30–50% of all leprosy patients. These sudden changes occur in patients with borderline and lepromatous leprosy, typically during the initial years after infection (sometimes as the initial presentation), but can occur before, during, or after completion of treatment. There are two main types of leprosy reactions, which require immediate treatment to prevent long-term complications. In children <15 years old, leprosy reactions range from 1% to 30% and are mainly type 1 reactions.

Type 1 reactions (also known as **reversal reactions**) occur in one third of patients with borderline disease. These reactions are characterized by acute edema and increased erythema, warmth, and painful inflammation of preexisting cutaneous plaques or nodules, with acute swelling and tenderness of peripheral nerves that can quickly progress to cause nerve abscesses and necrosis. There may be a peripheral lymphocytosis and an increased cytokine response, but systemic symptoms are uncommon and appear to be associated with an increase in Th1-mediated reactivity to mycobacterial antigens. Increased serum concentrations of CXCL10 have been found in type 1 reactions. Rapid and sustained reversal of the inflammatory process using corticosteroids is essential to prevent continued nerve damage.

Type 2 reactions, or **erythema nodosum leprosum (ENL)**, occur in borderline lepromatous and lepromatous forms, as these patients have the highest levels of *M. leprae* antigens and antibodies, most often in the first 2 years after starting therapy. ENL is distinguished from reversal reactions by the development of new painful, erythematous subcutaneous nodules with an accompanying systemic inflammatory response. ENL is accompanied by high circulating concentrations of TNF-α. Patients develop high fever and signs

of systemic toxicity, and in severe cases, ENL can be life threatening, presenting with features similar to septic shock. Deposition of extravascular immune complexes leads to neutrophil infiltration and activation of complement in the skin and other organs. Tender, erythematous dermal papules or nodules (resembling erythema nodosum) occur in clusters, typically on extensor surfaces of the lower extremities and face. Immune complex deposition also contributes to migrating polyarthralgias, painful swelling of lymph nodes and spleen, iridocyclitis, vasculitis, orchitis, and, rarely, nephritis. Patients may present with a single acute episode, a relapsing form comprising multiple acute episodes, or a chronic continuous form. Management of type 2 reactions is usually more complicated because of recurrence and systemic involvement.

Lucio phenomenon (erythema necroticans) is an uncommon but potentially fatal reaction distinct from type 1 or 2 reactions and occurs in patients with untreated lepromatous leprosy and in patients whose ancestry is from Mexico. It is a necrotizing vasculitis caused by *M. leprae* directly invading the endothelium. Clinically, patients develop violaceous or hemorrhagic plaques, followed by ulcerations in the absence of systemic complaints. Secondary bacterial infections are common.

DIAGNOSIS

The diagnosis of HD requires high clinical suspicion and should be considered in any patient with a **hypoesthetic or anesthetic skin lesion that does not respond to standard treatment**, especially if there is a history of travel or residence in an endemic region or a history of contact with leprosy patients or armadillos. There are no reliable tests to diagnose subclinical leprosy. Full-thickness skin biopsy and polymerase chain reaction (PCR) are the main laboratory tests to aid in the diagnosis. Patients are considered to have HD if they have **one or more of the three cardinal signs**: loss of sensation in a localized skin lesion (pale or erythematous), thickened peripheral nerve with loss of sensation and/or weakness of muscles enervated by that nerve, or the presence of AFB on biopsy. The positive predictive value for the diagnosis of leprosy in patients meeting all three criteria is 98%.

To confirm the diagnosis and determine the extent of nerve involvement and the type of infiltrate, a full-thickness skin biopsy from the most active lesion should be performed. *M. leprae* is best identified in tissue using the *Fite stain*. Lesions from patients with the lepromatous form reveal numerous AFB in clumps (globi), whereas patients with the tuberculoid form rarely have mycobacteria identified, but the diagnosis can be made by demonstration of well-formed noncaseating granulomas and nerve involvement. The presence of **neural inflammation** differentiates leprosy from other granulomatous disorders. Mycobacterial culture of lesions should be performed to exclude *M. tuberculosis* and nontuberculous cutaneous infections. If no resources are available, slit-skin (skin smear) biopsies represent an alternative. Slit-skin smears have high specificity but low sensitivity; only 30% of adults and 10–30% of children <15 years old are smear positive (usually patients with the lepromatous form). The bacterial index can range from 0 (no bacilli in 100 oil-immersion fields), as generally seen in paucibacillary disease, to 6+ (>1,000 bacilli/field), as can be seen in multibacillary disease.

Diagnostic and histopathologic consultation in the United States is available through the **National Hansen's Disease Program** (**NHDP**; http://www.hrsa.gov/hansens or 800-642-2477). Specimens (formalin or paraffin embedded) can be sent to the NHDP for pathologic analysis free of charge. A PCR test for *M. leprae* is not readily available in clinical practice but may be performed at the NHDP. In nonendemic areas, PCR may be useful for diagnosis when AFB are discernible in tissue but clinical and histopathologic features are not typical. *M. leprae* DNA is detectable by PCR in 95% of lepromatous disease and 55% of tuberculoid lepra. PCR has also allowed detection of the organism in nasal secretions from asymptomatic people. Molecular testing for mutations causing drug resistance is also available through the NHDP and is usually used in the setting of relapse.

Antibodies to *M. leprae* are present in 90% of patients with untreated lepromatous disease, 40–50% of patients with paucibacillary disease, and 1–5% of healthy controls. However, serologic testing is insensitive and is not used for diagnosis.

TREATMENT

The primary goal of treatment is early antimicrobial therapy to prevent permanent neuropathy. Leprosy is curable. Effective treatment requires multidrug therapy (MDT) with **dapsone**, **clofazimine**, and **rifampin**. Combination therapy is employed to prevent antimicrobial resistance. In the United States, clinical providers considering a diagnosis and treatment of a patient with HD should obtain **consultation from the NHDP**. The recommended combination MDT can be obtained free of charge from the NHDP (Table 262.1) and in other countries through the WHO (Table 262.2). Compared with the WHO, the NHDP advocates for a longer duration of treatment and daily rather than monthly administration of rifampin because shorter antimicrobial regimens have been associated with a greater risk of relapse. The recommended duration by the WHO for tuberculoid disease is 6 months and for lepromatous disease is 12 months. Since 2018, the WHO has advocated for a three-drug regimen for all leprosy forms; however, NHDP guidelines recommend two drugs (dapsone and rifampin) for the treatment of paucibacillary disease.

Before starting combination MDT, patients should be tested for glucose-6-phosphate dehydrogenase deficiency, have a baseline

Table 262.1 NHDP-Recommended Multidrug Therapy Regimens for Hansen Disease in the United States

TYPE OF LEPROSY	PATIENT POPULATION	ANTIMICROBIAL THERAPY	DURATION OF THERAPY
Multibacillary (LL, BL, BB)	Adult	Dapsone 100 mg/day *and* rifampin* 600 mg/day *and* clofazimine 50 mg/day	24 mo
	Pediatric†	Dapsone 1 mg/kg/day *and* rifampin 10-20 mg/kg/day *and* clofazimine 1 mg/kg/day‡	
Paucibacillary (TT, BT)	Adult	Dapsone 100 mg/day *and* rifampin 600 mg/day	12 mo
	Pediatric†	Dapsone 1 mg/kg/day *and* rifampin 10-20 mg/kg/day	

*Rifampin is taken monthly if the patient is on prednisone.
†Daily pediatric mg/kg dose should not exceed the adult daily maximum.
‡Clofazimine is only available through NHDP Investigational New Drug (IND) program; minimum formulation is 50 mg, and capsules should not be cut. Alternative dosing includes clofazimine 2 mg/kg every other day
NHDP, National Hansen's Disease Program; BB, borderline; BL, borderline lepromatous; BT, borderline tuberculoid; LL, lepromatous; TT, tuberculoid.
NHDP multidrug therapy is daily and of longer duration than WHO-recommended regimen. All drugs are administered orally. For immunologically compromised or elderly patients, these protocols may be modified. Consultation with the NHDP is advised.

Table 262.2 WHO-Recommended Multidrug Therapy (MDT) Regimens for Hansen Disease

TYPE OF LEPROSY	PATIENT POPULATION	ANTIMICROBIAL THERAPY	DURATION OF THERAPY
Multibacillary (LL, BL, BB)	Adult	Rifampicin 600 mg once monthly *and* dapsone 100 mg/day *and* clofazimine 300 mg once monthly and 50 mg/day	12 mo
	Pediatric*	Rifampicin 450 mg once monthly *and* dapsone 50 mg/day *and* clofazimine 150 mg once monthly and 50 mg every other day	
Paucibacillary (TT, BT)	Adult	Rifampicin 600 mg once monthly *and* dapsone 100 mg/day *and* clofazimine 300 mg once monthly and 50 mg/day	6 mo
	Pediatric*	Rifampicin 450 mg once monthly *and* dapsone 50 mg/day *and* clofazimine 150 mg once monthly and 50 mg every other day	

*In children <10 yr old, or <than 40Kg, MDT dosages should be in mg/kg, not to exceed the adult daily maximum: rifampicin 10 mg/kg once monthly, dapsone 2 mg/kg/day, and clofazimine100 mg once a month, 50 mg twice weekly.
WHO, World Health Organization; BB, borderline; BL, borderline lepromatous; BT, borderline tuberculoid; LL, lepromatous; TT, tuberculoid.

complete blood cell count and liver function testing, and be evaluated for evidence of active tuberculosis, in which monotherapy with rifampin should be avoided. Response to therapy is seen clinically as flattening or disappearance of skin lesions and improvement in nerve function, usually within 1-2 months after initiating MDT. Complete resolution or improvement may take 6-12 months, depending on the severity of infection. Most skin lesions heal without scarring. Identification of biomarkers for the optimal identification and management of leprosy continue to be under study. CXCL10 (IP-10) has been identified as a potential marker to help monitor treatment efficacy in patients with multibacillary disease, as higher levels of CXCL-10 are important for the control of bacillary load.

Alternative agents to treat HD include minocycline, clarithromycin, and some fluoroquinolones (levofloxacin, ofloxacin, moxifloxacin). Given limited data, these alternative antimicrobials are used in selected cases of intolerance to the routine combination MDT regimen or for documented resistance. It is important to note that some patients who have been adequately treated for HD may later show evidence of chronic reversal reactions and late neuropathies, but these are bacillus negative and thus should not be considered relapses. Neuritis must be treated promptly to minimize nerve injury and disability. Treatment with corticosteroids appears to improve nerve function in two thirds of patients.

Bone marrow suppression and hepatotoxicity have been reported and should be monitored every 3 months during therapy. A screening urinalysis should be performed annually. Other reactions, such as methemoglobinemia and hypersensitivity reactions to dapsone, are rare. An ophthalmologic evaluation should routinely be performed in all patients with HD because ocular complications can occur. Given the proclivity for testicular invasion in multibacillary leprosy with resultant testicular dysfunction and infertility, males should be screened for elevated follicle-stimulating hormone or luteinizing hormone concentrations and decreased testosterone levels.

After completion of MDT, annual follow-up for ≥5 years for paucibacillary and ≥10 years for multibacillary disease is warranted. Relapse of the disease after completion of MDT is rare (0.01–1.4%) and must be distinguished from the more common leprosy immunologic reactions. Patients who have a bacillary index of ≥4 pre-MDT or ≥3 at the completion of MDT have the highest risk of relapse (approximately 20%). When relapse occurs, it is usually within 5-10 years of MDT completion and a result of reactivation of drug-susceptible mycobacteria. Thus patients who are expected to relapse are generally treated with the same MDT regimen. Resistance to all three drugs has been documented, although it rarely occurs with combination therapy. There is no role for routine baseline resistance testing, but the NHDP can provide it if needed.

Leprosy Reactions

Immunologic reactions can occur before, during, and years after treatment and should be treated aggressively to prevent peripheral nerve damage. In general, antimycobacterial drugs should be continued. Fatigue, malaise, or fever can be present, and the inflammation associated with these reactions can cause severe nerve injury. Prompt therapy with corticosteroids with or without other antiinflammatory agents, adequate analgesia, and physical support are essential for patients with active neuritis to prevent nerve damage. **If corticosteroids are indicated for a prolonged time, the frequency of rifampicin administration should be decreased from daily to monthly** administration (to avoid drug interactions). In 2020, to aid with the management of leprosy reactions, the WHO published the technical guide: *Leprosy/Hansen Disease: Management of Reactions and Prevention of Disabilities*.

For severe **type 1 reactions**, **prednisone is recommended**, 1 mg/kg/day orally (40-60 mg) with a slow taper (decreasing by 5 mg every 2-4 weeks after evidence of improvement over 3-6 months) in addition to standard MDT. If there is evidence of peripheral nerve deterioration, higher doses and longer tapers may be needed. Nerve function improves after corticosteroid treatment in 30–80% of patients who did not have preexisting neuritis. In patients not responding to corticosteroids, cyclosporine may be used as a second-line agent.

For severe **type 2 reactions**, **prednisone is routinely used** at 1 mg/kg/day for 12 weeks. However, given the recurrence and chronicity of ENL, **corticosteroid-sparing agents should be considered** to avoid complications associated with their prolonged use. **Thalidomide** (100-400 mg/daily for 48-72 hours, tapering over 2 weeks to 100 mg/daily) is effective in treating these types of reactions. Given the teratogenicity of thalidomide (contraindicated for children <12 years old and women of childbearing age), the drug is only available through a restrictive distribution program approved by the U.S. Food and Drug Administration (FDA). **Clofazimine** (300 mg/day for several months, tapering to <100 mg/day, within a year) alone or in combination with corticosteroids, has also been useful in managing patients with chronic ENL and is generally used until all signs of the reaction have abated. Other immunosuppressive drugs have been used to treat type 2 reactions with inconsistent results, including cyclosporine, mycophenolate, and methotrexate. **Lucio phenomenon is managed similarly to ENL** and treatment of underlying infections.

LONG-TERM COMPLICATIONS

Leprosy is a leading cause of permanent physical disability among communicable diseases worldwide. The major chronic complications and deformities of leprosy are caused by **nerve injury**. Nerve impairment may be purely sensory, motor, or autonomic or may be a combination. The prognosis for arresting progression of tissue and nerve damage is good if therapy is started early, but recovery of lost sensory and motor function is variable and frequently incomplete. Nerve function impairment can occur before diagnosis, during MDT, or after MDT and can develop without overt signs of skin or nerve inflammation (silent neuropathy). Patients at highest risk of nerve impairment are those with multibacillary leprosy and preexisting nerve damage. These patients should undergo regular monthly surveillance during therapy and for at least 2 years from the time of diagnosis. In children, deformities can occur in 3–10% of cases and mainly in those with nerve enlargement. Other factors contributing to risk of deformities include increasing age in children, delay in accessing medical care, multiple skin lesions, multibacillary disease, smear positivity, multiple nerve involvement, and leprosy reaction at presentation.

PREVENTION

In addition to treating active leprosy cases, control measures for HD include the management of **contacts** of index patients. In endemic countries, close monitoring of household contacts of HD patients, particularly HD patients with multibacillary disease, is warranted to ensure that early treatment can be implemented if evidence of early HD develops. These household contacts should be examined at baseline and then yearly for 5 years. In nonendemic areas, disease presenting in the contacts of patients with HD is rare. A single dose of bacille Calmette-Guérin (BCG) vaccine has variable protective efficacy against leprosy, ranging from 10% to 80%; an additional dose results in increased protection. Any suspected or newly diagnosed case of leprosy in the United States should be reported to local and state public health departments, the Centers for Disease Control and Prevention (CDC), and NHDP. There are no leprosy vaccines available or recommended for use in the United States. In the hospital setting, **standard precautions** should be implemented. Hand hygiene is recommended for all people in contact with a patient with lepromatous leprosy. The use of chemoprophylaxis with a single dose of rifampin (SDR) within endemic areas is recommended by the WHO, but not the NHDP, for adults and children ≥2 years in contact with leprosy patients. Because leprosy is a highly stigmatized disease, caution must be exercised when implementing SDR in contacts, particularly for those outside the patient's family.

Chapter 263

Nontuberculous Mycobacteria

Ericka V. Hayes

Nontuberculous mycobacteria **(NTM)**, also referred to as **atypical mycobacteria** and **mycobacteria other than tuberculosis** (MOTT), are all members of the genus *Mycobacterium* and include species other than *Mycobacterium tuberculosis* complex and *Mycobacterium leprae*. The NTM constitute a highly diverse group of bacteria that differ from *M. tuberculosis* complex bacteria in their pathogenicity, interhuman transmissibility, nutritional requirements, ability to produce pigments, enzymatic activity, and drug susceptibility. In contrast to the *M. tuberculosis* complex, NTM are acquired from environmental sources and not by person-to-person spread, although the latter is under debate, especially in patients with cystic fibrosis (CF). Their omnipresence in the environment means that the clinical relevance of NTM isolation from clinical specimens is sometimes unclear; a positive culture might reflect occasional presence or contamination rather than true NTM disease. NTM are associated with pediatric lymphadenitis, otomastoiditis, serious lung infections, and, rarely, disseminated disease. Treatment is long-term and cumbersome and often requires adjunctive surgical intervention. Comprehensive guidelines on diagnosis and treatment are provided by the American Thoracic Society (ATS) and British Thoracic Society (BTS).

ETIOLOGY

NTM are ubiquitous in the environment all over the world, existing as saprophytes in soil and water (including municipal water supplies, tap water, hot tubs, and shower heads), environmental niches that are the supposed sources of human infections. With the introduction of molecular identification tools such as 16S recombinant DNA gene sequencing, the number of identified NTM species has grown to more than 150; the *clinical relevance* (i.e., percentage of isolates that are causative agents of true NTM disease, rather than occasional contaminants) differs significantly by species.

Mycobacterium avium complex (**MAC**; i.e., *M. avium, Mycobacterium intracellulare,* and several closely related but rarer species) and *Mycobacterium kansasii* are most often isolated from clinical samples, yet the isolation frequency of these species differs significantly by geographic area. MAC bacteria have been frequently isolated from natural and synthetic environments, and cases of MAC disease have been successfully linked to home exposure to shower and tap water. Although the designation *M. avium* suggests that human infections are acquired from birds (Latin *avium*), molecular typing has established that *M. avium* strains that cause pediatric lymphadenitis and adult pulmonary disease represent the *M. avium* hominis suis subgrouping, mainly found in humans and pigs and not in birds.

Some NTM have well-defined ecologic niches that help explain infection patterns. The natural reservoir for *Mycobacterium marinum* is fish and other cold-blooded animals, and the **fish tank granuloma**, a localized skin infection caused by *M. marinum,* follows skin injury in an aquatic environment. *Mycobacterium fortuitum* complex bacteria and *Mycobacterium chelonae* are ubiquitous in water and have caused clusters of nosocomial surgical wound and venous catheter–related infections. *Mycobacterium ulcerans* is associated with severe, chronic skin infections **(Buruli ulcer disease)** and is endemic mainly in West Africa and Australia, although other foci exist. Its incidence is highest in children <15 years old. *M. ulcerans* had been detected in environmental samples by polymerase chain reaction (PCR) and has been recovered by culture from a water strider (an insect of the *Gerris* genus) from Benin.

EPIDEMIOLOGY

Humans are exposed to NTM on a daily basis. In rural U.S. counties, where *M. avium* is common in swamps, the prevalence of asymptomatic infections with *M. avium* complex, as measured by skin test sensitization, approaches 70% by adulthood. Still, the incidence and prevalence of the various NTM disease types remain largely unknown, especially for pediatric NTM disease. In Australian children, the overall incidence of NTM infection is 0.84 per 100,000, with lymphadenitis accounting for two thirds of cases. The incidence of pediatric NTM disease in the Netherlands is estimated at 0.77 infections per 100,000 children per year, with lymphadenitis making up 92% of all infections.

In comparison, estimations of the prevalence of NTM from respiratory samples in adults are 5-15 per 100,000 persons per year, with important differences between countries or regions. Because pulmonary NTM disease progresses slowly, over years rather than months, and usually takes several years to cure, the prevalence of pulmonary NTM disease is much higher than incidence rates would suggest.

The paradigm that NTM disease is a rare entity limited to resource-rich countries is changing. In recent studies in African countries with a high prevalence of HIV infection, it has been found that NTM might play a much larger role as a cause of tuberculosis-like disease of children and adults than previously assumed and thus confuse the diagnosis of tuberculosis.

Although it is generally believed that NTM infections are contracted from environmental sources, whole genome sequence analysis of *Mycobacterium abscessus* strains of patients in a CF clinic in the United Kingdom supports the possibility of nosocomial horizontal transmission among CF patients.

PATHOGENESIS

The histologic appearances of lesions caused by *M. tuberculosis* and NTM are often indistinguishable. The classic pathologic lesion consists of caseating granulomas. Compared with *M. tuberculosis* infections, NTM infections are more likely to result in **granulomas that are non-caseating**, poorly defined (nonpalisading), irregular or serpiginous, or even absent, with only chronic inflammatory changes observed. The histology likely reflects the immune status of the patient.

In patients with AIDS and disseminated NTM infection, the inflammatory reaction is usually scant, and tissues are filled with large numbers of histiocytes packed with acid-fast bacilli (AFB). These disseminated NTM infections typically occur only after the number of CD4 T lymphocytes has fallen below 50/μL in children ≥6 years, below 75/μL in children 2 to <6 years, below 500/μL in children 1 to <2 years, and below 750/μL in children <1 year, suggesting that specific T-cell products or activities are required for immunity to mycobacteria.

The pivotal roles of interferon (IFN)-γ, interleukin (IL)-12, and tumor necrosis factor (TNF)-α in disease pathogenesis are demonstrated by the high incidence of mostly disseminated NTM disease in children with IFN-γ and IL-12 pathway deficiencies and in persons treated with agents that neutralize TNF-α.

Observed differences in pathogenicity, clinical relevance, and spectrum of clinical disease associated with the various NTM species emphasize the importance of bacterial factors in the pathogenesis of NTM disease, although exact virulence factors remain largely unknown.

CLINICAL MANIFESTATIONS

Lymphadenitis of the superior anterior cervical or submandibular lymph nodes is the most common manifestation of NTM infection in children (Table 263.1). Preauricular, posterior cervical, axillary, and inguinal nodes are involved occasionally. Lymphadenitis is most

Table 263.1 Major Clinical Syndromes Associated with Nontuberculous Mycobacterial Infection

SYNDROME	MOST COMMON CAUSES	LESS FREQUENT CAUSES*
Chronic nodular disease (adults with bronchiectasis; cystic fibrosis)	MAC (*M. intracellulare, M. avium*), *M. kansasii, M. abscessus*	*M. xenopi, M. malmoense, M. szulgai, M. smegmatis, M. celatum, M. simiae, M. goodii, M. asiaticum, M. heckeshornense, M. branderi, M. lentiflavum, M. triplex, M. fortuitum, M. arupense, M. abscessus* subsp. *bolletii, M. phocaicum, M. aubagnense, M. florentinum, M. abscessus* subsp. *massiliense, M. nebraskense, M. saskatchewanense, M. seoulense, M. senuense, M. paraseoulense, M. europaeum, M. sherrisii, M. kyorinense, M. noviomagense, M. mantenii, M. shinjukuense, M. koreense, M. heraklionense, M. parascrofulaceum, M. arosiense*
Cervical or other lymphadenitis (especially children)	MAC	*M. scrofulaceum, M. malmoense* (northern Europe), *M. abscessus, M. fortuitum, M. lentiflavum, M. tusciae, M. palustre, M. interjectum, M. elephantis, M. heidelbergense, M. parmense, M. bohemicum, M. haemophilum, M. europaeum, M. florentinum, M. triplex, M. asiaticum, M. kansasii, M. heckeshornense*
Skin and soft tissue disease	*M. fortuitum* group, *M. chelonae, M. abscessus, M. marinum, M. ulcerans* (Australia, tropical countries only)	*M. kansasii, M. haemophilum, M. porcinum, M. smegmatis, M. genavense, M. lacus, M. novocastrense, M. houstonense, M. goodii, M. immunogenum, M. mageritense, M. abscessus* subsp. *massiliense, M. arupense, M. monacense, M. bohemicum, M. branderi, M. shigaense, M. szulgai, M. asiaticum, M. xenopi, M. kumamotense, M. setense, M. montefiorense* (eels), *M. pseudoshottsii* (fish), *M. shottsii* (fish)
Skeletal (bone, joint, tendon) infection	*M. marinum*, MAC, *M. kansasii, M. fortuitum* group, *M. abscessus, M. chelonae*	*M. haemophilum, M. scrofulaceum, M. heckeshornense, M. smegmatis, M. terrae/chromogenicum* complex, *M. wolinskyi, M. goodii, M. arupense, M. xenopi, M. triplex, M. lacus, M. arosiense*
Disseminated infection		*M. genavense, M. haemophilum, M. xenopi*
HIV-seropositive host	*M. avium, M. kansasii*	*M. marinum, M. simiae, M. intracellulare, M. scrofulaceum, M. fortuitum, M. conspicuum, M. celatum, M. lentiflavum, M. triplex, M. colombiense, M. sherrisii, M. heckeshornense*
HIV-seronegative host	*M. abscessus, M. chelonae*	*M. marinum, M. kansasii, M. haemophilum, M. chimaera, M. conspicuum, M. shottsii* (fish), *M. pseudoshottsii* (fish)
Catheter-related infections	*M. fortuitum, M. abscessus, M. chelonae*	*M. mucogenicum, M. immunogenum, M. mageritense, M. septicum, M. porcinum, M. bacteremicum, M. brumae*
Hypersensitivity pneumonitis (metal workers; hot tub users)	*M. immunogenum, M. avium*	

*The available information is sparse for selected pathogens such as *M. xenopi, M. malmoense, M. szulgai, M. celatum*, and *M. asiaticum* and the newly described species.

In Bennett JF, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of* Infectious *Diseases*, 8th ed. Philadelphia: Elsevier; 2015: Table 254-1.

Fig. 263.1 Enlarging cervical lymph node infected with *Mycobacterium avium* complex infection. The node is firm, painless, freely movable, and not erythematous.

Fig. 263.2 Suppurating cervical lymph node infected with *Mycobacterium avium* complex.

Fig. 263.3 Ruptured cervical lymph node infected with *Mycobacterium avium* complex, which resembles the classic scrofula of tuberculosis.

common in children 1-5 years of age and has been related to soil exposure (e.g., playing in sandboxes) and teething, although exact predisposing conditions have not been identified. Given the constant environmental exposure to NTM, the occurrence of these infections might also reflect an atypical immune response of a subset of the infected children during or after their first contact with NTM. However, in healthy children with isolated NTM lymphadenitis, immunodeficiency is quite rare.

Affected children usually lack constitutional symptoms and present with a unilateral, subacute, and slowly enlarging lymph node or group of closely approximated nodes >1.5 cm in diameter that are firm, painless, freely movable, and not erythematous (Fig. 263.1). The involved nodes occasionally resolve without progression, but most undergo rapid suppuration after several weeks (Fig. 263.2). The center of the node becomes fluctuant, and the overlying skin thins and becomes erythematous and often even violaceous. Eventually, the nodes rupture and can form cutaneous sinus tracts that can drain persistently, reminiscent of scrofula from tuberculosis (Fig. 263.3).

In the United States and Western Europe, MAC accounts for approximately 80% of NTM lymphadenitis in children. *M. kansasii* accounts for most other cases of lymphadenitis in the United States. *M. malmoense* and *M. haemophilum* have also been described as causative agents of lymphadenitis. *M. malmoense* is most common in Northwestern Europe. For *M. haemophilum,* underestimation of its importance is likely because the bacteria require specific culture conditions (hemin-enriched media, low incubation temperatures). On the basis of PCR analysis of lymph node samples from lymphadenitis cases in The Netherlands, *M. haemophilum* is the second most common cause of this infection, after MAC. One study suggests that children with MAC lymphadenitis are significantly younger than those infected by *M. haemophilum,* possibly related to age-specific environmental exposures. *Mycobacterium lentiflavum* is also an emerging NTM associated with lymphadenitis.

Cutaneous disease caused by NTM is rare in children (see Table 263.1). Infection usually follows percutaneous inoculation with fresh or salt water contaminated by *M. marinum.* Within 2-6 weeks after exposure, an erythematous papule develops at the site of minor abrasions on the elbows, knees, or feet **(swimming pool granuloma)** and on the hands and fingers of fish tank owners, mostly inflicted during tank cleaning **(fish tank granuloma)**. These lesions are usually nontender and enlarge over 3-5 weeks to form violaceous plaques. Nodules or pustules can develop and occasionally will ulcerate, resulting in a serosanguineous discharge. The lesions sometimes resemble sporotrichosis, with satellite lesions near the site of entry, extending along the superficial lymphatics. Lymphadenopathy is usually absent. Although most infections remain localized to the skin, penetrating *M. marinum* infections can result in tenosynovitis, bursitis, osteomyelitis, or arthritis.

M. ulcerans infection is the third most common mycobacterial infection in immunocompetent patients, after *M. tuberculosis* and *M. leprae* infection, and causes cutaneous disease in children living in tropical regions of Africa, South America, Asia, and parts of Australia. In some communities in West Africa, up to 16% of people have been affected. Children <15 years old are particularly affected in rural tropical counties, accounting for 48% of infected individuals in Africa. Infection follows percutaneous inoculation from minor trauma, such as pricks and cuts from plants or insect bites. After an incubation period of approximately 3 months, lesions appear as an erythematous nodule, usually on the legs or arms. The lesion undergoes central necrosis and ulceration. The lesion, often called a **Buruli ulcer** after the region in Uganda where a large case series was reported, has a characteristic undermined edge, expands over several weeks, and can result in extensive, deep soft tissue destruction or bone involvement (Fig. 263.4). Lesions are typically painless, and constitutional symptoms are unusual. Lesions might heal slowly over 6-9 months or might continue to spread, leading to deformities, contractures, and disability. Depending on the location of the ulcer, these can be significantly disfiguring.

Skin and soft tissue infections caused by **rapidly growing mycobacteria**, such as *M. fortuitum, M. chelonae,* or *M. abscessus,* are rare in children and usually follow percutaneous inoculation from puncture or surgical wounds, minor abrasions, or tattooing. There has been a large outbreak of *M. fortuitum* furunculosis related to nail salon footbaths. Clinical disease usually arises after a 4- to 6-week incubation period and manifests as localized cellulitis, painful nodules, or a draining abscess. *M. haemophilum* can cause painful subcutaneous nodules, which often ulcerate and suppurate in immunocompromised patients, particularly after kidney transplantation.

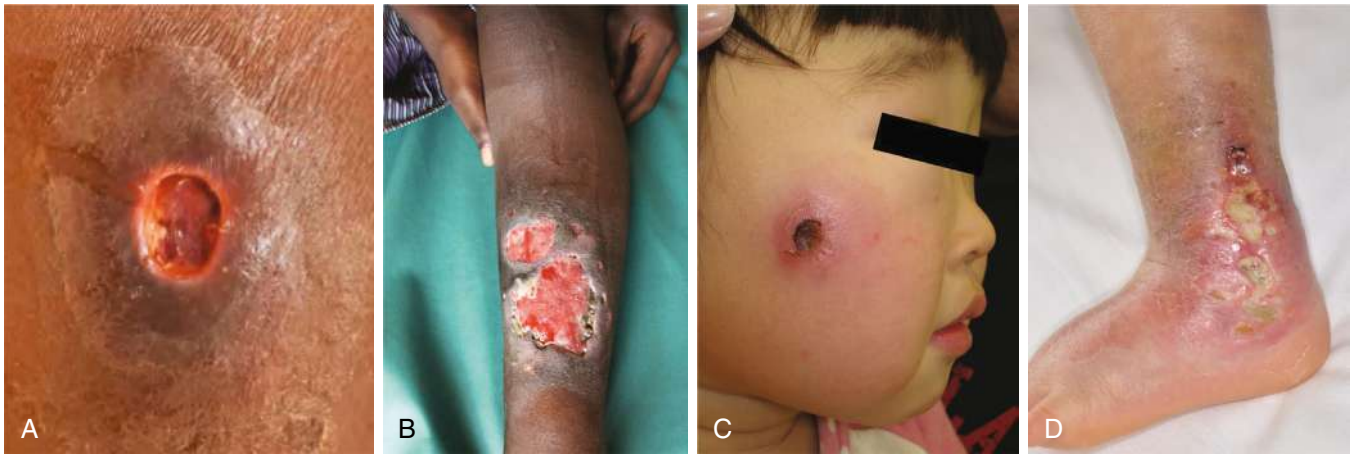

Fig. 263.4 Buruli ulcer lesions in patients from West Africa (**A** and **B**) and Japan (**C** and **D**). *(A, B from Röltgen K, Pluschke G. Buruli ulcer: history and disease burden. In: Pluschke G, Röltgen K, eds. Buruli Ulcer. Cham: Springer; 2019; C, D courtesy Dr Mikio Ohtsuka, Fukushima Medical University.)*

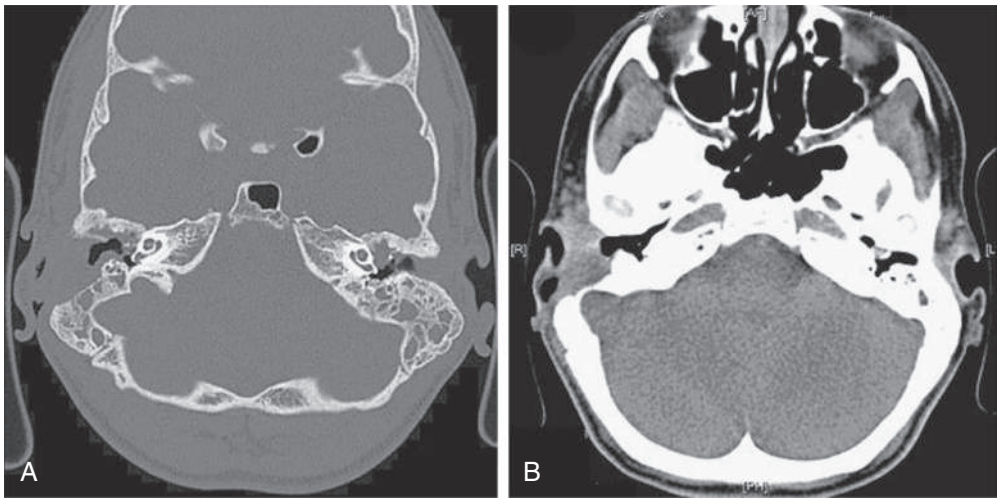

Fig. 263.5 CT images of the middle ear of 6-yr-old child infected with *Mycobacterium abscessus*, demonstrating extensive bone destruction in the right mastoid and associated right-sided mucosal swelling. **A,** Bone tissue window setting. **B,** Soft tissue window setting.

NTM are an uncommon cause of **catheter-associated infections** but are becoming increasingly recognized in this respect. Infections caused by *M. fortuitum, M. chelonae,* or *M. abscessus* can manifest as bacteremia or localized catheter tunnel infections.

Otomastoiditis, or chronic otitis media, is a rare extrapulmonary NTM disease type that specifically affects children with tympanostomy tubes and a history of topical antibiotic or steroid use. *M. abscessus* is the most common causative agent, followed by MAC (see Table 263.1). Patients present with painless, chronic otorrhea resistant to antibiotic therapy. CT can reveal destruction of the mastoid bone with mucosal swelling (Fig. 263.5).

Delayed or unsuccessful treatment can result in permanent hearing loss. In unusual circumstances, NTM cause other bone and joint infections that are indistinguishable from those produced by *M. tuberculosis* or other bacterial agents. Such infections usually result from operative incision or accidental puncture wounds. *M. fortuitum* infections from puncture wounds of the foot resemble infections caused by *Pseudomonas aeruginosa* and *Staphylococcus aureus*.

Pulmonary infections are the most common form of NTM illness in adults but are rare in children. MAC bacteria, the most commonly identified organisms (see Table 263.1), are capable of causing acute pneumonitis, chronic cough, or wheezing associated with paratracheal or peribronchial lymphadenitis and airway compression in normal children. Associated constitutional symptoms such as fever, anorexia, and weight loss occur in 60% of these children. Chest radiographic findings are similar to those for primary tuberculosis, with unilateral infiltrates and hilar lymphadenopathy (Fig. 263.6). Pleural effusion is

Fig. 263.6 Chest radiograph of 2-yr-old child infected with *Mycobacterium avium* complex, demonstrating a left upper lobe infiltrate and left hilar lymphadenopathy.

uncommon. Rare cases of progression to endobronchial granulation tissue have been reported.

Pulmonary infections usually occur in adults with underlying chronic lung disease. The onset is insidious and consists of cough and fatigue, progressing to weight loss, night sweats, low-grade fever, and generalized malaise in severe cases. Thin-walled cavities with minimal surrounding parenchymal infiltrates are characteristic, but radiographic findings can resemble those of tuberculosis. A separate disease manifestation occurs typically in postmenopausal women and is radiologically characterized by bronchiectasis and nodular lesions, often affecting the middle lobe and lingula (Lady Windemere's syndrome).

Chronic pulmonary infections specifically affect children with CF and are generally caused by *M. abscessus* or MAC. *M. abscessus* primarily affects children, and MAC is most common among adults. The percentage of CF patients with at least one sputum culture positive for NTM is 6–8.1% overall and increases with age; in CF patients <12 years old, a prevalence of 3.9% has been reported. The strong representation of *M. abscessus* in these patients is remarkable, because this bacterium is an uncommon isolate in other categories of patients. There are indications that NTM infections in CF patients further accelerate the decline in lung function; antimycobacterial therapy can result in weight gain and improved lung function in affected patients.

Disseminated disease is usually associated with MAC infection and occurs in immunocompromised children. The first category of patients with disseminated disease includes persons with mutations in genes coding for the interferon-γ receptor (IFNGR) or the IL-12 receptor or for IL-12 production. Patients with complete **IFNGR deficiency** have severe, difficult-to-treat disease. Those with partial IFNGR deficiency or IL-12 pathway mutations have milder disease that can respond to IFN-γ and antimycobacterial therapy. **Multifocal osteomyelitis** is particularly prevalent in persons with the IFNGR1 818del4 mutation. Recurrences, even years after a course of treatment, and multiple infections are well documented. The second category of patients affected by disseminated disease is patients with **AIDS**. Disseminated NTM disease in patients with AIDS usually appears when CD4 cell counts are <50/μL for children ≥6 years , <75/μL in children 2 to <6 years, <500/μL in children 1 to <2 years, and <750/μL in children <1 year. The most recent estimate of the incidence of disseminated NTM disease is 0.14-0.2 episodes per 100 person-years, a 10-fold decrease from its incidence before combination antiretroviral therapy (cART) was available.

Colonization of the respiratory or gastrointestinal (GI) tract probably precedes disseminated MAC infections, but screening studies of respiratory secretions or stool samples are not useful to predict dissemination. Continuous high-grade bacteremia is common, and multiple organs are infected, typically including the lymph nodes, liver, spleen, bone marrow, and GI tract. The thyroid, pancreas, adrenal gland, kidney, muscle, and brain can also be involved. The most common signs and symptoms of disseminated MAC infections in patients with AIDS are fever, night sweats, chills, anorexia, marked weight loss, wasting, weakness, generalized lymphadenopathy, and hepatosplenomegaly. Jaundice, elevated alkaline phosphatase or lactate dehydrogenase levels, anemia, and neutropenia can occur. Imaging studies usually demonstrate massive lymphadenopathy of hilar, mediastinal, mesenteric, or retroperitoneal nodes. Successful treatment of disseminated infection in children with AIDS requires immune reconstitution and cART in addition to specific NTM therapy. The survival in children with AIDS has improved considerably with the availability of cART.

Disseminated disease in children without any apparent immunodeficiency is exceedingly rare.

DIAGNOSIS

For infections of lymph nodes, skin, bone, and soft tissues, isolation of the causative NTM bacteria by *Mycobacterium* culture, preferably with histologic confirmation of granulomatous inflammation, normally suffices for diagnosis. The differential diagnosis of NTM lymphadenitis includes acute bacterial lymphadenitis, tuberculosis, cat scratch disease *(Bartonella henselae* infection*)*, mononucleosis, toxoplasmosis, brucellosis, tularemia, and malignancies, especially lymphomas.

Table 263.2 American Thoracic Society Clinical and Microbiologic Criteria for Diagnosis of Nontuberculous Mycobacteria (NTM) Pulmonary Disease

CLINICAL*	PULMONARY OR SYSTEMIC SYMPTOMS
Radiologic*	Nodular or cavitary opacities on chest radiograph or a high-resolution computed tomography (HRCT) scan that shows bronchiectasis with multiple small nodules
AND	Appropriate exclusion of other diagnoses
Microbiologic	1. Positive culture results from at least two separate expectorated sputum samples. If the results are nondiagnostic, consider repeat sputum AFB smears and cultures. or 2. Positive culture results from at least one bronchial wash or lavage. or 3. Transbronchial or other lung biopsy with mycobacterial histologic features (granulomatous inflammation or AFB) and positive culture for NTM or biopsy showing mycobacterial histologic features (granulomatous inflammation or AFB) and one or more sputum or bronchial washings that are culture-positive for NTM.

*Note: Both clinical and radiologic criteria are required.
AFB, Acid-fast bacilli.
From Daley CL, Iaccarino JM, Lange C, et al. Treatment of nontuberculous mycobacterial pulmonary disease: an official ATS/ERS/ESCMID/IDSA Clinical Practice Guideline [published correction appears in Clin Infect Dis. 2020 Dec 31;71(11):3023]. *Clin Infect Dis.* 2020;71(4):e1–e36.

Differentiation between NTM and *M. tuberculosis* may be difficult, but children with NTM lymphadenitis usually have a Mantoux tuberculin skin test reaction of <15 mm induration, unilateral anterior cervical node involvement, a normal chest radiograph, and no history of exposure to tuberculosis. Definitive diagnosis requires excision of the involved nodes for culture and histology. Fine-needle aspiration for PCR and culture can enable earlier diagnosis, before excisional biopsy.

The diagnosis of pulmonary NTM infection in children is difficult because many species of NTM, including MAC, are omnipresent in our environment and can contaminate clinical samples or be present but not causative of disease. As a result, isolation of these bacteria from nonsterile specimens (respiratory and digestive tract) does not necessarily reflect true disease. To determine the clinical relevance of isolation of NTM, the ATS/BTS diagnostic criteria are an important support (Table 263.2). These criteria take into consideration clinical features and radiologic, pathologic, and microbiologic findings. Their hallmark is the need for multiple positive cultures yielding the same NTM species to make a definitive diagnosis of pulmonary NTM disease, though a single culture from bronchoalveolar lavage (BAL)/bronchial lavage is acceptable in patients who meet clinical and radiologic criteria. In children, definitive diagnosis often requires invasive procedures such as bronchoscopy and pulmonary or endobronchial biopsy; in CF patients, more aggressive sample pretreatment in the clinical microbiology laboratory is necessary to prevent overgrowth by other species, especially *Pseudomonas*. The chance of NTM isolation being clinically relevant differs significantly by species; some species are more likely causative agents of true pulmonary disease *(M. avium, M. kansasii*, *M. abscessus, M. malmoense)*, whereas others are more likely contaminants (*M. gordonae, M. fortuitum, M. chelonae)*.

Blood cultures are 90–95% sensitive in AIDS patients with disseminated infection. MAC may be detected within 7-10 days of inoculation in almost all patients by automated blood culture systems. In adults, some studies have shown that liver biopsy cultures and stains are more sensitive than blood culture or bone marrow biopsy workup. Commercially available DNA probes differentiate NTM from *M.*

tuberculosis. If DNA probes cannot identify the causative mycobacteria, DNA sequencing of bacterial housekeeping genes can yield a clue to the identity of these NTM. Identification of histiocytes containing numerous AFB from bone marrow and other biopsy tissues provides a rapid presumptive diagnosis of disseminated mycobacterial infection.

TREATMENT

Therapy for NTM infections is long-term and cumbersome; expert consultation is advised. Therapy involves medical, surgical, or often combined treatment (see Chapter 260, Table 260.3). Isolation of the infecting strain followed by drug-susceptibility testing is ideal, because it provides a baseline for drug susceptibility. Important discrepancies exist between in vitro drug susceptibility and in vivo response to treatment, explained in part by synergism, mainly among first-line antituberculosis drugs. In vitro, **slow growers** *(M. kansasii, M. marinum, M. xenopi, M. ulcerans, M. malmoense)* are usually susceptible to the first-line antituberculosis drugs **rifampin** and **ethambutol**; MAC bacteria are often resistant to these drugs alone but susceptible to the combination and have variable susceptibility to other antibiotics, most importantly the macrolides. **Rapid growers** *(M. fortuitum, M. chelonae, M. abscessus)* are highly resistant to antituberculosis drugs and often have inducible macrolide-resistance mechanisms. Susceptibility to macrolides, aminoglycosides, carbapenems, tetracyclines, and glycylcyclines are most relevant for therapy guidance. In all NTM infections, multidrug therapy (MDT) is essential to avoid development of resistance.

The preferred treatment of NTM lymphadenitis is complete surgical excision. Clinical trials revealed that surgery is more effective than antibiotic treatment (see Table 260.3). Nodes should be removed while still firm and encapsulated. Excision is more difficult if extensive caseation with extension to surrounding tissue has occurred, and complications of facial nerve damage or relapse of infection are more likely in such cases. Incomplete surgical excision is not advised, because chronic drainage can develop. If there are concerns or risk factors for possible *M. tuberculosis* infection, therapy with isoniazid, rifampin, ethambutol, and pyrazinamide should be administered until cultures confirm the cause to be NTM (see Chapter 261). If surgery of NTM lymphadenitis cannot be performed, or removal of infected tissue is incomplete, or recurrence or chronic drainage develops, a 3-month trial of antibiotic therapy should be considered. **Clarithromycin or azithromycin combined with rifampin or ethambutol are the most common therapy regimens reported for MAC lymphadenitis** (see Table 260.3). Suppuration may still occur on appropriate antibiotic therapy. In immunocompetent patients, **an observational approach** to NTM lymphadenitis can be chosen without antibiotic therapy, although resolution will take up to 12 months.

Posttraumatic cutaneous NTM lesions in immunocompetent patients usually heal spontaneously after incision and drainage without other therapy. *M. marinum* is susceptible to rifampin, amikacin, ethambutol, sulfonamides, trimethoprim-sulfamethoxazole, and tetracycline. Therapy with a combination of these drugs, particularly clarithromycin and ethambutol, may be given until 1 month after the lesion has disappeared. Corticosteroid injections should not be used. Superficial infections with *M. fortuitum* or *M. chelonae* usually resolve after surgical incision and open drainage, but deep-seated or catheter-related infections require removal of infected central lines and therapy with parenteral amikacin plus cefoxitin, ciprofloxacin, or clarithromycin.

Some localized forms of *M. ulcerans* skin disease (Buruli ulcer) can heal spontaneously; for most forms, excisional surgery with primary closure or skin grafting is recommended. **The combination of rifampin (10 mg/kg once daily) and clarithromycin (7.5 mg/kg twice daily) for 8 weeks results in excellent outcomes and is now the recommended treatment for early limited Buruli ulcer.** Another agent that shows great promise is telacebec (also known as *Q203*), a novel first-in-class antituberculosis drug targeting cellular energy production through inhibition of the mycobacterial cytochrome bc1 complex; animal studies have demonstrated significant potency against *M. ulcerans,* possibly allowing for shorter courses of treatment. In January 2021, the U.S. Food and Drug Administration granted orphan drug designation (ODD) to telacebec for Buruli ulcer treatment. **Physiotherapy** after surgery is essential to prevent contractures and functional disabilities.

For patients who meet diagnostic criteria for pulmonary NTM infections (see Table 263.2), treatment rather than observation is recommended, particularly with persistently positive sputum smears and/or cavitary lung disease. Although treatment offers possibility of cure, there can be significant adverse effects of treatment and low cure rates for some forms of infection. Patients who require treatment for NTM pulmonary disease should have isolates sent for susceptibility testing, with the caveat that this testing is helpful for NTM for antibiotics where there is a well-documented correlation between in vitro activity and microbiologic response to therapy. Drugs for which this correlation exist include macrolides (azithromycin, clarithromycin) and amikacin for MAC and *M. abscessus* and rifampin for *M. kansasii*. **For macrolide-susceptible MAC pulmonary disease, treatment with three drugs for at least 12 months after culture conversion is recommended, generally azithromycin, rifampin, and ethambutol.** For macrolide-resistant isolates, parenteral amikacin is often used, as MAC isolates are usually susceptible in vitro to this agent.

Macrolides are a mainstay in the treatment of *M. abscessus* pulmonary disease. However, macrolide resistance can develop via chromosomal mutation or through induction of the erm(41) gene. **For *M. abscessus* disease caused by strains without inducible or chromosomal macrolide resistance, a macrolide-containing treatment regimen is recommended, typically with at least three active drugs. If macrolide resistance (chromosomal or inducible) is present, at least four active drugs are recommended. Treatment regimens for *M. abscessus* are complex, usually with oral plus parental drugs. Regimens typically include two to three oral agents, which may include azithromycin, clofazimine, or linezolid, and at least one parenteral agent, with options including amikacin, imipenem, and tigecycline.** In CF patients, inhaled agents may also have a role. Choice of treatment regimens and duration of therapy should be guided by expert consultation. For select patients, surgical resection of severely diseased lung in addition to medical therapy may be indicated.

For *M. kansasii* pulmonary disease, susceptibility-based treatment for rifampin is recommended over empirical therapy. The recommended treatment regimen for rifampin-susceptible *M. kansasii* infections is rifampin, ethambutol, and either isoniazid or a macrolide for at least 12 months. Fluoroquinolones also have good activity against *M. kanasasii* but are reserved for rifampin-resistant *M. kansasii* infection treatment and for patients who have intolerance to one of the first-line antibiotics.

Patients with disseminated MAC and IL-12 pathway defects or IFNGR deficiency should be treated for at least 12 months with clarithromycin or azithromycin combined with rifampin or rifabutin and ethambutol. In vitro susceptibility testing for macrolides is important to guide therapy. Once the clinical illness has resolved, lifelong daily prophylaxis with azithromycin or clarithromycin is advisable to prevent recurrent disease. The use of IFN adjunctive therapy is determined by the specific genetic defect.

In children with AIDS, prophylaxis with azithromycin or clarithromycin is indicated to prevent infection with MAC. Although few pediatric studies exist, the U.S. Public Health Service recommends either **azithromycin** (20 mg/kg once weekly PO, maximum 1,200 mg/dose *or* 5 mg/kg once daily PO, maximum 250 mg/dose in patients intolerant of the larger dose) or **clarithromycin** (7.5 mg/kg/dose twice daily PO; maximum 500 mg/dose) for HIV-infected children with significant immune deficiency, as defined by the CD4 count (children ≥6 years old, CD4 count <50 cells/μL; 2 to <6 years old, <75/μL; 1 to <2 years old, <500/μL; <1 year old, <750/μL). Rifabutin may also be used. Primary prophylaxis may be safely discontinued in children >2 years old receiving stable highly active antiretroviral therapy (HAART) for >6 months and experiencing sustained (>3 months) CD4 cell recovery well above the age-specific target for initiation of prophylaxis: >100 cells/μL for children ≥6 years old and >200/μL for children 2-5 years old. For children <2 years old, no specific recommendations for discontinuing MAC prophylaxis exist.

Section 8

Spirochetal Infections

Chapter 264

Syphilis (*Treponema pallidum*)

Alice I. Sato and H. Dele Davies

Syphilis is a chronic systemic sexually or vertically (mother to child) transmitted infection that can be easily treated if detected early but manifests with protean clinical symptoms and significant morbidity if left unchecked. (Please note that the terms *mother* and *maternal* are used to designate the birthing parent throughout this chapter and are not intended to exclude other birthing parents.)

ETIOLOGY

Syphilis is caused by *Treponema pallidum,* a delicate, tightly spiraled, motile spirochete with finely tapered ends belonging to the family Spirochaetaceae. The pathogenic members of this genus include *T. pallidum* subspecies *pallidum* (venereal syphilis), *T. pallidum* subspecies *pertenue* (yaws), *T. pallidum* subspecies *endemicum* (bejel or endemic syphilis), and *T. pallidum* subspecies *carateum* (pinta). Because these microorganisms stain poorly and are below the detection limits of conventional light microscopy, detection in clinical specimens requires dark-field, phase-contrast microscopy or direct immunofluorescent or silver staining. *T. pallidum* has only recently been successfully grown in vitro via co-culture with mammalian tissue culture cells, and a method has now been described for inoculation of fresh and frozen needle aspirates from primary experimental syphilis lesions onto culture plates but remains to be developed for clinical use. Use of nucleic acid amplification testing by polymerase chain reaction (PCR) may have a role in diagnosis, particularly in seronegative patients or those with discrepant serology results.

EPIDEMIOLOGY

Acquired syphilis is transmitted almost exclusively by sexual contact, including vaginal, anal, and oral exposure. Less common modes of transmission include transfusion of contaminated blood or direct contact with infected tissues. Syphilis in men who have sex with men (MSM) may be acquired in the absence of visible lesions. DNA-based *T. pallidum* testing has identified organisms in oral rinse or swab samples and in anal canal swabs, urine, semen, and peripheral blood; the risk is highest in secondary and early latent syphilis. The incubation period for acquired primary syphilis is about 3 weeks (range 10-90 days). After an epidemic resurgence of primary and secondary syphilis in the United States that peaked in 1989, the annual rate declined 90% to the lowest-ever rate by 2000. The total number of cases of primary and secondary syphilis has subsequently rebounded since 2000 (Fig. 264.1). MSM have been disproportionately impacted: ~46% of cases in 2021. Rates of primary and secondary syphilis in women remain lower than in men yet still have increased 55% during 2021. Cases of congenital syphilis reached an historic low in 2005 but have subsequently increased annually since 2013, reflecting the rates among women. In 2021, the US national congenital syphilis rate was 77.9 cases per 100,000 live births, representing a 30.5% increase from 2020 and a 219.3% increase from 2017 (Fig. 264.2); syphilitic still births also increased over this period. The increase occurs across every region and all races and ethnicities, but marked disparities exist,

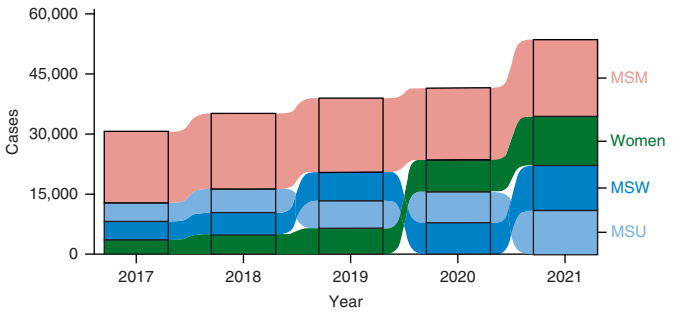

Fig 264.1 Primary and secondary syphilis – Reported cases by sex and sex of sex partners 2017–2021. Note: Over the 5-yr period, 0.2% of cases were missing sex and were not included. MSM, Gay, bisexual, and other men who have sex with men; MSU, Men with unknown sex of sex partners; MSW, men who have sex with women only. *(From Centers for Disease Control and Prevention. Sexually transmitted disease surveillance. National overview of STDs, 2021. https://www.cdc.gov/std/statistics/2021/overview.htm)*

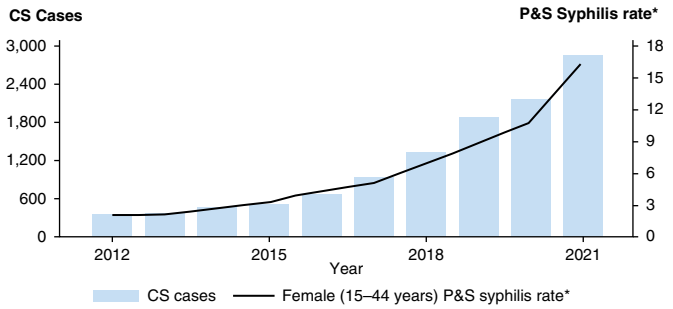

Fig. 264.2 Congenital syphilis — Reported cases by year of birth and rates of reported cases of primary and secondary syphilis among women age 15-44 years, United States, 2012–2021. *Per 100,000. CS, Congenital syphilis; P&S syphilis, Primary and secondary syphilis. *(From Centers for Disease Control and Prevention. Sexually transmitted disease surveillance. National overview of STDs, 2021. https://www.cdc.gov/std/statistics/2021/overview.htm)*

with minority groups, gay and bisexual men, and youth most affected. The COVID-19 pandemic disrupted screening programs and access to care, and increased cases are expected.

Congenital syphilis results from transplacental transmission of spirochetes or occasionally by intrapartum contact with infectious lesions or possibly involved mucosa without obvious lesions. Women with primary and secondary syphilis and spirochetemia are more likely to transmit infection to the fetus than are women with latent infection. Transmission can occur at any stage of pregnancy, resulting in early fetal loss, preterm or low birthweight infants, stillbirths, neonatal deaths, or infants born with congenital disease. The incidence of congenital infection in offspring of untreated or inadequately treated infected women remains highest during the first 4 years after acquisition of primary infection, secondary infection, and early latent disease. Maternal (parental) factors associated with congenital syphilis include limited access to healthcare, late or no prenatal care, drug use, multiple sex partners, unprotected sexual contact, incarceration, work in the sex trade, and inadequate treatment of syphilis during pregnancy. Congenital syphilis may be seen in the context of untreated, inadequately treated, or undocumented treatment before or during pregnancy. In addition, the mother may have been treated appropriately but did not have an adequate serologic response to therapy and the infant was inadequately evaluated, or the infant had documented congenital syphilis. Confirmed cases of both acquired and congenital syphilis must be reported to the local health department.

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

Many persons infected with syphilis are *asymptomatic for years,* or do not recognize the early signs of disease, or do not seek or have access

to treatment. The Centers for Disease Control and Prevention (CDC) recommends testing all pregnant persons and selective testing of adolescents, based on lesions or risk factors (those with other sexually transmitted diseases including HIV, MSM, incarcerated individuals, or persons who exchange sex for money or drugs). CDC/MMWR sexually transmitted infection (STI) guidelines should be consulted to ensure that all appropriate screening is performed. All 50 states and the District of Columbia explicitly allow minors to consent for STI services, though as of 2022, 18 states allow (but do not require) physicians to notify parents of STI services provided to a minor (https://www.cdc.gov/hiv/policies/law/states/minors.html). Periods of active clinical disease alternate with periods of latency (Fig. 264.3). **Primary syphilis** is characterized by a chancre and regional lymphadenitis. A **painless papule** (which may be overlooked) appears at the site of entry (usually the genitalia) 2-6 weeks after inoculation and develops into a clean, painless but highly contagious ulcer with raised borders **(chancre)** containing abundant *T. pallidum*. Extragenital chancres can occur at other sites of primary entry and pose a diagnostic challenge. Oral lesions can be mistaken for aphthous ulcers or herpes. Lesions on the nipple can be confused with cellulitis or eczema. Adjacent lymph nodes are generally enlarged and nontender. The chancre heals spontaneously within 4-6 weeks, leaving a thin scar.

Untreated patients develop manifestations of **secondary syphilis** related to spirochetemia 2-10 weeks after the chancre heals. Manifestations of secondary syphilis include a generalized nonpruritic maculopapular rash, notably involving the palms and soles (Fig. 264.4). Pustular lesions can also develop. **Condylomata lata**, gray-white to erythematous wartlike plaques, can occur in moist areas around the anus, scrotum, or vagina, and white plaques **(mucous patches)** may be found in mucous membranes. Secondary syphilis should be considered in the differential diagnosis of virtually any rash of unknown etiology. A **flulike illness** with low-grade fever, headache, malaise, anorexia, weight loss, sore throat, myalgias, arthralgias, and generalized lymphadenopathy is often present. Renal, hepatic, or ocular manifestations may be present. Meningitis occurs in about 30% of patients with untreated syphilis, occurring at any stage but most commonly in

Fig. 264.4 Secondary syphilis. Ham-colored palmar macules on an adolescent with secondary syphilis. *(From Weston WL, Lane AT, Morelli J. Color Textbook of Pediatric Dermatology, 3rd ed. St. Louis: Mosby; 2002.)*

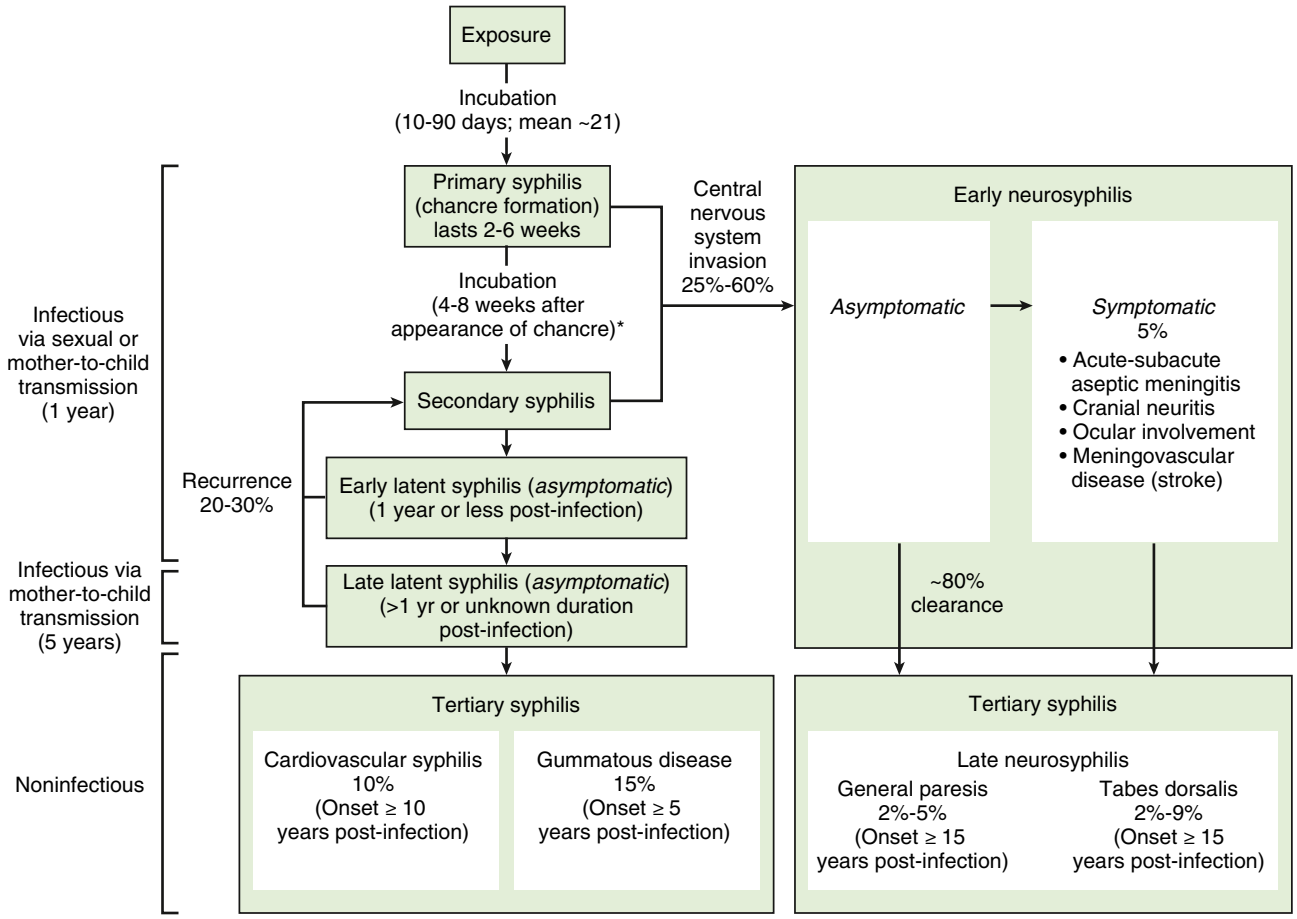

Fig. 264.3 Natural course of untreated syphilis. As of January 2018, the Centers for Disease Control and Prevention renamed early and late latent syphilis *early syphilis, nonprimary, nonsecondary* and *syphilis, unknown duration or late*, respectively. *HIV infection may modify the progression of syphilis; the chancre may coexist with the secondary syphilis stage, suggesting a more rapid progression to the secondary stage. *(Modified from Radolf JD, Tramont EC, Salazar JC. Syphilis [Treponema pallidum]. In: Bennett JE, Dolin R, Blaser MJ, eds. Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases, 9th ed. Philadelphia: Elsevier; 2020: Fig. 237.5, p. 2874.)*

secondary syphilis (see Fig. 264.3). It is characterized by cerebrospinal fluid (CSF) pleocytosis and elevated protein level. Patients with meningitis might not show neurologic symptoms. Even without treatment, secondary infection becomes **latent** within 1-2 months after onset of rash. Relapses with secondary manifestations can occur during the first year of latency (the **early latent period**). **Late syphilis** follows and may be either asymptomatic **(late latent)** or symptomatic **(tertiary)**. Tertiary disease follows in about one-third of untreated cases and is marked by neurologic, cardiovascular, and **gummatous lesions** (nonsuppurative granulomas of the skin, bone, and liver resulting from the host cytotoxic T-cell response). In the preantibiotic era, neurologic manifestations of tertiary syphilis **(tabes dorsalis** and **paresis)** were common. The clinical course of syphilis and its tissue manifestations reflect the immunopathobiology of the host humoral and delayed-type hypersensitivity responses. A robust timeline of progression through the overlapping stages occurs in immunocompromised HIV patients

Congenital Infection

Untreated syphilis during pregnancy results in a vertical transmission rate approaching 100%, with profound effects on pregnancy outcome, reflecting obliterating endarteritis. Fetal or perinatal death occurs in 40% of affected infants. Premature delivery can also occur. Neonates can also be infected at delivery by contact with an active genital lesion. Most infected infants are asymptomatic at birth, including up to 40% with CSF seeding, and are identified only by routine prenatal screening. In the absence of treatment, symptoms develop within weeks or months. Among infants symptomatic at birth or in the first few months of life, manifestations have traditionally been divided into early and late stages. All stages of congenital syphilis are characterized by a vasculitis, with progression to necrosis and fibrosis. The **early signs** appear during the first 2 years of life, and the **late signs** appear gradually during the first 2 decades. Early manifestations vary and involve multiple organ systems, resulting from transplacental spirochetemia, and are analogous to the secondary stage of acquired syphilis. Hepatosplenomegaly, jaundice, and elevated liver enzymes are common. Histologically, liver involvement includes bile stasis, fibrosis, and extramedullary hematopoiesis. Lymphadenopathy tends to be diffuse and resolve spontaneously, although shotty nodes can persist.

Fig. 264.5 Osteochondritis and periostitis in a newborn with congenital syphilis.

Coombs-negative hemolytic anemia is characteristic. Thrombocytopenia is often associated with platelet trapping in an enlarged spleen. Characteristic **osteochondritis** and **periostitis** (Fig. 264.5) and a mucocutaneous rash (Fig. 264.6A and B) manifesting with erythematous maculopapular or vesiculobullous lesions followed by desquamation involving the hands and feet (see Fig. 264.6C) are common. Mucous patches, persistent rhinitis **(snuffles)**, and condylomatous lesions (Fig. 264.7) are highly characteristic features of mucous membrane involvement containing abundant spirochetes. Blood and moist, open lesions from infants with congenital syphilis and children with acquired primary or secondary syphilis are infectious until 24 hours of appropriate treatment.

Bone involvement is common. Roentgenographic abnormalities include **Wimberger lines** (demineralization of the medial proximal tibial metaphysis); multiple sites of osteochondritis at the wrists, elbows, ankles, and knees; and periostitis of the long bones and, rarely, the skull. The osteochondritis is painful, often resulting in irritability and refusal to move the involved extremity **(pseudoparalysis of Parrot)**.

Congenital neurosyphilis is often asymptomatic in the neonatal period, although CSF abnormalities can occur even in asymptomatic infants. Failure to thrive, chorioretinitis, nephritis, and nephrotic syndrome can also be seen. Manifestations of renal involvement include hypertension, hematuria, proteinuria, hypoproteinemia, hypercholesterolemia, and hypocomplementemia, probably related to glomerular deposition of circulating immune complexes. Less common clinical manifestations of early congenital syphilis include gastroenteritis, peritonitis, pancreatitis, pneumonia, eye involvement (glaucoma and chorioretinitis), nonimmune hydrops, and testicular masses.

Late manifestations (children >2 years of age) are rarely seen in developed countries. These result primarily from chronic granulomatous inflammation of bone, teeth, and the central nervous system and are summarized in Table 264.1. Skeletal changes are caused by persistent or recurrent periostitis and associated thickening of the involved

Fig. 264.8 Hutchinson teeth as a late manifestation of congenital syphilis.

Table 264.1 Late Manifestations of Congenital Syphilis

SYMPTOM/SIGN	DESCRIPTION/COMMENTS
Olympian brow	Bony prominence of the forehead caused by persistent or recurrent periostitis
Clavicular or Higoumenakis sign	Unilateral or bilateral thickening of the sternoclavicular third of the clavicle
Saber shins	Anterior bowing of the midportion of the tibia
Scaphoid scapula	Convexity along the medial border of the scapula
Hutchinson teeth	Peg-shaped upper central incisors; they erupt during sixth yr of life with abnormal enamel, resulting in a notch along the biting surface
Mulberry molars	Abnormal first lower (6 yr) molars characterized by small biting surface and excessive number of cusps
Saddle nose*	Depression of the nasal root, a result of syphilitic rhinitis destroying adjacent bone and cartilage
Rhagades	Linear scars that extend in a spokelike pattern from previous mucocutaneous fissures of the mouth, anus, and genitalia
Juvenile paresis	Latent meningovascular infection; it is rare and typically occurs during adolescence with behavioral changes, focal seizures, or loss of intellectual function
Juvenile tabes	Rare spinal cord involvement and cardiovascular involvement with aortitis
Hutchinson triad	Hutchinson teeth, interstitial keratitis, and eighth cranial nerve deafness
Clutton joint	Unilateral or bilateral painless joint swelling (usually involving the knees) from synovitis with sterile synovial fluid; spontaneous remission usually occurs after several weeks
Interstitial keratitis	Manifests with intense photophobia and lacrimation, followed within weeks or months by corneal opacification and complete blindness
Eighth cranial nerve deafness	May be unilateral or bilateral, appears at any age, manifests initially as vertigo and high-tone hearing loss, and progresses to permanent deafness

*A perforated nasal septum may be an associated abnormality.

Fig. 264.9 Saddle nose in a newborn with congenital syphilis.

bone. Dental abnormalities, such as **Hutchinson teeth** (Fig. 264.8), are common. Defects in enamel formation lead to repeated caries and eventual tooth destruction. **Saddle nose** (Fig. 264.9) is a depression of the nasal root and may be associated with a perforated nasal septum.

Other late manifestations of congenital syphilis can manifest as hypersensitivity phenomena. These include unilateral or bilateral interstitial keratitis and the **Clutton joint** (see Table 264.1). Other common ocular manifestations include choroiditis, retinitis, vascular occlusion, and optic atrophy. Soft tissue gummas (identical to those of acquired disease) and paroxysmal cold hemoglobinuria are rare hypersensitivity phenomena.

DIAGNOSIS

Fundamental limitations of the currently available tests for syphilis are vexing, but results must always be interpreted in the context of patient history and physical examination. Physicians should remain aware of their local prevalence rates and treat presumptively when syphilis is suspected by clinical and epidemiologic data. The diagnosis of primary syphilis is confirmed when *T. pallidum* is demonstrated by dark-field microscopy or direct fluorescent antibody testing on specimens from skin lesions, placenta, or umbilical cord. Nucleic acid–based amplification assays, such as PCR, are also used in some specialized laboratories but are not commercially available. Despite the absence of a true

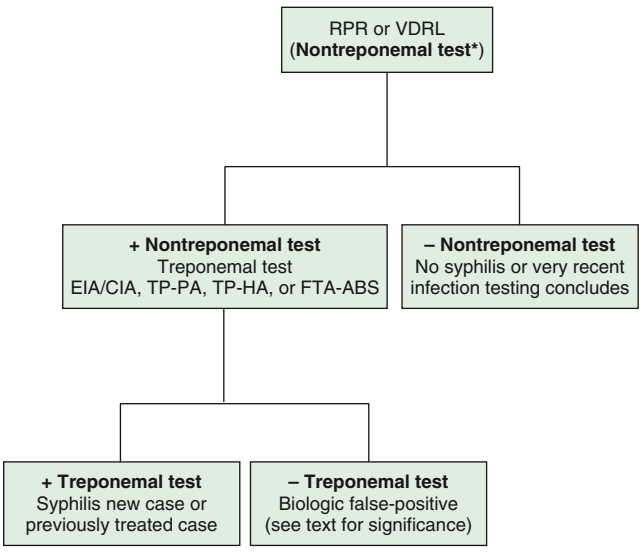
gold-standard serologic assay, serologic testing for syphilis remains the principal means for diagnosis and traditionally involves a two-step screening process with a nontreponemal test followed by a confirmatory treponemal test (Fig. 264.10A). Both test types are required for serologic-based diagnosis. False-negative tests may occur in early syphilis, and high-risk individuals may need repeat testing in 2-4 weeks if clinically indicated.

The **Venereal Disease Research Laboratory (VDRL)** and **rapid plasma reagin (RPR)** tests are sensitive **nontreponemal tests** that detect antibodies against phospholipid antigens on the treponeme surface that cross react with cardiolipin-lecithin-cholesterol antigens of damaged host cells. The quantitative results of these tests are helpful both in screening and in monitoring therapy. Titers increase with active disease, including treatment failure or reinfection, and decline with adequate treatment (Fig. 264.11). Nontreponemal tests usually become nonreactive within 1 year of adequate therapy for primary syphilis and within 2 years of adequate treatment for secondary disease. Fifteen to twenty percent of patients become **serofast** (nontreponemal titers persisting at low levels for long periods). In congenital infection, nontreponemal tests become nonreactive within a few months after adequate treatment. Certain conditions such as infectious mononucleosis and other viral infections, autoimmune diseases, and pregnancy can give false-positive VDRL results. False-positive results are less common with the use of purified cardiolipin-lecithin-cholesterol antigen. All pregnant women should be screened early in pregnancy and at delivery. All positive maternal (parental) serologic tests for syphilis, regardless of titer, necessitate thorough investigation. Antibody excess can give a false-negative reading unless the serum is diluted **(prozone effect) as the formation of the antigen-antibody lattice needed to visualize a positive flocculation test is disrupted.** False-negative results can also occur in early primary syphilis, in latent syphilis of long duration, and in late congenital syphilis.

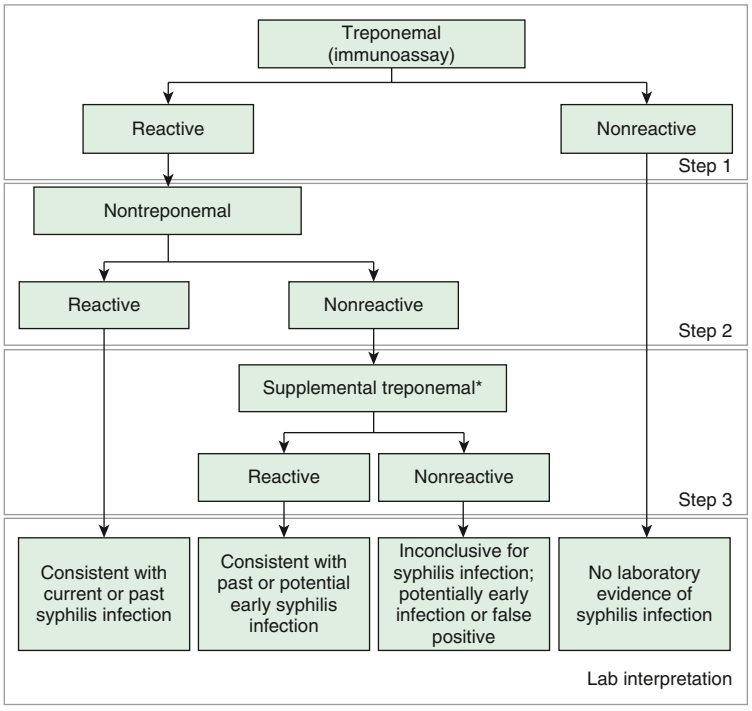
Treponemal tests traditionally are used to confirm diagnosis and measure specific *T. pallidum* antibodies (immunoglobulin [Ig] G, IgM, and IgA), which appear earlier than nontreponemal antibodies. Treponemal tests include the *T. pallidum* particle agglutination test (TP-PA, which is the preferred treponemal test) and the fluorescent treponemal antibody absorption test (FTA-ABS). Treponemal antibody titers become positive soon after initial infection and usually remain positive for life, even with adequate therapy (see Fig. 264.11). These antibody titers do not correlate with disease activity. Traditionally they are useful for diagnosis of a first episode of syphilis and for distinguishing false-positive results of nontreponemal antibody tests but cannot accurately identify length of time of infection, response to therapy, or reinfection.

There is limited cross reactivity of treponemal antibody tests with other spirochetes, including the causative organisms of Lyme disease *(Borrelia burgdorferi),* yaws, endemic syphilis, and pinta. Only venereal syphilis and Lyme disease are found in the United States. Nontreponemal tests (VDRL, RPR) are uniformly nonreactive in Lyme disease.

Various enzyme-linked, chemiluminescence, and multiplex flow immunoassays to detect treponemal IgG and IgM have been developed. These assays have increased sensitivity and are amenable to automation and high-volume use. Rapid point-of-care tests are available to allow quality screening programs in resource-limited settings where the World Health Organization otherwise relies on syndromic management of STIs and patients are treated for all likely causes of their constellation of signs and symptoms. In the United States, use of immunoassays has confounded screening because it switches the traditional algorithm: the treponemal-specific testing is done before the nontreponemal testing. Because the former remain positive for life, clinical and epidemiologic data are required to provide guidelines to distinguish cured disease, early syphilis, untreated late latent disease, and true false-positive tests. Benefits of **reverse screening** are



A



**The supplemental treponemal test should use a unique platform and/or antigen, different from the first treponemal test.*

increased detection of transmissible early syphilis and of late latent disease to afford monitoring for tertiary disease. Although the CDC and American Academy of Pediatrics (AAP) Red Book continue to recommend the traditional screen ("conventional diagnostic approach"; see Fig. 264.10A), they have provided guidelines for interpretation of the reverse screening algorithm (see Fig. 264.10B). Reverse screening may yield false-positive results, particularly in low-prevalence populations where testing results should be interpreted with caution, as false-positive testing in children may have serious adverse consequences. If reverse testing yields a positive treponemal result but a negative nontreponemal result, a second treponemal test targeting a different treponemal antigen is needed for confirmation. Interpretation of nontreponemal and treponemal serologic tests in the newborn can be confounded by maternal IgG antibodies transferred to the fetus. Passively acquired antibody is suggested by a neonatal titer at least fourfold (i.e., a two-tube dilution) less than the maternal (parental) titer. This conclusion can be verified by a gradual decline in antibody in the infant, usually becoming undetectable by 3-6 months of age. Conversely, an infant nontreponemal titer fourfold higher than the mother's at the time of delivery or a persistent or rising nontreponemal titer in the infant suggests congenital infection.

Neurologic involvement can occur at any stage of syphilis. The diagnosis of neurosyphilis remains difficult but is often established by demonstrating pleocytosis and increased protein in the CSF and a positive CSF VDRL test along with neurologic symptoms. The CSF VDRL test is specific but relatively insensitive (22–69%) for neurosyphilis. CSF PCR and IgM immunoblot tests are being studied but not currently recommended for use in making the diagnosis of neurosyphilis.

Dark-field or direct fluorescent antibody microscopy of scrapings from primary lesions or congenital or secondary lesions can reveal *T. pallidum,* often before serology becomes positive, but these modalities are usually not available in clinical practice. Since 2015 different methods of PCR, including routine PCR, nested PCR, reverse-transcriptase PCR, and quantitative PCR targeting different DNA gene sequences, have been used by many laboratories as methods to detect *T. pallidum* in primary disease. However, there are currently no commercially available test kits, and each test must be validated for use in each laboratory. Furthermore, these tests are not useful for asymptomatic patients, and interpretation may be complicated by the fact that they amplify both dead and living organisms. Placental examination by gross and microscopic techniques can be useful in the diagnosis of congenital syphilis. The disproportionately large placentas are characterized histologically by focal proliferative villitis, endovascular and perivascular arteritis, and focal or diffuse immaturity of placental villi.

Congenital Syphilis

A diagnosis of congenital syphilis requires a thorough review of maternal (parental) history of syphilis treatment preconception and the testing, treatment, and dynamics of response during the current pregnancy. Regardless of maternal (parental) treatment and the presence/absence of symptoms in the infant, proactive evaluation and treatment of exposed neonates is critical (Fig. 264.12 and Table 264.2). Symptomatic infants should be thoroughly evaluated and treated. Figure 264.12 and Table 264.3 describe the guidelines for evaluating and managing asymptomatic infants who are considered at risk for congenital syphilis because the maternal (parental) nontreponemal and treponemal serology is positive. Internationally adopted, refugee, and immigrant children should also be screened, regardless of history or report of treatment. Diagnostic testing risk-stratifies infants to probability of congenital infection: proven or highly probable congenital syphilis, possible congenital syphilis, congenital syphilis less likely, or congenital syphilis unlikely.

A diagnosis of neurosyphilis in the newborn with syphilitic infection is confounded by poor sensitivity of the CSF VDRL test in this age-group and lack of CSF abnormalities. A positive CSF VDRL test in a newborn warrants treatment for neurosyphilis, even though it might reflect passive transfer of antibodies from serum to CSF. It is now accepted that all infants with a presumptive diagnosis of congenital syphilis should be treated with regimens effective for neurosyphilis because central nervous system involvement cannot be reliably excluded. A diagnosis of syphilis beyond early infancy should lead to consideration of possible child abuse.

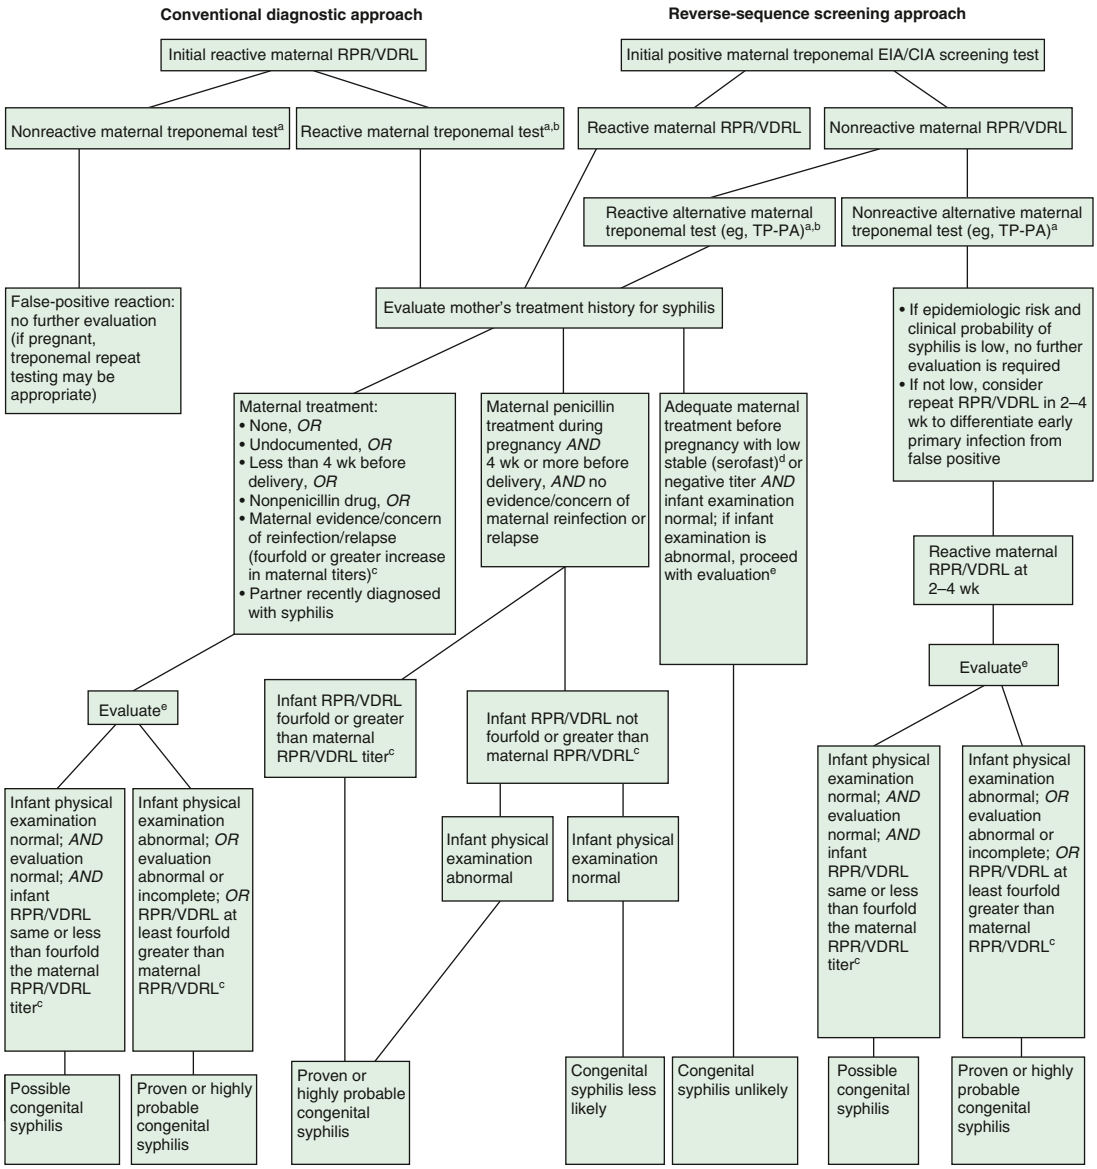

Fig. 264.12 Algorithm for the diagnostic approach of infants born to mothers (birthing parents) with reactive serologic tests for syphilis. [a]*Treponema pallidum* particle agglutination (TP-PA) (which is the preferred treponemal test) or fluorescent treponemal antibody absorption (FTA-ABS). [b]Test for human immunodeficiency virus (HIV) antibody. Infants of HIV-infected mothers do not require different evaluation or treatment for syphilis. [c]A fourfold change in titer is the same as a change of two dilutions. For example, a titer of 1:64 is fourfold greater than a titer of 1:16, and a titer of 1:4 is fourfold lower than a titer of 1:16. When comparing titers, the same type of nontreponemal test should be used (e.g., if the initial test was an RPR, the follow-up test should also be an RPR). [d]Stable VDRL titers 1:2 or less or RPR 1:4 or less beyond 1 year after successful treatment are considered low serofast. [e]Complete blood cell (CBC) and platelet count; cerebrospinal fluid (CSF) examination for cell count, protein, and quantitative VDRL; other tests as clinically indicated (e.g., chest radiographs, long-bone radiographs, eye examination, liver function tests, neuroimaging, and auditory brainstem response). For neonates, pathologic examination of the placenta or umbilical cord with specific fluorescent antitreponemal antibody staining, if possible. RPR, Rapid plasma regain; VDRL, Venereal Disease Research Laboratory. *(From American Academy of Pediatrics. Syphilis. In Kimberlin DW, Barnett ED, Lynfield R, Sawyer MH, eds. Red Book: 2021–2024 Report of the Committee on Infectious Diseases, 32nd ed. Itasca, IL: American Academy of Pediatrics; 2021: Fig. 3.15, p. 734.)*

For infants with proven or highly probable disease or abnormal physical findings, complete evaluation, including serologic tests (RPR or VDRL), complete blood count with differential and platelet count, liver function tests, long-bone radiographs, ophthalmology examination, auditory brainstem response, and other tests as indicated, should be performed. If possible, pathologic examination of the placenta and/or umbilical cord with specific fluorescent antitreponemal antibody staining is recommend by the AAP. For infants with a positive VDRL or RPR test result and normal physical examination whose mothers were inadequately treated, further evaluation is not necessary if 10 days of parenteral therapy are administered.

TREATMENT

The goals of early detection and treatment include treatment of current infection and prevention of both late-stage disease and sexual or vertical transmission. *T. pallidum* remains extremely sensitive to penicillin, with no evidence of emerging penicillin resistance, and thus penicillin remains the treatment drug of choice (additional information available in Table 264.4 and at http://www.cdc.gov/std/treatment for patients over 1 month old). Parenteral penicillin G is the only documented effective treatment for congenital syphilis, syphilis during pregnancy, and neurosyphilis and is recommended for treatment of syphilis in persons with HIV. Aqueous crystalline penicillin G is preferred over

Table 264.2 Clues that Suggest a Diagnosis of Congenital Syphilis

EPIDEMIOLOGIC BACKGROUND	CLINICAL FINDINGS
Untreated early syphilis in the mother	Osteochondritis, periostitis
Untreated latent syphilis in the mother	Snuffles, hemorrhagic or mucopurulent rhinitis
An untreated mother who has contact with a known patient with syphilis during pregnancy	Condylomata lata
Mother treated less than 30 days before delivery	Bullous lesions, palmar or plantar rash
Mother treated for syphilis during pregnancy with a drug other than penicillin	Mucous patches
Mother treated for syphilis during pregnancy without follow-up to demonstrate fourfold decrease in titer	Hepatomegaly, splenomegaly
Mother co-infected with HIV	Jaundice, hepatitis
	Nonimmune hydrops fetalis
	Generalized lymphadenopathy
	Central nervous system signs; elevated cell count or protein in cerebrospinal fluid
	Hemolytic anemia, diffuse intravascular coagulation, thrombocytopenia
	Pneumonitis
	Nephrotic syndrome
	Placental villitis or vasculitis (unexplained enlarged placenta)
	Intrauterine growth restriction

Arranged in decreasing order of confidence of diagnosis.
Modified from Remington JS, Klein JO, Wilson CB, et al., eds. *Infectious Diseases of the Fetus and Newborn Infant*, 6th ed. Philadelphia: WB Saunders; 2006:556.

Table 264.3 Confirmed Proven or Highly Probable Congenital Syphilis

DIAGNOSIS AND TREATMENT

Any neonate with:

- An abnormal physical examination that is consistent with congenital syphilis;
- A serum quantitative nontreponemal serologic titer that is fourfold (or greater) higher than the mother's titer at delivery (e.g., maternal titer = 1:2, neonatal titer ≥1:8 or maternal titer = 1:8, neonatal titer ≥1:32); or
- A positive dark-field test or PCR of placenta, cord, lesions, or body fluids or a positive silver stain of the placenta or cord.

Recommended evaluation:

- CSF analysis for VDRL, cell count, and protein
- Complete blood count (CBC) and differential and platelet count
- Long-bone radiographs
- Other tests as clinically indicated (e.g., chest radiograph, liver function tests, neuroimaging, ophthalmologic examination, and auditory brainstem response)

Recommended regimens, confirmed or highly probable congenital syphilis:

Aqueous crystalline penicillin G 100,000-150,000 units/kg body weight/day, administered as 50,000 units/kg body weight/dose by IV every 12 hr during the first 7 days of life and every 8 hr thereafter for a total of 10 days*

OR

Procaine penicillin G 50,000 units/kg body weight/dose IM in a single daily dose for 10 days

If >1 day of therapy is missed, the entire course should be restarted. Data are insufficient regarding use of other antimicrobial agents (e.g., ampicillin). When possible, a full 10-day course of penicillin is preferred, even if ampicillin was initially provided for possible sepsis. Using agents other than penicillin requires close serologic follow-up for assessing therapy adequacy.

*Preferred therapy per the 2021-2024 AAP Red Book
From Centers for Disease Control and Prevention. Congenital syphilis. Sexually Transmitted Diseases and Treatment Guidelines, 2021. Scenario 1. https://www.cdc.gov/std/treatment-guidelines/congenital-syphilis.htm.

procaine penicillin, because it better achieves and sustains the minimum concentration of 0.018 μg/mL (0.03 units/mL) needed for 7-10 days to achieve the prolonged treponemicidal levels required for the long dividing time of *T. pallidum*.

In 2023, due to manufacturing limitations and increased demand, the United States entered a period of penicillin G shortage, requiring prioritization of pregnant persons to receive this antibiotic, as no other medication is proven to prevent vertical transmission. Penicillin G is often preferred for IM injection in treatment of other syphilis infections as an approach to ensure adherence to therapy, and thus the shortage may lead to increased transmission.

For proven or highly probable congenital syphilis, procaine penicillin G (50,000 U/kg IM daily × 10 days) should only be used if access to IV penicillin G is limited (such as in a low-resource setting) or if IV access cannot be obtained. For infants with possible congenital syphilis, aqueous penicillin G (50,000 U/kg IV every 12 hours when 1 wk or younger, then every 8 hours for infants older than 1 wk, for a total of 10 days of therapy) is preferred, though procaine penicillin G (50,000 U/kg IM daily x 10 days) may be given. Benzathine penicillin G (50,000 U/kg IM) as a single dose can be considered but only if all components of the evaluation are normal and follow-up is certain. Infants in whom congenital syphilis is less likely may be treated with benzathine penicillin G (50,000 U/kg IM) as a single dose. If no treatment is given, infants must be closely followed until the nontreponemal test becomes nonreactive. If any portion of the assessment for congenital syphilis is abnormal or not obtained, or the CSF studies are uninterpretable, or outpatient follow-up cannot be assured, treatment with procaine penicillin G is preferred. Patients with persistent or increasing titers require repeat evaluation and treatment with a 10-day course of parenteral penicillin G, even if previously treated.

Although nonpenicillin regimens are available to the penicillin-allergic patient, desensitization followed by standard penicillin therapy is the most reliable strategy. Success of treatment also depends on the integrity of the host immune response. A transient acute systemic febrile reaction called the **Jarisch-Herxheimer reaction** (caused by massive release of endotoxin-like antigens during bacterial lysis) occurs in 15–20% of patients with acquired or congenital syphilis treated with penicillin. It is not an indication for discontinuing penicillin therapy. Use of other agents for congenital syphilis should only be done in consultation with a pediatric infectious diseases specialist and requires close clinical and serologic follow-up.

Acquired Syphilis

Primary, secondary, and early latent disease is treated with a single dose of benzathine penicillin G (50,000 units/kg IM, maximum 2.4 million units, in a single dose). Persons with late latent or tertiary disease require three doses at 1-week intervals. Nonpregnant penicillin-allergic patients without neurosyphilis may be treated with either doxycycline (4.4 mg/kg divided in 2 doses, max 200 mg per day, orally twice a day for 14 days) or tetracycline (25-50 mg/kg divided in 4 doses, max 2 g per day, orally for 14 days, for age ≥8 years). Emerging *azalide* and *macrolide resistance* has been documented throughout the United States (a 23S ribosomal NA [rRNA] point mutation at position 2058) and, more recently, worldwide (a 23S rRNA point mutation at position 2059), compromising the effective use of these antibiotics. Careful serologic follow-up is always necessary. Documentation of serologic cure is an essential part of syphilis treatment. Less than a fourfold decline in titer reflects treatment failure.

The CDC recommends that all persons with syphilis be tested for HIV and other STIs. Patients diagnosed with syphilis with a negative HIV test should undergo repeat testing 3 months later. Diagnosis of syphilis in high-risk individuals, particularly men or transgender women who have sex with men, is associated with increased risk of

Table 264.4 Recommended Treatment for Syphilis in People Older Than 1 Mo

STATUS	CHILDREN	ADULTS
Congenital syphilis in patients >1 mo old; OR children >2 mo with late and previously untreated congenital syphilis	Aqueous crystalline penicillin G 200,000-300,000 U/kg/day IV administered as 50,000 U/kg, every 4-6 hr for 10 days*	
Primary, secondary, and early latent syphilis†	Penicillin G benzathine‡ 50,000 U/kg IM, up to the adult dose of 2.4 million U in a single dose *If allergic to penicillin and not pregnant,* Doxycycline 4.4 mg/kg divided in 2 doses, max 200 mg per day, orally twice a day for 14 days (for ages ≥8 yr) *OR* Tetracycline 25-50 mg/kg divided in 4 doses, max 2 g per day, orally for 14 days (for ages ≥8 yr)	Penicillin G benzathine 2.4 million U IM in a single dose *OR* *If allergic to penicillin and not pregnant,* doxycycline 100 mg orally twice a day for 14 days *OR* Tetracycline 500 mg orally 4 times/day for 14 days
Late latent syphilis§	Penicillin G benzathine 50,000 U/kg IM, up to the adult dose of 2.4 million U, administered as 3 single doses at 1-wk intervals (total 150,000 U/kg, up to the adult dose of 7.2 million U) *If allergic to penicillin and not pregnant,* Doxycycline 4.4 mg/kg divided in 2 doses, max 200 mg per day, orally twice a day for 4 weeks (for ages ≥8 yr) *OR* Tetracycline 25-50 mg/kg divided in 4 doses, max 2 g per day, orally for 4 weeks (for ages ≥8 yr)	Penicillin G benzathine 7.2 million U total, administered as 3 doses of 2.4 million U IM, each at 1-wk intervals; pregnant women who have delays in any dose of therapy beyond 9 days between doses should repeat the full course of therapy *OR* *If allergic to penicillin and not pregnant,* Doxycycline 100 mg orally twice a day for 4 wk *OR* Tetracycline 500 mg orally, 4 times/day for 4 wk
Tertiary	—	Penicillin G benzathine 7.2 million U total, administered as 3 doses of 2.4 million U IM at 1-wk intervals *If allergic to penicillin and not pregnant, consult an infectious diseases expert*
Neurosyphilis‖	Aqueous crystalline penicillin G 200,000-300,000 U/kg/day IV every 4-6 hr for 10-14 days, in doses not to exceed the adult dose	Aqueous crystalline penicillin G 18-24 million U per day, administered as 3-4 million U IV every 4 hr for 10-14 days¶ *OR* Penicillin G procaine‡ 2.4 million U IM once daily PLUS probenecid 500 mg orally 4 times/day, both for 10-14 days¶

*If the patient has no clinical manifestations of disease, the cerebrospinal fluid (CSF) examination is normal, and the CSF Venereal Disease Research Laboratory (VDRL) test result is negative, some experts would treat with up to 3 weekly doses of penicillin G benzathine 50,000 U/kg IM. Some experts also suggest giving these patients a single dose of penicillin G benzathine 50,000 U/kg IM after the 10-day course of intravenous aqueous penicillin.
†Early latent syphilis is defined as being acquired within the preceding year.
‡Penicillin G benzathine and penicillin G procaine are approved for intramuscular administration only.
§Late latent syphilis is defined as syphilis beyond 1 year's duration.
‖Patients who are allergic to penicillin should be desensitized.
¶Some experts administer penicillin G benzathine 2.4 million U IM once per week for up to 3 weeks after completion of these neurosyphilis treatment regimens.
IV, Intravenously; *IM*, intramuscularly.
From American Academy of Pediatrics. Syphilis. In: Kimberlin DW, Barnett ED, Lynfield R, Sawyer MH, eds. *Red Book: 2021–2024 Report of the Committee on Infectious Diseases*, 32nd ed. Itasca, IL: American Academy of Pediatrics; 2021: Table 3.67, pp. 741–742.

subsequent HIV acquisition, and preexposure prophylaxis (PrEP) should be considered. Patients co-infected with HIV are at increased risk for neurologic complications and higher rates of treatment failure. CDC guidelines recommend the same treatment of primary and secondary syphilis as for patients who are not infected with HIV, but some experts recommend three weekly doses of benzathine penicillin G. HIV-infected patients with late latent syphilis or latent syphilis of unknown duration should have a CSF evaluation for neurosyphilis before treatment.

Sex partners of infected persons of any stage should be evaluated and treated. Persons exposed for 90 days or less preceding diagnosis in a sex partner should be treated presumptively even if seronegative. Persons exposed for more than 90 days before the diagnosis in a sex partner should be treated if seropositive or if serologic tests are not available. Follow-up serology should be performed on treated patients to establish adequacy of therapy, and all patients should be tested for other sexually transmitted diseases, including HIV. Children with acquired primary, secondary, or latent syphilis should undergo evaluation for possible sexual assault or abuse.

Syphilis in Pregnancy

When clinical or serologic findings suggest active infection or when the diagnosis of active syphilis cannot be excluded with certainty, treatment is indicated. The goals of treatment of the pregnant person include eradication of maternal (parental) disease, prevention of parent-to-child transmission, and treatment of fetal infection. Patients should be treated immediately with the penicillin regimen appropriate for the pregnant person's stage of syphilis. Those who have been

adequately treated in the past do not require additional therapy unless quantitative serology suggests evidence of reinfection **(fourfold elevation in titer)**.

Penicillin G is the only agent known to be effective for treating fetal infection and for prevention of congenital infection. Pregnant patients who are allergic to penicillin should be desensitized and treated with penicillin. If doses for late latent syphilis are delayed beyond 9 days from the prior dose, the full course of therapy needs to be repeated. Additional therapy may be considered for pregnant persons with primary, secondary, or early latent syphilis or when syphilis is diagnosed during the second half of pregnancy and sonographic evidence of fetal or placental syphilis is noted. In these cases, a second dose of benzathine penicillin G (2.4 million units IM given 1 week after the initial dose) may decrease the risk of vertical transmission. Jarisch-Herxheimer reaction in the second half of pregnancy may induce premature labor or fetal distress, and patients with reactions should seek obstetric attention promptly.

Congenital Syphilis

Adequate maternal (parental) treatment at least 30 days before delivery is likely to prevent congenital syphilis. All infants born to pregnant persons with syphilis should be followed until nontreponemal serology is negative. The infant should be treated if there is any uncertainty about the adequacy of maternal (parental) treatment. The goal of infant treatment is prevention of organ damage, skeletal deformity, and developmental delay. Any infant at risk of congenital syphilis should be evaluated for HIV.

Congenital syphilis is treated in infants up to 1 month of age with aqueous penicillin G (100,000-150,000 units/kg/24 hr IV divided every 12 hours for the first week of life and every 8 hours thereafter) or procaine penicillin G (50,000 units/kg IM once daily) given for 10 days. Both penicillin regimens are recognized as adequate therapy for congenital syphilis, but higher concentrations of penicillin are achieved in the CSF of infants treated with intravenous aqueous penicillin G than in those treated with intramuscular procaine penicillin. Treated infants should be closely monitored at 2-, 4-, 6-, and 12-month well child care visits and serologic nontreponemal titers repeated every 2-3 months until nonreactive. Titers generally decrease by 3 months of age and become nonreactive by 6 months of age if adequately treated or if antibody was merely transplacentally acquired without infection. Infants diagnosed and treated for congenital syphilis after 1 month of age should be treated with aqueous crystalline penicillin G 200,000-300,000 U/kg/day IV administered as 50,000 U/kg, every 4-6 hr for 10 days (Table 264.4). Nontreponemal titers may resolve more slowly if the patient was treated after 1 month old. Increasing or persistent stable titers 6-12 months after initial treatment suggest possible ongoing infection, and repeat evaluation, including CSF, is indicated. Repeat treatment (penicillin G IV for 10 days) may be indicated. Infants with a negative nontreponemal test born to a person seroreactive at the time of delivery could have incubating congenital infection and so should be retested at 3 months. Infants with initial abnormal CSF studies only require repeat lumbar puncture if they have persistent nontreponemal serologic titers at 6-12 months old. If CSF has a persistent positive VDRL or abnormal indices not attributable to another ongoing illness, retreatment is indicated after 2 years of follow-up. At age 2 previously treated infants should receive a full developmental assessment. In a very low-risk neonate who is asymptomatic and whose mother was treated appropriately, without evidence of relapse or reinfection but with a low and stable VDRL titer (serofast), no evaluation is necessary. Some specialists, however, would treat such an infant with a single dose of benzathine penicillin G 50,000 units/kg IM.

PREVENTION

Syphilis, including congenital syphilis, is a reportable disease in all 50 states and the District of Columbia. Testing is indicated at any time for persons with suspicious lesions, a history of recent sexual exposure to a person with syphilis, or diagnosis of another sexually transmitted infection, including HIV infection. Screening for syphilis in asymptomatic, nonpregnant persons at increased risk for infection has received an A recommendation from the US Preventive Services Task Force (USPSTF) as providing significant benefit. Direct-to-consumer test services for STIs (or "home tests") have become more acceptable following consumer experience with similar testing during the COVID-19 pandemic, and best practices for implementation are an area of intense research. As of late 2023, the US CDC had posted request for comment on proposed guidelines for the use of doxycycline as post-exposure prophylaxis for bacterial STI prevention, including syphilis, to be offered to MSM and transgender women with a history of at least one bacterial STI in the last 12 months; insufficient evidence is currently available to give recommendations for other groups, including children, cisgender women or heterosexual men, transgender men, or other queer and nonbinary individuals. The resurgence of syphilis compels clinicians to remain cognizant of its protean manifestations to avoid missed or late diagnosis. Timely treatment lessens risk of community spread. Despite the genome sequencing of *T. pallidum* in 1998, vaccine development remains elusive, confounded by the treponeme's ability to evade the immune system.

Congenital Syphilis
